8. Metformin is a medication used in treating diabetes mellitus type 2. One of its actions is to decrease hepatic gluconeogenesis. A theoretical concern with this medication was lactic acidosis, which in practice does not occur in patients taking metformin. Which one of the following explains why lactic acidosis does not occur with the use of this medication?
 - A. The Cori cycle overcomes the lactate buildup in the liver
 - B. Red blood cells utilize lactate as fuel
 - C. Renal medullary cells utilize lactate as fuel
 - D. The heart utilizes lactate as fuel
 - E. The eye utilizes lactate as fuel
9. As glucose has several metabolic routes it might take once it arrives in the cytoplasm which one of the following reactions would commit the glucose to following the glycolytic pathway?
 - A. Glucose-to-glucose 1-phosphate
 - B. Glucose-to-glucose 6-phosphate
 - C. Fructose 6-phosphate to fructose 1,6-bisphosphate
 - D. Fructose 1,6-bisphosphate to dihydroxyacetone phosphate and glyceraldehyde 3-phosphate
 - E. Glucose 1-phosphate to glucose 6-phosphate
10. The red blood cells require ATP to maintain ion gradients across their membrane. In the absence of these ion gradients, the red blood cells will swell and burst, bringing about a hemolytic anemia. Red cells generate their energy via which one of the following?
 - A. Substrate-level phosphorylation
 - B. TCA cycle
 - C. Oxidative phosphorylation
 - D. Electron transfer to oxygen
 - E. Oxidation of glucose to CO_2 and H_2O
1. Assume an individual has ingested 1 mol of lactose, and there is 100% absorption of the ingested material in the intestines. If all of the ingested lactose is metabolized anaerobically in the liver how many moles of ATP and NADH will be generated in the liver?
 - A. 3 mol of ATP and 2 mol of NADH
 - B. 4 mol of ATP and 0 mol of NADH
 - C. 4 mol of ATP and 2 mol of NADH
 - D. 6 mol of ATP and 0 mol of NADH
 - E. 6 mol of ATP and 2 mol of NADH
2. Assume liver PFK-2 is inhibited by a new investigational drug. In vitro studies indicate that this drug binds to liver PFK-2 and completely inhibits its kinase activity while stimulating the phosphatase activity. A potential effect of this drug if utilized in humans would be which one of the following?
 - A. An increased ATP yield per glucose molecule through aerobic glycolysis
 - B. A decreased ATP yield per glucose molecule through aerobic glycolysis
 - C. An increased rate of glycolysis
 - D. A decreased rate of glycolysis
 - E. Lactic acidemia
3. Rapidly exercising muscle generates lactic acid to directly allow which one of the following reactions to continue to proceed in the forward direction?
 - A. Glucose to glucose 6-phosphate
 - B. Fructose 1,6-bisphosphate to glyceraldehyde 3-phosphate and dihydroxyacetone phosphate
 - C. Glyceraldehyde 3-phosphate to 1,3-bisphosphoglycerate
 - D. 1,3-bisphosphoglycerate to 3-phosphoglycerate
 - E. Phosphoenolpyruvate to pyruvate
4. An individual who has had type 1 diabetes for the past 27 years notices a slight blurring of vision. Upon visiting an ophthalmologist, the patient learns that this is being caused by a particular type of reaction within

the eye. This reaction is best described by which one of the following?

- A. An oxidation of a sugar
 - B. A reduction of a sugar
 - C. Phosphorylation of a sugar
 - D. Oxidation of a protein
 - E. Reduction of a protein
5. The release of glucagon will lead to the phosphorylation and inactivation of which of the following liver enzyme activities? Choose the one best answer.

	Glucokinase	PFK-2 Phosphatase Activity	Glyceraldehyde 3-Phosphate Dehydrogenase	Pyruvate Kinase
A	Yes	Yes	Yes	No
B	Yes	No	Yes	No
C	Yes	Yes	Yes	Yes
D	No	No	No	Yes
E	No	Yes	No	Yes
F	No	No	No	No

ANSWERS TO REVIEW QUESTIONS

- The answer is B.** The major roles of glycolysis are to generate energy and to produce precursors for other biosynthetic pathways. Gluconeogenesis is the pathway that generates glucose (thus, A is incorrect); FAD(2H) is produced in the mitochondria by a variety of reactions but not glycolysis (thus, C is incorrect); glycogen synthesis occurs under conditions in which glycolysis is inhibited (thus, D is incorrect); and glycolysis does not hydrolyze ATP to generate heat (that is due to nonshivering thermogenesis, thus E is incorrect).
- The answer is D.** By starting with glyceraldehyde 3-phosphate, the energy-requiring steps of glycolysis are bypassed. Thus, as glyceraldehyde 3-phosphate is converted to pyruvate, two molecules of ATP will be produced (at the phosphoglycerate kinase and pyruvate kinase steps) and one molecule of NADH will be produced (at the glyceraldehyde 3-phosphate dehydrogenase step).
- The answer is H.** Glucose 1-phosphate is isomerized to glucose 6-phosphate, which then enters glycolysis. This skips the HK step, which utilizes 1 ATP. Thus, starting from glucose 1-phosphate, one would get the normal 2 ATP and 2 NADH, but with one less ATP utilized in the priming steps, the total yield would be 3 ATP and 2 NADH.
- The answer is B.** The pathway consumes 2 ATP at the beginning of the pathway and produces 4 ATP at the end of the pathway for each molecule of glucose. Therefore, the net energy production is 2 ATP for each molecule of glucose. Glycolysis synthesizes ATP via substrate-level phosphorylation, not oxidative phosphorylation (thus, A is incorrect) and synthesizes two molecules of pyruvate in the process (thus, D is incorrect). The pathway is cytosolic (thus, D is incorrect), and the rate-limiting step is the one catalyzed by PFK-1 (thus, C is incorrect).
- The answer is E.** Fructose 1-phosphate is found only in fructose metabolism. Glucose 1-phosphate is derived from glycogen degradation. Fructose 6-phosphate and fructose 1,6-bisphosphate are found in glycolysis but not in fructose metabolism. Both fructose and glucose are converted to glyceraldehyde 3-phosphate, and this is where the two pathways intersect. Their continued metabolisms are identical from this point on.

6. **The answer is E.** The child has a form of galactosemia in which galactose cannot be metabolized, such that free galactose enters the blood and is excreted via the urine. The below-normal blood glucose levels indicate that glucose is not being excreted in the urine. The high levels of galactose lead to galactose entering the lens of the eye, where it is converted to galactitol via aldose reductase, trapping the galactitol in the lens. This leads to an osmotic imbalance across the lens resulting in swelling and cataract formation. High levels of fructose do not lead to cataract formation. Lactose is a disaccharide that is cleaved to glucose and galactose in the small intestine, such that lactose does not enter the blood. Maltose is another disaccharide (glucose-glucose) that does not enter the blood.
7. **The answer is C.** The child either has classical galactosemia (due to a deficiency of galactose 1-phosphate uridylyl transferase) or nonclassical galactosemia (due to a deficiency of galactokinase). Measurement of galactose 1-phosphate levels would enable one to determine if galactokinase were deficient (if it were galactose 1-phosphate levels would be low) or if galactose 1-phosphate uridylyl transferase were defective (in which case galactose 1-phosphate levels would be elevated). Measurement of the other compounds listed would not allow for a determination as to whether galactokinase or galactose 1-phosphate uridylyl transferase were defective.
8. **The answer is D.** Metformin interrupts the Cori cycle (gluconeogenesis in the liver using lactate, derived from the muscle, as a source of carbons). The heart, with its huge mitochondrial content and oxidative capacity, uses lactate as fuel and easily metabolizes the excess lactate (which is why heart failure is a contraindication to the use of metformin, otherwise lactic acidosis would occur). The red blood cells, renal medullary cells, and tissues of the eye all use anaerobic glycolysis to generate energy, producing lactate, but cannot utilize lactate as a fuel.
9. **The answer is C.** The committed step for glycolysis is the one catalyzed by phosphofructokinase-1 (PFK-1), which converts fructose 6-phosphate to fructose 1,6-bisphosphate. Glucose is not directly converted to glucose 1-phosphate; glucose must first be phosphorylated to glucose 6-phosphate, then isomerized to glucose 1-phosphate. Glucose 6-phosphate has other potential fates (glycogen synthesis, HMP shunt) so the generation of glucose 6-phosphate from glucose does not commit the sugar to the glycolytic pathway. Aldolase cleaves fructose 1,6-bisphosphate into two triose phosphates in a reversible reaction and is not considered a regulated step of glycolysis, as the aldolase reaction is also utilized in gluconeogenesis.
10. **The answer is A.** Red blood cells do not contain mitochondria and can only generate energy via anaerobic mechanisms. Without mitochondria, aerobic glycolysis cannot occur through the TCA cycle or oxidative phosphorylation of glucose to CO_2 and H_2O . Only anaerobic glycolysis can occur with production of lactate and the production of ATP by substrate-level phosphorylation. The electron transport chain occurs within the mitochondria.
11. **The answer is B.** Lactose is a disaccharide composed of glucose and galactose. In the intestine, the lactose would be split into 1 mol of glucose and 1 mol of galactose, both of which would be absorbed by the intestinal epithelial cells and sent into the blood. The liver will then transport the sugars from the blood into the hepatocytes and metabolize the sugars to lactate (anaerobic glycolysis). The net yield of energy from both glucose and galactose to two molecules of lactate are 2 ATP, so for both the energy yield would be 4 ATP. There is no accumulation of NADH, as the NADH produced is used to convert pyruvate to lactate, thereby regenerating oxidized NAD^+ to allow glycolysis to continue.
12. **The answer is D.** The drug stimulates liver PFK-2 to convert fructose 2,6-bisphosphate to fructose 6-phosphate plus inorganic phosphate and blocks the production of more fructose 2,6-bisphosphate. The reduction in the concentration of fructose 2,6-bisphosphate removes the most potent activator of PFK-1 from the cell, which will reduce the rate of glycolysis as PFK-1 is the rate-limiting step in the glycolytic pathway. The inhibitor will not alter the reactions of glycolysis, so the overall ATP yield will not be changed as glucose proceeds through the pathway. Since the rate of glycolysis will be reduced less pyruvate will be produced, and lactate levels will also be reduced (since lactate is derived from pyruvate), reducing the chances of lactic acidemia.
13. **The answer is C.** The conversion of pyruvate to lactate requires NADH and generates NAD^+ . The NAD^+ is required for the glyceraldehyde 3-phosphate dehydrogenase reaction to proceed. In the presence of oxygen, the NADH will donate its electrons, after using a shuttle system to transfer the electrons to the matrix of the mitochondria, to oxygen, but in the absence of oxygen, pyruvate will accept the electrons and be reduced to lactate. If the lactate dehydrogenase reaction were blocked from proceeding in the absence of oxygen the intracellular levels of NAD^+ would be too low to support the glyceraldehyde 3-phosphate dehydrogenase reaction, and glycolysis would stop.
14. **The answer is B.** The patient has experienced a slow increase of free glucose in the lens of the eye due to

less than optimally controlled blood glucose levels, and the requirement for insulin shots to mimic what the pancreas normally does. Once in the lens of the eye, the glucose is reduced by aldose reductase to produce the sugar alcohol sorbitol, which accumulates in the lens. As the sorbitol concentration increases within the lens, an osmotic imbalance occurs across the lens membrane, leading to distortion and the start of cataract formation. Nonenzymatic glycation of lens proteins also contributes to this effect. Glycation does not lead to either the oxidation or reduction of amino acid sidechains on a protein. Phosphorylation of a sugar within the lens does not lead to cataract formation.

15. **The answer is D.** Glucagon is released from the pancreas when blood glucose levels drop and will signal the liver to stop glycolysis and promote the export of glucose from the liver. Glucagon release leads to the inactivation of pyruvate kinase in the liver (via phosphorylation) and the reduction of fructose 2,6-bisphosphate levels in the liver (due to phosphorylation of PFK-2 and activation of its phosphatase activity). The reduction of fructose 2,6-bisphosphate levels reduces the activity of PFK-1, which slows down glycolysis. Glucagon release does not affect either glucokinase or glyceraldehyde 3-phosphate dehydrogenase activity.

Tricarboxylic Acid Cycle

The **tricarboxylic acid cycle** (TCA cycle) accounts for more than two-thirds of the adenosine triphosphate (ATP) generated from fuel oxidation. The pathways for oxidation of fatty acids, glucose, amino acids, acetate, and ketone bodies all generate **acetyl coenzyme A (acetyl CoA)**, which is the substrate for the TCA cycle. As the activated two-carbon acetyl group is oxidized to two molecules of **CO₂**, energy is conserved as **NADH**, **FAD(2H)**, and guanosine triphosphate (**GTP**) (Fig. 23.1). NADH and FAD(2H) subsequently donate electrons to O₂ via the electron transport chain, with the generation of ATP from oxidative phosphorylation. Thus, the TCA cycle is central to energy generation from **cellular respiration**.

FIGURE 23.1 Summary of the TCA cycle. The major pathways of fuel oxidation generate acetyl CoA, which is the substrate for the TCA cycle. The number of carbons in each intermediate of the cycle is indicated in parentheses by the name of the compound. Acetyl CoA, acetyl coenzyme A; CoASH, coenzyme A; FAD, flavin adenine dinucleotide; GDP, guanosine diphosphate; GTP, guanosine triphosphate; NAD, nicotinamide adenine dinucleotide; Pi, inorganic phosphate; TCA, tricarboxylic acid.

Within the TCA cycle, the oxidative decarboxylation of α-ketoglutarate is catalyzed by the multisubunit **α-ketoglutarate dehydrogenase complex**, which contains the coenzymes **thiamin pyrophosphate**, **lipoate**, and **FAD**. A similar complex, the **pyruvate dehydrogenase complex (PDC)**, catalyzes the oxidation of pyruvate to acetyl CoA, thereby providing a link between the pathways of glycolysis and the TCA cycle (see Fig. 23.1).

The two-carbon acetyl group is the ultimate source of the electrons that are transferred to NAD⁺

and FAD and also the carbon in the two CO₂ molecules that are produced. Oxaloacetate is used and regenerated in each turn of the cycle (see Fig. 23.1). However, when cells use intermediates of the TCA cycle for biosynthetic reactions, the carbons of oxaloacetate must be replaced by **anaplerotic** (filling-up) reactions, such as the **pyruvate carboxylase reaction**.

The TCA cycle occurs in the mitochondrion, where its flux is tightly coordinated with the rate of the electron transport chain and oxidative phosphorylation through **feedback regulation that reflects the demand for ATP**. The rate of the TCA cycle is increased when ATP utilization in the cell is increased through the response of several enzymes to adenosine diphosphate (**ADP**) levels, the **NADH/NAD⁺ ratio**, the rate of FAD(2H) oxidation, or the **Ca²⁺ concentration**. For example, **isocitrate dehydrogenase is allosterically activated by ADP**.

There are two general consequences to impaired functioning of the TCA cycle: (1) an inability to generate ATP from fuel oxidation and (2) an accumulation of TCA cycle precursors. For example, inhibition of pyruvate oxidation in the TCA cycle results in its reduction to lactate, which can cause **lactic acidosis**. The most common situation leading to an impaired function of the TCA cycle is a relative lack of oxygen to accept electrons in the electron transport chain.

THE WAITING ROOM

Otto S., a 26-year-old medical student, has faithfully followed his diet and aerobic exercise program of daily tennis and jogging (see Chapter 20). He has lost a total of 33 lb and is just 23 lb from his college weight of 154 lb. His exercise capacity has markedly improved; he can run for a longer time at a faster pace before noting shortness of breath or palpitations of his heart. Even his test scores in his medical school classes have improved.

Confirmation of a suspected thiamin deficiency requires measuring thiamin levels. Currently, the most commonly used test is high-performance liquid chromatography (HPLC) analysis to quantify the levels of both free thiamin and the active form, TPP, in blood. In the past, a standard assay was used that determined if thiamin levels were sufficient for metabolic processes by utilizing the enzyme transketolase, which requires TPP for activity (see Chapter 27). Transketolase can be obtained from red blood cells, making sample collection relatively straightforward. The measurement of transketolase activity was done in the absence and presence of exogenous TPP. If the difference in activity levels is >25%, then a thiamin deficiency was confirmed.

Ann R. suffers from anorexia nervosa (see Chapters 1, 3, and 9). In addition to a low body weight, decreased muscle mass, glycogen, and fat stores, she has iron-deficiency anemia (see Chapter 15). She has started to gain weight and is trying a daily exercise program. However, she constantly feels weak and tired. When she walks, she feels pain in her calf muscles. On this visit to her nutritionist, they discuss the vitamin content of her diet and its role in energy metabolism.

Al M. has been hospitalized for congestive heart failure (see Chapter 8) and for head injuries sustained while driving under the influence of alcohol (Chapters 9 and 10). He completed an alcohol detoxification program, enrolled in a local Alcoholics Anonymous (AA) group, and began seeing a psychologist. During this time, his alcohol-related neurological and cardiac manifestations of alcohol toxicity and thiamin deficiency partially cleared. However, in spite of the support he was receiving, he began drinking excessive amounts of alcohol again while eating poorly. Three weeks later, he was readmitted with symptoms of “high-output” heart failure, sometimes referred to as wet beriberi or as the beriberi heart when related to thiamin deficiency.

I. Overview of the Tricarboxylic Acid Cycle

The tricarboxylic acid (TCA) cycle is frequently called the Krebs cycle because Sir Hans Krebs first formulated its reactions into a cycle. It is also called the citric acid cycle because citrate was one of the first compounds known to participate. The most common name for this pathway, the tricarboxylic acid or TCA cycle, denotes the involvement of the tricarboxylates citrate and isocitrate.

For the body to generate large amounts of ATP, the major pathways of fuel oxidation generate acetyl CoA, which is the substrate for the TCA cycle. In the first step of the TCA cycle, the acetyl portion of acetyl CoA combines with the four-carbon intermediate oxaloacetate to form citrate (six carbons), which is rearranged to form isocitrate. In the next two oxidative decarboxylation reactions, electrons are transferred to NAD^+ to form NADH, and two molecules of electron-depleted CO_2 are released. Subsequently, a high-energy phosphate bond in GTP is generated from substrate-level phosphorylation. In the remaining portion of the TCA cycle, succinate is oxidized to oxaloacetate with the generation of one $\text{FAD}(2\text{H})$ and one NADH. The **net** reaction of the TCA cycle, which is the sum of the equations for individual steps, shows that two carbons of the acetyl group have been entered the cycle, and two molecules of CO_2 are produced, with conservation of energy as three molecules of NADH, one of $\text{FAD}(2\text{H})$, and one of GTP.

The TCA cycle requires a large number of vitamins and minerals to function. These include niacin (NAD^+), riboflavin (FAD and FMN), pantothenic acid (coenzyme A), thiamin, Mg^{2+} , Ca^{2+} , Fe^{2+} , and phosphate.

II. Reactions of the Tricarboxylic Acid Cycle

In the TCA cycle, the two-carbon acetyl group of acetyl CoA enters the cycle, and two oxidized carbons are produced as CO_2 (see Fig. 23.1). The function of the cycle is to conserve the energy from this oxidation, which it accomplishes principally by transferring electrons from intermediates of the cycle to NAD^+ and FAD . The eight electrons donated by the acetyl group (four from each carbon) eventually end up in three molecules of NADH and one of $\text{FAD}(2\text{H})$ (Fig. 23.2). As a consequence, ATP can be generated from oxidative phosphorylation when NADH and $\text{FAD}(2\text{H})$ donate these electrons to O_2 via the electron transport chain.

FIGURE 23.2 The acetyl group of acetyl CoA. Acetyl CoA donates eight electrons to the TCA cycle, which are shown in red, and two carbons. The high-energy bond is shown by a ~. The acetyl group is the ultimate source of the carbons in the two molecules of CO_2 that are produced, and the source of electrons in the one molecule of reduced flavin adenine dinucleotide ($\text{FAD}[2\text{H}]$) and three molecules of reduced nicotinamide adenine dinucleotide (NADH), which have each accepted two electrons. However, the same carbon atoms and electrons that enter from one molecule of acetyl CoA do not leave as CO_2 , NADH, or $\text{FAD}(2\text{H})$ within the same turn of the cycle. Acetyl CoA, acetyl coenzyme A; SCoA, coenzyme A; TCA, tricarboxylic acid.

Initially, the acetyl group is incorporated into **citrate**, an intermediate of the TCA cycle (Fig. 23.3). As citrate progresses through the cycle to **oxaloacetate**, it is oxidized by four dehydrogenases (isocitrate dehydrogenase, α -ketoglutarate dehydrogenase, succinate dehydrogenase, and malate dehydrogenase), which remove electron-containing hydrogen or hydride atoms from a substrate and transfer them to electron-accepting coenzymes such as NAD^+ or FAD . The isomerase aconitase rearranges electrons in citrate, thereby forming isocitrate, to facilitate an electron transfer to NAD^+ . An iron cofactor in aconitase facilitates the isomerization.

FIGURE 23.3 Reactions of the TCA cycle. The oxidation–reduction enzymes and coenzymes are shown in red. Entry of the two carbons of acetyl CoA into the TCA cycle are indicated with the green box. The carbons released as CO_2 are shown with yellow boxes. Acetyl CoA, acetyl coenzyme A; ATP, adenosine triphosphate; CoASH, coenzyme A; FAD, flavin adenine dinucleotide; GDP, guanosine diphosphate; GTP, guanosine triphosphate; NAD, nicotinamide adenine dinucleotide; P_i , inorganic phosphate; TCA, tricarboxylic acid; SCoA, coenzyme A.

Although no oxygen is introduced into the TCA cycle, the two molecules of CO_2 produced have more oxygen than the acetyl group. These oxygen atoms are ultimately derived from the carbonyl group of acetyl CoA, two molecules of water added by fumarase and citrate synthase, and the PO_4^{2-} added to GDP.

The overall yield of energy-containing compounds from the TCA cycle is three NADH, one FAD(2H), and one GTP. The high-energy phosphate bond of GTP is generated from substrate-level phosphorylation catalyzed by succinate thiokinase (succinyl CoA synthetase). As the NADH and FAD(2H) are reoxidized in the electron transport chain, ~ 2.5 ATP are generated for each NADH, and 1.5 ATP for the FAD(2H) (see Chapter 24). Consequently, the net energy yield from the TCA cycle and oxidative phosphorylation is about 10 high-energy phosphate bonds for each acetyl group oxidized.

Otto S.'s exercise program increases his rate of ATP utilization and his rate of fuel oxidation in the TCA cycle. The TCA cycle generates NADH and FAD(2H), and the electron transport chain transfers electrons from NADH and FAD(2H) to O₂, thereby creating the electrochemical potential that drives ATP synthesis from ADP. As ATP is used in the cell, the rate of the electron transport chain increases. The TCA cycle and other fuel oxidative pathways respond by increasing their rates of NADH and FAD(2H) production.

A. Formation and Oxidation of Isocitrate

The TCA cycle begins with the condensation of the activated acetyl group and oxaloacetate to form the six-carbon intermediate citrate, a reaction that is catalyzed by the enzyme citrate synthase (see Fig. 23.3). Synthases, in general, catalyze the condensation of two organic molecules to form a carbon-carbon bond in the absence of high-energy phosphate bond energy. A synthetase catalyzes the same type of reaction but requires high-energy phosphate bonds to complete the reaction. Because oxaloacetate is regenerated with each turn of the cycle, it is not really considered a substrate of the cycle, or a source of electrons or carbon.

In the next step of the TCA cycle, the hydroxyl (alcohol) group of citrate is moved to an adjacent carbon so that it can be oxidized to form a keto group. The isomerization of citrate to isocitrate is catalyzed by the enzyme aconitase, which is named for an intermediate of the reaction. The enzyme isocitrate dehydrogenase catalyzes the oxidation of the alcohol group and the subsequent cleavage of the carboxyl group to release CO₂ (an oxidation followed by a decarboxylation), forming α -ketoglutarate.

From Figure 23.3, which enzymes in the TCA cycle release CO₂? How many moles of oxaloacetate are consumed in the TCA cycle for each mole of CO₂ produced?

B. α -Ketoglutarate to Succinyl Coenzyme A

The next step of the TCA cycle is the oxidative decarboxylation of α -ketoglutarate to succinyl CoA, catalyzed by the α -ketoglutarate dehydrogenase complex (see Fig. 23.3). The dehydrogenase complex contains the coenzymes thiamin pyrophosphate (TPP), lipoic acid, and FAD.

In this reaction, one of the carboxyl groups of α -ketoglutarate is released as CO₂, and the adjacent keto group is oxidized to the level of an acid, which then combines with the sulfhydryl group of coenzyme A (CoASH) to form succinyl CoA (see Fig. 23.3). Energy from the reaction is conserved principally in the reduction state of NADH, with a smaller amount present in the high-energy thioester bond of succinyl CoA.

C. Generation of Guanosine Triphosphate

Energy from the succinyl CoA thioester bond is used to generate GTP from GDP and inorganic phosphate (P_i) in the reaction catalyzed by succinate thiokinase (also known as succinyl CoA synthetase, for the reverse reaction) (see Fig. 23.3). This reaction is an example of **substrate-level phosphorylation**. By definition, substrate-level phosphorylation is the formation of a high-energy phosphate bond where none previously existed without the use of molecular O₂ (in other words, *not* oxidative phosphorylation). The high-energy phosphate bond of GTP is energetically equivalent to that of ATP and can be used directly for energy-requiring reactions like those involved in protein synthesis.

D. Oxidation of Succinate to Oxaloacetate

Up to this stage of the TCA cycle, two carbons have been stripped of their available electrons and released as CO₂. Two pairs of these electrons have been transferred to two NAD⁺, and one GTP has been generated. However, two additional pairs of electrons arising from acetyl CoA still remain in the TCA cycle as part of succinate. The remaining steps of the TCA cycle transfer these two pairs of electrons to FAD and NAD⁺ and add H₂O, thereby regenerating oxaloacetate.

Ann R. has been malnourished for some time and has developed subclinical deficiencies of many vitamins, including riboflavin. The coenzymes FAD (flavin adenine dinucleotide) and FMN (flavin mononucleotide) are synthesized from the vitamin riboflavin. Riboflavin is actively transported into cells, where the enzyme flavokinase adds a phosphate to form FMN. FAD synthetase then adds AMP to form FAD. FAD is the major coenzyme in tissues and is generally found tightly bound to proteins, with about 10% being covalently bound. Its turnover in the body is very slow, and people can live for long periods on low intakes without displaying any signs of a riboflavin deficiency.

The sequence of reactions converting succinate to oxaloacetate begins with the oxidation of succinate to fumarate (see Fig. 23.3). Single electrons are transferred from the two adjacent $-\text{CH}_2-$ methylene groups of succinate to an FAD bound to succinate dehydrogenase, thereby forming the double bond of fumarate. From the reduced enzyme-bound FAD, the electrons are passed into the electron transport chain. A hydroxyl group and a proton from water add to the double bond of fumarate, converting it to malate. In the last reaction of the TCA cycle, the alcohol group of malate is oxidized to a keto group through the donation of electrons to NAD^+ .

With the regeneration of oxaloacetate, the TCA cycle is complete; the chemical bond energy, carbon, and electrons donated by the acetyl group have been converted to CO_2 , NADH, FAD(2H), GTP, and heat.

The succinate-to-oxaloacetate sequence of reactions—oxidation through the formation of a double bond, addition of water to the double bond, and oxidation of the resultant alcohol to a ketone—is found in a number of oxidative pathways in the cell, such as the pathways for the oxidation of fatty acids and oxidation of the branched-chain amino acids.

III. Coenzymes of the Tricarboxylic Acid Cycle

The enzymes of the TCA cycle rely heavily on coenzymes for their catalytic function. Isocitrate dehydrogenase and malate dehydrogenase use NAD^+ as a coenzyme, and succinate dehydrogenase uses FAD. Citrate synthase catalyzes a reaction that uses a CoA derivative, acetyl CoA. The α -ketoglutarate dehydrogenase complex uses TPP, lipoate, and FAD as bound coenzymes, and NAD^+ and CoASH as substrates. Each of these coenzymes has unique structural features that enable it to fulfill its role in the TCA cycle.

Isocitrate dehydrogenase releases the first CO_2 , and α -ketoglutarate dehydrogenase releases the second CO_2 . There is no net consumption of oxaloacetate in the TCA cycle—the first step uses an oxaloacetate, and the last step produces one. The utilization and regeneration of oxaloacetate is the “cycle” part of the TCA cycle.

A. Flavin Adenine Dinucleotide and NAD^+

Both FAD and NAD^+ are electron-accepting coenzymes. Why is FAD used in some reactions and NAD^+ in others? Their unique structural features enable FAD and NAD^+ to act as electron acceptors in different types of reactions and to play different physiological roles in the cell. FAD is able to accept single electrons ($\text{H}\cdot$) and forms a half-reduced single-electron intermediate (Fig. 23.4). It thus participates in reactions in which single electrons are transferred independently from two different atoms, which occurs in double-bond formation (e.g., succinate to fumarate) and disulfide bond formation (e.g., lipoate to lipoate disulfide in the α -ketoglutarate dehydrogenase reaction). In contrast, NAD^+ accepts a pair of electrons as the hydride ion (H^-), which is attracted to the carbon opposite the positively charged pyridine ring (Fig. 23.5). This occurs, for example, in the oxidation of alcohols to ketones by malate dehydrogenase and isocitrate dehydrogenase. The nicotinamide ring accepts a hydride ion from the C–H bond, and the alcoholic hydrogen is released into the medium as a positively charged proton, H^+ .

FIGURE 23.4 One-electron steps in the reduction of FAD. When FAD and FMN accept single electrons, they are converted to the half-reduced semiquinone, a semistable free-radical form. They can also accept two electrons to form the fully reduced form, FADH₂. However, in most dehydrogenases, FADH₂ is never formed. Instead, the first electron is shared with a group on the protein as the next electron is transferred. Therefore, in this text, overall acceptance of two electrons by FAD has been denoted by the more general abbreviation, FAD(2H). FAD, flavin adenine dinucleotide; FMN, flavin mononucleotide.

FIGURE 23.5 Oxidation and decarboxylation of isocitrate. The alcohol group (C–OH) is oxidized to a ketone, with the C–H electrons donated to NAD⁺ as the hydride ion. Subsequent electron shifts in the pyridine ring remove the positive charge. The H of the –OH group dissociates into water as a proton, H⁺. NAD⁺, the electron acceptor, is reduced. NAD⁺, nicotinamide adenine dinucleotide.

The free-radical, single-electron forms of FAD are very reactive, and FADH can lose its electron through exposure to water or the initiation of chain reactions. As a consequence, FAD must remain very tightly, sometimes covalently, attached to its enzyme while it accepts and transfers electrons to another group bound on the enzyme. Because FAD interacts with many functional groups on amino acid side chains in the active site,

the E^0 for enzyme-bound FAD varies greatly and can be greater or much less than that of NAD^+ . In contrast, NAD^+ and NADH are more like substrate and product than coenzymes.

Q One of **Otto S.**'s tennis partners told him that he had heard about a health food designed for athletes that contained succinate. The advertisement made the claim that succinate would provide an excellent source of energy during exercise because it could be metabolized directly without oxygen. Do you see anything wrong with this statement?

NADH plays a regulatory role in balancing energy metabolism that FAD(2H) cannot because FAD(2H) remains attached to its enzyme. Free NAD^+ binds to a dehydrogenase and is reduced to NADH, which is then released into the medium, where it can bind and inhibit a different dehydrogenase. Consequently, oxidative enzymes are controlled by the NADH/NAD^+ ratio and do not generate NADH faster than it can be reoxidized in the electron transport chain. The regulation of the TCA cycle and other pathways of fuel oxidation by the NADH/NAD^+ ratio is part of the mechanism for coordinating the rate of fuel oxidation to the rate of ATP utilization.

A The claim that succinate oxidation can produce energy without oxygen is wrong. It is probably based on the fact that succinate is oxidized to fumarate by the donation of electrons to FAD. However, ATP can be generated from this process only when these electrons are donated to oxygen in the electron transport chain. The energy generated by the electron transport chain is used for ATP synthesis in the process of oxidative phosphorylation. After the covalently bound FAD(2H) is oxidized back to FAD by the electron transport chain, succinate dehydrogenase can oxidize another succinate molecule. If oxygen was not present, the FAD(2H) would remain reduced, and the enzyme could no longer convert succinate to fumarate.

B. Role of Coenzyme A in the Tricarboxylic Acid Cycle

Coenzyme A (CoASH), the acylation coenzyme, participates in reactions through the formation of a thioester bond between the sulfur (S) of CoASH and an acyl group (e.g., acetyl CoA, succinyl CoA) (Fig. 23.6). The complete structure of CoASH and its vitamin precursor, pantothenate, is shown in Figure 8.9A. A thioester bond differs from a typical oxygen ester bond because S, unlike O, does not share its electrons and participate in resonance formations. One of the consequences of this feature of sulfur chemistry is that the carbonyl carbon, the α -carbon, and the β -carbon of the acyl group in a CoA thioester can be activated for participation in different types of reactions (e.g., in the citrate synthase reaction, the α -carbon methyl group is activated for condensation with oxaloacetate; see Figs. 23.3 and 23.6A). Another consequence is that the thioester bond is a high-energy bond that has a large negative ΔG^0 of hydrolysis (~ -13 kcal/mol).

FIGURE 23.6 Utilization of the high-energy thioester bond of acyl CoAs. Energy transformations are shown in red. **A.** The energy released by hydrolysis of the thioester bond of acetyl CoA in the citrate synthase reaction contributes a large negative ΔG^0 to the forward direction of the TCA cycle. **B.** The energy of the succinyl CoA thioester bond is used for the synthesis of

the high-energy phosphate bond of GTP. Acetyl CoA, acetyl coenzyme A; GTP, guanosine triphosphate; SCoA, coenzyme A; TCA, tricarboxylic acid.

The energy from cleavage of the high-energy thioester bonds of succinyl CoA and acetyl CoA is used in two different ways in the TCA cycle. When the succinyl CoA thioester bond is cleaved by succinate thiokinase, the energy is used directly for activating an enzyme-bound phosphate that is transferred to GDP (see Fig. 23.6B). In contrast, when the thioester bond of acetyl CoA is cleaved in the citrate synthase reaction, the energy is released, giving the reaction a large negative ΔG° of -7.7 kcal/mol. The large negative ΔG° for citrate formation helps to keep the TCA cycle going in the forward direction.

CoASH is synthesized from the vitamin pantothenate in a sequence of reactions that phosphorylate pantothenate, add the sulfhydryl portion of CoA from cysteine, and then add AMP and an additional phosphate group from ATP (see Fig. 8.12A). Pantothenate is widely distributed in foods (“pantos” means everywhere), so it is unlikely that **Ann R.** has developed a pantothenate deficiency. Although CoA is required in ~100 different reactions in mammalian cells, no Recommended Daily Allowance (RDA) has been established for pantothenate, in part because indicators have not yet been found that specifically and sensitively reflect a deficiency of this vitamin in the human. The reported symptoms of pantothenate deficiency (fatigue, nausea, and loss of appetite) are characteristic of vitamin deficiencies in general.

C. The α -Keto Acid Dehydrogenase Complexes

The **α -ketoglutarate dehydrogenase complex** is one of a three-member family of similar **α -keto acid dehydrogenase complexes**. The other members of this family are the **pyruvate dehydrogenase complex** and the **branched-chain amino acid α -keto acid dehydrogenase complex**. Each of these complexes is specific for a different α -keto acid structure. In the sequence of reactions catalyzed by the complexes, the α -keto acid is decarboxylated (i.e., releases the carboxyl group as CO_2) (Fig. 23.7). The keto group is oxidized to the level of a carboxylic acid and then combined with CoASH to form an acyl CoA thioester (e.g., succinyl CoA).

α -Ketoglutarate

Succinyl CoA

FIGURE 23.7 Oxidative decarboxylation of α -ketoglutarate. The α -ketoglutarate dehydrogenase complex oxidizes α -ketoglutarate to succinyl coenzyme A (succinyl CoA). The carboxyl group is released as CO_2 . The keto group on the α -carbon is oxidized and then forms the acyl CoA thioester, succinyl CoA. The α , β , γ , and δ on succinyl CoA refer to the sequence of atoms in α -ketoglutarate. CoASH, coenzyme A; FAD, flavin adenine dinucleotide; NAD, nicotinamide adenine dinucleotide; SCoA, coenzyme A.

All of the α -keto acid dehydrogenase complexes are huge enzyme complexes composed of multiple subunits of three different enzymes, E_1 , E_2 , and E_3 . E_1 is an α -keto acid decarboxylase, which contains thiamin pyrophosphate (TPP); it cleaves off the carboxyl group of the α -keto acid. E_2 is a transacylase containing lipoate; it transfers the acyl portion of the α -keto acid from thiamin to CoASH. E_3 is dihydrolipoyl dehydrogenase, which contains FAD; it transfers electrons from reduced lipoate to FAD, which then transfers the electrons to NAD^+ . The collection of three enzyme activities into one huge complex enables the product of one enzyme to be transferred to the next enzyme without loss of energy. Complex formation also increases the rate of catalysis because the substrates for E_2 and E_3 remain bound to the enzyme complex. The mechanism of an oxidative decarboxylation is depicted in Figures e-23.1 and e-23.2 .

 The E^0 for FAD accepting electrons is -0.219 (see Table 20.4). The E^0 for NAD^+ accepting electrons is -0.32 . Thus, the transfer of electrons from FAD(2H) to NAD^+ is energetically unfavorable. How do the α -keto acid dehydrogenase complexes allow this electron transfer to occur?

1. Thiamin Pyrophosphate in the α -Ketoglutarate Dehydrogenase Complex

Thiamin pyrophosphate (TPP) is synthesized from the vitamin thiamin by the addition of pyrophosphate (see Fig. 8.8). The pyrophosphate group binds magnesium, which binds to amino acid side chains on the enzyme. This binding is relatively weak for a coenzyme, so thiamin turns over rapidly in the body, and a deficiency can develop rapidly in individuals who are on thiamin-free or low-thiamin diets.

The general function of TPP is the cleavage of a carbon–carbon bond next to a keto group. In the α -ketoglutarate, pyruvate, and branched-chain α -keto acid dehydrogenase complexes, the functional carbon on the thiazole ring forms a covalent bond with the α -keto carbon, thereby facilitating the cleavage of the bond between the α -keto carbon and the adjacent carboxylic acid group (see Fig. 8.8 for the mechanism of this reaction). TPP is also a coenzyme for transketolase in the pentose phosphate pathway, where it similarly facilitates the cleavage of the carbon–carbon bond next to a keto group. In thiamin deficiency, α -ketoglutarate, pyruvate, and other α -keto acids accumulate in the blood.

 In **AI M.'s** heart failure, which is caused by a dietary deficiency of the vitamin thiamin, pyruvate dehydrogenase, α -ketoglutarate dehydrogenase, and the branched-chain α -keto acid dehydrogenase complexes are less functional than normal. Because heart muscle, skeletal muscle, and nervous tissue have high rates of ATP production from the NADH produced by the oxidation of pyruvate to acetyl CoA and of acetyl CoA to CO_2 in the TCA cycle, these tissues present with the most obvious signs of thiamin deficiency.

In Western societies, gross thiamin deficiency is most often associated with alcohol use disorder. The mechanism for active absorption of thiamin is strongly and directly inhibited by alcohol. Subclinical deficiency of thiamin from malnutrition or anorexia may be common in the general population and is usually associated with multiple vitamin deficiencies.

2. Lipoate

Lipoate is a coenzyme found only in α -keto acid dehydrogenase complexes. It is synthesized in the human from carbohydrate and amino acids, and it does not require a vitamin precursor. Lipoate is attached to the transacylase enzyme through its carboxyl group, which is covalently bound to the terminal $-\text{NH}_2$ of a lysine in the protein (Fig. e-23.2) . At its functional end, lipoate contains a disulfide group that accepts electrons when it binds the acyl fragment of α -ketoglutarate. It can thus act like a long, flexible arm of the enzyme that reaches over to the decarboxylase to pick up the acyl fragment from thiamin and transfer it to the active site containing bound CoASH. It then swings over to dihydrolipoyl dehydrogenase to transfer electrons from the lipoyl sulfhydryl groups to FAD.

 Arsenic poisoning is caused by the presence of a large number of different arsenious compounds that are effective metabolic inhibitors. Acute accidental or intentional arsenic poisoning requires high doses and involves arsenate

(AsO_4^{2-}) and arsenite (AsO_3^{2-}). Arsenite, which is 10 times more toxic than arsenate, binds to neighboring sulfhydryl groups, such as those in dihydrolipoate and in nearby cysteine pairs (vicinal) found in α -keto acid dehydrogenase complexes and in succinic dehydrogenase. Arsenate weakly inhibits enzymatic reactions involving phosphate, including the enzyme glyceraldehyde 3-P dehydrogenase in glycolysis (see Chapter 22). Thus, both aerobic and anaerobic ATP production can be inhibited. The low doses of arsenic compounds found in water supplies are a major public health concern but are associated with an increased risk of cancer rather than direct toxicity.

3. Flavin Adenine Dinucleotide and Dihydrolipoyl Dehydrogenase

FAD on dihydrolipoyl dehydrogenase accepts electrons from the lipoyl sulfhydryl groups and transfers them to bound NAD^+ . FAD thus accepts and transfers electrons without leaving its binding site on the enzyme. The direction of the reaction is favored by interactions of FAD with groups on the enzyme, which change its reduction potential, and by the overall release of energy from cleavage and oxidation of α -ketoglutarate.

The E^0 values were calculated in a test tube under standard conditions. When FAD is bound to an enzyme, as it is in the α -keto acid dehydrogenase complexes, amino acid side chains can alter its E^0 value. Thus, the transfer of electrons from the bound FAD(2H) to NAD^+ in dihydrolipoyl dehydrogenase is actually energetically favorable.

IV. Energetics of the Tricarboxylic Acid cycle

Like all metabolic pathways, the TCA cycle operates with an overall net negative ΔG^0 (Fig. 23.8). The conversion of substrates to products is, therefore, energetically favorable. However, some of the reactions, such as the malate dehydrogenase reaction, have a positive value.

FIGURE 23.8 Approximate ΔG° values for the reactions in the tricarboxylic acid (TCA) cycle, given for the forward direction. The reactions with **large** negative ΔG° values are shown in red. The standard free-energy change (ΔG°) refers to the free-energy change for conversion of 1 mol of substrate to 1 mol of product at pH 7.0 under standard conditions. Acetyl CoA, acetyl coenzyme A; FAD, flavin adenine dinucleotide; GDP, guanosine diphosphate; GTP, guanosine triphosphate; NAD, nicotinamide adenine dinucleotide; Pi, inorganic phosphate; Succinyl CoA, Succinyl coenzyme A.

The net standard free-energy change for the TCA cycle, ΔG° , can be calculated from the sum of the ΔG° values for the individual reactions. The ΔG° , -13 kcal, is the amount of energy lost as heat. It can be considered the amount of energy spent to ensure that oxidation of the acetyl group to CO_2 goes to completion. This value is surprisingly small. However, oxidation of NADH and FAD(2H) in the electron transport chain helps to make acetyl oxidation more energetically favorable and pulls the TCA cycle forward.

A. Overall Efficiency of the Tricarboxylic Acid Cycle

The reactions of the TCA cycle are extremely efficient in converting energy in the chemical bonds of the acetyl group to other forms. The total amount of energy available from the acetyl group is about 228 kcal/mol (the amount of energy that could be released from complete combustion of 1 mol of acetyl groups to CO_2 in an experimental chamber). The products of the TCA cycle (NADH, FAD(2H), and GTP) contain about 207 kcal (Table 23.1). Thus, the TCA cycle reactions are able to conserve about 90% of the energy available from the oxidation of acetyl CoA.

TABLE 23.1 Energy Yield of the TCA Cycle

KCAL/MOL	
3 NADH: 3×53	= 159
1 FAD(2H)	= 41
1 GTP	= 7
Sum	= 207

FAD, flavin adenine dinucleotide; GTP, guanosine triphosphate; NAD, nicotinamide adenine dinucleotide.

The values given for energy yield from NADH and FAD(2H) are based on the equation $\Delta G = -n F \Delta E^0$, explained in Chapter 20.

B. Thermodynamically and Kinetically Reversible and Irreversible Reactions

Three reactions in the TCA cycle have large negative values for ΔG^0 that strongly favor the forward direction: the reactions catalyzed by citrate synthase, isocitrate dehydrogenase, and α -ketoglutarate dehydrogenase (see Fig. 23.8). Within the TCA cycle, these reactions are physiologically irreversible for two reasons: The products do not rise to high enough concentrations under physiological conditions to overcome the large negative ΔG^0 values, and the enzymes involved catalyze the reverse reaction very slowly. These reactions make the major contribution to the overall negative ΔG^0 for the TCA cycle and keep it going in the forward direction.

In contrast to these irreversible reactions, the reactions catalyzed by aconitase and malate dehydrogenase have a positive ΔG^0 for the forward direction and are thermodynamically and kinetically reversible. Because aconitase is rapid in both directions, equilibrium values for the concentration ratio of products to substrates are maintained, and the concentration of citrate is about 23 times that of isocitrate. The accumulation of citrate instead of isocitrate facilitates the transport of excess citrate to the cytosol, where it can provide a source of acetyl CoA for pathways like fatty acid and cholesterol synthesis. It also allows citrate to serve as an inhibitor of citrate synthase when flux through isocitrate dehydrogenase is decreased. Likewise, the equilibrium constant of the malate dehydrogenase reaction favors the accumulation of malate over oxaloacetate, resulting in a low oxaloacetate concentration that is influenced by the NADH/NAD⁺ ratio. Thus, there is a net flux of oxaloacetate toward malate in the liver during fasting (as a result of fatty acid oxidation, which raises the NADH/NAD⁺ ratio), and malate can then be transported out of the mitochondria to provide a substrate for gluconeogenesis.

Otto S. had difficulty losing weight because human fuel utilization is too efficient. His adipose tissue fatty acids are being converted to acetyl CoA, which is being oxidized in the TCA cycle, thereby generating NADH and FAD(2H). The energy in these compounds is used for ATP synthesis from oxidative phosphorylation. If his fuel utilization were less efficient and his ATP yield were lower, he would have to oxidize much greater amounts of fat to get the ATP he needs for exercise.

V. Regulation of the Tricarboxylic Acid Cycle

The oxidation of acetyl CoA in the TCA cycle and the conservation of this energy as NADH and FAD(2H) is essential for the generation of ATP in almost all tissues in the body. In spite of changes in the supply of fuels, type of fuels in the blood, or rate of ATP utilization, cells maintain ATP homeostasis (a constant level of ATP). The rate of the TCA cycle, like that of all fuel oxidation pathways, is principally regulated to correspond to the rate of the electron transport chain, which is regulated by the ATP/ADP ratio and the rate of ATP utilization (see Chapter 24). The major sites of regulation are shown in Figure 23.9.

FIGURE 23.9 Major regulatory interactions in the tricarboxylic acid (TCA) cycle. The rate of adenosine triphosphate (ATP) hydrolysis controls the rate of ATP synthesis, which controls the rate of NADH oxidation in the electron transport chain (ETC). All reduced nicotinamide adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide (FAD(2H)) produced by the cycle donate electrons to this chain (shown on the *right*). Thus, oxidation of acetyl coenzyme A (acetyl CoA) in the TCA cycle can go only as fast as electrons from NADH enter the electron transport chain, which is controlled by the ATP and adenosine diphosphate (ADP) content of the cells. The ADP and NADH concentrations feed information on the rate of oxidative phosphorylation back to the TCA cycle. Isocitrate dehydrogenase (DH), α -ketoglutarate DH, and malate DH are inhibited by increased NADH concentration. The NADH/NAD⁺ ratio changes the concentration of oxaloacetate. Citrate is a product inhibitor of citrate synthase. ADP is an allosteric activator of isocitrate DH. During muscular contraction, increased Ca²⁺ concentrations activate isocitrate DH and α -ketoglutarate DH (as well as pyruvate DH). GDP, guanosine diphosphate; GTP, guanosine triphosphate; Pi, inorganic phosphate; Succinyl CoA, Succinyl coenzyme A.

Two major messengers feed information on the rate of ATP utilization back to the TCA cycle: (1) the phosphorylation state of ATP, as reflected in ATP and ADP levels; and (2) the reduction state of NAD⁺, as reflected in the ratio of NADH/NAD⁺. Within the cell, even within the mitochondrion, the total adenine nucleotide pool (AMP, ADP, plus ATP) and the total NAD pool (NAD⁺ plus NADH) are relatively constant. Thus, an increased rate of ATP utilization results in a small decrease of ATP concentration and an increase of ADP. Likewise, increased NADH oxidation to NAD⁺ by the electron transport chain increases the rate of pathways that produce NADH. Under normal physiological conditions, the TCA cycle and other oxidative pathways respond so rapidly to increased ATP demand that the ATP concentration does not significantly change.

As **Otto S.** exercises, his myosin ATPase hydrolyzes ATP to provide the energy for movement of myofibrils. The decrease of ATP and increase of ADP stimulates the electron transport chain to oxidize more NADH and FAD(2H). The TCA cycle is stimulated to provide more NADH and FAD(2H) to the electron transport chain. The activation of the TCA cycle occurs through a decrease of the NADH/NAD⁺ ratio, an increase of ADP concentration, and an increase of Ca²⁺. Although regulation of the transcription of genes for TCA cycle enzymes is too slow to respond to changes of ATP demands during exercise, the number and size of mitochondria increase during training. Thus **Otto S.** is increasing his capacity for fuel oxidation as he trains.

A. Regulation of Citrate Synthase

Citrate synthase, which is the first enzyme of the TCA cycle, is a simple enzyme that has no allosteric regulators. Its rate is controlled principally by the concentration of oxaloacetate, its substrate, and the concentration of citrate, a product inhibitor, that is competitive with oxaloacetate (see Fig. 23.9). The malate–oxaloacetate equilibrium favors malate, so the oxaloacetate concentration is very low inside the mitochondrion and is below the apparent K_m (see Chapter 9, Section II.A.5) of citrate synthase. When the NADH/NAD⁺ ratio decreases, the ratio of oxaloacetate to malate increases. When isocitrate dehydrogenase is activated, the concentration of citrate decreases, thus relieving the product inhibition of citrate synthase. Thus, both increased oxaloacetate and decreased citrate levels regulate the response of citrate synthase to conditions established by the electron transport chain and oxidative phosphorylation. In the liver, the NADH/NAD⁺ ratio helps determine whether acetyl CoA enters the TCA cycle or goes into the alternative pathway for ketone body synthesis.

B. Allosteric Regulation of Isocitrate Dehydrogenase

Isocitrate dehydrogenase, which consists of eight subunits, is considered one of the rate-limiting steps of the TCA cycle, and it is allosterically activated by ADP and inhibited by NADH (Fig. 23.10). In the absence of ADP, the enzyme exhibits positive cooperativity; as isocitrate binds to one subunit, other subunits are converted to an active conformation (see Chapter 9, Section III.A, on allosteric enzymes). In the presence of ADP, all of the subunits are in their active conformation, and isocitrate binds more readily. Consequently, the apparent $K_{m,app}$ (the $S_{0.5}$) shifts to a much lower value. Thus, at the concentration of isocitrate found in the mitochondrial matrix, a small change in the concentration of ADP can produce a large change in the rate of the isocitrate dehydrogenase reaction. Small changes in the concentration of the product, NADH, and of the cosubstrate, NAD⁺, also affect the rate of the enzyme more than they would a nonallosteric enzyme.

FIGURE 23.10 Allosteric regulation of isocitrate dehydrogenase (ICDH). Isocitrate, nicotinamide adenine dinucleotide (NAD⁺), and NADH bind in the active site; adenosine diphosphate (ADP) and Ca²⁺ are activators and bind to separate allosteric sites. **A.** A graph of velocity versus isocitrate concentration shows positive cooperativity (sigmoid curve) in the absence of ADP. The allosteric activator ADP changes the curve into one closer to a rectangular hyperbola and decreases the K_m ($S_{0.5}$) for isocitrate. **B.** The allosteric activation by ADP is not an all-or-nothing response. The extent of activation by ADP depends on its concentration. **C.** Increases in the concentration of product, NADH, decrease the velocity of the enzyme through effects on the allosteric activation.

C. Regulation of α -Ketoglutarate Dehydrogenase

The α -ketoglutarate dehydrogenase complex, although not an allosteric enzyme, is product-inhibited by NADH and succinyl CoA, and may also be inhibited by GTP (see Fig. 23.9). Thus, both α -ketoglutarate dehydrogenase and isocitrate dehydrogenase respond directly to changes in the relative levels of ADP and hence the rate at which NADH is oxidized by electron transport. Both of these enzymes are also activated by Ca²⁺. In contracting heart muscle, and possibly other muscle tissues, the release of Ca²⁺ from the sarcoplasmic reticulum during muscle contraction may provide an additional activation of these enzymes when ATP is being rapidly hydrolyzed.

D. Regulation of Tricarboxylic Acid Cycle Intermediates

Regulation of the TCA cycle serves two functions: It ensures that NADH is generated fast enough to maintain ATP homeostasis, and it regulates the concentration of TCA cycle intermediates. For example, in the liver, a decreased rate of isocitrate dehydrogenase increases citrate concentration, which stimulates citrate efflux to the cytosol. In the cytosol, citrate can act as an inhibitor of PFK-1, as well as activating fatty acid synthesis and providing a substrate for fatty acid synthesis (see Chapter 31). Citrate efflux from the mitochondria sends the message that energy levels are high within the mitochondria. A number of regulatory interactions occur in the TCA cycle, in addition to those mentioned above, that control the levels of TCA intermediates and their flux into pathways that adjoin the TCA cycle.

VI. Precursors of Acetyl Coenzyme A

Compounds enter the TCA cycle as acetyl CoA or as an intermediate that can be converted to malate or oxaloacetate. Compounds that enter as acetyl CoA are oxidized to CO₂. Compounds that enter as TCA cycle intermediates replenish intermediates that have been used in biosynthetic pathways, such as gluconeogenesis or heme synthesis, but cannot be fully oxidized to CO₂.

A. Sources of Acetyl Coenzyme A

Acetyl CoA serves as a common point of convergence for the major pathways of fuel oxidation. It is generated directly from the β -oxidation of fatty acids and degradation of the ketone bodies β -hydroxybutyrate and acetoacetate (Fig. 23.11). It is also formed from acetate, which can arise from the diet or from ethanol oxidation. Glucose and other carbohydrates enter glycolysis, a pathway common to all cells, and are oxidized to pyruvate. The amino acids alanine and serine are also converted to pyruvate. Pyruvate is oxidized to acetyl CoA by the PDC. A number of amino acids, such as leucine and lysine, are also oxidized to acetyl CoA. Thus, the final oxidation of acetyl CoA to CO₂ in the TCA cycle is the last step in all the major pathways of fuel oxidation.

FIGURE 23.11 Origin of the acetyl group from various fuels. Acetyl coenzyme A (acetyl CoA) is derived from the oxidation of fuels. The portions of fatty acids, ketone bodies, glucose, pyruvate, the amino acid alanine, and ethanol that are converted to the acetyl group of acetyl CoA are shown in boxes. SCoA, coenzyme A.

B. Pyruvate Dehydrogenase Complex

The pyruvate dehydrogenase complex (PDC) oxidizes pyruvate to acetyl CoA, thus linking glycolysis and the TCA cycle. In the brain, which is dependent on the oxidation of glucose to CO_2 to fulfill its ATP needs, regulation of the PDC is a life-and-death matter.

1. Structure of the Pyruvate Dehydrogenase Complex

PDC belongs to the α -keto acid dehydrogenase complex family and thus shares structural and catalytic features with the α -ketoglutarate dehydrogenase complex and the branched-chain α -keto acid dehydrogenase complex (Fig. 23.12). It contains the same three basic types of catalytic subunits: (1) pyruvate decarboxylase subunits that bind TPP (E_1); (2) transacetylase subunits that bind lipoate (E_2); and (3) dihydrolipoyl dehydrogenase subunits that bind FAD (E_3). Although the E_1 and E_2 enzymes in PDC are relatively specific for pyruvate, the same dihydrolipoyl dehydrogenase subunit participates in all of the α -keto acid dehydrogenase complexes. In addition to these three types of subunits, the PDC complex contains one additional subunit, an E_3 -binding protein ($E_3\text{BP}$). Each functional component of the PDC complex is present in multiple copies (e.g., bovine heart PDC has 30 subunits of E_1 , 60 subunits of E_2 , and 6 subunits each of E_3 and $E_3\text{BP}$). The E_1 enzyme is itself a tetramer of two different types of subunits, α and β .

FIGURE 23.12 The pyruvate dehydrogenase complex (PDC) catalyzes the oxidation of the α -keto acid pyruvate to acetyl coenzyme A. Acetyl CoA, acetyl coenzyme A; CoASH, coenzyme A; FAD, flavin adenine dinucleotide; NAD, nicotinamide adenine dinucleotide; SCoA, coenzyme A.

 Deficiencies of the pyruvate dehydrogenase complex (PDC) although rare, are among the most common inherited diseases leading to lactic acidemia and, similar to pyruvate carboxylase deficiency, are grouped into the category of Leigh syndrome (subacute necrotizing encephalopathy). When PDC is defective, pyruvate will accumulate and ATP production will drop. The low ATP will stimulate glycolysis (see Chapter 22) to proceed anaerobically, and to do so, pyruvate is reduced to lactate. In its severe form, PDC deficiency presents with overwhelming lactic acidosis at birth, with death in the neonatal period. In a second form of presentation, the lactic acidemia is moderate, but there is profound psychomotor disability with increasing age. In many cases, concomitant damage to the brainstem and basal ganglia lead to death in infancy. The neurological symptoms arise because the brain has a very limited ability to use fatty acids as a fuel and is, therefore, dependent on glucose metabolism for its energy supply.

The most common PDC genetic defects are in the gene for the α -subunit of E₁. The E₁ α -gene is X-linked. Because of its importance in central nervous system metabolism, pyruvate dehydrogenase deficiency is a problem in both males and females, even if the female is a carrier. For this reason, it is classified as an X-linked dominant disorder.

2. Regulation of the Pyruvate Dehydrogenase Complex

PDC activity is controlled principally through phosphorylation by pyruvate dehydrogenase kinase, which

inhibits the enzyme, and dephosphorylation by pyruvate dehydrogenase phosphatase, which activates it (Fig. 23.13). Pyruvate dehydrogenase kinase and pyruvate dehydrogenase phosphatase are regulatory subunits within the PDC complex and act only on the complex. PDC kinase transfers a phosphate from ATP to specific serine hydroxyl (ser-OH) groups on pyruvate decarboxylase (E_1). PDC phosphatase removes these phosphate groups by hydrolysis. Phosphorylation of just one serine on the PDC E_1 α -subunit can decrease its activity by >99%. PDC kinase is present in complexes as tissue-specific isozymes that vary in their regulatory properties.

FIGURE 23.13 Regulation of pyruvate dehydrogenase complex (PDC). PDC kinase, a subunit of the enzyme, phosphorylates PDC at a specific serine residue, thereby converting PDC to an inactive form. The kinase is inhibited by adenosine diphosphate (ADP) and pyruvate. PDC phosphatase, another subunit of the enzyme, removes the phosphate, thereby activating PDC. The phosphatase is activated by Ca²⁺. When the substrates, pyruvate and coenzyme A (CoASH), are bound to PDC, the kinase activity is inhibited and PDC is active. When the products acetyl coenzyme A and NADH bind to PDC, the kinase activity is stimulated, and the enzyme is phosphorylated to the inactive form. E₁ and the kinase exist as tissue-specific isozymes with overlapping tissue specificity and somewhat different regulatory properties. Acetyl CoA, acetyl coenzyme A;

ATP, adenosine triphosphate; CoASH, coenzyme A; NAD, nicotinamide adenine dinucleotide; Pi, inorganic phosphate.

PDC kinase is itself inhibited by ADP and pyruvate. Thus, when rapid ATP utilization results in an increase of ADP, or when activation of glycolysis increases pyruvate levels, PDC kinase is inhibited and PDC remains in an active, nonphosphorylated form. PDC phosphatase requires Ca^{2+} for full activity. In the heart, increased intramitochondrial Ca^{2+} during rapid contraction activates the phosphatase, thereby increasing the amount of active, nonphosphorylated PDC.

PDC is also regulated through inhibition by its products, acetyl CoA and NADH. This inhibition is stronger than regular product inhibition because their binding to PDC stimulates its phosphorylation to the inactive form. The substrates of the enzyme, CoASH and NAD^+ , antagonize this product inhibition. Thus, when an ample supply of acetyl CoA for the TCA cycle is already available from fatty acid oxidation, acetyl CoA, and NADH build up and dramatically decrease their own further synthesis by PDC.

PDC can also be activated rapidly through a mechanism involving insulin, which plays a prominent role in adipocytes. In many tissues, insulin may, over time, slowly increase the amount of PDC present.

The rate of other fuel oxidation pathways that feed into the TCA cycle is also increased when ATP utilization increases. Insulin, other hormones, and diet control the availability of fuels for these oxidative pathways.

3. Pyruvate Dehydrogenase Complex: Regulation and Glycolysis

PDC is also regulated principally by the rate of ATP utilization through rapid phosphorylation to an inactive form (see Fig. 23.13). Thus, in a normally respiring cell, with an adequate supply of oxygen, glycolysis and the TCA cycle are activated together, and glucose can be completely oxidized to carbon dioxide. However, when tissues do not have an adequate supply of oxygen to meet their ATP demands, the increased NADH/ NAD^+ ratio inhibits pyruvate dehydrogenase, but AMP activates glycolysis. A proportion of the pyruvate is then reduced to lactate to allow glycolysis to continue.

VII. Tricarboxylic Acid Cycle Intermediates and Anaplerotic Reactions

A. Tricarboxylic Acid Cycle Intermediates Are Precursors for Biosynthetic Pathways

The intermediates of the TCA cycle serve as precursors for a variety of different pathways present in different cell types (Fig. 23.14). This is particularly important in the central metabolic role of the liver. The TCA cycle in the liver is often called an “open cycle” because there is such a high efflux of intermediates. After a high-carbohydrate meal, citrate efflux and cleavage to acetyl CoA provides acetyl units for cytosolic fatty acid synthesis. During fasting, gluconeogenic precursors are converted to malate, which leaves the mitochondria for cytosolic gluconeogenesis. The liver also uses TCA cycle intermediates to synthesize carbon skeletons of amino acids. Succinyl CoA may be removed from the TCA cycle to form heme in cells of the liver and bone marrow. In the brain, α -ketoglutarate is converted to glutamate and then to γ -aminobutyric acid (GABA), a neurotransmitter. In skeletal muscle, α -ketoglutarate is converted to glutamine, which is transported through the blood to other tissues.

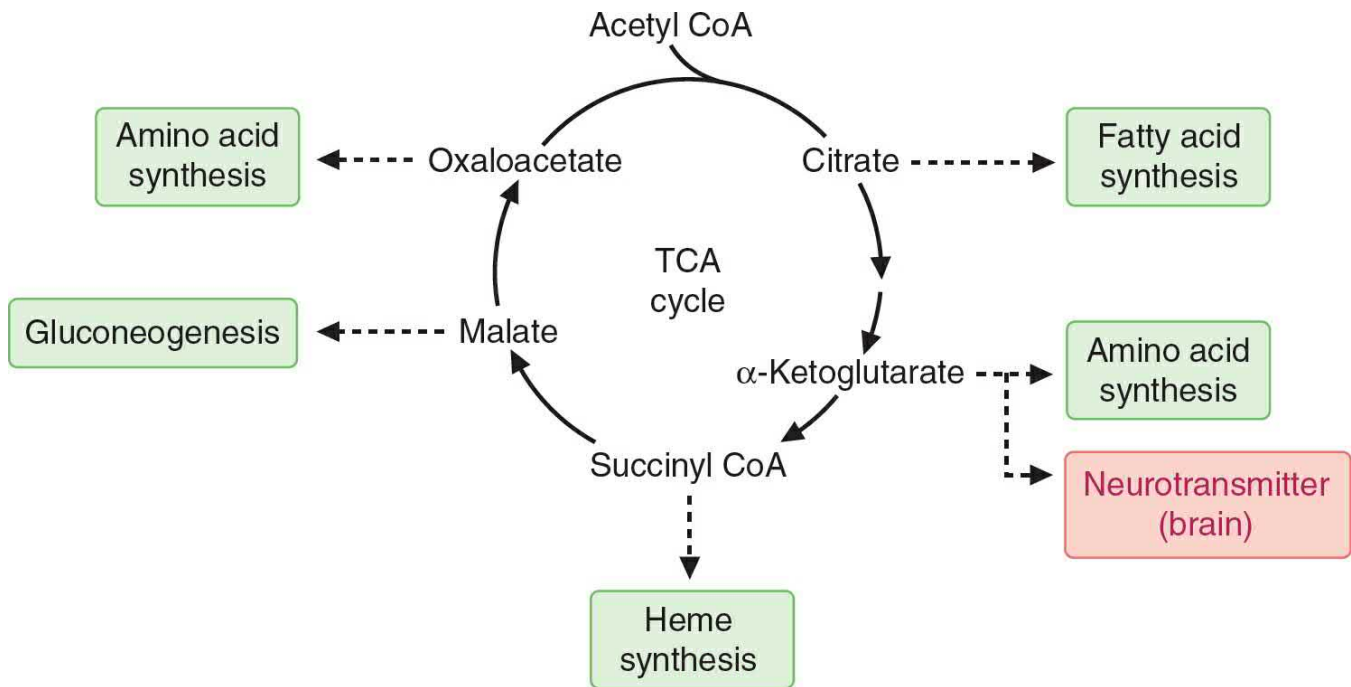

FIGURE 23.14 Efflux of intermediates from the tricarboxylic acid (TCA) cycle. In the liver, TCA cycle intermediates are continuously withdrawn into the pathways of fatty acid synthesis, amino acid synthesis, gluconeogenesis, and heme synthesis. In the brain, α -ketoglutarate is converted to glutamate and γ -aminobutyric acid (GABA), both of which are neurotransmitters. Acetyl CoA, acetyl coenzyme A; SCoA, coenzyme A.

Pyruvate, citrate, α -ketoglutarate and malate, ADP, ATP, and phosphate (as well as many other compounds) have specific transporters in the inner mitochondrial membrane that transport compounds between the mitochondrial matrix and cytosol in exchange for a compound of similar charge. In contrast, CoASH, acetyl CoA, other CoA derivatives, NAD^+ and NADH, and oxaloacetate are not transported at a metabolically significant rate. To obtain cytosolic acetyl CoA, many cells transport citrate to the cytosol, where it is cleaved to acetyl CoA and oxaloacetate by citrate lyase.

B. Anaplerotic Reactions

Removal of any of the intermediates from the TCA cycle removes the four carbons that are used to regenerate oxaloacetate during each turn of the cycle. With depletion of oxaloacetate, it is impossible to continue oxidizing acetyl CoA. To enable the TCA cycle to keep running, cells have to supply enough four-carbon intermediates from the degradation of carbohydrates or certain amino acids to compensate for the rate of removal. Pathways or reactions that replenish the intermediates of the TCA cycle are referred to as **anaplerotic** (“filling up”).

Pyruvate carboxylase deficiency is one of the genetic diseases grouped together under the clinical manifestations of Leigh syndrome. In the mild form, the patient presents early in life with delayed development and a mild-to-moderate lactic acidemia (similar to PDC defects, pyruvate will accumulate when pyruvate decarboxylase is defective). Patients who survive have severe intellectual disabilities, and there is a loss of cerebral neurons. In the brain, pyruvate carboxylase is present in the astrocytes, which use TCA cycle intermediates to synthesize glutamine. This pathway is essential for neuronal survival. The major cause of the lactic acidemia is that cells dependent on pyruvate carboxylase for an anaplerotic supply of oxaloacetate cannot oxidize pyruvate in the TCA cycle (because of low oxaloacetate levels), and the liver cannot convert pyruvate to glucose (because the pyruvate carboxylase reaction is required for this pathway to occur), so the excess pyruvate is converted to lactate.

1. Pyruvate Carboxylase

Pyruvate carboxylase is one of the major anaplerotic enzymes in the cell. It catalyzes the addition of CO_2 to pyruvate to form oxaloacetate (Fig. 23.15). Like most carboxylases, pyruvate carboxylase contains biotin (a vitamin), which forms a covalent intermediate with CO_2 in a reaction that requires ATP and Mg^{2+} (see Fig. 8.9). The activated CO_2 is then transferred to pyruvate to form the carboxyl group of oxaloacetate.

FIGURE 23.15 Pyruvate carboxylase reaction. Pyruvate carboxylase adds a carboxyl group from bicarbonate (which is in equilibrium with CO_2) to pyruvate to form oxaloacetate. Biotin is used to activate and transfer the CO_2 . The energy to form the covalent biotin- CO_2 complex is provided by the high-energy phosphate bond of adenosine triphosphate (ATP), which is cleaved in the reaction. The enzyme is activated by acetyl coenzyme A. Acetyl CoA; acetyl coenzyme A; ADP, adenosine diphosphate; P_i , inorganic phosphate.

Pyruvate carboxylase is found in many tissues, such as liver, brain, adipocytes, and fibroblasts, where its function is anaplerotic. Its concentration is high in liver and kidney cortex, where there is a continuous removal of oxaloacetate and malate from the TCA cycle to enter the gluconeogenic pathway.

Pyruvate carboxylase is activated by acetyl CoA and inhibited by high concentrations of many acyl CoA derivatives. As the concentration of oxaloacetate is depleted through the efflux of TCA cycle intermediates, the rate of the citrate synthase reaction decreases and acetyl CoA concentration rises. The acetyl CoA then activates pyruvate carboxylase to synthesize more oxaloacetate.

2. Amino Acid Degradation

The pathways for oxidation of many amino acids convert their carbon skeletons into five- and four-carbon intermediates of the TCA cycle that can regenerate oxaloacetate (Fig. 23.16). Alanine and serine carbons can enter through pyruvate carboxylase (see Fig. 23.16, circle 1). In all tissues with mitochondria (except for, surprisingly, the liver), oxidation of the two branched-chain amino acids isoleucine and valine to succinyl CoA forms a major anaplerotic route (see Fig. 23.16, circle 3). In the liver, other compounds forming propionyl CoA (e.g., methionine, threonine, and odd-chain-length or branched fatty acids) also enter the TCA cycle as succinyl CoA. In most tissues, glutamine is taken up from the blood, converted to glutamate, and then oxidized to α -ketoglutarate, forming another major anaplerotic route (see Fig. 23.16, circle 2). However, the TCA cycle cannot be resupplied with intermediates of fatty acid oxidation of even chain length, or ketone body oxidation, both of which only produce acetyl CoA. In the TCA cycle, two carbons are lost from citrate before succinyl CoA is formed, so there is no net conversion of acetyl carbon to oxaloacetate.

FIGURE 23.16 Major anaplerotic pathways of the tricarboxylic acid (TCA) cycle. (1) and (3) (red arrows) are the two major anaplerotic pathways. (1) Pyruvate carboxylase. (2) Glutamate is reversibly converted to α -ketoglutarate by transaminases (TA) and glutamate dehydrogenase (GDH) in many tissues. (3) The carbon skeletons of valine and isoleucine, a three-carbon unit from odd-chain fatty acid oxidation, and a number of other compounds enter the TCA cycle at the level of succinyl coenzyme A. Other amino acids are also degraded to fumarate (4) and oxaloacetate (5), principally in the liver. Acetyl CoA, acetyl coenzyme A; ADP, adenosine diphosphate; ATP, adenosine triphosphate; NAD, nicotinamide adenine dinucleotide; P_i , inorganic phosphate; Propionyl CoA, propionyl coenzyme A; Succinyl CoA, succinyl coenzyme A.

CLINICAL COMMENTS

Otto S. is experiencing the benefits of physical conditioning. A variety of functional adaptations in the heart, lungs, vascular system, and skeletal muscle occur in response to regular graded exercise. The pumping efficiency of the heart increases, allowing greater cardiac output with fewer beats per minute and at a lower rate of oxygen utilization. The lungs extract a greater percentage of oxygen from the inspired air, allowing fewer respirations per unit of activity. The vasodilatory capacity of the arterial beds in skeletal muscle increases, promoting greater delivery of oxygen and fuels to exercising muscle. Concurrently, the venous drainage capacity in muscle is enhanced, ensuring that lactic acid will not accumulate in contracting tissues. These adaptive changes in physiological responses are accompanied by increases in the number, size, and activity of skeletal muscle mitochondria, along with the content of TCA cycle enzymes and components of the electron transport chain. These changes markedly enhance the oxidative capacity of exercising muscle.

In skeletal muscle and other tissues, ATP is generated by anaerobic glycolysis when the rate of aerobic respiration is inadequate to meet the rate of ATP utilization. Under these circumstances, the rate of pyruvate production exceeds the cell's capacity to oxidize NADH in the electron transport chain, and hence to oxidize pyruvate in the TCA cycle. The excess pyruvate is reduced to lactate. Because lactate is an acid, its accumulation affects the muscle and causes pain and swelling.

Ann R. is experiencing fatigue for several reasons. She has iron-deficiency anemia, which affects iron-containing hemoglobin in her red blood cells, iron in aconitase and succinate dehydrogenase, as well as iron in the heme proteins of the electron transport chain. She may also be experiencing the consequences of multiple vitamin deficiencies, including thiamin, riboflavin, and niacin (the vitamin precursor of NAD⁺). It is less likely, but possible, that she also has subclinical deficiencies of pantothenate (the precursor of CoA) or biotin. As a result, **Ann R.**'s muscles must use glycolysis as their primary source of energy, which results in sore muscles.

Riboflavin deficiency generally occurs in conjunction with other water-soluble-vitamin deficiencies. The classic deficiency symptoms are cheilosis (inflammation of the corners of the mouth), glossitis (magenta tongue), and seborrheic (“greasy”) dermatitis. It is also characterized by sore throat, edema of the pharyngeal and oral mucus membranes, and normochromic, normocytic anemia. However, it is not known whether the glossitis and dermatitis are actually due to multiple vitamin deficiencies.

Riboflavin has a wide distribution in foods, and small amounts are present as coenzymes in most plant and animal tissues. Eggs, lean meats, milk, broccoli, and enriched breads and cereals are especially good sources. A portion of our niacin requirement can be met by synthesis from tryptophan. Meat (especially red meat), liver, legumes, milk, eggs, alfalfa, cereal grains, yeast, and fish are good sources of niacin and tryptophan.

Beriberi, now known to be caused by thiamin deficiency, was attributed to lack of a nitrogenous component in food by Takaki, a Japanese surgeon, in 1884. In 1890, Eijkman, a Dutch physician working in Java, noted that the polyneuritis associated with beriberi could be prevented by rice bran that had been removed during polishing. Thiamin is present in the bran portion of grains, and it is abundant in pork and legumes. In contrast to most vitamins, milk and milk products, seafood, fruits, and vegetables are *not* good sources of thiamin.

Al M. presents a second time with an alcohol-related high-output form of heart failure from thiamin deficiency that is sometimes referred to as “wet” beriberi or as the “beriberi heart” (see Chapter 9). The word “wet” refers to the fluid retention, which may eventually occur when left ventricular contractility is so compromised that cardiac output, although initially relatively “high,” cannot meet the “demands” of the peripheral vascular beds, which have dilated in response to the thiamin deficiency.

The cardiomyopathy is due to the persistent high output required because of the dilated peripheral vasculature and also likely related to a reduction in the normal biochemical function of the vitamin thiamin in heart muscle. Inhibition of the α -keto acid dehydrogenase complexes causes accumulation of α -keto acids in heart muscle (and in blood), which may result in a chemically induced cardiomyopathy. Impairment of two other functions of thiamin may also contribute to the cardiomyopathy. TPP serves as the coenzyme for transketolase in the pentose phosphate pathway, and pentose phosphates accumulate in thiamin deficiency. In addition, thiamin triphosphate (a different coenzyme form) may function in Na⁺ conductance channels.

Immediate treatment with large doses (50 to 500 mg) of intravenous thiamin may produce a measurable decrease in cardiac output and increase in peripheral vascular resistance as early as 30 minutes after the initial

injection. Dietary supplementation of thiamin is not as effective because ethanol consumption interferes with thiamin absorption. Because ethanol also affects the absorption of most water-soluble vitamins, or their conversion to the coenzyme form, **Al M.** was also given a bolus containing a multivitamin supplement.

BIOCHEMICAL COMMENTS

Compartmentation of Mitochondrial Enzymes. The mitochondrion forms a structural, functional, and regulatory compartment within the cell. The inner mitochondrial membrane is impermeable to anions and cations, and compounds can cross the membrane only on specific transport proteins. The enzymes of the TCA cycle, therefore, have more direct access to products of the previous reaction in the pathway than they would if these products were able to diffuse throughout the cell. Complex formation between enzymes also restricts access to pathway intermediates. Malate dehydrogenase and citrate synthase may form a loosely associated complex. The multienzyme pyruvate dehydrogenase and α -ketoglutarate dehydrogenase complexes are examples of substrate channeling by tightly bound enzymes; only the transacylase enzyme has access to the thiamin-bound intermediate of the reaction, and only lipoamide dehydrogenase has access to reduced lipoic acid.

Compartmentation plays an important role in regulation. The close association between the rate of the electron transport chain and the rate of the TCA cycle is maintained by their mutual access to the same pool of NADH and NAD⁺ in the mitochondrial matrix. NAD⁺, NADH, CoASH, and acyl CoA derivatives have no transport proteins and cannot cross the mitochondrial membrane. Thus, all of the dehydrogenases compete for the same NAD⁺ molecules and are inhibited when NADH rises. Likewise, the accumulation of acyl CoA derivatives (e.g., acetyl CoA) within the mitochondrial matrix affects other CoA-utilizing reactions, either by competing at the active site or by limiting CoASH availability.

Import of Nuclear-Encoded Proteins. All mitochondrial matrix proteins, such as the TCA cycle enzymes, are encoded by the nuclear genome. They are imported into the mitochondrial matrix as unfolded proteins that are pushed and pulled through channels in the outer and inner mitochondrial membranes (Fig. 23.17). Proteins destined for the mitochondrial matrix have either a targeting *N*-terminal presequence of about 23 amino acids that includes several positively charged amino acid residues, or an internal mitochondrial localizing signal. The mitochondrial matrix proteins are synthesized on free ribosomes in the cytosol and maintain an unfolded conformation by binding to hsp 70 chaperonins. This basic presequence binds to a receptor in a TOM complex (**t**ranslocases of the **o**uter **m**embrane) (see Fig. 23.17, Step 1). The TOM complexes consist of channel proteins, assembly proteins, and receptor proteins with different specificities (e.g., TOM23 binds the matrix protein presequence). Negatively charged acidic residues on the receptors and in the channel pore assist in translocation of the matrix protein through the channel, presequence first.

FIGURE 23.17 A simplified model for the import of nuclear-encoded proteins into the mitochondrial matrix. The matrix preprotein with its positively charged *N*-terminal presequence is shown in red. ADP, adenosine diphosphate; ATP, adenosine triphosphate; hsp, heat shock protein; IM, inner mitochondrial membrane; IMS, intermembrane space; mthsp 70, mitochondrial heat shock protein 70; OM, outer mitochondrial membrane; TIM, translocases of the inner mitochondrial membrane; TOM, translocases of the outer mitochondrial membrane.

The matrix preprotein is translocated across the inner membrane through a TIM complex (translocases of the inner membrane) (see Fig. 23.17, Step 2). Insertion of the preprotein into the TIM channel is driven by the potential difference across the membrane, $\Delta\psi$. Mitochondrial hsp 70 (mthsp 70), which is bound to the matrix side of the TIM complex, binds the incoming preprotein and may “ratchet” it through the membrane. ATP is required for binding of mthsp 70 to the TIM complex and again for the subsequent dissociation of the mthsp 70 and the matrix preprotein. In the matrix, the preprotein may require another heat shock protein, hsp 60, for proper folding. The final step in the import process is cleavage of the signal sequence by a matrix-processing protease (see Fig. 23.17, Step 3).

Proteins of the inner mitochondrial membrane are imported through a similar process, using TOM and TIM complexes containing different protein components.

KEY CONCEPTS

- ◆ The TCA cycle accounts for more than two-thirds of the ATP generated from fuel oxidation.
- ◆ All of the enzymes required for the TCA cycle are in the mitochondria.
- ◆ Acetyl CoA, generated from fuel oxidation, is the substrate for the TCA cycle.
- ◆ Acetyl CoA, when oxidized via the cycle, generates CO₂, reduced electron carriers, and GTP.
- ◆ The reduced electron carriers [NADH, FAD(2H)] donate electrons to O₂ via the electron transport chain, which leads to ATP generation from oxidative phosphorylation.
- ◆ The cycle requires a number of cofactors to function properly, some of which are derived from vitamins. These include TPP (derived from vitamin B₁), FAD (derived from vitamin B₂, riboflavin), and coenzyme A (derived from pantothenic acid).
- ◆ Intermediates of the TCA cycle are used for many biosynthetic reactions and are replaced by anaplerotic (refilling) reactions within the cell.
- ◆ The cycle is carefully regulated within the mitochondria by energy and the levels of reduced electron carriers. As energy levels decrease, the rate of the cycle increases.
- ◆ Impaired functioning of the TCA cycle leads to an inability to generate ATP from fuel oxidation and an accumulation of TCA cycle precursors.
- ◆ Diseases discussed in this chapter are summarized in Table 23.2.

TABLE 23.2 Diseases Discussed in Chapter 23

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Obesity	Both	Increased physical activity, without increasing caloric intake, will lead to weight loss and increased exercise capacity. One effect of increased aerobic exercise is increasing the number and size of mitochondria in the muscle cells.
Anorexia nervosa	Both	Patients who have been malnourished for some time may exhibit subclinical deficiencies in many vitamins, including riboflavin and niacin, factors required for energy generation.
Congestive heart failure linked to alcohol use disorder	Both	Thiamin deficiency, brought about by chronic alcohol ingestion, leads to dilation of the blood vessels, inefficient energy production by the heart, and failure to adequately pump blood throughout the body. The vitamin B1 deficiency reduces the activity of pyruvate dehydrogenase and the TCA cycle, severely restricting ATP generation.
Arsenic poisoning	Environmental	Arsenite inhibits enzymes and cofactors with free adjacent sulfhydryl groups (lipoic acid is a target of arsenite), whereas arsenate acts as a phosphate analog and inhibits substrate-level phosphorylation reactions.

Leigh syndrome (subacute necrotizing encephalopathy)

Genetic

Deficiencies of the pyruvate dehydrogenase complex (PDC), as well as of pyruvate carboxylase, are inherited disorders leading to lactic acidemia. In its most severe form, PDC deficiency presents with overwhelming lactic acidosis at birth, with death in the neonatal period. Even in less severe forms, neurologic symptoms arise due to the brain's dependence on glucose metabolism for energy. The most common PDC deficiency is X-linked, in the α -subunit of the pyruvate decarboxylase (E_1) subunit. Pyruvate carboxylase deficiency also leads to intellectual disability.

REVIEW QUESTIONS—CHAPTER 23

1. An individual displays lactic acidemia, as well as a reduced activity of α -ketoglutarate dehydrogenase activity. The most likely single enzymatic mutation that leads to these changes would be in which one of the following proteins?
 - A. The E_3 subunit of pyruvate dehydrogenase
 - B. The E_1 subunit of pyruvate dehydrogenase
 - C. The E_2 subunit of pyruvate dehydrogenase
 - D. Lactate dehydrogenase
 - E. Pyruvate carboxylase
2. A patient diagnosed with thiamin deficiency exhibited fatigue and muscle cramps. The muscle cramps have been related to an accumulation of metabolic acids. Which one of the following metabolic acids is most likely to accumulate in a thiamin deficiency?
 - A. Isocitric acid
 - B. Pyruvic acid
 - C. Succinic acid
 - D. Malic acid
 - E. Oxaloacetic acid
3. Succinate dehydrogenase differs from all other enzymes in the TCA cycle in that it is the only enzyme that displays which one of the following characteristics?
 - A. It is embedded in the inner mitochondrial membrane.
 - B. It is inhibited by NADH.
 - C. It contains bound FAD.
 - D. It contains Fe–S centers.
 - E. It is regulated by a kinase.
4. During exercise, stimulation of the TCA cycle results principally from which one of the following?
 - A. Allosteric activation of isocitrate dehydrogenase by increased NADH
 - B. Allosteric activation of fumarase by increased ADP
 - C. A rapid decrease in the concentration of four-carbon intermediates
 - D. Product inhibition of citrate synthase
 - E. Stimulation of the flux through a number of enzymes by a decreased NADH/NAD⁺ ratio
5. A deficiency of which one of the following compounds would lead to an inability to produce coenzyme A?
 - A. Niacin
 - B. Riboflavin
 - C. Vitamin A
 - D. Pantothenate
 - E. Vitamin C
6. One of the major roles of the TCA cycle is to generate reduced cofactors for ATP production from oxidative phosphorylation. The compound donating the net eight electrons to the cofactors is which one of the following?
 - A. Pyruvate
 - B. Acetyl CoA
 - C. Lactate
 - D. Oxaloacetate
 - E. Phosphoenolpyruvate

7. Atherosclerosis can narrow the coronary arteries leading to decreased blood flow and hypoxia of cardiac cells (cardiomyocytes). This causes the patient to experience angina. Which one of the following is likely to occur in the cardiomyocytes during the hypoxic event?
- A. The TCA cycle in the cytosol is greatly impaired
 - B. Pyruvate oxidation is increased
 - C. Lactate cannot be utilized as a fuel
 - D. Citrate accumulates
 - E. Succinyl CoA accumulates
8. A distance runner is training for her half marathon and as part of the training is allowing her muscles to utilize fatty acids as a fuel source. Fatty acids are converted to acetyl CoA in the mitochondria, at which point the acetyl CoA can be oxidized in the TCA cycle to generate reduced cofactors. Which one of the following correctly describes how the acetyl CoA is metabolized in the mitochondria?
- A. One molecule of acetyl CoA produces two molecules of CO_2 , three molecules of NADH, one molecule of FAD(2H), and one molecule of ATP
 - B. All of the energy for high-energy phosphate bonds is derived from oxidative phosphorylation
 - C. NAD^+ is the only electron acceptor in the cycle
 - D. Substrate-level phosphorylation generates one high-energy phosphate bond during the cycle
 - E. The TCA cycle requires large amounts of vitamins C and D as coenzymes
9. At birth, a full-term male neonate was found to be severely acidotic. His condition was found to result from an X-linked dominant mutation of the α -subunit of E_1 in the PDC. Compared with a healthy neonate in the same dietary state, what would be the consequences of this mutation?
- A. An increase in plasma concentrations of lactate and pyruvate
 - B. A higher ATP/ADP ratio in cells of the brain
 - C. A decrease in the rate of glycolysis in brain cells
 - D. An increase in the activity of the electron transfer chain in brain cells
 - E. An increase in plasma acetyl CoA levels
10. A pyruvate carboxylase deficiency will lead to lactic acidemia due to which one of the following?
- A. An accumulation of acetyl CoA in the mitochondria
 - B. Allosteric activation of lactate dehydrogenase
 - C. An accumulation of NADH in the mitochondrial matrix
 - D. Allosteric activation of PDC
 - E. An accumulation of ATP in the matrix
1. Assume that the liver PDC kinase exhibited reduced activity due to a single amino acid substitution in the primary structure. A potential consequence of this mutation would be which one of the following?
- A. Lactic acidemia
 - B. A reduction in ATP production
 - C. A reduction in the rate of acetyl CoA metabolism through the TCA cycle
 - D. An increased flux of acetyl CoA through the TCA cycle
 - E. Reduced pyruvate carboxylase activity
2. An elevated NADH/NAD⁺ ratio in the mitochondria can lead to the allosteric inhibition of which one of the following enzymes?
- A. Glyceraldehyde 3-phosphate dehydrogenase
 - B. PFK-1
 - C. PFK-2
 - D. Pyruvate kinase
 - E. Succinate dehydrogenase
3. A child has a mitochondrial disorder, due to a mutation in the mitochondrial genome. A result of this mutation is a greatly reduced flow of electrons through the electron transfer chain from NADH in the mitochondria harboring this mutated genome. Such a mutation would result in the direct inhibition of which of the following enzymes?

	Citrate Synthase	α-Ketoglutarate Dehydrogenase	Succinate Thiokinase	Malate Dehydrogenase
A	Yes	No	Yes	No
B	Yes	Yes	No	No
C	Yes	No	Yes	Yes
D	No	Yes	No	No
E	No	No	Yes	Yes
F	No	Yes	No	Yes

4. Anaplerotic reactions can refill the TCA cycle through which of the following TCA cycle intermediates?

	Citrate	Isocitrate	Succinyl CoA	Oxaloacetate
A	No	No	Yes	Yes
B	No	Yes	Yes	No
C	No	No	Yes	No
D	Yes	Yes	No	Yes
E	Yes	No	No	No
F	Yes	Yes	No	Yes

5. Arsenic, which contains arsenite and arsenate, can lead to a loss of high-energy phosphate bond formation as catalyzed by which of the following enzymes?

	Pyruvate Kinase	Glyceraldehyde 3-Phosphate Dehydrogenase	Succinate Thiokinase	PFK-I
A	No	Yes	Yes	Yes
B	Yes	Yes	No	Yes
C	No	Yes	Yes	No
D	Yes	No	No	No
E	No	No	Yes	Yes
F	Yes	No	No	No

ANSWERS TO REVIEW QUESTIONS

- The answer is A.** The E3 subunit of pyruvate dehydrogenase, the dihydrolipoyl dehydrogenase activity (with bound FAD), is shared among all the α -keto acid dehydrogenases. Thus, with this mutation, both pyruvate dehydrogenase activity, and α -ketoglutarate dehydrogenase activity would be defective. This defect would then lead to an accumulation of pyruvate (since pyruvate dehydrogenase activity is reduced), and the accumulated pyruvate is converted to lactate (to regenerate NAD^+ to allow glycolysis to continue), leading to an elevation of lactate in the bloodstream (lactic acidemia), and a lowering of blood pH (lactic acidosis). A defect in pyruvate carboxylase will also result in an elevation of pyruvate levels, and lactic acidemia, but there would be no defect in α -ketoglutarate dehydrogenase activity with a pyruvate carboxylase deficiency. The E1 and E2 subunits of pyruvate dehydrogenase are unique to pyruvate dehydrogenase and are not shared with any other enzymes, so defects in these subunits will lead to lactic acidemia, but would not affect α -ketoglutarate dehydrogenase. A defect in lactate dehydrogenase would result in an inability to produce lactate, and lactic acidemia would not result from a defect in that enzyme.
- The answer is B.** TPP is a required coenzyme for the α -ketoglutarate dehydrogenase and pyruvate dehydrogenase complexes. With these complexes inactive, pyruvic acid and α -ketoglutaric acid accumulate and dissociate to generate the anion and H^+ . As α -ketoglutarate is not listed as an answer, the only possible answer is pyruvate.
- The answer is A.** Succinate dehydrogenase is the only TCA cycle enzyme located in the inner mitochondrial membrane. The other enzymes are in the mitochondrial matrix. Answer B is incorrect because succinate dehydrogenase is not regulated by NADH. Answer C is incorrect because α -ketoglutarate dehydrogenase also contains a bound FAD (the difference is that the FAD(2H) in α -ketoglutarate dehydrogenase donates its electrons to NAD^+ , whereas the FAD(2H) in succinate dehydrogenase donates its electrons directly to the electron transfer chain). Answer D is incorrect because both succinate dehydrogenase and aconitase have Fe-S centers. Answer E is incorrect because succinate dehydrogenase is not regulated by a kinase. Kinases regulate enzymes by phosphorylation (e.g., the regulation of pyruvate dehydrogenase occurs through reversible phosphorylation).
- The answer is E.** NADH decreases during exercise to generate energy for the exercise (if it were increased, it would inhibit the cycle and slow it down), thus the NADH/NAD^+ ratio is decreased, and the lack of NADH activates flux through isocitrate dehydrogenase, α -ketoglutarate dehydrogenase, and malate dehydrogenase. Isocitrate dehydrogenase is inhibited by NADH, so answer A is not correct. Fumarate is not regulated, thus answer B is incorrect. The four-carbon intermediates of the cycle are regenerated during each turn of the cycle, so their concentrations do not decrease (thus, C is incorrect). Product inhibition of citrate synthase would slow the cycle and not generate more energy, hence D is

incorrect.

5. **The answer is D.** Pantothenate is the vitamin precursor of coenzyme A. Niacin is the vitamin precursor of NAD, and riboflavin is the vitamin precursor of FAD and FMN. Vitamins A and C are used with only minor modifications, if any, and are not involved in any TCA cycle reactions.
6. **The answer is B.** The net equation of the TCA cycle, in terms of carbon atoms, is acetyl CoA is converted to two molecules of CO₂. The eight electrons associated with the two carbon atoms of acetyl CoA are removed and placed in three molecules of NADH and one molecule of FAD(2H). The TCA cycle does not generate reduced cofactors from pyruvate, lactate, oxaloacetate, or phosphoenolpyruvate. Those compounds would need to be converted to acetyl CoA for the cycle to generate the reduced cofactors.
7. **The answer is C.** With hypoxia the TCA cycle would slow down due to the accumulation of NADH, which cannot donate electrons to oxygen, due to the lack of oxygen. The high NADH inhibits pyruvate dehydrogenase, so pyruvate will accumulate, and the high levels of pyruvate will block lactate from being converted to pyruvate (the lactate dehydrogenase reaction), leading to lactate accumulation. Since the operation of the TCA cycle is greatly reduced, citrate and succinyl CoA will not be produced, so they will not accumulate. The enzymes of the TCA cycle are located in the mitochondria, not the cytoplasm.
8. **The answer is D.** GTP is generated from substrate-level phosphorylation during the TCA cycle (not ATP). Mitochondrial ATP is generated by oxidative phosphorylation, using the electrons from the electron carriers NADH and FAD(2H). The TCA cycle requires some B vitamins but not vitamins C or D. One molecule of acetyl CoA (2 carbons) produces 2 CO₂, 3 NADH, one FAD(2H), and one GTP (not ATP).
9. **The answer is A.** A deficiency of the E1 subunit of pyruvate dehydrogenase would decrease the conversion of pyruvate to acetyl CoA, leading to an accumulation of pyruvate. Pyruvate is converted to lactate to allow glycolysis to continue to generate ATP from substrate-level phosphorylation. The pyruvate to lactate conversion regenerates the NAD⁺, which is required for glycolysis to proceed. Cells of the brain have a high ATP requirement and are highly dependent on glycolysis and pyruvate oxidation in the TCA cycle to meet this demand for ATP. Without pyruvate oxidation in the TCA cycle, glycolysis will try to produce ATP as fast as possible (due to an increase of AMP levels, which activates PFK-1); however, the amount of ATP produced by glycolysis alone is not sufficient to meet the brain's needs. Thus, the ATP/ADP ratio actually decreases. Even though the brain cells are low in ATP levels, the decreased production of acetyl CoA from pyruvate will not provide sufficient substrate to substantially increase the activity of the electron transfer chain in brain cells. Fatty acids do not cross the blood-brain barrier, so ketone body oxidation would be required to increase acetyl CoA levels within the mitochondria to allow rapid functioning of the TCA cycle. Acetyl CoA is not produced from glucose when pyruvate dehydrogenase is defective, and acetyl CoA cannot be exported to the circulation.
10. **The answer is A.** When pyruvate carboxylase is deficient, pyruvate cannot be converted to oxaloacetate, thereby reducing the ability to replenish TCA cycle intermediates as they are being used for other pathways. As oxaloacetate levels decrease, acetyl CoA cannot be converted to citrate, and acetyl CoA will accumulate within the mitochondria. The elevated acetyl CoA inhibits pyruvate dehydrogenase, which, coupled with the reduced activity of pyruvate carboxylase, leads to pyruvate accumulation in the cytoplasm. The increased pyruvate is then converted to lactic acid, leading to lactic acidemia. Pyruvate is not an allosteric activator of lactate dehydrogenase. Since the TCA cycle is slowed due to lack of oxaloacetate, NADH is not accumulating in the mitochondrial matrix, nor is ATP. Pyruvate is not an activator of the PDC (NAD⁺ and free coenzyme A are the primary activators, along with ADP).
11. **The answer is D.** The PDC kinase, when active, phosphorylates the E1 subunit of pyruvate dehydrogenase, inactivating the subunit and blocking enzyme activity. PDC kinase is activated by acetyl CoA and NADH, so when acetyl CoA levels are high, pyruvate dehydrogenase would be inhibited. If the kinase were inactive PDH would continue to be active, and acetyl CoA levels inside the mitochondria would increase. The high acetyl CoA would activate pyruvate carboxylase, which would produce more oxaloacetate. The increased oxaloacetate would condense with the acetyl CoA, forming citrate and increasing the rate of the TCA cycle. An increased rate of the TCA cycle would lead to an increase in ATP production, and a reduced production of lactate, as the pyruvate would be converted to acetyl CoA.
12. **The answer is B.** As the NADH accumulates in the mitochondria the TCA cycle slows down, due to inhibition of the NADH generating dehydrogenases—isocitrate dehydrogenase, α-ketoglutarate dehydrogenase, and malate dehydrogenase. This will lead to isocitrate accumulating, which isomerizes to citrate, and citrate will accumulate in the mitochondria. As the citrate levels increase the citrate will be

transported into the cytoplasm, where it can bind to an allosteric site on PFK-1 and inhibit its activity. The citrate is indicating to PFK-1 that energy levels are high in the mitochondria and that glycolysis can slow down. Citrate is not an allosteric effector for any of the other answer choices. While NADH is a product of the glyceraldehyde 3-phosphate dehydrogenase reaction, NADH in the mitochondria cannot be transported across the inner mitochondrial membrane, so high mitochondrial NADH does not lead to elevated NADH in the cytoplasm.

13. **The answer is F.** Due to the mutation in the mitochondrial genome NADH will accumulate in the mitochondrial matrix, as it cannot donate its electrons to the electron transport chain. As such, the dehydrogenases which produce NADH in the mitochondria will be inhibited by the elevated NADH, and these include pyruvate dehydrogenase, isocitrate dehydrogenase, α -ketoglutarate dehydrogenase, and malate dehydrogenase. Citrate synthase is not regulated by NADH levels (citrate inhibits citrate synthase), and succinate thiokinase converts succinyl CoA + GDP + Pi to succinate and GTP. Succinate thiokinase is not inhibited by NADH.
14. **The answer is A.** Anaplerotic reactions can generate succinyl CoA (through the generation of propionyl CoA) as well as oxaloacetate (via pyruvate carboxylase or the transamination of aspartic acid to oxaloacetate). Other anaplerotic reactions can lead to α -ketoglutarate (glutamate, glutamine, proline) as well as fumarate. There are no anaplerotic reactions that give rise to citrate or isocitrate.
15. **The answer is C.** Arsenite will reduce the activity of enzymes that require lipoic acid (compounds with disulfide bonds), and arsenate acts as a phosphate analog and can replace phosphate in reactions that require phosphate. Once arsenate is incorporated into an organic molecule in place of phosphate it is easily removed by hydrolysis. Arsenite will therefore lead to an inhibition of pyruvate dehydrogenase or α -ketoglutarate dehydrogenase, but not any of the enzymes listed as possible answers. Arsenate will lead to the loss of high-energy phosphate bond formation from succinate thiokinase (which requires inorganic phosphate as a substrate) and glyceraldehyde 3-phosphate dehydrogenase (which also requires inorganic phosphate as a substrate). Pyruvate kinase does not utilize inorganic phosphate in its reaction (PEP to pyruvate) and is not inhibited by arsenate.

Oxidative Phosphorylation and Mitochondrial Function

Energy from fuel oxidation is converted to the high-energy phosphate bonds of adenosine triphosphate (ATP) by the process of **oxidative phosphorylation**. Most of the energy from oxidation of fuels in the tricarboxylic acid (TCA) cycle and other pathways is conserved in the form of the reduced electron-accepting coenzymes, NADH and FAD(2H). The **electron transport chain** oxidizes **NADH** and **FAD(2H)** and donates the electrons to O_2 , which is reduced to H_2O (Fig. 24.1). Energy from reduction of O_2 is used for phosphorylation of adenosine diphosphate (ADP) to ATP by **ATP synthase** (F_0F_1 ATPase). The net yield of oxidative phosphorylation is ~ 2.5 mol of ATP per mole of NADH oxidized or 1.5 mol of ATP per mole of FAD(2H) oxidized.

FIGURE 24.1 Oxidative phosphorylation. Red arrows show the path of electron transport from NADH to O_2 . As electrons pass through the chain, protons are pumped from the mitochondrial matrix to the intermembrane space, thereby establishing an electrochemical potential gradient, $\Delta\psi$, across the inner mitochondrial membrane. The positive and negative charges on the membrane denote the membrane potential ($\Delta\psi$). $\Delta\psi$ drives protons into the matrix through a pore in ATP synthase, which uses the energy to form ATP from ADP and P_i . ADP, adenosine diphosphate; ATP, adenosine triphosphate; NAD, nicotinamide adenine dinucleotide; P_i , inorganic phosphate.

Chemiosmotic Model of ATP Synthesis. The **chemiosmotic model** explains how energy from transport of electrons to O_2 is transformed into the high-energy phosphate bonds of ATP (see Fig. 24.1). Basically, the electron transport chain contains three large **protein complexes** (I, III, and IV) that span the inner mitochondrial membrane. As electrons pass through these complexes in a series of oxidation–reduction reactions, protons are transferred from the mitochondrial matrix to the cytosolic side of the inner mitochondrial membrane. The pumping of protons generates an **electrochemical gradient** ($\Delta\psi$) across the membrane composed of the membrane potential and the proton gradient. ATP synthase contains a proton pore that spans the inner mitochondrial membrane and a catalytic headpiece that protrudes into the matrix. As protons are driven into the matrix through the pore, they change the conformation of the headpiece, which releases ATP from one site and

catalyzes formation of ATP from ADP and inorganic phosphate (P_i) at another site.

Deficiencies of Electron Transport. In cells, complete transfer of electrons from NADH and FAD(2H) through the chain to O_2 is necessary for ATP generation. Impaired transfer through any complex can have pathological consequences. Fatigue can result from iron-deficiency **anemia**, which decreases **Fe** for **Fe-S centers** and **cytochromes**. **Cytochrome c_1 oxidase**, which contains the **O_2 -binding site**, is inhibited by **cyanide**. **Mitochondrial DNA (mtDNA)**, which is maternally inherited, encodes some of the subunits of the electron transport chain complexes and ATP synthase. **OXPHOS diseases** are caused by **mutations** in **nuclear DNA** or **mtDNA** that decrease mitochondrial capacity for oxidative phosphorylation.

Regulation of Oxidative Phosphorylation. The rate of the electron transport chain is **coupled** to the rate of ATP synthesis by the transmembrane electrochemical gradient. As ATP is used for energy-requiring processes and ADP levels increase, proton influx through the ATP synthase pore generates more ATP, and the electron transport chain responds to restore Δp . In **uncoupling**, protons return to the matrix by a mechanism that bypasses the ATP synthase pore, and the energy is released as heat. **Proton leakage**, **chemical uncouplers**, and regulated **uncoupling proteins** increase our metabolic rate and heat generation.

Mitochondria and Cell Death. Although oxidative phosphorylation is a mitochondrial process, most ATP utilization occurs outside of the mitochondrion. ATP synthesized from oxidative phosphorylation is actively transported from the matrix to the intermembrane space by **adenine nucleotide translocase (ANT)**. **Porins form voltage-dependent anion channels (VDACs)** through the outer mitochondrial membrane for the diffusion of H_2O , ATP metabolites, and other ions. Under certain types of stress, ANT, VDACs, and other proteins form a nonspecific open channel known as the **mitochondrial permeability transition pore**. This pore is associated with events that lead rapidly to **necrotic cell death**.

THE WAITING ROOM

Cora N. was recovering uneventfully from her heart attack 1 month earlier (see Chapter 20) when she won the Georgia state lottery. When she heard her number announced over television, she experienced crushing chest pain again and grew short of breath. Her family called 911 and she was rushed to the hospital emergency department.

On initial examination, her blood pressure was extremely high and her heart rhythm irregular. **Cora N.** was experiencing yet another myocardial infarction. An electrocardiogram showed unequivocal evidence of severe lack of oxygen (ischemia) in the muscles of the anterior and lateral walls of her heart. She was given nasal oxygen, and an intravenous drip of nitroglycerin, a vasodilating agent, was started in an effort to reduce her hypertension (it will also help to decrease her “preload” by vasodilating the vessels going to the heart). At this time, she did not show signs of systolic heart failure, so she was also given a β -blocker, which will help decrease her blood pressure as well as decrease the work of her heart by slowing her heart rate. After her blood pressure was well controlled, and because the hospital did not have a cardiac catheterization laboratory and a transfer to a hospital with a cath lab was not possible, a decision was made to administer intravenous tissue plasminogen activator (TPA) in an attempt to break up any intracoronary artery blood clots in vessels supplying the ischemic myocardium (thrombolytic therapy).

Cora N. is experiencing a second myocardial infarction. Ischemia (low blood flow) has caused hypoxia (low levels of oxygen) in the threatened area of her heart muscle, resulting in inadequate generation of ATP for the maintenance of low intracellular Na^+ and Ca^{2+} levels (see Chapter 20). As a consequence, the myocardial cells in that specific location have become swollen, and the cytosolic proteins creatine kinase (MB isoform) and troponin (heart isoform) have leaked into the blood. (See **Anne J.**, Chapters 6 and 7.)

Stanley T. A ^{123}I thyroid uptake and scan performed on **Stanley T.** confirmed that his hyperthyroidism was the

result of Graves disease (see Chapter 20). Graves disease is an autoimmune genetic disorder caused by the generation of human thyroid-stimulating immunoglobulins. These immunoglobulins stimulate the growth of the thyroid gland (goiter) and excess secretion of the thyroid hormones, T_3 and T_4 . Because heat production is increased under these circumstances, his heat intolerance and sweating were growing worse with time.

Isabel S., who has opioid use disorder and injects opioids intravenously, appeared to be responding well to her multidrug regimens to treat pulmonary tuberculosis and human immunodeficiency virus (HIV) (see Chapters 11, 12, 13, and 16). In the past 6 weeks, however, she has developed increasing weakness in her extremities, to the point that she has difficulty carrying light objects or walking. Physical examination indicates a diffuse proximal and distal muscle weakness associated with muscle atrophy. The muscles are not painful on motion but mildly tender to palpation. The blood level of the muscle enzymes, creatine phosphokinase (CK), and aldolase are elevated. An electromyogram (EMG) revealed a generalized reduction in the muscle action potentials, suggestive of a primary myopathic process. Proton spectroscopy of her brain and upper spinal cord showed no anatomic or biochemical abnormalities. The diffuse and progressive skeletal muscle weakness was out of proportion to that expected from her HIV or tuberculosis. This information led her physicians to consider other etiologies.

Electromyography (EMG) measures the electrical potential of muscle cells both at rest and while contracting. Electrodes are inserted through the skin and into the muscle, and baseline recordings (no contraction) are obtained, followed by measurements of electrical activity when the muscle contracts. The electrode is retracted a small amount, and the measurements are repeated. This occurs for up to 10 to 20 measurements, thereby sampling many distinct areas of the muscle. Under normal conditions, muscles at rest will have minimal electrical activity, which increases significantly as the muscle contracts. EMG results that deviate from the norm suggest an underlying pathology interfering with membrane polarization–depolarization as the nerve cells instruct the muscle cells to contract.

I. Oxidative Phosphorylation

Generation of ATP from **oxidative phosphorylation** requires an electron donor (NADH or FAD[2H]), an electron acceptor (O_2), an intact inner mitochondrial membrane that is impermeable to protons, all the components of the electron transport chain, and ATP synthase. It is regulated by the rate of ATP utilization.

Most cells are dependent on oxidative phosphorylation for ATP homeostasis. During oxygen deprivation from ischemia (low blood flow), an inability to generate energy from the electron transport chain results in increased permeability of the inner mitochondrial membrane and mitochondrial swelling. Mitochondrial swelling is a key element in the pathogenesis of irreversible cell injury leading to cell lysis and death (necrosis).

Charles F., who has a follicular-type non-Hodgkin lymphoma, was being treated with the anthracycline drug doxorubicin (see Chapter 15). During the course of his treatment, he developed biventricular heart failure. Although doxorubicin is a highly effective anticancer agent against a wide variety of human tumors, its clinical use is limited by a specific, cumulative, dose-dependent cardiotoxicity. Impairment of mitochondrial function may play a major role in this toxicity. Doxorubicin binds to cardiolipin, a lipid component of the inner membrane of mitochondria, where it might directly affect components of oxidative phosphorylation. Doxorubicin inhibits succinate oxidation, inactivates cytochrome oxidase, interacts with CoQ, adversely affects ion pumps, and inhibits ATP synthase, resulting in decreased ATP levels and mildly swollen mitochondria. It decreases the ability of the mitochondria to sequester Ca^{2+} and increases free radicals (highly reactive single-electron forms), leading to damage of the mitochondrial membrane (see Chapter 25). It also might affect heart function indirectly through other mechanisms.

A. Overview of Oxidative Phosphorylation

Our understanding of oxidative phosphorylation is based on the **chemiosmotic hypothesis**, which proposes that the energy for ATP synthesis is provided by an electrochemical gradient across the inner mitochondrial membrane. This electrochemical gradient is generated by the components of the electron transport chain, which pump protons across the inner mitochondrial membrane as they sequentially accept and donate electrons (see Fig. 24.1). The final acceptor is O_2 , which is reduced to H_2O .

1. Electron Transfer from NADH to O_2

In the **electron transport chain**, electrons donated by NADH or FAD(2H) are passed sequentially through a

series of electron carriers embedded in the inner mitochondrial membrane. Each of the components of the electron transfer chain is reduced as it accepts an electron and then oxidized as it passes the electrons to the next member of the chain. From NADH, electrons are transferred sequentially through **NADH:CoQ oxidoreductase** (complex I, also known as **NADH dehydrogenase**), **coenzyme Q** (CoQ), the **cytochrome b-c₁ complex** (complex III), **cytochrome c**, and finally **cytochrome c oxidase** (complex IV). NADH:CoQ oxidoreductase, the cytochrome b-c₁ complex, and cytochrome c oxidase are multisubunit protein complexes that span the inner mitochondrial membrane. CoQ is a lipid-soluble quinone that is not protein bound and is free to diffuse in the lipid membrane. It transports electrons from complex I to complex III and is an intrinsic part of the proton pump for each of these complexes. Cytochrome c is a small protein in the intermembrane space that transfers electrons from the b-c₁ complex to cytochrome oxidase. The terminal complex, cytochrome c oxidase, contains the binding site for O₂. As O₂ accepts electrons from the chain, it is reduced to H₂O.

2. The Electrochemical Potential Gradient

At each of the three large membrane-spanning complexes in the chain, electron transfer is accompanied by proton pumping across the membrane. There is an energy drop of ~16 kcal in reduction potential as electrons pass through each of these complexes, which provides the energy required to move protons against a concentration gradient. The membrane is impermeable to protons, so they cannot diffuse through the lipid bilayer back into the matrix. Thus, in actively respiring mitochondria, the intermembrane space and cytosol may be ~0.75 pH unit lower than the matrix.

The transmembrane movement of protons generates an electrochemical gradient with two components: the membrane potential (the external face of the membrane is charged positive relative to the matrix side) and the proton gradient (the intermembrane space has a higher proton concentration and is, therefore, more acidic than the matrix) (Fig. 24.2). The electrochemical gradient is sometimes called the **proton motive force** because it is the energy that pushes the protons to reenter the matrix to equilibrate on both sides of the membrane. The protons are attracted to the more negatively charged matrix side of the membrane, where the pH is more alkaline.

FIGURE 24.2 Proton motive force (electrochemical gradient) across the inner mitochondrial membrane. The proton motive force consists of a membrane potential, $\Delta\psi$, and a proton gradient, denoted by ΔpH for the difference in pH across the membrane. The electrochemical potential is called the proton motive force because it represents the potential energy of driving protons to return to the more negatively charged alkaline matrix.

3. ATP synthase

ATP synthase (F_0F_1 ATPase), the enzyme that generates ATP, is a multisubunit enzyme that contains an inner membrane portion (F_0) and a stalk and headpiece (F_1) that project into the matrix (Fig. 24.3). The 12 **c** subunits in the membrane form a rotor that is attached to a central asymmetric shaft composed of the ϵ and γ subunits. The headpiece is composed of three $\alpha\beta$ subunit pairs. Each β subunit contains a catalytic site for ATP synthesis. The headpiece is held stationary by a δ subunit attached to a long **b** subunit connected to subunit **a** in the membrane.

FIGURE 24.3 ATP synthase (F₀F₁ATPase). Note that the matrix side of the mitochondrial inner membrane is at the *top* of the figure. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i, inorganic phosphate.

The influx of protons through the proton channel turns the rotor. The proton channel is formed by the c subunits on one side and the a subunits on the other side. Although the channel is continuous, it has two offset

portions: one portion opens directly to the intermembrane space and one portion opens directly to the matrix. In the current model, each **c** subunit contains a glutamyl carboxyl group that extends into the proton channel. Because this carboxyl group accepts a proton from the intermembrane space, the **c** subunit rotates into the hydrophobic lipid membrane. The rotation exposes a different proton-containing **c** subunit to the portion of the channel that is open directly to the matrix side. Because the matrix has a lower proton concentration, the glutamyl carboxylic acid group releases a proton into the matrix portion of the channel. Rotation is completed by an attraction between the negatively charged glutamyl residue and a positively charged arginyl group on the **a** subunit.

According to the binding change mechanism, as the asymmetric shaft rotates to a new position, it forms different binding associations with the $\alpha\beta$ subunits (Fig. 24.4). The new position of the shaft alters the conformation of one β subunit so that it releases a molecule of ATP and another subunit spontaneously catalyzes synthesis of ATP from inorganic phosphate, one proton, and ADP. Thus, energy from the electrochemical gradient is used to change the conformation of the ATP synthase subunits so that the newly synthesized ATP is released.

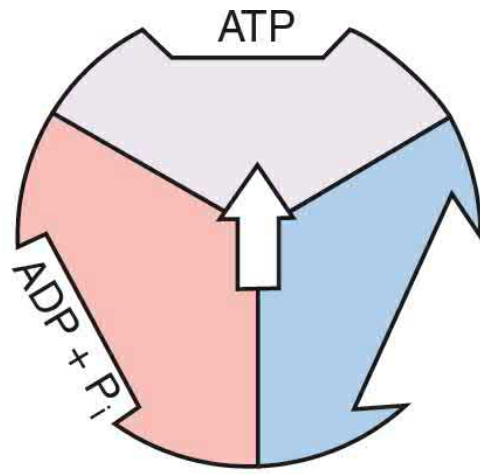

FIGURE 24.4 Binding change mechanism for ATP synthesis. The three $\alpha\beta$ -subunit pairs of the ATP synthase headpiece have binding sites that can exist in three different conformations, depending on the position of the γ -stalk subunit. (1) When ADP + P_i bind to an open site and the proton influx rotates the γ -spindle (white arrow), the conformation of the subunits change and ATP is released from one site. (ATP dissociation is thus the energy-requiring step). Bound ADP and P_i combine to form ATP at another site. (2) As the ADP + P_i bind to the new open site, and the γ -shaft rotates, the conformations of the sites change again, and ATP is released. ADP and P_i combine to form another ATP. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i , inorganic phosphate.

B. Oxidation–Reduction Components of the Electron Transport Chain

Electron transport to O_2 occurs via a series of oxidation–reduction steps in which each successive component of the chain is reduced as it accepts electrons and oxidized as it passes electrons to the next component of the chain. The oxidation–reduction components of the chain include flavin mononucleotide (FMN), Fe–S centers, CoQ, and Fe in cytochromes b, c_1 , c, a, and a_3 . Copper (Cu) is also a component of cytochrome c oxidase (Fig. 24.5). With the exception of CoQ, all of these electron acceptors are tightly bound to the protein subunits of the carriers. FMN, like FAD, is synthesized from the vitamin riboflavin (see Fig. 23.4).

FIGURE 24.5 Components of the electron transport chain. NADH:CoQ oxidoreductase (complex I) spans the membrane and has a proton pumping mechanism involving CoQ. The electrons go from CoQ to the cytochrome b– c_1 complex (complex III); electron transfer does **not** involve complex II. Succinate dehydrogenase (complex II), glycerol 3-phosphate dehydrogenase, and ETF:CoQ oxidoreductase all transfer electrons to CoQ, but they do not span the membrane and do not have proton pumping mechanisms. As CoQ accepts electrons and protons from the matrix side, it is converted to CoQH₂. Electrons are transferred from complex III to complex IV (cytochrome c oxidase) by cytochrome c, a small cytochrome in the intermembrane space that has reversible binding sites on the b– c_1 complex and cytochrome c oxidase. CoQ, coenzyme Q; ETF, electron-transferring flavoprotein; FMN, flavin mononucleotide; NAD, nicotinamide adenine dinucleotide.

The reduction potential of each complex of the chain is at a lower energy level than the previous complex, so energy is released as electrons pass through each complex. This energy is used to move protons against their concentration gradient, so they become concentrated on the cytosolic side of the inner membrane.

1. NADH:CoQ Oxidoreductase

NADH:CoQ oxidoreductase (also named NADH dehydrogenase) is an enormous 45-subunit complex that contains a binding site for NADH, several FMN, and iron–sulfur (Fe–S) center binding proteins, and binding sites for CoQ (see Fig. 24.5). An FMN accepts two electrons from NADH and is able to pass single electrons to the Fe–S centers. Fe–S centers, which are able to delocalize single electrons into large orbitals, transfer electrons to and from CoQ. Fe–S centers are also present in other enzyme systems, such as proteins within the cytochrome b– c_1 complex, which transfer electrons to CoQ, and in aconitase in the TCA cycle.

Although iron-deficiency anemia is characterized by decreased levels of hemoglobin and other iron-containing proteins in the blood, the iron-containing cytochromes and Fe–S centers of the electron transport chain in tissues such as skeletal muscle are affected as rapidly. Fatigue in iron-deficiency anemia, in patients such as **Ann R.** (see Chapter 15),

results, in part, from the lack of electron transport for ATP production.

2. Succinate Dehydrogenase and Other Flavoproteins

In addition to NADH:CoQ oxidoreductase, **succinate dehydrogenase** and other flavoproteins in the inner mitochondrial membrane also pass electrons to CoQ (see Fig. 24.5). Succinate dehydrogenase is part of the TCA cycle and also a component of complex II of the electron transport chain. ETF-CoQ oxidoreductase accepts electrons from ETF (**e**lectron-t**e**rring flavoprotein), which acquires them from fatty acid oxidation and other pathways. Both of these flavoproteins have Fe–S centers. Glycerol 3-phosphate dehydrogenase is a flavoprotein that is part of a shuttle for reoxidizing cytoplasmic NADH (see Section I.E).

The free energy drop in electron transfer between NADH and CoQ of ~ -13 to -14 kcal is able to support movement of four protons. However, the FAD in succinate dehydrogenase (as well as ETF-CoQ oxidoreductase and glycerol 3-phosphate dehydrogenase) is at roughly the same redox potential as CoQ, and no energy is released as they transfer electrons to CoQ. These proteins do not span the membrane and consequently do not have a proton pumping mechanism.

3. Coenzyme Q

CoQ is the only component of the electron transport chain that is not protein bound. The large hydrophobic side chain of 10 isoprenoid units (50 carbons) confers lipid solubility, and CoQ is able to diffuse freely through the lipids of the inner mitochondrial membrane (Fig. 24.6). When the oxidized quinone form accepts a single electron (to form the semiquinone), it forms a free radical (a compound with a single electron in an orbital). The transfer of single electrons makes it the major site for the generation of toxic oxygen free radicals in the body (see Chapter 25).

FIGURE 24.6 Structure of coenzyme Q. Coenzyme Q contains a quinone with a long lipophilic side chain comprising 10 isoprenoid units (thus, it is sometimes called CoQ $_{10}$). CoQ can accept one electron (e^-) to become the half-reduced form or two e^- s to become fully reduced.

The semiquinone can accept a second electron and two protons from the matrix side of the membrane to form the fully reduced quinone. The mobility of CoQ in the membrane, its ability to accept one or two electrons, and its ability to accept and donate protons enable it to participate in the proton pumps for both complexes I and III as it shuttles electrons between them (see Section I.C). CoQ is also called **ubiquinone** (the ubiquitous quinone), because quinones with similar structures are found in all plants and animals.

4. Cytochromes

The remaining components in the electron transport chain are cytochromes (see Fig. 24.5). Each cytochrome is a protein that contains a bound heme (i.e., an Fe atom bound to a porphyrin nucleus similar in structure to the heme in hemoglobin) (Fig. 24.7).

FIGURE 24.7 Heme A. Heme A is found in cytochromes a and a₃. Cytochromes are proteins that contain a heme chelated with an iron atom. Hemes are derivatives of protoporphyrin IX. Each cytochrome has a heme with different modifications of the side chains (indicated with *dashed lines*), resulting in a slightly different reduction potential and, consequently, a different position in the sequence of electron transfer.

Because of differences in the protein component of the cytochromes and small differences in the heme structure, each heme has a different reduction potential. The cytochromes of the b-c₁ complex have a higher energy level than those of cytochrome oxidase (a and a₃). Thus, energy is released by electron transfer between complexes III and IV. The iron atoms in the cytochromes are in the Fe³⁺ state. As they accept an electron, they are reduced to Fe²⁺. As they are reoxidized to Fe³⁺, the electrons pass to the next component of the electron transport chain.

The iron in the heme in hemoglobin, unlike the iron in the heme of cytochromes, never changes its oxidation state (it is Fe²⁺ in hemoglobin). If the iron in hemoglobin were to become oxidized (Fe³⁺), the oxygen-binding capacity of the molecule would be lost. What accounts for this difference in iron oxidation states between hemoglobin and cytochromes?

5. Copper (Cu¹) and the Reduction of Oxygen

The last cytochrome complex is cytochrome oxidase, which passes electrons from cytochrome c to O₂ (see Fig. 24.5). It contains cytochromes a and a₃ and the oxygen-binding site. A whole oxygen molecule, O₂, must accept four electrons to be reduced to two H₂O molecules. Bound copper (Cu¹) ions in the cytochrome oxidase complex facilitate the collection of the four electrons and the reduction of O₂.

Cytochrome oxidase has a much lower K_m for O_2 than myoglobin (the heme-containing intracellular oxygen carrier) or hemoglobin (the heme-containing oxygen transporter in the blood). Thus, O_2 is “pulled” from the erythrocyte to myoglobin and from myoglobin to cytochrome oxidase, where it is reduced to H_2O .

C. Pumping of Protons

One of the tenets of the chemiosmotic theory is that energy from the oxidation–reduction reactions of the electron transport chain is used to transport protons from the matrix to the intermembrane space. This proton pumping is generally facilitated by the vectorial arrangement of the membrane-spanning complexes. Their structure allows them to pick up electrons and protons on one side of the membrane and release protons on the other side of the membrane as they transfer an electron to the next component of the chain. The direct physical link between proton movement and electron transfer can be illustrated by an examination of the Q cycle for the b–c₁ complex (Fig. 24.8). The Q cycle involves a double cycle of CoQ reduction and oxidation. CoQ accepts two protons at the matrix side together with two electrons; it then releases protons into the intermembrane space while donating one electron back to another component of the cytochrome b–c₁ complex and one to cytochrome c.

FIGURE 24.8 The proton motive Q cycle for the b–c₁ complex. (1) From 2QH₂, electrons go down two different paths: One path is through an Fe–S center protein (ISP) toward cytochrome c (red arrows). Another path is “backward” to one of the b cytochromes (dashed arrows). (2) Electrons are transferred from ISP through cytochrome c₁. Cytochrome c, which is in the intermembrane space, binds to the b–c₁ complex to accept an electron. (3) Returning electrons go through another b cytochrome and are directed toward the matrix. (4) At the matrix side, electrons and 2H⁺ are accepted by Q. Q, coenzyme Q; Q⁻, CoQ semiquinone; QH₂, CoQ hydroquinone.

The mechanism for pumping protons at the NADH:CoQ oxidoreductase complex is not well understood, but it involves a Q cycle in which the Fe–S centers and FMN might participate. However, transmembrane proton movement at cytochrome c oxidase probably involves direct transport of the proton through a series of bound water molecules or amino acid side chains in the protein complex, a mechanism that has been described as a “proton wire.”

Normally, the protein structures binding the heme either protect the iron from oxidation (such as the globin proteins) or allow oxidation to occur (such as that happens in the cytochromes). However, in hemoglobin M, a rare hemoglobin variant found in the human population, a tyrosine is substituted for the histidine at position F8 in the normal hemoglobin A. This tyrosine stabilizes the Fe³⁺ form of heme, and these subunits cannot bind oxygen. This is a lethal condition if it is homozygous.

The significance of the direct link between the electron transfer and proton movement is that one cannot occur without the other (the processes are said to be “coupled”). Thus, when protons are not being used for ATP synthesis, the proton gradient and the membrane potential build up. This “proton back pressure” controls the rate of proton pumping, which controls electron transport and O₂ consumption.

D. Energy Yield from the Electron Transport Chain

The overall free energy release from oxidation of NADH by O₂ is ~–53 kcal, and from FAD(2H), it is ~–41 kcal. This ΔG^0 is so negative that the chain is never reversible; we never synthesize oxygen from H₂O. The negative ΔG^0 also drives NADH and FAD(2H) formation from the pathways of fuel oxidation, such as the TCA cycle and glycolysis, to completion.

Overall, each NADH donates two electrons, equivalent to the reduction of one half of an O₂ molecule. A generally (but not universally) accepted estimate of the stoichiometry of ATP synthesis is that four protons are pumped at complex I, four protons at complex III, and two at complex IV. With three protons translocated for each ATP synthesized and one proton for each phosphate transported into the matrix (see Section IV.A), an estimated 2.5 ATPs are formed for each NADH oxidized, and 1.5 ATPs are formed for each of the other FAD(2H)-containing flavoproteins that donate electrons to CoQ. (This calculation neglects the basal proton leak.) Thus, only ~30% of the energy available from NADH and FAD(2H) oxidation by O₂ is used for ATP synthesis. Some of the remaining energy in the electrochemical potential is used for the transport of anions and Ca²⁺ into the mitochondrion. The remainder of the energy is released as heat. Consequently, the electron transport chain is also our major source of heat.

Cora N. has a lack of oxygen in the anterior and lateral walls of her heart caused by severe ischemia (lack of blood flow) resulting from blockage of the coronary arteries supplying blood to this area of her heart. The arteries are blocked by a clot at the site of ruptured atherosclerotic plaques. The limited availability of O₂ to act as an electron acceptor will decrease proton pumping and generation of an electrochemical potential gradient across the inner mitochondrial membrane of ischemic cells. As a consequence, the rate of ATP generation in these specific areas of her heart will decrease, thereby triggering events that lead to irreversible cell injury.

E. Cytoplasmic NADH

There is no transport system for cytoplasmic NADH to cross the inner mitochondrial membrane or for mitochondrial NADH to enter the cytoplasm. However, there are two shuttle systems to transport the electrons from NADH (cytoplasmic) to NAD⁺ (mitochondrial). NADH can be reoxidized to NAD⁺ in the cytosol by a reaction that transfers the electrons to dihydroxyacetone phosphate (DHAP) in the glycerol 3-phosphate (glycerol 3-P) shuttle or to oxaloacetate in the malate–aspartate shuttle. The NAD⁺ that is formed in the cytosol returns to glycolysis, while glycerol 3-P or malate carries the reducing equivalents that are ultimately transferred across the inner mitochondrial membrane. Thus, these shuttles transfer electrons and not NADH per se.

1. Glycerol 3-Phosphate Shuttle

The glycerol 3-phosphate shuttle is the major shuttle in most tissues. In this shuttle, cytosolic NAD⁺ is regenerated by cytoplasmic glycerol 3-phosphate dehydrogenase, which transfers electrons from NADH to DHAP to form glycerol 3-phosphate (Fig. 24.9). Glycerol 3-phosphate then diffuses through the outer mitochondrial membrane to the inner mitochondrial membrane, where the electrons are donated to a

membrane-bound flavin adenine dinucleotide (FAD)-containing glycerophosphate dehydrogenase. This enzyme, like succinate dehydrogenase, ultimately donates electrons to CoQ, resulting in an energy yield of ~1.5 ATPs from oxidative phosphorylation. DHAP returns to the cytosol to continue the shuttle. The sum of the reactions in this shuttle system is simply

FIGURE 24.9 Glycerol 3-phosphate shuttle. Because NAD⁺ and NADH cannot cross the mitochondrial membrane, shuttles transfer the reducing equivalents into mitochondria. Dihydroxyacetone phosphate (DHAP) is reduced to glycerol 3-P by cytosolic glycerol 3-P dehydrogenase, using cytosolic NADH produced in glycolysis. Glycerol 3-P then reacts in the inner mitochondrial membrane with mitochondrial glycerol 3-P dehydrogenase, which transfers the electrons to FAD and regenerates DHAP, which returns to the cytosol. The electron transport chain transfers the electrons to O₂, which generates ~1.5 ATP for each FAD(2H) that is oxidized. ATP, adenosine triphosphate; FAD, flavin adenine dinucleotide; NAD, nicotinamide adenine dinucleotide.

2. Malate–Aspartate Shuttle

Many tissues contain both the glycerol 3-P shuttle and the malate–aspartate shuttle. In the malate–aspartate shuttle (Fig. 24.10), cytosolic NAD^+ is regenerated by cytosolic malate dehydrogenase, which transfers electrons from NADH to cytosolic oxaloacetate to form malate. Malate is transported across the inner mitochondrial membrane by a specific translocase, which exchanges malate for α -ketoglutarate. In the matrix, malate is oxidized back to oxaloacetate by mitochondrial malate dehydrogenase, and NADH is generated. This NADH can donate electrons to the electron transport chain with generation of ~ 2.5 mol of ATP per mole of NADH . The newly formed oxaloacetate cannot pass back through the inner mitochondrial membrane under physiological conditions, so aspartate is used to return the oxaloacetate carbon skeleton to the cytosol. In the matrix, transamination reactions transfer an amino group to oxaloacetate to form aspartate, which is transported out to the cytosol (using an aspartate–glutamate exchange translocase) and converted back to oxaloacetate through another transamination reaction. The sum of all the reactions of this shuttle system is simply

FIGURE 24.10 Malate–aspartate shuttle. NADH produced by glycolysis reduces oxaloacetate (OAA) to malate, which crosses the mitochondrial membrane and is reoxidized to OAA. The mitochondrial NADH donates electrons to the electron transport chain, with 2.5 ATPs generated for each NADH . To complete the shuttle, oxaloacetate must return to the cytosol, although it cannot be transported directly on a translocase. Instead, it is transaminated to aspartate, which is then transported out to the cytosol, where it is transaminated back to oxaloacetate. The translocators exchange compounds in such a way that the shuttle is completely balanced. ATP, adenosine triphosphate; α -KG, α -ketoglutarate; ETC, electron transport chain; NAD , nicotinamide adenine dinucleotide; TA, transamination reaction.

What are the energy-generating steps as pyruvate is completely oxidized to carbon dioxide to generate 12.5 molecules of ATP per pyruvate?

3. Energy Yield of Aerobic versus Anaerobic Glycolysis

In both aerobic and anaerobic glycolysis, each mole of glucose generates 2 mol of ATP, 2 mol of NADH , and 2 mol of pyruvate. The energy yield from anaerobic glycolysis (1 mol of glucose to 2 mol of lactate) is only 2 mol of ATP per mole of glucose, as the NADH is recycled to NAD^+ by reducing pyruvate to lactate. Neither the NADH nor the lactate produced is thus used for further energy generation. However, when oxygen is available and cytosolic NADH can be oxidized via a shuttle system, pyruvate can also enter the mitochondria and be completely oxidized to CO_2 via pyruvate dehydrogenase (PDH) and the TCA cycle. The oxidation of pyruvate via this route generates roughly 12.5 mol of ATP per mole of pyruvate. If the cytosolic NADH is oxidized by the glycerol 3-P shuttle, ~ 1.5 mol of ATP is produced per NADH . If, instead, the NADH is oxidized by the malate–aspartate shuttle, ~ 2.5 mol is produced. Thus, the 2 mol of NADH produced during glycolysis can lead to 3 to 5 mol of ATP being produced, depending on which shuttle system is used to transfer the reducing equivalents. Because each mole of pyruvate produced can give rise to 12.5 mol of ATP, altogether 30 to 32 mol

of ATP can be produced from 1 mol of glucose oxidized to carbon dioxide.

To produce the same amount of ATP per unit time from anaerobic glycolysis as from the complete aerobic oxidation of glucose to CO₂, anaerobic glycolysis must occur ~15 times faster and use ~15 times more glucose. Cells achieve this high rate of glycolysis by expressing high levels of glycolytic enzymes. In certain skeletal muscles and in most cells during hypoxic crises, high rates of glycolysis are associated with rapid degradation of internal glycogen stores to supply the required glucose 6-phosphatase.

In the complete oxidation of pyruvate to carbon dioxide, four steps generate NADH (pyruvate dehydrogenase, isocitrate dehydrogenase, α -ketoglutarate dehydrogenase, and malate dehydrogenase). One step generates FAD(2H) (succinate dehydrogenase) and one substrate-level phosphorylation (succinate thiokinase). Thus, because each NADH generates 2.5 ATPs, the overall contribution by NADH is 10 ATP molecules. The FAD(2H) generates an additional 1.5 ATPs, and the substrate-level phosphorylation provides one more. Therefore, $10 + 1.5 + 1 = 12.5$ molecules of ATP.

F. Respiratory Chain Inhibition and Sequential Transfer

In the cell, electron flow in the electron transport chain must be sequential from NADH or a flavoprotein all the way to O₂ to generate ATP (see Fig. 24.5). In the absence of O₂ (anoxia), there is no ATP generated from oxidative phosphorylation because electrons back up in the chain. Even complex I cannot pump protons to generate the electrochemical gradient, because every molecule of CoQ already has electrons that it cannot pass down the chain without an O₂ to accept them at the end. The action of the respiratory chain inhibitor **cyanide**, which binds to cytochrome oxidase, is similar to that of anoxia: It prevents proton pumping by all three complexes. Complete inhibition of the b-c₁ complex prevents pumping at cytochrome oxidase because there is no donor of electrons; it prevents pumping at complex I because there is no electron acceptor. Although complete inhibition of any one complex inhibits proton pumping at all of the complexes, partial inhibition of proton pumping can occur when only a fraction of the molecules of a complex contains bound inhibitor. The partial inhibition results in a partial decrease of the maximal rate of ATP synthesis. Table 24.1 lists chemical inhibitors of oxidative phosphorylation, and indicates the steps within either electron transport or ATP synthesis at which they act.

TABLE 24.1 Inhibitors of Oxidative Phosphorylation

INHIBITOR	SITE OF INHIBITION
Rotenone, amytal	Transfer of electrons from complex I to coenzyme Q
Antimycin C	Transfer of electrons from complex III to cytochrome c
Carbon monoxide (CO)	Transfer of electrons from complex IV to oxygen
Cyanide (CN)	Transfer of electrons through complex IV to oxygen
Atractyloside	Inhibits the adenine nucleotide translocase (ANT)
Oligomycin	Inhibits proton flow through the F ₀ component of the adenosine triphosphate (ATP) synthase
Dinitrophenol	An uncoupler; facilitates proton transfer across the inner mitochondrial membrane
Valinomycin	A potassium ionophore; facilitates potassium ion transfer across the inner mitochondrial membrane

Intravenous nitroprusside is an intravenous medication that can be used to treat severe hypertension and rapidly lowers elevated blood pressure through its direct vasodilating action. Because of newer available blood pressure medications, nitroprusside is used infrequently because with prolonged infusions of 24 to 48 hours or more, nitroprusside slowly breaks down to produce cyanide, an inhibitor of the cytochrome c oxidase complex. Because small amounts of cyanide are detoxified in the liver by conversion to thiocyanate, which is excreted in the urine, the conversion of nitroprusside to cyanide can be monitored by following blood thiocyanate levels.

II. OXPHOS Diseases

Clinical diseases involving components of oxidative phosphorylation (referred to as **OXPHOS diseases**) are among the most commonly encountered degenerative diseases. The clinical pathology may be caused by gene mutations in either mitochondrial DNA (mtDNA) or nuclear DNA (nDNA) that encode proteins required for normal oxidative phosphorylation.

Cyanide binds to the Fe^{3+} in the heme of the cytochromes a and a_3 , components of cytochrome c oxidase, and prevents electron transport to O_2 . Mitochondrial respiration and energy production cease, and cell death rapidly occurs. The central nervous system is the primary target for cyanide toxicity. Acute inhalation of high concentrations of cyanide (e.g., smoke inhalation during a fire) provokes a brief central nervous system stimulation followed rapidly by convulsion, coma, and death. Acute exposure to lower amounts can cause light-headedness, breathlessness, dizziness, numbness, and headaches. Cyanide is present in the air as hydrogen cyanide (HCN), in soil and water as cyanide salts (e.g., sodium cyanide [NaCN]), and in foods as cyanoglycosides. Most of the cyanide in the air usually comes from automobile exhaust. Examples of population with potentially high exposures include active and passive smokers, people who are exposed to house or other building fires, residents who live near cyanide- or thiocyanate-containing hazardous waste sites, and workers involved in a number of manufacturing processes (e.g., photography or pesticide application). Cyanoglycosides such as amygdalin are present in edible plants such as almonds, pits from stone fruits (e.g., apricots, peaches, plums, and cherries), sorghum, cassava, soybeans, spinach, lima beans, sweet potatoes, maize, millet, sugar cane, and bamboo shoots.

Amygdalin, a cyanoglycoside

HCN is released from cyanoglycosides by β -glucosidases present in the plant or in intestinal bacteria. Small amounts are inactivated in the liver principally by rhodanese, which converts it to thiocyanate.

In the United States, toxic amounts of cyanoglycosides have been ingested as ground apricot pits, either as a result of their promotion as a health food or as a treatment for cancer. The drug Laetrile (amygdalin) was used as a cancer therapeutic agent, although it was banned in the United States because it was ineffective and potentially toxic. Commercial fruit juices made from unpitted fruits could provide toxic amounts of cyanide, particularly in infants or children. In countries in which cassava is a dietary staple, improper processing results in retention of its high cyanide content at potentially toxic levels.

A. Mitochondrial DNA and OXPHOS Diseases

The mtDNA is a small double-stranded circular DNA consisting of 16,569 nucleotide pairs. It encodes 13 subunits of the complexes involved in oxidative phosphorylation: 7 of the 45 subunits of complex I (NADH:CoQ oxidoreductase complex), 1 of the 11 subunits of complex III (cytochrome b - c_1 complex), 3 of the 13 subunits of complex IV (cytochrome oxidase), and 2 subunits of the F_0 portion ATP-synthase complex. In addition, mtDNA encodes the necessary components for translation of its mRNA: a large and small ribosomal RNA (rRNA) and 22 transfer RNAs (tRNAs). Mutations in mtDNA have been identified as deletions, duplications, or point mutations. Disorders associated with these mutations are outlined in Table 24.2.

TABLE 24.2 Examples of OXPHOS Diseases Arising from mtDNA Mutations

SYNDROME	CHARACTERISTIC SYMPTOMS	mtDNA MUTATION
<i>I. mtDNA Rearrangements in Which Genes Are Deleted or Duplicated</i>		

Kearns–Sayre syndrome	Onset before 20 years of age, characterized by ophthalmoplegia, atypical retinitis pigmentosa, mitochondrial myopathy, as well as a cardiac conduction defect, cerebellar syndrome, or elevated CSF proteins	Deletion of contiguous segments of tRNA and OXPHOS polypeptides or duplication mutations consisting of tandemly arranged normal mtDNA and a mtDNA with a deletion mutation
Pearson syndrome	Systemic disorder of OXPHOS that predominantly affects bone marrow and pancreas	Deletion of contiguous segments of tRNA and OXPHOS polypeptides or duplication mutations consisting of tandemly arranged normal mtDNA and a mtDNA with a deletion mutation
<i>II. mtDNA Point Mutations in tRNA or Ribosomal RNA Genes</i>		
MERRF (myoclonic epilepsy with ragged red fibers)	Progressive myoclonic epilepsy, a mitochondrial myopathy with ragged red fibers, and a slowly progressive dementia. Onset of symptoms: late childhood to adult	tRNA ^{Lys}
MELAS (mitochondrial myopathy, encephalomyopathy, lactic acidosis, and strokelike episodes)	Progressive neurodegenerative disease characterized by strokelike episodes that usually first occur in childhood and a mitochondrial myopathy	80%–90% mutations in tRNA ^{Leu}
<i>III. mtDNA Missense Mutations in OXPHOS Polypeptides</i>		
Leigh syndrome (subacute necrotizing encephalopathy)	Mean age of onset, 1.5–5 years; clinical manifestations include optic atrophy, ophthalmoplegia, nystagmus, respiratory abnormalities, ataxia, hypotonia, spasticity, and developmental delay or regression	7%–20% of cases have mutations in F ₀ subunits of the F ₀ F ₁ ATPase.
LHON (Leber hereditary optic neuropathy)	Late onset, acute optic atrophy	90% of European and Asian cases result from mutation in NADH dehydrogenase (complex I)

CSF, cerebrospinal fluid; mtDNA, mitochondrial DNA; OXPHOS, oxidative phosphorylation; tRNA, transfer RNA.

The genetics of mutations in mtDNA are defined by maternal inheritance, replicative segregation, threshold expression, a high mtDNA mutation rate, and the accumulation of somatic mutations with age (see Chapter 18). The maternal inheritance pattern reflects the exclusive transmission of mtDNA from the mother to her children. The egg contains ~300,000 molecules of mtDNA packaged into mitochondria. These are retained during fertilization, whereas those of the sperm do not enter the egg or are lost. Usually, some mitochondria are present that have the mutant mtDNAs and some have normal (wild-type) DNAs. As cells divide during mitosis and meiosis, mitochondria replicate by fission, but various amounts of mitochondria with mutant and wild-type DNAs are distributed to each daughter cell (replicative segregation). Thus, any cell can have a mixture of mitochondria, each with mutant or wild-type mtDNAs (termed **heteroplasmy**). The mitotic and meiotic segregation of the heteroplasmic mtDNA mutation results in variable oxidative phosphorylation deficiencies between patients with the same mutation and even among a patient's own tissues.

The disease pathology usually becomes worse with age, because a small amount of normal mitochondria might confer normal function and exercise capacity while the patient is young. As the patient ages, somatic (spontaneous) mutations in mtDNA accumulate from the generation of free radicals within the mitochondria (see Chapter 25). These mutations frequently become permanent, partly because mtDNA does not have access to the same repair mechanisms available for nuclear DNA (high mutation rate). Even in normal individuals, somatic mutations result in a decline of oxidative phosphorylation capacity with age (accumulation of somatic mutations with age). At some stage, the ATP-generating capacity of a tissue falls below the tissue-specific threshold for normal function (threshold expression). In general, symptoms of these defects appear in one or more of the tissues with the highest ATP demands: nervous tissue, heart, skeletal muscle, and kidney.

Oxidative phosphorylation (OXPHOS) is responsible for producing most of the ATP that our cells require. The genes responsible for the polypeptides that comprise the OXPHOS complexes within the mitochondria are located within either the nuclear DNA (nDNA) or the mitochondrial DNA (mtDNA). A broad spectrum of human disorders (the OXPHOS diseases) may result from genetic mutations or nongenetic alterations (spontaneous mutations) in either the nDNA or the mtDNA.

Increasingly, such changes appear to be responsible for at least some aspects of common disorders, such as Parkinson disease, dilated and hypertrophic cardiomyopathies, diabetes mellitus, Alzheimer disease, depressive disorders, and a host of less well-known clinical entities.

B. Other Genetic Disorders of Oxidative Phosphorylation

Genetic mutations also have been reported for mitochondrial proteins that are encoded by nuclear DNA. Most of the estimated 1,000 proteins required for oxidative phosphorylation are encoded by nuclear DNA, whereas mtDNA encodes only 13 subunits of the oxidative phosphorylation complexes (including ATP synthase). Nuclear DNA encodes the additional 70 or more subunits of the oxidative phosphorylation complexes, as well as the ANT and other anion translocators. Coordinated regulation of expression of nuclear and mtDNA, import of proteins into the mitochondria, assembly of the complexes, and regulation of mitochondrial fission are nuclear-encoded. The nuclear respiratory factors (NRF-1 and NRF-2) are nuclear transcription factors that bind to and activate promoter regions of the nuclear genes that encode subunits of the respiratory chain complexes, including cytochrome *c*. They also activate the transcription of the nuclear gene for the mitochondrial transcription factor (mTF)-A. The protein product of this gene translocates into the mitochondrial matrix, where it stimulates transcription and replication of the mitochondrial genome.

Nuclear DNA mutations differ from mtDNA mutations in several important respects. These mutations do not show a pattern of maternal inheritance but are usually autosomal recessive. The mutations are uniformly distributed to daughter cells and, therefore, are expressed in all tissues containing the allele for a particular tissue-specific isoform. However, phenotypic expression will still be most apparent in tissues with high ATP requirements.

Decreased activity of the electron transport chain can result from inhibitors as well as from mutations in mtDNA and nDNA. Why does an impairment of the electron transport chain result in lactic acidosis?

C. Lactic Acidosis

Lactic acidosis generally results from a greatly increased NADH/NAD⁺ ratio in tissues (Fig. 24.11). The increased NADH concentration prevents pyruvate oxidation in the TCA cycle and directs pyruvate to lactate. To compensate for the decreased ATP production from oxidative metabolism, phosphofructokinase-1 (PFK-1), and, therefore, the entire glycolytic pathway, is activated. For example, consumption of large amounts of alcohol, which is rapidly oxidized in the liver and increases NADH levels, can result in lactic acidosis. Hypoxia in any tissue increases lactate production as cells attempt to compensate for a lack of O₂ for oxidative phosphorylation.

FIGURE 24.11 Pathways leading to lactic acidemia. Acetyl CoA, acetyl coenzyme A; ADP, adenosine diphosphate; ATP, adenosine triphosphate; CoQ, coenzyme Q; Cyt c, cytochrome c; DH, dehydrogenase; ET, electron transport; FAD, flavin adenine dinucleotide; FMN, flavin mononucleotide; Glycerol-P, glycerol 3-phosphate; LDH, lactate dehydrogenase; mtDNA, mitochondrial DNA; NAD, nicotinamide adenine dinucleotide; OAA, oxaloacetate; PDH, pyruvate dehydrogenase; SDH, succinate dehydrogenase; TCA, tricarboxylic acid.

A The effect of inhibition of electron transport is an impaired oxidation of pyruvate, fatty acids, and other fuels. In many cases, the inhibition of mitochondrial electron transport results in higher-than-normal levels of lactate and pyruvate in the blood and an increased lactate to pyruvate ratio. NADH oxidation requires the complete transfer of electrons from NADH to O₂, and a defect anywhere along the chain will result in the accumulation of NADH and a decrease of NAD⁺. The increase in NADH/NAD⁺ inhibits pyruvate dehydrogenase and causes the accumulation of pyruvate. It also increases the conversion of pyruvate to lactate (anaerobic glycolysis), and elevated levels of lactate appear in the blood. A large number of genetic defects of the proteins in respiratory chain complexes have, therefore, been classified together as “congenital lactic acidosis.”

A number of other problems that interfere with either the electron transport chain or pyruvate oxidation in the TCA cycle result in lactic acidemia (see Fig. 24.11). For example, OXPHOS diseases (inherited deficiencies in subunits of complexes in the electron transport chain, such as myoclonic epilepsy with ragged red fibers [MERRF]) increase the NADH/NAD⁺ ratio and inhibit PDH (see Chapter 23). Pyruvate accumulates and is converted to lactate, to allow glycolytic ATP production to proceed. Similarly, impaired PDH activity

from an inherited deficiency of E_1 (the decarboxylase subunit of the complex), or from severe thiamin deficiency, increases blood lactate levels (see Chapter 23). Pyruvate carboxylase deficiency also can result in lactic acidosis (see Chapter 23), because of an accumulation of pyruvate.

Lactic acidosis can also result from inhibition of lactate utilization in gluconeogenesis (e.g., hereditary fructose intolerance, which is due to a defective aldolase gene). If other pathways that use glucose 6-P are blocked, glucose 6-P can be shunted into glycolysis and lactate production (e.g., glucose 6-P deficiency).

III. Coupling of Electron Transport and ATP Synthesis

The electrochemical gradient couples the rate of the electron transport chain to the rate of ATP synthesis. Because electron flow requires proton pumping, electron flow cannot occur faster than protons are used for ATP synthesis (coupled oxidative phosphorylation) or returned to the matrix by a mechanism that short-circuits the ATP synthase pore (uncoupling).

A patient experienced spontaneous muscle jerking (myoclonus) in her mid-teens, and her condition progressed over 10 years to include debilitating myoclonus, neurosensory hearing loss, dementia, hypoventilation, and mild cardiomyopathy. Energy metabolism was affected in the central nervous system, heart, and skeletal muscle, resulting in lactic acidosis. A history indicated that the patient's mother, her grandmother, and two maternal aunts had symptoms involving either nervous or muscular tissue (clearly a case of maternal inheritance). However, no other relative had identical symptoms. The symptoms and history of the patient are those of myoclonic epileptic ragged red fiber disease (MERRF). The affected tissues (central nervous system and muscle) are two of the tissues with the highest ATP requirements. Most cases of MERRF are caused by a point mutation in mitochondrial tRNA^{LYS} (mtRNA^{LYS}). The mitochondria, obtained by muscle biopsy, are enlarged and show abnormal patterns of cristae. The muscle tissue also shows ragged red fibers.

A. Regulation through Coupling

As ATP chemical bond energy is used by energy-requiring reactions, ADP and P_i concentrations increase. The more ADP present to bind to the ATP synthase, the greater will be proton flow through the ATP synthase pore from the intermembrane space to the matrix. Thus, as ADP levels rise, proton influx increases, and the electrochemical gradient decreases (Fig. 24.12). The proton pumps of the electron transport chain respond with increased proton pumping and electron flow to maintain the electrochemical gradient. The result is increased O_2 consumption. The increased oxidation of NADH in the electron transport chain and the increased concentration of ADP stimulate the pathways of fuel oxidation, such as the TCA cycle, to supply more NADH and FAD(2H) to the electron transport chain. For example, during exercise, we use more ATP for muscle contraction, consume more oxygen, oxidize more fuel (which means burn more calories), and generate more heat from the electron transport chain. If we rest, the rate of ATP utilization decreases, proton influx decreases, the electrochemical gradient increases, and proton back pressure decreases the rate of the electron transport chain. NADH and FAD(2H) cannot be oxidized as rapidly in the electron transport chain, and consequently, their buildup inhibits the enzymes that generate them.

FIGURE 24.12 The concentration of ADP (or the phosphate potential, $[ATP]/[ADP][P_i]$) controls the rate of oxygen consumption. (1) ADP is phosphorylated to ATP by ATP synthase. (2) The release of the ATP requires proton flow through ATP synthase into the matrix. (3) The use of protons from the intermembrane space for ATP synthesis decreases the proton gradient. (4) As a result, the electron transport chain pumps more protons, and oxygen is reduced to H_2O . (5) As NADH donates electrons to the electron transport chain, NAD^+ is regenerated and returns to the TCA cycle or other NADH-producing pathways. ADP, adenosine diphosphate; ATP, adenosine triphosphate; NAD, nicotinamide adenine dinucleotide; P_i , inorganic phosphate; TCA, tricarboxylic acid.

The system is poised to maintain very high levels of ATP at all times. In most tissues, the rate of ATP utilization is nearly constant over time. However, in skeletal muscles, the rates of ATP hydrolysis change dramatically as the muscle goes from rest to rapid contraction. Even under these circumstances, ATP concentration decreases by only $\sim 20\%$ because it is so rapidly regenerated. In the heart, Ca^{2+} activation of TCA cycle enzymes provides an extra push to NADH generation so that neither ATP nor NADH levels fall as ATP demand is increased. The electron transport chain has a very high capacity and can respond very rapidly to any

increase in ATP utilization.

How does shivering generate heat?

B. Uncoupling ATP Synthesis from Electron Transport

When protons leak back into the matrix without going through the ATP synthase pore, they dissipate the electrochemical gradient across the membrane without generating ATP. This phenomenon is called “uncoupling” oxidative phosphorylation. It occurs with chemical compounds, known as uncouplers, and it occurs physiologically with uncoupling proteins (UCPs) that form proton conductance channels through the membrane. Uncoupling of oxidative phosphorylation results in increased oxygen consumption and heat production as electron flow and proton pumping attempt to maintain the electrochemical gradient.

1. Chemical Uncouplers of Oxidative Phosphorylation

Chemical uncouplers, also known as **proton ionophores**, are lipid-soluble compounds that rapidly transport protons from the cytosolic to the matrix side of the inner mitochondrial membrane (Fig. 24.13). Because the proton concentration is higher in the intermembrane space than in the matrix, uncouplers pick up protons from the intermembrane space. Their lipid solubility enables them to diffuse through the inner mitochondrial membrane while carrying protons and release these protons on the matrix side. The rapid influx of protons dissipates the electrochemical potential gradient; therefore, the mitochondria are unable to synthesize ATP. Eventually, mitochondrial integrity and function are lost.

FIGURE 24.13 Action of uncouplers. Dinitrophenol (DNP) is lipid-soluble and can therefore diffuse across the membrane. It has a dissociable proton with a pK_a near 7.2. Thus, in the intermembrane space where $[H^+]$ is high (pH low), DNP picks up a proton, which it carries across the membrane. At the lower proton concentration of the matrix, the H^+ dissociates. As a consequence, cells cannot maintain their electrochemical gradient or synthesize ATP. DNP was once recommended in the United States as a weight-loss drug, based on the principle that decreased $[ATP]$ and increased electron transport stimulate fuel oxidation. However, several deaths resulted from its use. ATP, adenosine triphosphate.

Historically, a skeletal muscle biopsy performed on patients treated with zidovudine and myopathy would show proliferation of subsarcolemmal mitochondria with degeneration of muscle fibers (ragged red fibers). An analysis of

mitochondrial DNA (mtDNA) would show a quantitative depletion of mtDNA.

Isabel S.'s HIV was being treated with a multidrug regimen including a nucleoside analog reverse transcriptase inhibitor. One of the first drugs of this class was zidovudine (azidothymidine, AZT), which also can act as an inhibitor of the mitochondrial DNA polymerase (polymerase γ). A review of the drug's potential adverse effects showed that, rarely, it may cause varying degrees of mtDNA depletion in different tissues, including skeletal muscle. The depletion may cause a severe mitochondrial myopathy, including ragged red fiber accumulation within the skeletal muscle cells associated with ultrastructural abnormalities in their mitochondria. This occurs more rarely in other drugs of this class and has not occurred at all in those with weaker inhibitors of mitochondrial function.

2. Uncoupling Proteins and Thermogenesis

Uncoupling proteins (UCPs) form channels through the inner mitochondrial membrane that are able to conduct protons from the intermembrane space to the matrix, thereby short-circuiting ATP synthase.

UCP1 (thermogenin) is associated with heat production in brown adipose tissue. The major function of brown adipose tissue is nonshivering thermogenesis, whereas the major function of white adipose tissue is the storage of triacylglycerols. The brown color arises from the large number of mitochondria that are present in brown adipose tissue. Human infants, who have little voluntary control over their environment and may kick their blankets off at night, have brown fat deposits along the neck, the breastplate, between the scapulae, and around the kidneys to protect them from cold. However, there is very little brown fat in most adults.

A Shivering results from muscular contraction, which increases the rate of ATP hydrolysis. As a consequence of proton entry for ATP synthesis, the electron transport chain is stimulated. Oxygen consumption increases, as does the amount of energy lost as heat by the electron transport chain.

In response to cold, sympathetic nerve endings release norepinephrine, which activates a lipase in brown adipose tissue that releases fatty acids from triacylglycerols (Fig. 24.14). Fatty acids serve as a fuel for the tissue (i.e., are oxidized to generate the electrochemical potential gradient and ATP) and participate directly in the proton conductance channel by activating UCP1 along with reduced CoQ. When UCP1 is activated by fatty acids, it transports protons from the cytosolic side of the inner mitochondrial membrane back into the mitochondrial matrix without ATP generation. Thus, it partially uncouples oxidative phosphorylation and generates additional heat.

FIGURE 24.14 Brown fat is a tissue specialized for nonshivering thermogenesis. Cold or excessive food intake stimulates the

release of norepinephrine from the sympathetic nerve endings. As a result, a lipase is activated that releases fatty acids for oxidation. The proton conductance protein, thermogenin, is activated, and protons are brought into the matrix. This stimulates the electron transport chain, which increases its rate of NADH and FAD(2H) oxidation and produces more heat. FAD, flavin adenine dinucleotide; NAD, nicotinamide adenine dinucleotide.

The uncoupling proteins exist as a family of proteins: UCP1 (thermogenin) is expressed in brown adipose tissue; UCP2 is found in most cells; UCP3 is found principally in skeletal muscle; UCP4 and UCP5 are found in the nervous system. These are highly regulated proteins that, when activated, increase the amount of energy from fuel oxidation that is being released as heat. However, recent data indicate that this may not be the primary role of UCP2 and UCP3. It has been hypothesized that UCP3 acts as a transport protein to remove fatty acid anions and lipid peroxides from the mitochondria, thereby reducing the risk of forming oxygen free radicals (see Chapter 25) and thus decreasing the occurrence of mitochondrial and cell injury.

Salicylate, which is a degradation product of aspirin in humans, is lipid-soluble and has a dissociable proton. In high concentrations, as in salicylate poisoning, salicylate is able to partially uncouple mitochondria. The decline of ATP concentration in the cell and consequent increase of AMP in the cytosol stimulates glycolysis. The overstimulation of the glycolytic pathway (see Chapter 22) results in increased levels of lactic acid in the blood and a metabolic acidosis. Fortunately, **Dennis V.** did not develop this consequence of aspirin poisoning (see Chapter 4).

3. Proton Leak and Resting Metabolic Rate

A low level of proton leak across the inner mitochondrial membrane occurs in our mitochondria all the time, and our mitochondria thus are normally partially uncoupled. It has been estimated that >20% of our resting metabolic rate is the energy expended to maintain the electrochemical gradient dissipated by our basal proton leak (also referred to as global proton leak). Some of the proton leak results from permeability of the membrane associated with proteins embedded in the lipid bilayer. An unknown amount may result from UCPs.

IV. Transport through Inner and Outer Mitochondrial Membranes

Most of the newly synthesized ATP that is released into the mitochondrial matrix must be transported out of the mitochondria, where it is used for energy-requiring processes such as active ion transport, muscle contraction, or biosynthetic reactions. Likewise, ADP, phosphate, pyruvate, and other metabolites must be transported into the matrix. This requires transport of compounds through both the inner and outer mitochondrial membranes.

A. Transport through the Inner Mitochondrial Membrane

The inner mitochondrial membrane forms a tight permeability barrier to all polar molecules, including ATP, ADP, P_i, anions such as pyruvate, and cations such as Ca²⁺, H⁺, and K⁺. Yet the process of oxidative phosphorylation depends on rapid and continuous transport of many of these molecules across the inner mitochondrial membrane (Fig. 24.15). Ions and other polar molecules are transported across the inner mitochondrial membrane by specific protein translocases that nearly balance charge during the transport process. Most of the exchange transport is a form of active transport that generally uses energy from the electrochemical potential gradient, either the membrane potential or the proton gradient.

FIGURE 24.15 Transport of compounds across the inner and outer mitochondrial membranes. The electrochemical potential gradient drives the transport of ions across the inner mitochondrial membrane on specific translocases. Each translocase is composed of specific membrane-spanning helices that bind only specific compounds (ANT). In contrast, the outer membrane contains relatively large unspecific pores called VDACs through which a wide range of ions diffuse. These bind cytosolic proteins such as hexokinase (HK), which enables HK to have access to newly exported ATP. ADP, adenosine diphosphate; ANT, adenine nucleotide translocase; ATP, adenosine triphosphate; Pi, inorganic phosphate; VDACs, voltage-dependent anion channels.

ATP–ADP translocase (also called ANT, for **adenine nucleotide translocase**) transports ATP formed in the mitochondrial matrix to the intermembrane space in a specific 1:1 exchange for ADP produced from energy-requiring reactions outside of the mitochondria (see Fig. 24.15). Because ATP contains four negative charges and ADP contains only three, the exchange is promoted by the electrochemical potential gradient because the net effect is the transport of one negative charge from the matrix to the cytosol. Similar antiports exist for most metabolic anions. In contrast, inorganic phosphate and pyruvate are transported into the mitochondrial matrix on specific transporters called **symports** together with a proton. A specific transport protein for Ca^{2+} uptake, called the Ca^{2+} uniporter, is driven by the electrochemical potential gradient, which is negatively charged on the matrix side of the membrane relative to the cytosolic side. Other transporters include the dicarboxylate transporter (phosphate–malate exchange), the tricarboxylate transporter (citrate–malate exchange), the aspartate–glutamate transporter, and the malate– α -ketoglutarate transporter (the last two as seen previously in the malate–aspartate shuttle for transferring reducing equivalents across the inner mitochondrial membrane).

B. Transport through the Outer Mitochondrial Membrane

Whereas the inner mitochondrial membrane is highly impermeable, the outer mitochondrial membrane is permeable to compounds with a molecular weight up to ~6,000 Da because it contains large nonspecific pores called **voltage-dependent anion channels (VDACs)** that are formed by mitochondrial porins (see Fig. 24.15). Unlike most transport proteins, which are membrane-spanning helices with specific binding sites, VDACs are

composed of porin homodimers that form a β -barrel with a relatively large nonspecific water-filled pore through the center. These channels are “open” at low transmembrane potential, with a preference for anions such as phosphate, chloride, pyruvate, citrate, and adenine nucleotides. VDACs thus facilitate translocation of these anions between the intermembrane space and the cytosol. A number of cytosolic kinases, such as the hexokinase that initiates glycolysis, bind to the cytosolic side of the channel, where they have a ready access to newly synthesized ATP.

C. The Mitochondrial Permeability Transition Pore

The mitochondrial permeability transition involves the opening of a large nonspecific pore (called MPTP, the **mitochondrial permeability transition pore**) through the inner mitochondrial membrane and outer membranes at sites where they form a junction (Fig. 24.16). In the original model of the MPTP, the basic components of the pore are ANT, the VDAC, and cyclophilin D (CD) (which is a *cis-trans* isomerase for the proline peptide bond). Normally, ANT is a closed pore that functions specifically in a 1:1 exchange of matrix ATP for ADP in the intermembrane space. However, increased mitochondrial matrix Ca^{2+} , excess phosphate, or reactive oxygen species (ROS), which form oxygen or oxygen–nitrogen radicals, can activate the opening of the pore. Conversely, ATP on the cytosolic side of the pore (and possibly a $\text{pH} < 7.0$) and a membrane potential across the inner membrane protect against pore opening. Opening of the MPTP can be triggered by ischemia (hypoxia), which results in a temporary lack of O_2 for maintaining the proton gradient and ATP synthesis. When the proton gradient is not being generated by the electron transport chain, ATP synthase runs backward and hydrolyzes ATP in an attempt to restore the gradient, thus rapidly depleting cellular levels of ATP. As ATP is hydrolyzed to ADP, the ADP is converted to adenine, and the nucleotide pool is no longer able to protect against pore opening. This can lead to a downward spiral of cellular events. A lack of ATP for maintaining the low mitochondrial Ca^{2+} can contribute to pore opening. When the MPTP opens, protons flood in, and maintaining a proton gradient becomes impossible. Anions and cations enter the matrix, mitochondrial swelling ensues, and the mitochondria become irreversibly damaged. The result is cell lysis and death (necrosis). More recent models implicate CD, ANT, the phosphate carrier, and the ATP synthase as components of the MPTP. In these models, the ATP synthase is playing a regulator role, while the pore is formed by the phosphate carrier and the ANT, with the presence and enzymatic activity of CD.

FIGURE 24.16 The mitochondrial permeability transition pore (MPTP). In the MPTP, ANT is thought to complex with the voltage-dependent anion channel (VDAC). The conformation of ANT is regulated by cyclophilin D (CD) and Ca^{2+} . The change to an open pore is activated by Ca^{2+} , depletion of adenine nucleotides, and ROS that alter sulfhydryl (SH) groups. It is inhibited by the electrochemical potential gradient (Δp), by cytosolic ATP, and by a low cytosolic pH. VDACS bind a number of proteins, including Bcl-2 and Bax, which regulate apoptosis. Binding of pro-apoptotic members of the Bcl-2 family to VDAC may change the permeability of the outer membrane so as to either favor or block events leading to apoptosis (such as cytochrome c release; see Biochemical Comments and Chapter 17). ANT, adenine nucleotide translocase; ATP, adenosine triphosphate; VDAC, voltage-dependent anion channel.

A variety of neurodegenerative diseases, such as Parkinson disease, Alzheimer disease, amyotrophic lateral sclerosis, and prion disease, are all associated with inappropriate opening of the MPTP in neurons.

CLINICAL COMMENTS

Cora N. Thrombolysis stimulated by intravenous recombinant tissue plasminogen activator (TPA) restored O_2

to **Cora N.**'s heart muscle and successfully decreased the extent of ischemic damage. The rationale for the use of TPA as soon as possible after onset of symptoms (ideally within 4 to 6 hours) relates to the function of the normal intrinsic fibrinolytic system (see Chapter 43). This system is designed to dissolve unwanted intravascular clots through the action of the enzyme plasmin, a protease that digests the fibrin matrix within the clot. TPA stimulates the conversion of plasminogen to its active form, plasmin. The result is a lysis of the thrombus and improved blood flow through the previously obstructed vessel, allowing fuels and oxygen to reach the heart cells. The human TPA protein administered to **Cora N.** is produced by recombinant DNA technology (see Chapter 17). This treatment rapidly restored oxygen supply to her heart.

Stanley T. could be treated with antithyroid drugs, by total or near-total resection of the thyroid gland, or with radioactive iodine. Successful treatment normalizes thyroid hormone secretion, and all of the signs, symptoms, and metabolic alterations of hyperthyroidism quickly subside.

Isabel S. In the case of **Isabel S.**, there was a concern for a myopathic process superimposed on her HIV and her pulmonary tuberculosis, either of which could have caused progressive weakness. In addition, she could have been suffering from a congenital mtDNA myopathy, symptomatic only as she ages. If she was being treated with zidovudine (AZT), an older drug not used very commonly anymore, her myopathy could have been caused by a disorder of oxidative phosphorylation induced by zidovudine (AZT). A systematic diagnostic process finally led her physician to conclude that she had HIV-associated myopathy.

As infusion of TPA lysed the clot blocking blood flow to **Cora N.**'s heart, oxygenated blood was reintroduced into the ischemic heart. Although oxygen may rapidly restore the capacity to generate ATP, it can also increase cell death, a phenomenon called ischemia-reperfusion injury. During ischemia, a number of factors may protect heart cells against irreversible injury and cell death until oxygen is reintroduced. The stimulation of anaerobic glycolysis in the cytosol generates ATP without oxygen as glucose is converted to lactic acid. Lactic acid decreases cytosolic pH. Both cytosolic ATP and a lowering of the pH protect against opening of the MPTP. In addition, Ca^{2+} uptake by mitochondria requires a membrane potential, and it is matrix Ca^{2+} that activates opening of the MPTP. Thus, depending on the severity of the ischemic insult, the MPTP may not open, or may open and reseal, until oxygen is reintroduced. Then, depending on the sequence of events, re-establishment of the proton gradient, mitochondrial uptake of Ca^{2+} , or an increase of pH above 7.0 may activate the MPTP before the cell has recovered. In addition, the reintroduction of O_2 generates oxygen free radicals, particularly through free radical forms of CoQ in the electron transport chain. These also may open the MPTP. The role of free radicals in ischemia-reperfusion injury is discussed in more detail in Chapter 25.

BIOCHEMICAL COMMENTS

Mitochondria and Apoptosis. The loss of mitochondrial integrity is a major route initiating apoptosis (see Chapter 17, Section V). The intermembrane space contains procaspases 2, 3, and 9, which are proteolytic enzymes that are in the zymogen form (i.e., they must be proteolytically cleaved to be active). It also contains apoptosis-initiating factor (AIF) and caspase-activated DNAase (CAD). AIF has a nuclear-targeting sequence and is transported into the nucleus under appropriate conditions. Once AIF is inside the nucleus, it initiates chromatin condensation and degradation. Cytochrome c, which is loosely bound to the inner mitochondrial membrane, may also enter the intermembrane space when the electrochemical potential gradient is lost. The release of cytochrome c and the other proteins into the cytosol initiates apoptosis (see Chapter 17).

What is the trigger for the release of cytochrome c and the other proteins from the mitochondria? The VDAC pore is not large enough to allow the passage of proteins. A number of theories have been proposed, each supported and contradicted by experimental evidence. One is that Bax (a member of the Bcl-2 family of proteins that forms an ion channel in the outer mitochondrial membrane) allows the entry of ions into the intermembrane space, causing swelling of this space and rupture of the outer mitochondrial membrane. Another theory is that Bax and VDAC (which is known to bind Bax and other Bcl-2 family members) combine to form an extremely large pore, much larger than is formed by either alone. Finally, it is possible that the MPTP or ANT participates in rupture of the outer membrane, but that they close in a way that still provides the energy for apoptosis.

In addition to increased transcription of genes that encode TCA cycle enzymes and certain other enzymes of fuel oxidation, thyroid hormones increase the level of UCP2 and UCP3. In hyperthyroidism, the efficiency with which energy is derived from the oxidation of these fuels is significantly less than normal. As a consequence of the increased rate of the electron transport chain, hyperthyroidism results in increased heat production. Patients with hyperthyroidism, such as **Stanley T.**, complain of constantly feeling hot and sweaty.

KEY CONCEPTS

- ◆ The reduced cofactors generated during fuel oxidation donate their electrons to the mitochondrial electron transport chain.
- ◆ The electron transport chain transfers the electrons to O₂, which is reduced to water.
- ◆ As electrons travel through the electron transport chain, protons are transferred from the mitochondrial matrix to the cytosolic side of the inner mitochondrial membrane.
- ◆ The asymmetric distribution of protons across the inner mitochondrial membrane generates an electrochemical gradient across the membrane.
- ◆ The electrochemical gradient consists of a change in pH (ΔpH) across the membrane and a difference in charge ($\Delta\psi$) across the membrane.
- ◆ Proton entry into the mitochondrial matrix is energetically favorable and drives the synthesis of ATP via the ATP synthase.
- ◆ Respiration (oxygen consumption) is normally coupled to ATP synthesis; if one process is inhibited, the other is also inhibited.
- ◆ Uncouplers allow respiration to continue in the absence of ATP synthesis, as the energy inherent in the proton gradient is released as heat.
- ◆ OXPHOS diseases are caused by mutations in either nuclear or mitochondrial DNA that lead to a decrease in mitochondrial capacity for synthesizing ATP via oxidative phosphorylation.
- ◆ As the inner mitochondrial membrane is impermeable to virtually all biochemical compounds, transport systems exist to allow entry and exit of appropriate metabolites.
- ◆ The transfer of cytoplasmic reducing equivalents into the mitochondria occurs via shuttle systems; either the glycerol 3-phosphate shuttle or the malate–aspartate shuttle.
- ◆ Under appropriate stress, mitochondria will generate a nonspecific channel across both the inner and outer membranes that is known as the MPTP. The opening of the pore is associated with events that lead to necrotic cell death.
- ◆ Diseases discussed in this chapter are summarized in Table 24.3.

TABLE 24.3 Diseases Discussed in This Chapter

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Myocardial infarction	Both	The lack of oxygen in the heart muscle is caused by severe ischemia due to clots formed within certain coronary arteries at the site of ruptured atherosclerotic plaques. The limited availability of oxygen to act as an electron acceptor decreases the proton motive force across the inner mitochondrial membrane of ischemic cells. This leads to reduced ATP generation, triggering events that lead to irreversible cell injury.
Hyperthyroidism	Both	Graves disease is an autoimmune genetic disorder caused by the generation of human thyroid-stimulating immunoglobulins. These immunoglobulins stimulate growth of the thyroid gland and excess secretion of the thyroid hormones T3 and T4.
HIV treatment complication	Environmental	One of the first drugs used to treat HIV was zidovudine (ZDV), formerly called AZT, a nucleoside analog reverse transcriptase inhibitor. This class of drugs can act as an inhibitor of mitochondrial DNA polymerase. Under rare conditions, it can lead to a depletion of mitochondrial DNA in cells, leading to a severe mitochondrial myopathy.
Iron-deficiency anemia	Environmental	Lack of iron for heme synthesis, leading to reduced oxygen delivery to cells, and reduced iron in the electron transfer chain, leading to muscle weakness.
Cyanide poisoning	Environmental	Cyanide binds to the Fe ³⁺ in the heme of cytochromes a and a ₃ ,

		components of cytochrome oxidase. Mitochondrial respiration and energy production cease, and cell death rapidly occurs.
Mitochondrial disorders	Genetic	Many types of mutations, leading to altered mitochondrial function and reduced energy production, due to mutations in the mitochondrial DNA. See Table 24.2 for a partial listing of these disorders.

ATP, adenosine triphosphate; AZT, azidothymidine; HIV, human immunodeficiency virus.

REVIEW QUESTIONS—CHAPTER 24

- Consider the following experiment. Carefully isolated liver mitochondria are incubated in the presence of a limiting amount of malate. Three minutes after adding the substrate, cyanide is added, and the reaction is allowed to proceed for another 7 minutes. At this point, which of the following components of the electron transfer chain will be in an oxidized state?
 - Complex I
 - Complex II
 - Complex III
 - CoQ
 - Cytochrome c
- Consider the following experiment. Carefully isolated liver mitochondria are placed in a weakly buffered solution. Malate is added as an energy source, and an increase in oxygen consumption confirms that the electron transport chain is functioning properly within these organelles. Valinomycin and potassium are then added to the mitochondrial suspension. Valinomycin is a drug that allows potassium ions to freely cross the inner mitochondrial membrane. What is the effect of valinomycin on the proton motive force that had been generated by the oxidation of malate?
 - The proton motive force will be reduced to a value of zero.
 - There will be no change in the proton motive force.
 - The proton motive force will be increased.
 - The proton motive force will be decreased, but to a value greater than zero.
 - The proton motive force will be decreased to a value less than zero.
- Dinitrophenol, which was once tested as a weight loss agent, acts as an uncoupler of oxidative phosphorylation by which one of the following mechanisms?
 - Activating the H^+ -ATPase
 - Activating CoQ
 - Blocking proton transport across the inner mitochondrial membrane
 - Allowing for proton exchange across the inner mitochondrial membrane
 - Enhancing oxygen transport across the inner mitochondrial membrane
- A 25-year-old woman presents with chronic fatigue. A series of blood tests is ordered, and the results suggest that her red blood cell count is low because of iron-deficiency anemia. Such a deficiency would lead to fatigue because of which one of the following?
 - Her decrease in Fe-S centers is impairing the transfer of electrons in the electron transport chain.
 - She is not producing enough H_2O in the electron transport chain, leading to dehydration, which has resulted in fatigue.
 - Iron forms a chelate with NADH and FAD(2H) that is necessary for them to donate their electrons to the electron transport chain.
 - Iron acts as a cofactor for α -ketoglutarate dehydrogenase in the TCA cycle, a reaction required for the flow of electrons through the electron transport chain.
 - Iron accompanies the protons that are pumped from the mitochondrial matrix to the cytosolic side of the inner mitochondrial membrane. Without iron, the proton gradient cannot be maintained to produce adequate ATP.
- Which one of the following would be expected for a patient with an OXPHOS disease?
 - A high ATP:ADP ratio in the mitochondria
 - A high NADH:NAD⁺ ratio in the mitochondria
 - A deletion on the X chromosome
 - A high activity of complex II of the electron transport chain

- E. A defect in the integrity of the inner mitochondrial membrane
6. A 5-year-old boy was eating paint chips from the windowsill in his 125-year-old home and developed an anemia. Blood work indicated high levels of lead, which interfere with heme synthesis. Reduced heme synthesis would have little effect on the function of which one of the following proteins or complexes?
- Myoglobin
 - Hemoglobin
 - Complex I
 - Complex III
 - Complex IV
7. Rotenone, an inhibitor of NADH dehydrogenase, was originally used for fishing. When it was sprinkled on a lake, fish would absorb it through their gills and die. Until recently, it was used in the United States as an organic pesticide and was recommended for tomato plants. It was considered nontoxic to mammals and birds, neither of which can readily absorb it. What effect would rotenone have on ATP production by heart mitochondria, if it could be absorbed?
- There would be no reduction in ATP production.
 - There would be a 95% reduction in ATP production.
 - There would be a 10% reduction in ATP production.
 - There would be a 50% reduction in ATP production.
 - There would be a 50% increase in ATP production.
8. In order for cells to function properly, energy is required, and for most cells, the energy is primarily derived from the high-energy phosphate bonds of ATP, which is produced through oxidative phosphorylation. Which one of the following is a key component of oxidative phosphorylation?
- Utilizing NADH and FAD(H₂) to accept electrons as substrates are oxidized.
 - Creating a permeable inner mitochondrial membrane to allow mitochondrial ATP to enter the cytoplasm as it is made.
 - An ATP synthase to synthesize ATP
 - An ATP synthetase to synthesize ATP
 - A source of electrons, which is usually oxygen in most tissues
9. Carefully isolated intact mitochondria were incubated with a high salt solution, which is capable of disrupting noncovalent interactions between molecules at the membrane surface. After washing the mitochondria, pyruvate and oxygen were added to initiate electron flow. Oxygen consumption was minimal under these conditions due to the loss of which one of the following components from the electron transfer chain?
- Complex I
 - CoQ
 - Complex III
 - Cytochrome c
 - Complex IV
10. UCPs allow oxidation to be uncoupled from phosphorylation. Assume that a drug company has developed a reagent that can activate several UCPs with the goal being the development of a weight-loss drug. A potential side effect of this drug could be which one of the following?
- Decreased oxidation of acetyl coenzyme A (acetyl CoA)
 - Decreased glycolytic rate
 - Increase in body temperature
 - Increased ATP production by the ATP synthase
 - Inhibition of the electron transport chain
1. In the absence of lactate production, cytoplasmic NADH would accumulate and inhibit glycolysis. The electrons on NADH can be transferred to the mitochondrial matrix as a component of which of the following molecules? Choose the one best answer.

	NADH	Oxaloacetate	Glycerol 3-Phosphate	Malate
A	No	No	No	No
B	No	Yes	No	Yes
C	No	No	No	Yes
D	Yes	Yes	Yes	Yes
E	Yes	No	Yes	No
F	Yes	Yes	Yes	No

- A number of neurodegenerative diseases exhibit reduced mitochondrial function due to the opening of the mitochondrial permeability transition pore (MPTP). A key component of this pore is a protein that catalyzes which one of the following reactions?
 - Proline to hydroxyproline
 - A *cis*-prolyl peptide bond to a *trans*-prolyl peptide bond
 - Oxygen plus electrons generates water.
 - NADH + complex I yields NAD⁺ and reduced complex I.
 - Succinate + FAD yields fumarate and FAD(2H).
- The drug atractyloside inhibits the ANT. If freshly isolated mitochondria are incubated in a lightly buffered solution containing ADP, atractyloside, and pyruvate, and then oxygen is added to the system, what would one expect to happen?
 - A significant and constant increase in ATP production
 - A significant and constant increase in oxygen consumption
 - Increased transport of ATP into the inner membrane space
 - A slight, short-term increase in oxygen consumption, followed by no oxygen consumption
 - A decrease in the proton gradient across the inner mitochondrial membrane
- A scientist has developed a drug that inhibits cytoplasmic glycerol 3-phosphate dehydrogenase. The drug is being tested on a cell line that lacks the malate–aspartate shuttle for transferring electrons from the cytoplasm to the mitochondria. In the presence of glucose and oxygen, what would be expected to increase in this cell line in the presence of the drug, as compared to in the absence of the drug?
 - Lactate
 - Oxaloacetate
 - Oxygen consumption
 - Acetyl CoA
 - FAD(2H)
- Freshly isolated mitochondria were placed in a lightly buffered solution in the presence of ADP and inorganic phosphate, but in the absence of oxygen. At time zero, a small amount of dilute HCl was added to the mitochondria. At time = 1 min after adding the acid, what would one expect to observe?
 - An increase in extramitochondrial adenosine monophosphate levels (AMP) levels
 - An increase in oxygen consumption
 - An increase in ATP levels in the mitochondrial matrix
 - Inhibition of the electron transfer chain
 - Increased NADH levels in the mitochondrial matrix

ANSWERS TO REVIEW QUESTIONS

- The answer is B.** For a component to be in the oxidized state, it must have donated, or never received, electrons. Complex II will metabolize succinate to produce fumarate (generating FAD[2H]), but no

succinate is available in this experiment. Thus, complex II never sees any electrons and is always in an oxidized state. The substrate malate is oxidized to oxaloacetate, generating NADH, which donates electrons to complex I of the electron transport chain. These electrons are transferred to CoQ, which donates electrons to complex III, to cytochrome c, and then to complex IV. Cyanide will block the transfer of electrons from complex IV to oxygen, so all previous complexes containing electrons will be backed up and the electrons will be “stuck” in the complexes, making these components reduced. Thus, answers A and C through E must be incorrect.

2. **The answer is D.** The proton motive force consists of two components: a ΔpH and a $\Delta\psi$ (electrical component). The addition of valinomycin and potassium will destroy the electrical component but not the pH component. Thus, the proton motive force will decrease but will still be greater than zero. Thus, the other answers are all incorrect.
3. **The answer is D.** Dinitrophenol equilibrates the proton concentration across the inner mitochondrial membrane, thereby destroying the proton motive force. Thus, none of the other answers is correct.
4. **The answer is A.** A deficiency of Fe–S centers in the electron transport chain would impair the transfer of electrons down the chain and reduce ATP production by oxidative phosphorylation. Answer B is incorrect because the decreased production of water from the electron transport chain is not of sufficient magnitude to cause her to become dehydrated. Answer C is incorrect because iron does not form a chelate with NADH and FAD(2H). Answer D is incorrect because iron is not a cofactor for α -ketoglutarate DH. Answer E is incorrect because iron does not accompany the protons that make up the proton gradient.
5. **The answer is B.** NADH would not be reoxidized as efficiently by the electron transport chain, and the NADH/NAD⁺ ratio would increase. Answer A is incorrect because ATP would not be produced at a high rate. Therefore, ADP would build up, and the ATP:ADP ratio would be low. Answer C is incorrect because OXPHOS diseases can be caused by mutations in nDNA or mtDNA, and not all OXPHOS proteins are encoded by the X chromosome. Answer D is incorrect because, depending on the nature of the mutation, the activity of complex II of the electron transport chain might be normal or decreased, but there is no reason to expect increased activity. Answer E is incorrect because the integrity of the inner mitochondrial membrane would not necessarily be affected. It could be, but it would not be expected for all patients with OXPHOS disorders.
6. **The answer is C.** Heme is required for the synthesis of cytochromes. Complex I, while containing iron, does so in iron–sulfur centers and contains no cytochromes. Complexes III and IV contain cytochromes, whereas myoglobin and hemoglobin contain heme as the oxygen-binding component of those proteins. Defects in heme synthesis, then, would negatively impact the function of complexes III and IV, as well as hemoglobin and myoglobin, without greatly affecting the functioning of complex I.
7. **The answer is B.** Because rotenone inhibits the oxidation of NADH, it would completely block the generation of the electrochemical potential gradient in vivo and, therefore, it would block ATP generation. In the presence of rotenone, NADH would accumulate and NAD⁺ concentrations would decrease. Although the mitochondria might still be able to oxidize compounds like succinate, which transfer electrons to FAD, no succinate would be produced in vivo if the NAD⁺-dependent dehydrogenases of the TCA cycle were inhibited. Thus, very shortly after rotenone administration, there would not be any substrates available for the electron transfer chain, and NADH dehydrogenase would be blocked, so oxidative phosphorylation would be completely inhibited. If glucose supplies were high, anaerobic glycolysis could provide some ATP, but not nearly enough to keep the heart pumping. Anaerobic glycolysis produces 2 ATPs per glucose molecule, compared with 32 ATP molecules generated by oxidative phosphorylation, which is a reduction of ~95%.
8. **The answer is C.** NAD⁺ and FAD are electron acceptors and NADH and FAD(2H) are electron donors. Oxygen is the terminal electron acceptor and is not an electron donor. The inner mitochondrial membrane must be impermeable to most compounds, including protons; otherwise, the proton gradient that drives ATP synthesis could not be created or maintained. The enzyme ATP synthase contains a proton pore that spans the inner mitochondrial membrane and a catalytic headpiece that protrudes into the matrix. Protons are driven through the pore and change the conformation of the subunits in the headpiece, thereby producing ATP. If protons enter the mitochondria other ways than through the pore, no ATP is generated by the ATP synthase (partial uncoupling). A synthetase is an enzyme that uses high-energy phosphate bonds (usually from ATP) to catalyze its reaction, and the ATP synthase creates high-energy phosphate bonds and does not use them.
9. **The answer is D.** Complexes I, III, and IV are protein complexes that span the inner mitochondrial membrane, and their location within the membrane would not be disrupted by a high salt solution.

Cytochrome c is a small protein in the intermembrane space that binds to the inner mitochondrial membrane through noncovalent interactions. High salt can dislodge cytochrome c from the inner membrane, and the mitochondria would become cytochrome c deficient. Electron flow would stop in the absence of cytochrome c due to an inability to transfer electrons from complex III to complex IV. CoQ is a lipid-soluble quinone that diffuses in the lipid membrane and would not be removed from the membrane by a high salt solution.

10. **The answer is C.** Uncouplers uncouple oxidation from phosphorylation such that oxygen consumption is increased, there is an increased flow of electrons through the electron transfer chain, but ATP synthesis via oxidative phosphorylation is diminished. ATP production is reduced due to the reduction in the size of the proton gradient across the inner mitochondrial membrane, due to the UCPs allowing protons to enter the matrix of the mitochondria without going through the ATP synthase. As the energy of electron transfer is no longer being used to generate a proton gradient, it is released as heat, and an individual taking such a drug would be expected to exhibit an increased body temperature. Due to the uncoupling, the oxidation of acetyl CoA would increase, as would the glycolytic rate, in attempts to generate ATP for the cell. The ATP synthase would be producing less ATP, and glycolysis would be producing more ATP. The weight loss would come about due to the inefficiency in ATP generation via acetyl CoA oxidation, as more fatty acids would have to be metabolized in order to generate a certain amount of ATP from the acetyl CoA derived from the fatty acids.
11. **The answer is C.** The electrons on NADH can be transferred to the mitochondria either via the glycerol 3-P shuttle or via the malate–aspartate shuttle. The glycerol 3-P shuttle utilizes glycerol 3-P dehydrogenase to reduce DHAP to glycerol 3-P, with the electrons being donated by NADH. The glycerol 3-P, however, does not enter the mitochondrial matrix, as an inner membrane–bound mitochondrial glycerol 3-P dehydrogenase will oxidize the glycerol 3-P, with the electrons being accepted by FAD to produce FAD(2H). There are no transporters for NADH or oxaloacetate across the inner mitochondrial membrane, whereas malate can enter the mitochondrial matrix via the malate– α -ketoglutarate exchanger. Oxaloacetate is reduced to malate in the cytoplasm, and the malate will carry the electrons into the mitochondrial matrix.
12. **The answer is B.** The MPTP consists of the protein cyclophilin, which isomerizes peptidyl prolyl bonds (a reversible reaction of *cis* to *trans*). Other proteins within the MPTP are the ANT, the VDAC (in the classical model), the phosphate channel (in the new model), and the ATP synthase (new model). Prolyl hydroxylase (which catalyzes the conversion of proline to hydroxyproline), cytochrome oxidase (oxygen being reduced to water), NADH dehydrogenase (the oxidation of NADH), and succinate dehydrogenase (succinate to fumarate) are not components of the MPTP.
13. **The answer is D.** Once oxygen is introduced into the system, the pyruvate will enter the mitochondria and be converted to acetyl CoA, generating NADH. The NADH will donate electrons to the electron transfer chain, consuming oxygen and generating a proton gradient. As the proton gradient is established, protons will enter the ATP synthase to synthesize ATP, but once the ADP levels in the mitochondria are depleted, they cannot be replenished due to the inhibition of the ANT. As ATP synthesis stops the proton gradient will become large such that further proton pumping will not be able to occur, which will stop electron transfer through the chain, and oxygen would no longer be consumed.
14. **The answer is A.** In this cell line, the inhibition of the cytoplasmic glycerol 3-P dehydrogenase will lead to an accumulation of NADH in the cytoplasm (due to glucose being metabolized through glycolysis), and in order to regenerate NAD⁺ to allow glycolysis to proceed, pyruvate would be reduced to lactate. If some pyruvate enters the mitochondria, it can be oxidized by conversion to acetyl CoA and then to carbon dioxide through the TCA cycle, but this would lead to an increase in cytoplasmic NADH levels, lowered NAD⁺ levels, and an inhibition of glycolysis, reducing the rate of pyruvate formation. Oxaloacetate levels would not increase as pyruvate carboxylase is activated by acetyl CoA, which is not increasing significantly either in the presence or in the absence of the drug. Oxygen consumption would decrease as less pyruvate would be entering the mitochondria in the presence of the drug (due to its conversion to lactate). FAD(2H) levels will not increase as glucose metabolism does not significantly elevate FAD(2H) levels.
15. **The answer is C.** The addition of acid to the mitochondrial suspension creates an artificial proton gradient across the inner mitochondrial membrane, which will drive ATP synthesis through the ATP synthase. Newly synthesized ATP can leave the matrix in exchange for ADP, and inorganic phosphate can enter the matrix due to the presence of the proton gradient, thereby providing the substrates for further ATP synthesis. As there is no oxygen present, there cannot be an increase in oxygen consumption, nor is

there an inhibition of the electron transfer chain. As no oxidizable substrates are present in the reaction mixture, there would not be an increase in NADH levels in the mitochondrial matrix.

Oxygen Toxicity and Free-Radical Injury

O_2 is both essential to human life and **toxic**. We are dependent on O_2 for oxidation reactions in the pathways of adenosine triphosphate (ATP) generation, detoxification, and biosynthesis. However, when O_2 accepts single electrons, it is transformed into highly reactive **oxygen radicals** that damage cellular lipids, proteins, and DNA. Damage by reactive oxygen radicals contributes to cellular death and degeneration in a wide range of diseases (Table 25.1).

TABLE 25.1 Some Disease States Associated with Free-Radical Injury

<i>Atherogenesis</i>	<i>Cerebrovascular disorders</i>
<i>Chronic Obstructive Pulmonary Disease (COPD)</i>	<i>Ischemia/reperfusion injury</i>
<i>Duchenne-type muscular dystrophy</i>	<i>Neurodegenerative disorders</i>
<i>Pregnancy/pre-eclampsia</i>	<i>Amyotrophic lateral sclerosis (Lou Gehrig disease)</i>
<i>Retrolental fibroplasia</i>	
<i>Cervical cancer</i>	<i>Alzheimer disease</i>
<i>Alcohol-induced liver disease</i>	<i>Down syndrome</i>
<i>Hemodialysis</i>	<i>Ischemia-reperfusion injury following stroke</i>
<i>Diabetes</i>	<i>OXPPOS diseases (mitochondrial DNA disorders)</i>
<i>Acute renal failure</i>	<i>Multiple sclerosis</i>
<i>Aging</i>	<i>Parkinson disease</i>

OXPPOS, oxidative phosphorylation.

Radicals are compounds that contain a single electron, usually in an outside orbital. Oxygen is a **biradical**, a molecule that has two unpaired electrons in separate orbitals (Fig. 25.1). Through a number of enzymatic and nonenzymatic processes that routinely occur in cells, O_2 accepts **single electrons** to form highly **reactive oxygen species (ROS)**. The ROS formed by the reduction of O_2 are the radical **superoxide** (O_2^-), the nonradical **hydrogen peroxide** (H_2O_2), and the **hydroxyl radical** ($OH\cdot$).

FIGURE 25.1 O_2 is a biradical. It has two antibonding electrons with parallel spins (*parallel arrows*). It has a tendency to form toxic reactive oxygen species (ROS), such as superoxide (O_2^-), the nonradical hydrogen peroxide (H_2O_2), and the hydroxyl radical ($\text{OH}\cdot$).

ROS may be generated nonenzymatically or enzymatically as accidental by-products or major products of reactions. Superoxide may be generated nonenzymatically from CoQ, or metal-containing enzymes (e.g., **cytochrome P450**, **xanthine oxidase**, and **NADPH oxidase**). The highly toxic hydroxyl radical is formed nonenzymatically from superoxide in the presence of Fe^{2+} or Cu^+ by the **Fenton reaction**, and from hydrogen peroxide in the **Haber-Weiss reaction**.

Oxygen radicals and their derivatives can be deadly to cells. The hydroxyl radical causes oxidative damage to proteins and DNA. It also forms **lipid peroxides** and **malondialdehyde** from membrane lipids containing **polyunsaturated fatty acids**. In some cases, free-radical damage is the direct cause of a disease state (e.g., tissue damage initiated by exposure to ionizing radiation). In **neurodegenerative diseases**, such as Parkinson disease, or in ischemia-reperfusion injury, ROS may perpetuate the cellular damage caused by another process.

Oxygen radicals are joined in their destructive damage by the free-radical nitric oxide (NO) and the reactive oxygen species **hypochlorous acid (HOCl)**. NO combines with O_2 or superoxide to form **reactive nitrogen-oxygen species (RNOS)**, such as the nonradical peroxynitrite or the radical **nitrogen dioxide**. RNOS are present in the environment (e.g., cigarette smoke) and generated in cells. During phagocytosis of invading microorganisms, cells of the immune system produce O_2^- , HOCl, and NO through the actions of **NADPH oxidase**, **myeloperoxidase**, and **inducible nitric oxide synthase**, respectively. In addition to killing phagocytosed invading microorganisms, these toxic metabolites may damage surrounding tissue components.

Cells **protect** themselves against damage by ROS and other radicals through **repair processes**, **compartmentalization** of free-radical production, **defense enzymes**, and **endogenous and exogenous antioxidants (free-radical scavengers)**. The defense enzyme **superoxide dismutase (SOD)** removes the superoxide free radical. Catalase and glutathione peroxidase remove hydrogen peroxide and lipid peroxides. **Vitamin E**, **vitamin C**, and **plant flavonoids** act as **antioxidants**.

Oxidative stress occurs when the rate of ROS generation exceeds the capacity of the cell for their removal (Fig. 25.2).

FIGURE 25.2 Oxidative stress. Oxidative stress occurs when the rate of ROS and RNOS production overbalances the rate of their removal by cellular defense mechanisms. These defense mechanisms include a number of enzymes and antioxidants. Antioxidants usually react nonenzymatically with ROS. RNOS, reactive oxygen species; ROS, reactive nitrogen–oxygen species.

THE WAITING ROOM

Two years ago, **Les G.**, a 62-year-old man, noted an increasing tremor of his right hand when sitting quietly (resting tremor). The tremor disappeared if he actively used this hand to do purposeful movement. As this symptom progressed, he also complained of stiffness in his muscles that slowed his movements (bradykinesia). His wife noticed a change in his gait; he had begun taking short, shuffling steps and leaned forward as he walked (postural imbalance). He often appeared to be staring ahead with a rather immobile facial expression. She noted a tremor of his eyelids when he was asleep and, recently, a tremor of his legs when he was at rest. Because of these progressive symptoms and some subtle personality changes (anxiety and emotional lability), she convinced **Les G.** to see their family doctor.

The basal ganglia are part of a neuronal feedback loop that modulates and integrates the flow of information from the cerebral cortex to the motor neurons of the spinal cord. The neostriatum is the major input structure from the cerebral cortex. The substantia nigra pars compacta consists of neurons that provide integrative input to the neostriatum through pigmented neurons that use dopamine as a neurotransmitter (the nigrostriatal pathway). Integrated information feeds back to the basal ganglia and to the cerebral cortex to control voluntary movement. In Parkinson disease, a decrease in the amount of dopamine reaching the basal ganglia results in the movement disorder.

The doctor suspected that her patient probably had idiopathic parkinsonism (Parkinson disease) and referred **Les G.** to a neurologist. In Parkinson disease, neurons of the substantia nigra pars compacta, containing the pigment melanin and the neurotransmitter dopamine, degenerate.

Cora N. had done well since the successful lysis of blood clots in her coronary arteries with the use of intravenous recombinant tissue plasminogen activator (TPA) (see Chapters 20 and 22). This therapy quickly relieved the crushing chest pain (angina) she experienced when she won the lottery. At her first office visit after her discharge from the hospital, her cardiologist told her that in the hospital she had developed multiple premature contractions of the ventricular muscle of her heart as the clots were being lysed. This process could have led to a life-threatening arrhythmia known as ventricular tachycardia or ventricular fibrillation. However, her arrhythmia responded quickly to pharmacological suppression and did not recur during the remainder of her hospitalization.

In ventricular tachycardia, rapid premature beats from an irritative focus in ventricular muscle occur in runs of varying duration. Persistent ventricular tachycardia compromises cardiac output, leading to death. This arrhythmia can result from severe ischemia (lack of blood flow) in the ventricular muscle of the heart caused by clots forming at the site of a ruptured atherosclerotic plaque. However, **Cora N.**'s rapid beats began during the infusion of TPA as the clot was lysed. Thus, they probably resulted from reperfusing a previously ischemic area of her heart with oxygenated blood. This phenomenon is known as ischemia-reperfusion injury, and it is caused by cytotoxic ROS derived from oxygen in the blood that reperfuses previously hypoxic cells. Ischemia-reperfusion injury also may occur when tissue oxygenation is interrupted during surgery or transplantation.

I. O₂ and the Generation of Reactive Oxygen Species

The generation of **reactive oxygen species (ROS)** from O₂ in our cells is a natural, everyday occurrence. The electrons that contribute to their formation are usually derived from reduced electron carriers of the electron transport chain (ETC). ROS are formed as accidental products of nonenzymatic and enzymatic reactions. Occasionally, they are deliberately synthesized in enzyme-catalyzed reactions. Ultraviolet radiation and pollutants in the air can increase the formation of toxic oxygen-containing compounds.

Catecholamine (epinephrine, norepinephrine, dopamine) measurements, which were ordered for **Les G.**, utilize either serum or a 25-hour urine collection as samples for assay. After appropriate removal of cells and/or particulate matter, the sample is placed over an ion-exchange high-pressure liquid chromatography (HPLC) column and the eluate from the column is analyzed by sensitive electrochemical detection. Through comparison with retention times of standard catecholamines on the column, the various catecholamine species can be clearly resolved from each other. The electrochemical detection utilizes electrodes that are oxidized by the samples, and the amplitude current that is generated via the redox reaction allows one to determine the concentration of catecholamines in the specimen.

A. The Radical Nature of O₂

A **radical**, by definition, is a molecule that has a single unpaired electron in an orbital. A **free radical** is a radical that is capable of independent existence. (Radicals formed in an enzyme active site during a reaction, for example, are not considered free radicals unless they can dissociate from the protein to interact with other molecules.) Radicals are highly reactive and initiate chain reactions by extracting an electron from a neighboring molecule to complete their own orbitals. Although the transition metals (e.g., Fe, Cu, and Mo) have single electrons in orbitals, they are not usually considered free radicals because they are relatively stable, do not initiate chain reactions, and are bound to proteins in the cell.

The oxygen molecule is a **biradical**, which means it has two single electrons in different orbitals. These electrons cannot both travel in the same orbital because they have parallel spins (they spin in the same direction). Although oxygen is very reactive from a thermodynamic standpoint, its single electrons cannot react rapidly with the paired electrons found in the covalent bonds of organic molecules. As a consequence, O₂ reacts slowly through the acceptance of single electrons in reactions that require a catalyst (such as a metal-containing enzyme).

Because the two unpaired electrons in oxygen have the same (parallel) spin, they are called antibonding electrons. In contrast, carbon-carbon and carbon-hydrogen bonds each contain two electrons, which have antiparallel spins and form a thermodynamically stable pair. As a consequence, O₂ cannot readily oxidize a covalent bond because one of its electrons would have to flip its spin around to make new pairs. The difficulty

in changing spins is called spin restriction. Without spin restriction, organic life forms could not have developed in the oxygen atmosphere on earth because they would be spontaneously oxidized by O₂.

O₂ is capable of accepting a total of four electrons, which reduces it to water (Fig. 25.3). When O₂ accepts one electron, **superoxide** is formed. Superoxide is still a radical because it has one unpaired electron remaining. This reaction is not thermodynamically favorable and requires a moderately strong reducing agent that can donate single electrons (e.g., the radical form of coenzyme Q [CoQH•] in the electron transport chain). When superoxide accepts an electron, it is reduced to **hydrogen peroxide** (H₂O₂), which is not a radical. The **hydroxyl radical** is formed in the next one-electron reduction step in the reduction sequence. Finally, acceptance of the last electron reduces the hydroxyl radical to H₂O.

FIGURE 25.3 Reduction of oxygen by four one-electron steps. The four one-electron reduction steps for O_2 progressively generate superoxide, hydrogen peroxide, and the hydroxyl radical plus water. Superoxide is sometimes written O_2^- to better illustrate its single unpaired electron. H_2O_2 , the half-reduced form of O_2 , has accepted two electrons and is, therefore, not an oxygen radical.

B. Characteristics of Reactive Oxygen Species

ROS are oxygen-containing compounds that are highly reactive free radicals, or compounds that are readily converted to these oxygen-free radicals in the cell. The major oxygen metabolites produced by one-electron reduction of oxygen (superoxide, hydrogen peroxide, and the hydroxyl radical) are classified as ROS (Table 25.2).

REACTIVE SPECIES	PROPERTIES
Superoxide anion (O_2^-)	Produced by the electron transport chain and at other sites. Cannot diffuse far from the site of origin. Generates other reactive oxygen species (ROS).
Hydrogen peroxide (H_2O_2)	Not a free radical, but can generate free radicals by reaction with a transition metal (e.g., Fe^{2+}). Can diffuse into and through cell membranes.
Hydroxyl radical ($OH\cdot$)	The most reactive species in attacking biological molecules. Produced from H_2O_2 in the Fenton reaction in the presence of Fe^{2+} or Cu^+ .
Organic radicals ($RO\cdot$, $R\cdot$, $R-S$)	Organic free radicals (R denotes the remainder of the compound). Produced from ROH, RH (e.g., at the carbon of a double bond in a fatty acid), or RSH $OH\cdot$ attack.
Peroxy radical ($RCOO\cdot$)	An organic peroxy radical, such as occurs during lipid degradation (also denoted $LOO\cdot$).
Hypochlorous acid (HOCl)	Produced in neutrophils during the respiratory burst to destroy invading organisms. Toxicity is through halogenation and oxidation reactions. Attacking species is OCl^- .
Singlet oxygen ($O_2\downarrow\uparrow$)	Oxygen with antiparallel spins. Produced at high oxygen tensions from absorption of UV light. Decays so fast that it is probably not a significant in vivo source of toxicity.
Nitric oxide (NO)	Reactive nitrogen–oxygen species (RNOS). A free radical is produced endogenously by nitric oxide synthase. Binds to metal ions. Combines with O_2 or other oxygen-containing radicals to produce additional RNOS.
Peroxynitrite ($ONOO^-$)	RNOS. A strong oxidizing agent that is not a free radical. It can generate nitrogen dioxide (NO_2), which is a radical.

Reactive free radicals extract electrons (usually as hydrogen atoms) from other compounds to complete their own orbitals, thereby initiating free-radical chain reactions. The hydroxyl radical is probably the most potent of the ROS. It initiates chain reactions that form lipid peroxides and organic radicals and adds directly to compounds. The superoxide anion is also highly reactive, but it has limited lipid solubility and cannot diffuse far. However, it can generate the more reactive hydroxyl and hydroperoxy radicals by reacting nonenzymatically with hydrogen peroxide in the Haber–Weiss reaction (Fig. 25.4).

The Fenton reaction

The Haber–Weiss reaction

FIGURE 25.4 Generation of the hydroxyl radical by the nonenzymatic Haber–Weiss and Fenton reactions. In the simplified versions of these reactions shown here, the transfer of single electrons generates the hydroxyl radical. ROS are shown in the boxes. In addition to Fe^{2+} , Cu^+ , and many other metals can also serve as single-electron donors in the Fenton reaction. The Haber–Weiss reaction is the sum of the Fenton reaction and the regeneration of Fe^{2+} by superoxide, forming oxygen from the superoxide.

Hydrogen peroxide, although not actually a radical, is a weak oxidizing agent that is classified as a ROS because it can generate the hydroxyl radical ($\text{OH}\cdot$). Transition metals, such as Fe^{2+} or Cu^+ , catalyze the formation of the hydroxyl radical from hydrogen peroxide in the nonenzymatic Fenton reaction (see Fig. 25.4). Because hydrogen peroxide is lipid-soluble, it can diffuse through membranes and generate $\text{OH}\cdot$ at localized Fe^{2+} - or Cu^+ -containing sites, such as the electron transport chain within the mitochondria. Hydrogen peroxide is also the precursor of hypochlorous acid (HOCl), a powerful oxidizing agent that is produced endogenously and enzymatically by phagocytic cells. To decrease the occurrence of the Fenton reaction, accessibility to transition metals, such as Fe^{2+} and Cu^+ , are highly restricted in cells, or in the body as a whole. Events that release iron from cellular storage sites, such as a crushing injury, are associated with increased free-radical injury.

Organic radicals are generated when superoxide or the hydroxyl radical indiscriminately extract electrons from other molecules. Organic peroxy radicals are intermediates of chain reactions, such as lipid peroxidation. Other organic radicals, such as the ethoxy radical, are intermediates of enzymatic reactions that escape into solution (see Table 25.2).

An additional group of oxygen-containing radicals, termed RNOS, contains nitrogen as well as oxygen. These radicals are derived principally from the free-radical nitric oxide (NO), which is produced endogenously by the enzyme nitric oxide synthase. Nitric oxide combines with O_2 or superoxide to produce additional RNOS.

C. Major Sources of Primary Reactive Oxygen Species in the Cell

ROS are constantly being formed in the cell; approximately 3% to 5% of the oxygen we consume is converted to oxygen-free radicals. Some are produced as accidental by-products of normal enzymatic reactions that escape from the active site of metal-containing enzymes during oxidation reactions. Others, such as hydrogen peroxide, are physiological products of oxidases in peroxisomes. Deliberate production of toxic free radicals occurs during the inflammatory response. Drugs, natural radiation, air pollutants, and other chemicals also can increase the formation of free radicals in cells.

With insufficient oxygen, **Cora N.**'s ischemic heart muscle mitochondria were unable to maintain cellular ATP levels, resulting in high intracellular Na^+ and Ca^{2+} levels. The reduced state of the electron carriers in the absence of oxygen, and loss of mitochondrial ion gradients or membrane integrity, leads to increased superoxide production once oxygen becomes available during reperfusion. The damage can be self-perpetuating, especially if iron bound to components of the electron transport chain becomes available for the Fenton reaction, or the mitochondrial permeability transition pore is activated.

1. Generation of Superoxide

One of the major sites of superoxide generation is coenzyme Q (CoQ) in the mitochondrial electron transport chain (Fig. 25.5). The one-electron reduced form of CoQ ($\text{CoQH}\cdot$) is free within the membrane and can accidentally transfer an electron to dissolved O_2 , thereby forming superoxide. In contrast, when O_2 binds to cytochrome oxidase and accepts electrons, none of the O_2 radical intermediates are released from the enzyme, and no ROS are generated.

FIGURE 25.5 Generation of superoxide by coenzyme Q (CoQ) in the electron transport chain. In the process of transporting electrons to O_2 , some of the electrons escape when $CoQH\cdot$ accidentally interacts with O_2 to form superoxide. Fe-H represents the Fe-heme center of the cytochromes. FMN, flavin mononucleotide; NAD, nicotinamide adenine dinucleotide.

2. Oxidases, Oxygenases, and Peroxidases

Most of the oxidases, peroxidases, and oxygenases in the cell bind O_2 and transfer single electrons to it via a metal. Free-radical intermediates of these reactions may be accidentally released before the reduction is complete.

Cytochrome P450 enzymes are a major source of free radicals “leaked” from reactions. Because these enzymes catalyze reactions in which single electrons are transferred to O_2 and an organic substrate, the possibility of accidentally generating and releasing free-radical intermediates is high (see Chapters 20 and 24). Induction of P450 enzymes by alcohol, drugs, or chemical toxicants leads to increased cellular injury. As an example, carbon tetrachloride (CCl_4), which was used as a solvent in the dry-cleaning industry, is converted by cytochrome P450 to a highly reactive free radical that led to hepatocellular necrosis in workers in that industry, resulting in the disuse of CCl_4 . When the enzyme-bound CCl_4 accepts an electron, it dissociates into $CCl_3\cdot$ and Cl. The $CCl_3\cdot$ radical, which cannot continue through the P450 reaction sequence, “leaks” from the enzyme active site and initiates chain reactions in the surrounding polyunsaturated lipids of the endoplasmic reticulum. These reactions spread into the plasma membrane and to proteins, eventually resulting in cell swelling, accumulation of lipids, and cell death. When substrates for cytochrome P450 enzymes are not present, its potential for destructive damage is diminished by repression of gene transcription.

If **Les G.**, had been diagnosed in the early stages of Parkinson disease, without motor symptoms, he could have been treated with a monoamine oxidase B inhibitor. Monoamine oxidase is a copper-containing enzyme that inactivates dopamine in neurons, producing H_2O_2 . The drug was originally administered to inhibit dopamine degradation. However, current theory suggests that the effectiveness of the drug is also related to a decrease of free-radical formation within the cells of the basal ganglia. The dopaminergic neurons involved are particularly susceptible to the cytotoxic effects of ROS and RNOS that may arise from H_2O_2 .

Hydrogen peroxide and lipid peroxides are generated enzymatically as major reaction products by a number of oxidases present in peroxisomes, mitochondria, and the endoplasmic reticulum. For example, monoamine oxidase, which oxidatively degrades the neurotransmitter dopamine, generates H_2O_2 at the mitochondrial membrane of certain neurons. Peroxisomal fatty acid oxidase generates H_2O_2 rather than $FAD(2H)$ during the oxidation of very-long-chain fatty acids (see Chapter 30). Xanthine oxidase, an enzyme of purine degradation that can reduce O_2 to O_2^- or H_2O_2 in the cytosol, is thought to be a major contributor to ischemia-reperfusion injury, especially in intestinal mucosal and endothelial cells. Lipid peroxides are also formed enzymatically as intermediates in the pathways for synthesis of many eicosanoids, including leukotrienes and prostaglandins.

3. Ionizing Radiation

Cosmic rays that continuously bombard the earth, radioactive chemicals, and x-rays are forms of **ionizing radiation**. Ionizing radiation has a high enough energy level that it can split water into hydroxyl and hydrogen radicals, thus leading to radiation damage to the skin, mutations, cancer, and cell death. It also may generate organic radicals through direct collision with organic cellular components.

Production of ROS by xanthine oxidase in endothelial cells may be enhanced during ischemia-reperfusion in **Cora N.**'s heart. In undamaged tissues, xanthine oxidase exists as a dehydrogenase that uses NAD^+ rather than O_2 as an electron acceptor in the pathway for degradation of purines (hypoxanthine \rightarrow xanthine \rightarrow uric acid; see Chapter 40). When O_2 levels decrease, phosphorylation of ADP to ATP decreases, and degradation of ADP and adenine through xanthine oxidase increases. In the process, xanthine dehydrogenase is converted to an oxidase. As long as O_2 levels are below the high K_m of the enzyme for O_2 , little damage is done. However, during reperfusion, when O_2 levels return to normal, xanthine oxidase generates H_2O_2 and O_2^- at the site of injury.

II. Oxygen Radical Reactions with Cellular Components

Oxygen radicals produce cellular dysfunction by reacting with lipids, proteins, carbohydrates, and DNA to

extract electrons (summarized in Fig. 25.6). Evidence of free-radical damage has been described in >100 disease states. In some of these diseases, free-radical damage is the primary cause of the disease; in others, it enhances complications of the disease.

FIGURE 25.6 Free-radical-mediated cellular injury. Superoxide and the hydroxyl radical initiate lipid peroxidation in the cellular, mitochondrial, nuclear, and endoplasmic reticulum membranes. The increase in cellular permeability results in an influx of Ca^{2+} , which causes further mitochondrial damage. The cysteine sulfhydryl groups and other amino acid residues on proteins are oxidized and degraded. Nuclear and mitochondrial DNA can be oxidized, resulting in strand breaks and other types of damage. RNOS (NO , NO_2 , and peroxynitrites) have similar effects. RER, rough endoplasmic reticulum; SER, smooth endoplasmic reticulum.

A. Membrane Attack: Formation of Lipid and Lipid Peroxy Radicals

Chain reactions that form lipid-free radicals and lipid peroxides in membranes make a major contribution to ROS-induced injury (Fig. 25.7). An initiator (such as a hydroxyl radical produced locally in the Fenton reaction) begins the chain reaction. It extracts a hydrogen atom, preferably from the double bond of a polyunsaturated fatty acid in a membrane lipid. The chain reaction is propagated when O_2 adds to form lipid peroxy radicals and lipid peroxides. Eventually, lipid degradation occurs, forming such products as malondialdehyde (from fatty acids with three or more double bonds), and ethane and pentane (from the ω -terminal carbons of three- and six-carbon fatty acids, respectively). Malondialdehyde appears in the blood and urine and is used as an indicator of free-radical damage.

A. Initiation

B. Propagation

C. Degradation

D. Termination

or

FIGURE 25.7 Lipid peroxidation: a free-radical chain reaction. **A.** Lipid peroxidation is initiated by a hydroxyl or other radical that extracts a hydrogen atom from a polyunsaturated lipid (LH), thereby forming a lipid radical (L•). **B.** The free-radical chain reaction is propagated by reaction with O₂, forming the lipid peroxy radical (LOO•) and lipid peroxide (LOOH). **C.** Rearrangements of the single electron result in the degradation of the lipid. Malondialdehyde, one of the compounds formed, is soluble and appears in blood. **D.** The chain reaction can be terminated by reduced vitamin E and other lipid-soluble antioxidants that donate single electrons. Two subsequent reduction steps form a stable, oxidized antioxidant.

The appearance of lipofuscin granules in many tissues increases during aging. The pigment lipofuscin (from the Greek “lipos,” for lipids, and the Latin “fuscus,” for dark) consists of a heterogeneous mixture of cross-linked polymerized lipids and protein formed by reactions between amino acid residues and lipid peroxidation products, such as malondialdehyde. These cross-linked products are probably derived from peroxidatively damaged cell organelles that were autophagocytized by lysosomes but could not be digested. When these dark pigments appear on the skin of the hands in aged individuals, they are referred to as “liver spots,” a traditional hallmark of aging. In **Les G.** and other patients with Parkinson disease, lipofuscin appears as Lewy bodies in degenerating neurons.

Peroxidation of lipid molecules invariably changes or damages lipid molecular structure. In addition to the self-destructive nature of membrane lipid peroxidation, the aldehydes that are formed can cross-link proteins. When the damaged lipids are the constituents of biological membranes, the cohesive lipid bilayer arrangement and stable structural organization are disrupted (see Fig. 25.6). Disruption of mitochondrial membrane integrity may result in further free-radical production.

B. Proteins and Peptides

In proteins, the amino acids proline, histidine, arginine, cysteine, and methionine are particularly susceptible to hydroxyl radical attack and oxidative damage. As a consequence of oxidative damage, the protein may fragment or residues cross-link with other residues. Free-radical attack on protein cysteine residues can result in cross-linking and formation of aggregates that prevents their degradation. However, oxidative damage increases the susceptibility of other proteins to proteolytic digestion.

Free-radical attack and oxidation of the cysteine sulfhydryl residues of the tripeptide glutathione (γ -glutamyl-cysteinyl glycine; see Section V.A.3) increases oxidative damage throughout the cell. Glutathione is a major component of cellular defense against free-radical injury, and its oxidation reduces its protective effects.

Evidence of protein damage shows up in many diseases, particularly those associated with aging. In patients with cataracts, proteins in the lens of the eye exhibit free-radical damage and contain methionine sulfoxide residues and tryptophan degradation products.

C. DNA

Oxygen-derived free radicals are also a major source of DNA damage. Approximately 20 types of oxidatively altered DNA molecules have been identified. The nonspecific binding of Fe²⁺ to DNA facilitates localized production of the hydroxyl radical, which can cause base alterations in the DNA (one example is generating 8-hydroxyguanine from guanine, in the presence of the hydroxyl radical). It also can attack the deoxyribose backbone and cause strand breaks. This DNA damage can be repaired to some extent by the cell (see Chapter 12), or minimized by apoptosis of the cell.

Nitroglycerin, in tablet form, is often given to patients with coronary artery disease who experience ischemia-induced chest pain (angina). The nitroglycerin decomposes in the blood, forming NO, a potent vasodilator. This decreases the preload (blood return to the heart) by dilating the veins and therefore the work of the heart and also increases blood flow to the heart by dilating arteries, which relieves the angina.

III. Nitric Oxide and Reactive Nitrogen–Oxygen Species

Nitric oxide (NO) is an oxygen-containing free radical that, like O₂, is both essential to life and toxic. NO has a single electron and therefore binds to other compounds that contain single electrons, such as Fe³⁺. At low concentrations, it functions physiologically as a neurotransmitter and as a hormone that causes vasodilation. At high concentrations, however, it combines with O₂ or with superoxide to form additional reactive and toxic species that contain both nitrogen and oxygen (RNOS). RNOS are involved in neurodegenerative diseases, such as Parkinson disease, and in chronic inflammatory diseases, such as rheumatoid arthritis.

A. Nitric Oxide Synthase

At low concentrations, nitric oxide serves as a neurotransmitter or as a hormone. It is synthesized from arginine by nitric oxide synthases (Fig. 25.8). As a gas, it is able to diffuse through water and lipid membranes and into target cells. In the target cell, it exerts its physiologic effects by high-affinity binding to Fe-heme in the enzyme guanylyl cyclase, thereby activating a signal transduction cascade. However, NO is rapidly inactivated by nonspecific binding to many molecules, and therefore cells that produce NO need to be close to the target cells.

FIGURE 25.8 Nitric oxide synthase (NOS) synthesizes the free-radical NO. Like cytochrome P450 enzymes, NO synthase uses Fe-heme, flavin adenine dinucleotide FAD, and flavin mononucleotide (FMN) to transfer single electrons from reduced nicotinamide adenine dinucleotide phosphate (NADPH) to O₂. NOS also requires the cofactor tetrahydrobiopterin (BH₄).

The body has three different tissue-specific isoforms of NO synthase, each encoded by a different gene: neuronal nitric oxide synthase (nNOS, isoform I), inducible nitric oxide synthase (iNOS, isoform II), and endothelial nitric oxide synthase (eNOS, isoform III). nNOS and eNOS are tightly regulated by the concentration of Ca²⁺ to produce the small amounts of NO required for its role as a neurotransmitter and hormone. In contrast, iNOS is present in many cells of the immune system and cell types with a similar lineage, such as macrophages and brain astroglia. This isoenzyme of nitric oxide synthase is regulated principally by induction of gene transcription, and not by changes in Ca²⁺ concentration. It produces high and toxic levels of NO to assist in killing invading microorganisms. It is these very high levels of NO that are associated with the generation of RNOS and NO toxicity.

B. NO Toxicity

The toxic actions of NO can be divided into two categories: direct toxic effects resulting from binding to Fe-containing proteins and indirect effects mediated by compounds formed when NO combines with O₂ or with superoxide to form RNOS.

1. Direct Toxic Effects of NO

NO, as a radical, exerts direct toxic effects by combining with Fe-containing compounds that also have single electrons. Major destructive sites of attack include Fe–S centers (e.g., electron transport chain complexes I through III, aconitase) and Fe-heme proteins (e.g., hemoglobin and electron transport chain cytochromes). However, there is usually little damage because NO is present in low concentrations and Fe-heme compounds are present in excess capacity. NO can cause serious damage, however, through direct inhibition of respiration in cells that are already compromised through oxidative phosphorylation diseases or ischemia.

2. RNOS Toxicity

When NO is present in very high concentrations (e.g., during inflammation), it combines nonenzymatically with superoxide to form peroxynitrite (ONOO⁻), or with O₂ to form dinitrogen trioxide (N₂O₃) (Fig. 25.9). Peroxynitrite, although it is not a free radical, is a strong oxidizing agent that is stable and directly toxic. It can diffuse through the cell and lipid membranes to interact with a wide range of targets, including the methionine side chain in proteins and –SH groups (e.g., Fe–S centers in the electron transport chain). It also breaks down to form additional RNOS, including the free-radical nitrogen dioxide (NO₂), which is an effective initiator of lipid peroxidation. Peroxynitrite products also react (nitration) with aromatic rings, forming compounds such as nitrotyrosine or nitroguanosine. N₂O₃, which can be derived from either NO₂ or nitrite, is the agent of nitrosative stress, and it nitrosylates sulfhydryl and similarly reactive groups in the cell. Nitrosylation usually interferes with the proper functioning of the protein or lipid that has been modified. Thus, RNOS can do as much oxidative and free-radical damage as non-nitrogen-containing ROS, as well as nitrating and nitrosylating compounds. The result is widespread and includes inhibition of a large number of enzymes; mitochondrial lipid peroxidation; inhibition of the electron transport chain and energy depletion; single or double-stranded breaks in DNA; and modification of bases in DNA.

FIGURE 25.9 Formation of reactive nitrogen–oxygen species (RNOS) from nitric oxide. RNOS are shown in red. The type of damage caused by each RNOS is shown in parentheses. Of all the nitrogen–oxygen-containing compounds shown, only nitrate is relatively nontoxic. Nitrogen dioxide (NO_2) is one of the toxic agents present in smog, automobile exhaust, gas ranges, pilot lights, cigarette smoke, and smoke from forest fires or burning buildings.

 In patients with chronic granulomatous disease, phagocytes have genetic defects in NADPH oxidase. NADPH oxidase, of which there are a number of isozymes, generally has six different subunits (two in the cell membrane, α and β , which together form flavoprotein b_{558} , and four recruited from the cytosol, which include the small GTPase Rac, as well as a complex of $p47^{\text{phox}}$, $p67^{\text{phox}}$, and $p40^{\text{phox}}$), and the genetic defect may be in any of four of the genes that encode these

subunits. The membrane catalytic β -subunit of NADPH oxidase is a 91-kDa flavocytochrome glycoprotein. It transfers electrons from bound NADPH to FAD, which transfers them to the Fe-heme components. The membranous α -subunit (p22) is required for stabilization. The cytosolic proteins are required for assembly of the complex. The 91-kDa β -subunit is affected most often in X-linked chronic granulomatous disease, whereas the α -subunit is affected in a rare autosomal recessive form. The cytosolic subunits p47 and p67 are affected most often in patients with the autosomal recessive form of granulomatous disease. In addition to their enhanced susceptibility to bacterial and fungal infections, these patients suffer from an apparent dysregulation of normal inflammatory responses.

IV. Formation of Free Radicals during Phagocytosis and Inflammation

In response to infectious agents and other stimuli, phagocytic cells of the immune system (neutrophils, eosinophils, and monocytes/macrophages) exhibit a rapid consumption of O_2 called the respiratory burst. The respiratory burst is a major source of superoxide, hydrogen peroxide, the hydroxyl radical, hypochlorous acid (HOCl), and RNOS. The generation of free radicals is part of the human antimicrobial defense system and is intended to destroy invading microorganisms, tumor cells, and other cells targeted for removal.

A. NADPH Oxidase

The respiratory burst results from the activity of NADPH oxidase, which catalyzes the transfer of an electron from NADPH to O_2 to form superoxide (Fig. 25.10). NADPH oxidase is assembled from cytosolic as well as membranous proteins recruited into the phagolysosome membrane as it surrounds an invading microorganism.

FIGURE 25.10 Production of ROS during the phagocytic respiratory burst by activated neutrophils. (1) Activation of reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase on the outer side of the plasma membrane initiates the respiratory burst with the generation of superoxide. During phagocytosis, the plasma membrane invaginates, so superoxide is released into the vacuole space. (2) Superoxide (either spontaneously or enzymatically via superoxide dismutase [SOD]) generates H_2O_2 . (3) Granules containing myeloperoxidase are secreted into the phagosome, where myeloperoxidase generates hypochlorous acid (HOCl) and other halides. (4) H_2O_2 can also generate the hydroxyl radical from the Fenton reaction. (5) Inducible NOS (iNOS) may be activated and generate NO. (6) Nitric oxide combines with superoxide to form peroxynitrite, which may generate additional reactive nitrogen–oxygen species (RNOS). The result is an attack on the

membranes and other components of phagocytosed cells and eventual lysis. The whole process is referred to as the respiratory burst because it lasts only 30 to 60 minutes and consumes O_2 .

Superoxide is released into the intramembranous space of the phagolysosome, where it is generally converted to hydrogen peroxide and other ROS that are effective against bacteria and fungal pathogens. Hydrogen peroxide is formed by SOD, which may come from the phagocytic cell or the invading microorganism.

B. Myeloperoxidase and HOCl

The formation of hypochlorous acid from H_2O_2 is catalyzed by myeloperoxidase, a heme-containing enzyme that is present only in phagocytic cells of the immune system (predominantly neutrophils). The hypochlorous acid rapidly dissociates and loses a proton.

During **Cora N.**'s myocardial ischemia (decreased blood flow), the ability of her heart to generate ATP from oxidative phosphorylation was compromised. The damage appeared to accelerate when oxygen was first reintroduced (reperfused) into the tissue. During ischemia, CoQ and the other single-electron components of the electron transport chain become saturated with electrons. When oxygen is reintroduced (reperfusion), electron donation to O_2 to form superoxide is increased. The increase of superoxide results in enhanced formation of hydrogen peroxide and the hydroxyl radical. Macrophages in the area clean up cell debris from ischemic injury and produce nitric oxide, which may further damage mitochondria by generating RNOS that attack Fe-S centers and cytochromes in the ETC. These radicals, which increase in concentration when oxygen is introduced into the system, may actually amplify the damage done by the original ischemic event and increase the infarct size.

Myeloperoxidase contains two Fe-hemelike centers, which give it the green color seen in pus. Hypochlorous acid is a powerful toxin that destroys bacteria within seconds through halogenation and oxidation reactions. It oxidizes many Fe- and S-containing groups (e.g., sulfhydryl groups, Fe-S centers, ferredoxin, heme proteins, methionine), oxidatively decarboxylates and deaminates proteins, and cleaves peptide bonds. Aerobic bacteria under attack rapidly lose membrane transport, possibly because of damage to ATP synthase or electron transport chain components (which reside in the plasma membrane of bacteria).

C. RNOS and Inflammation

When human neutrophils of the immune system are activated to produce NO, NADPH oxidase is also activated. NO reacts rapidly with superoxide to generate peroxynitrite, which forms additional RNOS. NO also may be released into the surrounding medium, to combine with superoxide in target cells.

In a number of disease states, free-radical release by neutrophils or macrophages during inflammation contributes to injury in the surrounding tissues. During stroke or myocardial infarction, phagocytic cells that move into the ischemic area to remove dead cells may increase the area and extent of damage. The self-perpetuating mechanism of radical release by neutrophils during inflammation and immune-complex formation may explain some of the features of chronic inflammation in patients with rheumatoid arthritis. As a result of free-radical release, the immunoglobulin G (IgG) proteins present in the synovial fluid are partially oxidized, which improves their binding with the rheumatoid-induced antibody (also called the rheumatoid factor). This binding, in turn, stimulates the neutrophils to release more free radicals.

V. Cellular Defenses against Oxygen Toxicity

Our defenses against oxygen toxicity fall into the categories of antioxidant defense enzymes, dietary and endogenous antioxidants (free-radical scavengers), cellular compartmentation, metal sequestration, and repair of damaged cellular components. The antioxidant defense enzymes react with ROS and cellular products of free-radical chain reactions to convert them to nontoxic products.

Dietary antioxidants, such as vitamin E and flavonoids, and endogenous antioxidants, such as urate, can terminate free-radical chain reactions. Defense through compartmentation refers to the separation of species and sites involved in ROS generation from the rest of the cell (Fig. 25.11). For example, many of the enzymes that produce hydrogen peroxide are sequestered in peroxisomes with a high content of antioxidant enzymes.

Metals are bound to a wide range of proteins within the blood and in cells, preventing their participation in the Fenton reaction. Iron, for example, is tightly bound to its storage protein, ferritin, and cannot react with hydrogen peroxide. Repair mechanisms for DNA and for removal of oxidized fatty acids from membrane lipids are available to the cell. Oxidized amino acids on proteins are continuously repaired through protein degradation and resynthesis of new proteins.

FIGURE 25.11 Compartmentalization of free-radical defenses. A number of defenses against reactive oxygen species (ROS) are found in the various subcellular compartments of the cell. The location of free-radical defense enzymes (shown in red) matches the type and amount of ROS generated in each subcellular compartment. The highest activities of these enzymes are found in the liver, adrenal gland, and kidney, where mitochondrial and peroxisomal contents are high, and cytochrome P450 enzymes are found in abundance in the smooth endoplasmic reticulum. The enzymes superoxide dismutase (SOD) and glutathione peroxidase are present as isoforms in the various compartments. Another form of compartmentalization involves the sequestration of Fe, which is stored as mobilizable Fe in ferritin. Excess Fe is stored in nonmobilizable hemosiderin deposits. Glutathione (GSH) is a nonenzymatic antioxidant.

A. Antioxidant Scavenging Enzymes

The enzymatic defense against ROS includes SOD, catalase, and glutathione peroxidase.

The intracellular form of the Cu⁺-Zn²⁺ superoxide dismutase is encoded by the SOD1 gene. To date, 58 mutations in this gene have been discovered in individuals affected by familial amyotrophic lateral sclerosis (ALS, Lou Gehrig disease). How a mutation in this gene leads to the symptoms of this disease has yet to be understood. It is important to note that only 5% to 10% of the total cases of diagnosed ALS are caused by the familial form. Recent work has indicated that mutations in enzymes involved in RNA processing also lead to familial and sporadic ALS.

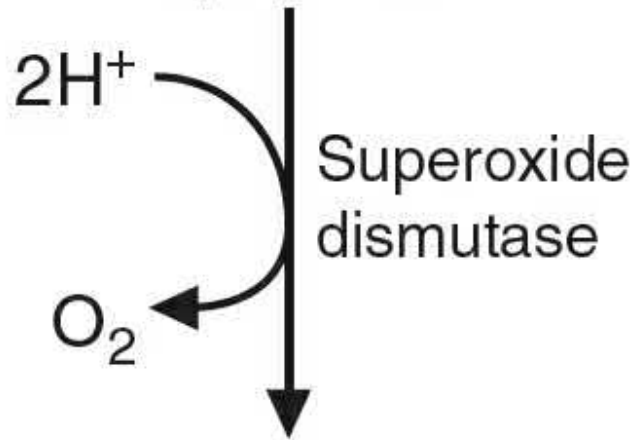

1. Superoxide Dismutase

Conversion of superoxide anion to hydrogen peroxide and O₂ (dismutation) by superoxide dismutase (SOD) is often called the primary defense against oxidative stress because superoxide is such a strong initiator of chain reactions (Fig. 25.12A). SOD exists as three isoenzyme forms, a Cu⁺-Zn²⁺ form present in the cytosol, a Mn²⁺ form present in mitochondria, and a Cu⁺-Zn²⁺ form found extracellularly. The activity of Cu⁺-Zn²⁺ SOD is increased by chemicals or conditions (such as hyperbaric oxygen) that increase the production of superoxide.

Superoxide

Hydrogen peroxide

B

Hydrogen peroxide

FIGURE 25.12 **A.** Superoxide dismutase converts superoxide to hydrogen peroxide, which is nontoxic unless it is converted to other reactive oxygen species (ROS). **B.** Catalase converts two molecules of hydrogen peroxide to two molecules of water and one molecule of oxygen. (ROS is shown in a *yellow box*.)

2. Catalase

Hydrogen peroxide, once formed, must be reduced to water to prevent it from forming the hydroxyl radical in the Fenton reaction or the Haber–Weiss reaction (see Fig. 25.4). One of the enzymes that is capable of reducing hydrogen peroxide is catalase (see Fig. 25.12B). Catalase is found principally in peroxisomes, and to a lesser extent in the cytosol and microsomal fraction of the cell. The highest activities are found in tissues with a high peroxisomal content (kidney and liver). In cells of the immune system, catalase serves to protect the cell against its own respiratory burst.

3. Glutathione Peroxidase and Glutathione Reductase

Glutathione (γ -glutamyl-cysteinyl glycine) is one of the body's principal means of protecting against oxidative damage (see also Chapter 27). Glutathione is a tripeptide composed of glutamate, cysteine, and glycine, with the amino group of cysteine joined in peptide linkage to the γ -carboxyl group of glutamate (Fig. 25.13). In reactions that are catalyzed by glutathione peroxidases, the reactive sulfhydryl groups reduce hydrogen peroxide to water and lipid peroxides to nontoxic alcohols. In these reactions, two glutathione molecules are oxidized to form a single molecule, glutathione disulfide. The sulfhydryl groups are also oxidized in nonenzymatic chain-terminating reactions with organic radicals.

FIGURE 25.13 Glutathione peroxidase reduces hydrogen peroxide to water. **A.** The structure of glutathione. The sulfhydryl group of glutathione, which is oxidized to a disulfide, is shown in *red*. **B.** Glutathione peroxidase transfers electrons from glutathione (GSH) to hydrogen peroxide. **C.** Glutathione redox cycle. Glutathione reductase regenerates reduced glutathione. (ROS is shown in the *yellow box*.)

Why does the cell need a high content of SOD in mitochondria?

Glutathione peroxidases exist as a family of selenium enzymes with somewhat different properties and tissue locations. Within cells, they are found principally in the cytosol and mitochondria and are the major means for removing H_2O_2 produced outside of peroxisomes. They contribute to our dietary requirement for selenium and account for the protective effect of selenium in the prevention of free-radical injury.

Once oxidized glutathione (GSSG) is formed, it must be reduced back to the sulfhydryl form by glutathione reductase in a redox cycle (see Fig. 25.13C). Glutathione reductase contains a FAD and catalyzes the transfer of electrons from NADPH to the disulfide bond of GSSG. NADPH is thus essential for protection against free-radical injury. The major source of NADPH for this reaction is the pentose phosphate pathway (see Chapter 27).

Mitochondria are major sites for the generation of superoxide from the interaction of CoQ and O_2 . The Mn^{2+} SOD present in mitochondria is not regulated through induction/repression of gene transcription, presumably because the rate of superoxide generation is always high. Mitochondria also have a high content of glutathione and glutathione peroxidase, and can thus convert H_2O_2 to H_2O and prevent lipid peroxidation.

Premature infants with low levels of lung surfactant (see Chapter 31) require oxygen therapy. The level of oxygen must be closely monitored to prevent ROS-induced retinopathy and subsequent blindness (the retinopathy of prematurity) and to prevent bronchial pulmonary dysplasia. The tendency for these complications to develop is enhanced by the possibility of low levels of SOD and vitamin E in the premature infant.

B. Nonenzymatic Antioxidants (Free-Radical Scavengers)

Free-radical scavengers convert free radicals to a nonradical, nontoxic form in nonenzymatic reactions. Most free-radical scavengers are antioxidants, compounds that neutralize free radicals by donating a hydrogen atom (with its one electron) to the radical. Antioxidants, therefore, reduce free radicals and are themselves oxidized in the reaction. Dietary free-radical scavengers (e.g., vitamin E, ascorbic acid, carotenoids, and flavonoids), as well as endogenously produced free-radical scavengers (e.g., urate and melatonin), have a common structural feature, which is a conjugated double bond system that may be an aromatic ring.

Selenium (Se) is present in human proteins principally as selenocysteine (cysteine with the sulfur group replaced by Se, abbreviated sec). This amino acid functions in catalysis and has been found in 11 or more human enzymes, including the four enzymes of the glutathione peroxidase family. Selenium is supplied in the diet as selenomethionine from plants (methionine with the Se replacing the sulfur), selenocysteine from animal foods, and inorganic selenium. Se from all of these sources can be converted to selenophosphate. Selenophosphate reacts with a unique tRNA-containing bound serine to form a selenocysteine-tRNA, which incorporates selenocysteine into the appropriate protein as it is being synthesized. Se homeostasis in the body is controlled principally through regulation of its secretion as methylated Se. The current dietary requirement is approximately 70 µg/day for adult males and 55 µg/day for females. Deficiency symptoms reflect diminished antioxidant defenses and include symptoms of vitamin E deficiency.

1. Vitamin E

Vitamin E (α -tocopherol), the most widely distributed antioxidant in nature, is a lipid-soluble antioxidant vitamin that functions principally to protect against lipid peroxidation in membranes (see Fig. 25.11). Vitamin E comprises a number of tocopherols that differ in their methylation pattern. Among these, α -tocopherol is the most potent antioxidant and is present in the largest amounts in our diet (Fig. 25.14).

FIGURE 25.14 Vitamin E (α -tocopherol) terminates free-radical lipid peroxidation by donating single electrons to lipid peroxy radicals ($\text{LOO}\cdot$) to form the more stable lipid peroxide, LOOH . In so doing, the α -tocopherol is converted to the fully oxidized tocopheryl quinone.

Vitamin E is an efficient antioxidant and nonenzymatic terminator of free-radical chain reactions, and it has little pro-oxidant activity. When vitamin E donates an electron to a lipid peroxy radical, it is converted to a free radical form that is stabilized by resonance. If this free radical form were to act as a pro-oxidant and abstract an electron from a polyunsaturated lipid, it would be oxidizing that lipid and actually propagate the free-radical chain reaction. The chemistry of vitamin E is such that it has a much greater tendency to donate a second electron and go to the fully oxidized form.

 Vitamin E is found in the diet in the lipid fractions of some vegetable oils and in liver, egg yolks, and cereals. It is absorbed together with lipids, and fat malabsorption results in symptomatic deficiencies. Vitamin E circulates in the blood in lipoprotein particles. Its deficiency causes neurologic symptoms, probably because the polyunsaturated lipids in myelin and other membranes of the nervous system are particularly sensitive to free-radical injury. Epidemiologic evidence suggests that individuals with a higher intake of foods containing vitamin E, β -carotene, and vitamin C have a somewhat lower risk of cancer and certain other ROS-related diseases than do individuals on diets that are deficient in these vitamins. However, studies in which well-nourished populations were given supplements of these antioxidant vitamins found either no effects or harmful effects compared with the beneficial effects from eating foods containing a wide variety of antioxidant compounds. Of the pure chemical supplements tested, there is evidence only for the efficacy of vitamin E. In two clinical trials, β -carotene (or β -carotene + vitamin A) was associated with a higher incidence of lung cancer among smokers and higher mortality rates. In one study, vitamin E intake was associated with a higher incidence of hemorrhagic stroke (possibly because of vitamin K mimicry).

2. Ascorbic Acid

Although ascorbate (vitamin C) is an oxidation–reduction coenzyme that functions in collagen synthesis and other reactions, it also plays a role in free-radical defense. Reduced ascorbate can regenerate the reduced form of vitamin E by donating electrons in a redox cycle (Fig. 25.15). It is water-soluble and circulates unbound in blood and extracellular fluid, where it has access to the lipid-soluble vitamin E present in membranes and

lipoprotein particles.

FIGURE 25.15 L-Ascorbate (the reduced form) donates single electrons to free radicals or disulfides in two steps as it is oxidized to dehydro-L-ascorbic acid. Its principal role in free-radical defense is probably regeneration of vitamin E. However, it also may react with superoxide, hydrogen peroxide, hypochlorite, the hydroxyl and peroxy radicals, and NO_2 .

3. Carotenoids

Carotenoids is a term applied to β -carotene (the precursor of vitamin A) and similar compounds with functional oxygen-containing substituents on the rings, such as zeaxanthin and lutein. These compounds can exert antioxidant effects, as well as quench singlet O_2 (singlet oxygen is a highly ROS in which there are no unpaired electrons in the outer orbitals, but there is one orbital that is completely empty). Epidemiologic studies have shown a correlation between diets that are high in fruits and vegetables and health benefits, leading to the hypothesis that carotenoids might slow the progression of cancer, atherosclerosis, and other degenerative diseases by acting as chain-breaking antioxidants. However, in clinical trials, β -carotene supplements had either no effect or an undesirable effect. Its ineffectiveness may be due to the pro-oxidant activity of the free-radical form.

In contrast, epidemiologic studies relating the intake of lutein and zeaxanthin with decreased incidence of age-related macular degeneration have received progressive support. These two carotenoids are concentrated in the macula (the central portion of the retina) and are called the macular carotenoids.

 Age-related macular degeneration (AMD) is the leading cause of blindness in the United States among persons older than 50 years of age, and it affects as many as 9 to 10 million people in the United States. In AMD, visual loss is related to oxidative damage to the retinal pigment epithelium (RPE) and the choriocapillaris epithelium. The photoreceptor/retinal pigment complex is exposed to sunlight, it is bathed in near-arterial levels of oxygen, and the membranes contain high concentrations of polyunsaturated fatty acids, all of which are conducive to oxidative damage. Lipofuscin granules, which accumulate in the RPE throughout life, may serve as photosensitizers, initiating damage by absorbing blue light and generating singlet oxygen (an energetically excited form of oxygen) that forms other radicals. Dark sunglasses are protective. Epidemiologic studies showed that the intake of lutein and zeaxanthin in dark green leafy vegetables (e.g., spinach and collard greens) also may be protective. Lutein and zeaxanthin accumulate in the macula and protect against free-radical damage by absorbing blue light and quenching singlet oxygen.

4. Other Dietary Antioxidants

Flavonoids are a group of structurally similar compounds that contain two spatially separate aromatic rings and are found in red wine, green tea, chocolate, and other plant-derived foods. Flavonoids have been hypothesized to contribute to our free-radical defenses in a number of ways. Some flavonoids inhibit enzymes responsible for superoxide anion production, such as xanthine oxidase. Others efficiently chelate Fe and Cu, making it impossible for these metals to participate in the Fenton reaction. They also may act as free-radical scavengers by donating electrons to superoxide or lipid peroxy radicals or stabilize free radicals by complexing with them.

It is difficult to tell how much dietary flavonoids contribute to our free-radical defense system; they have a high pro-oxidant activity and are poorly absorbed. Nonetheless, we generally consume large amounts of flavonoids (~ 800 mg/day), and there is evidence that they can contribute to the maintenance of vitamin E as an antioxidant.

5. Endogenous Antioxidants

A number of compounds that are synthesized endogenously for other functions, or as urinary excretion products, also function nonenzymatically as free-radical antioxidants. Uric acid is formed from the degradation of purines and is released into extracellular fluids, including blood, saliva, and lung lining fluid. Together with

protein thiols, it accounts for the major free-radical trapping capacity of plasma. It is particularly important in the upper airways, where there are few other antioxidants. It can directly scavenge hydroxyl radicals, oxyheme oxidants formed between the reaction of hemoglobin and peroxy radicals, and peroxy radicals themselves. Having acted as a scavenger, uric acid produces a range of oxidation products that are subsequently excreted.

Melatonin, which is a secretory product of the pineal gland, is a neurohormone that functions in regulation of our circadian rhythm, light–dark signal transduction, and sleep induction. In addition to these receptor-mediated functions, it functions as a nonenzymatic free-radical scavenger that donates an electron (as hydrogen) to “neutralize” free radicals. It also can react with ROS and RNOS to form additional products, thereby undergoing suicidal transformations. Its effectiveness is related to both its lack of pro-oxidant activity and its joint hydrophilic/hydrophobic nature, which allows it to pass through membranes and the blood–brain barrier.

CLINICAL COMMENTS

Les G. has Parkinson disease. The pathogenesis of this disease is not well established and may be multifactorial (Fig. 25.16). Recent work has identified a number of genes, which, when mutated and inactive, lead to rare familial Parkinson disease and others that affect the risk for Parkinson disease. The major clinical disturbances in Parkinson disease are a result of dopamine depletion in the neostriatum, resulting from degeneration of dopaminergic neurons whose cell bodies reside in the substantia nigra pars compacta. The decrease in dopamine production is the result of severe degeneration of these nigrostriatal neurons. Although the agent that initiates the disease is unknown, a variety of studies support a role for free radicals in Parkinson disease (mitochondrial dysfunction), along with alterations in the ubiquitin–proteasome pathway of protein degradation. Within these neurons, dopamine turnover is increased, dopamine levels are lower, glutathione is decreased, and lipofuscin (Lewy bodies) is increased. Iron levels are higher, and ferritin, the storage form of iron, is lower. Furthermore, the disease is mimicked by the compound 1-methyl-4-phenylpyridinium (MPP⁺), an inhibitor of NADH:CoQ oxidoreductase that increases superoxide production in these neurons and decreases ATP production. Analysis of mitochondria from patients with Parkinson disease indicates a 30% to 40% reduction in complex I activity. The reduced ATP levels may affect the ubiquitin–proteasome pathway negatively, reducing protein degradation and linking these two pathways, which can lead to Parkinson disease. Even so, it is not known whether oxidative stress makes a primary or secondary contribution to the disease process.

Dopamine inactivation

FIGURE 25.16 A model for the role of reactive oxygen species (ROS) and reactive nitrogen–oxygen species (RNOS) in neuronal degradation in Parkinson disease. (1) Dopamine levels are reduced by monoamine oxidase (MAO), which generates H_2O_2 . (2) Superoxide also can be produced by mitochondria, which superoxide dismutase (SOD) will convert to H_2O_2 . Iron levels increase, which allows the Fenton reaction to proceed, generating hydroxyl radicals. (3) Nitric oxide (NO), produced by inducible nitric oxide synthase, reacts with superoxide to form RNOS. (4) The RNOS and hydroxyl radical lead to radical chain reactions that result in lipid peroxidation, protein oxidation, the formation of lipofuscin, and neuronal degeneration. The end result is a reduced production and release of dopamine, which leads to the clinical symptoms observed.

Drug therapy is based on the severity of the disease and the impact of disease on the patient's quality of life. A number of options are available. In the early phases of the disease, if symptoms are mild, a monoamine oxidase B inhibitor can be used that inhibits dopamine degradation and decreases hydrogen peroxide formation. In later stages of the disease or more symptomatic stages, patients are treated with levodopa (L-dopa), a precursor of dopamine, sometimes in combination with the monoamine oxidase B inhibitor.

Cora N. experienced angina caused by severe ischemia in the ventricular muscle of her heart. The ischemia was caused by clots that formed at the site of atherosclerotic plaques within the lumen of the coronary arteries. When tissue plasminogen activator (TPA) was infused to dissolve the clots, the ischemic area of her heart was reperfused with oxygenated blood, resulting in ischemia-reperfusion injury. In her case, the reperfusion injury resulted in some short runs of ventricular tachycardia.

During ischemia, several events occur simultaneously in cardiomyocytes. A decreased O_2 supply results in decreased ATP generation from mitochondrial oxidative phosphorylation and inhibition of cardiac muscle contraction. As a consequence, cytosolic AMP levels increase, activating anaerobic glycolysis and lactic acid production. If ATP levels are inadequate to maintain Na^+ , K^+ -ATPase activity, intracellular Na^+ increases, resulting in cellular swelling, a further increase in H^+ concentration, and increases of cytosolic and subsequently mitochondrial Ca^{2+} levels. The decrease in ATP and increase in Ca^{2+} may open the mitochondrial permeability transition pore, resulting in permanent inhibition of oxidative phosphorylation. Damage to lipid membranes is further enhanced by Ca^{2+} activation of phospholipases.

Reperfusion with O_2 allows recovery of oxidative phosphorylation, provided that the mitochondrial membrane has maintained some integrity and the mitochondrial transition pore can close. However, it also increases the generation of free radicals. The transfer of electrons from $CoQ\cdot$ to O_2 to generate superoxide is increased. Endothelial production of superoxide by xanthine oxidase also may increase. These radicals may go on to form the hydroxyl radical, which can enhance the damage to components of the electron transport chain and mitochondrial lipids, as well as activate the mitochondrial permeability transition. As macrophages move into the area to clean up cellular debris, they may generate NO and superoxide, thus introducing peroxynitrite and other free radicals into the area. Depending on the route and timing involved, the acute results may be cell death through necrosis, with slower cell death through apoptosis in the surrounding tissue.

Currently, an intense study of ischemic insults to a variety of animal organs is underway, in an effort to discover ways of preventing reperfusion injury. These include methods designed to increase endogenous antioxidant activity, to reduce the generation of free radicals, and, finally, to develop exogenous antioxidants that, when administered before reperfusion, would prevent its injurious effects. Preconditioning tissues to hypoxia is also a viable option to reducing reperfusion injury. Each of these approaches has met with some success, but their clinical application awaits further refinement. With the growing number of invasive procedures aimed at restoring arterial blood flow through partially obstructed coronary vessels, such as clot lysis, balloon or laser angioplasty, and coronary artery bypass grafting, development of methods to prevent ischemia-reperfusion injury are becoming increasingly urgent.

In **Cora N.**'s case, oxygen was restored before permanent impairment of oxidative phosphorylation had occurred and the stage of irreversible injury was reached.

BIOCHEMICAL COMMENTS

Oxidases, the TCA cycle, and Cancer. The advent of whole-genome sequencing (see Chapter 16) has allowed a large number of tumor cells to be analyzed for mutations in the genome. Surprisingly, certain types of tumors contained mutations in enzymes related to the TCA cycle (see Chapter 23). Enzymes identified include succinate dehydrogenase, which was found in familial paraganglioma cells (this mutation is a loss of activity, in which succinate will accumulate); fumarase deficiency was found in multiple

cutaneous and uterine leiomyomas and exhibited autosomal dominant behavior (in this mutation, fumarate will accumulate); and certain isozymes of isocitrate dehydrogenase, in which a gain of function mutation enables the enzyme to produce 2-hydroxyglutarate instead of α -ketoglutarate, and is found in gliomas and acute myeloid leukemia. The accumulation of succinate, fumarate, or 2-hydroxyglutarate, in a manner described below, leads to an alteration in gene expression and oxygen sensing, which, in part, leads to tumor formation.

α -Ketoglutarate, in addition to being a key intermediate in the TCA cycle, is also required for vitamin C-dependent hydroxylation reactions (see Chapter 5). Enzymes catalyzing such reactions include *N*-methyl lysine hydroxylase (the first step in demethylating histones) and methylcytosine demethylase (the first step in demethylating 5-methyl cytosine, found in the promoter of genes, which are usually inactivated). The reaction catalyzed by these enzymes is oxygen + α -ketoglutarate + substrate to be hydroxylated yields succinate + CO₂ + hydroxylated product.

Isocitrate dehydrogenase exists as three different isozymes, IDH1, IDH2, and IDH3. IDH3 is the mitochondrial version, requires NAD⁺, and is part of the TCA cycle. Mutations in IDH3 do not lead to tumor formation. IDH1 and IDH2 are NADP⁺-dependent isozymes, with IDH1 being located in the cytoplasm, and IDH2 in the mitochondria. If IDH1 or IDH2 contains a mutation that alters a key arginine residue at the active site, the enzyme will utilize α -ketoglutarate as a substrate (instead of isocitrate) and generate 2-hydroxyglutarate as the product.

As described in Chapter 15, histone methylation occurs on the *N*-terminal tails of histones and is a component of the epigenetic regulation of gene expression. These methylation events can either activate or inhibit the expression of a gene, depending on the gene. The enzyme *N*-methyl lysine hydroxylase is the first step in the demethylation of the tails. The methyl group becomes hydroxylated, and the carbon is then lost in the form of formaldehyde, which is picked up by the one-carbon carrier tetrahydrofolate. If 2-hydroxyglutarate has accumulated it will bind to the active site of *N*-methyl lysine hydroxylase, inhibiting the enzyme, and not allowing histone demethylation to occur. Similarly, if succinate has accumulated due to a mutation in succinate dehydrogenase or fumarase, succinate will inhibit the hydroxylation reaction due to product inhibition (recall, succinate is a product of the hydroxylase).

In a similar fashion, the removal of methyl groups from cytosine in promoter regions of genes requires an initial hydroxylation reaction (the enzyme is methylcytosine dioxygenase) which is similarly inhibited by 2-hydroxyglutarate, succinate, or fumarate. This leads to a constant state of hypermethylation of the genome and altered gene expression. In cases of acute myeloid leukemia (AML), the methylation pattern of the genome resembles that of stem cells, and not that of differentiated blood cells.

The mutations in the TCA cycle enzymes and isozymes also affect the degradation of the transcription factor hypoxia-inducible factor (HIF). Under conditions of low oxygen concentration HIF binds to DNA regulatory elements to induce genes in response to low oxygen conditions, such as an increase in expression of glycolytic enzymes. HIF activity is regulated, in part, by proline hydroxylation (which requires α -ketoglutarate). An inability to hydroxylate the proline residue (due to 2-hydroxyglutarate, succinate, or fumarate accumulation) leads to HIF being active for extended periods of time, altering gene transcription and leading to cell proliferation.

Laboratory experiments using inhibitors of the altered IDH molecules are in progress, and drugs have been developed, which are candidates for clinical trials. Some of the drugs developed led to the reversal of both DNA and histone hypermethylation, and induced cellular differentiation, in cultured cells containing tumor-inducing IDH-2 mutations.

KEY CONCEPTS

- ◆ Oxygen radical generation contributes to cellular death and degeneration in a variety of diseases.
- ◆ Radical damage occurs via electron extraction from a biological molecule, creating a chain reaction of radical propagation.
- ◆ Reactive oxygen species (ROS) include superoxide, hydrogen peroxide, and the hydroxyl radical.
- ◆ ROS can be produced either enzymatically or nonenzymatically.
- ◆ ROS cause damage by oxidatively damaging DNA, proteins, and lipids, leading to mutations and cell death.
- ◆ Other radical species include NO and HOCl.
- ◆ NO reacts with oxygen or superoxide to form a family of reactive nitrogen species (RNOS).
- ◆ The immune response normally produces radical species (superoxide, HOCl, NO) to destroy invading

microorganisms. Escape of radicals from the immune cells during this protective event can damage surrounding tissues.

- ◆ Cellular defense mechanisms against radical damage include defense enzymes, antioxidants, and compartmentalization of free radicals.
- ◆ Cellular defense enzymes include SOD, catalase, and glutathione peroxidase.
- ◆ Antioxidants include vitamins E and C, and plant flavonoids.
- ◆ Diseases discussed in this chapter are summarized in Table 25.3.

TABLE 25.3 Diseases Discussed in Chapter 25

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Free-radical disease	Both	Damage caused to proteins and lipids due to free-radical generation may lead to cellular dysfunction.
Parkinson disease	Both	Inability to convert tyrosine to DOPA; DOPA treatment can temporarily reverse tremors and other symptoms.
Myocardial infarction	Both	The lack of oxygen in the walls of the heart is caused by severe ischemia due to clots forming within certain coronary arteries at the site of ruptured atherosclerotic plaques. The limited availability of oxygen to act as an electron acceptor decreases the proton motive force across the inner mitochondrial membrane of ischemic cells. This leads to reduced ATP generation, triggering events that lead to irreversible cell injury. Further damage to the heart muscle can occur due to free-radical generation after oxygen is reintroduced to the cells which were temporarily ischemic, a process known as ischemic reperfusion injury.
Chronic granulomatous disease	Genetic	This disorder occurs due to a reduced activity of NADPH oxidase, leading to a reduction in the oxidative burst by neutrophils, coupled with a dysregulated immune response to bacteria and fungi.
Respiratory distress syndrome of a newborn	Both	Either mutation in surfactant, or lack of surfactant production in newborns; lungs have difficulty inflating and compressing.
ALS	Both	A familial form of ALS is due to mutations in SOD, leading to difficulty in disposing of superoxide radicals, leading to cell damage due to excessive ROS.
Age-related macular degeneration	Both	Oxidative damage occurs in the RPE, leading to first, reduced vision, and second, to blindness.

ALS, amyotrophic lateral sclerosis; ATP, adenosine triphosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate; ROS, reactive oxygen species; RPE, retinal pigment epithelium, SOD, superoxide dismutase.

REVIEW QUESTIONS—CHAPTER 25

1. Which one of the following vitamins or enzymes is unable to protect against free-radical damage?
 - A. β -Carotene
 - B. Glutathione peroxidase
 - C. Superoxide dismutase
 - D. Vitamin B₆
 - E. Vitamin C
 - F. Vitamin E
2. Superoxide dismutase is one of the body's primary defense mechanisms against oxidative stress. The enzyme catalyzes which one of the following reactions?
 - A. $O_2^- + e^- + 2H^+ \rightarrow H_2O_2$
 - B. $2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$
 - C. $O_2^- + HO\cdot + H^+ \rightarrow CO_2 + H_2O$
 - D. $H_2O_2 + O_2 \rightarrow 4H_2O$
 - E. $O_2^- + H_2O_2 + H^+ \rightarrow 2H_2O + O_2$

3. The mechanism of vitamin E as an antioxidant is best described by which one of the following?
 - A. Vitamin E binds to free radicals and sequesters them from the contents of the cell.
 - B. Vitamin E participates in the oxidation of the radicals.
 - C. Vitamin E participates in the reduction of the radicals.
 - D. Vitamin E forms a covalent bond with the radicals, thereby stabilizing the radical state.
 - E. Vitamin E inhibits enzymes that produce free radicals.
4. An accumulation of hydrogen peroxide in a cellular compartment can be converted to dangerous radical forms in the presence of which metal?
 - A. Selenium
 - B. Iron
 - C. Manganese
 - D. Magnesium
 - E. Molybdenum
5. The level of oxidative damage to mitochondrial DNA is 10 times greater than that to nuclear DNA. This could be due, in part, to which of the following?
 - A. SOD is present in the mitochondria.
 - B. The nucleus lacks glutathione.
 - C. The nuclear membrane presents a barrier to ROS.
 - D. The mitochondrial membrane is permeable to ROS.
 - E. Mitochondrial DNA lacks histones.
6. A patient with chronic granulomatous disease, who is complaining of fever, dermatitis, and diarrhea, is seen in your clinic. The genetic form of this disease results in the inability to generate, primarily, which one of the following?
 - A. Superoxide
 - B. Hydrogen peroxide
 - C. Reduced glutathione
 - D. Hypochlorous acid
 - E. Nitric oxide
7. You diagnose a patient with amyotrophic lateral sclerosis and discover that his father also had the disease. The patient most likely had a mutation that leads to the inability to detoxify which one of the following?
 - A. Oxidized glutathione
 - B. Hydrogen peroxide
 - C. Nitric oxide
 - D. Hydroxy radical
 - E. Superoxide
8. Nitroglycerin and other medications used for treating erectile dysfunction work by forming nitric oxide (NO), a potent vasodilator (in low concentrations). In high concentrations, NO can produce RNOS (reactive nitrogen-oxygen species) that are involved in which one of the following diseases?
 - A. Ischemic heart disease
 - B. Infertility
 - C. Viral infections
 - D. Fungal infections
 - E. Rheumatoid arthritis
9. An individual taking xenobiotics, such as alcohol, medications, and other foreign chemicals, can increase their risk for free-radical injury through which one of the following mechanisms?
 - A. Reaction of O₂ with coenzyme Q
 - B. Induction of oxidases in peroxisomes
 - C. Induction of enzymes containing cytochrome P450
 - D. Production of ionizing radiation
 - E. Production of hydrogen peroxide in the manufacturing process, such that hydrogen peroxide is present in the ingested materials.
0. A balanced diet contains antioxidant molecules that help to protect cells from free-radical injury. Which one of the following foods would contain high levels of an antioxidant?
 - A. Citrus fruits
 - B. Enriched bread
 - C. Dairy products

- D. Energy drinks
 - E. Green leafy vegetables
1. The antioxidant glutathione is utilized to detoxify hydrogen peroxide by an enzyme that requires which one of the following?
 - A. NADPH
 - B. Magnesium
 - C. Copper
 - D. Selenium
 - E. Iron
 2. The regeneration of the protective form of glutathione utilizes an enzyme that requires which one of the following?
 - A. NADH
 - B. NADPH
 - C. FAD(2H)
 - D. NAD+
 - E. NADP+
 - F. FAD

Questions 13 and 14 refer to the following case history: A 67-year-old man exhibited a resting tremor, positional imbalance, and increased anxiety. These symptoms abated when the man has prescribed a monoamine oxidase inhibitor along with L-dopa. Unfortunately, after a year the treatment became less effective at alleviating the symptoms. The patient did not take any nutritional supplements during his illness but did eat a healthy diet.

3. Which one of the following would you expect to see elevated in the man's serum as his disease progresses?
 - A. Malondialdehyde
 - B. Fatty acids
 - C. Vitamin C
 - D. Vitamin E
 - E. Glucose
4. The patient was treated with a monoamine oxidase inhibitor, which will directly have which one of the following outcomes in the patient?
 - A. Increases hydrogen peroxide production
 - B. Reduces hydrogen peroxide production
 - C. Increases superoxide production
 - D. Reduces superoxide production
 - E. Increases hydroxyl radical production
 - F. Decreases hydroxyl radical production
5. The generation of reactive nitrogen–oxygen species (RNOS) is initialized by the synthesis of the nitric oxide radical (NO). The synthesis of NO requires which of the following? Choose the one best answer.

	Arginine	NADPH	Citrulline	Superoxide
A	Yes	Yes	No	Yes
B	Yes	No	Yes	Yes
C	Yes	Yes	No	No
D	No	No	Yes	No
E	No	Yes	No	No
F	No	No	Yes	Yes

ANSWERS TO REVIEW QUESTIONS

- The answer is D.** Pyridoxal phosphate is a water-soluble vitamin that is important for amino acid and glycogen metabolism but has no role in protecting against free-radical damage. Ascorbate (vitamin C), vitamin E, and β -carotene can all react with free radicals to terminate chain propagation, whereas SOD utilizes the superoxide radical as a substrate and converts it to hydrogen peroxide, and glutathione peroxidase removes hydrogen peroxide from the cell, converting it to water.
- The answer is B.** SOD combines two superoxide radicals to produce hydrogen peroxide and molecular oxygen. None of the other reactions is correct.
- The answer is C.** Vitamin E donates an electron and proton to the radical, thereby converting the radical to a stable form ($\text{LOO}\cdot \rightarrow \text{LOOH}$). The vitamin thus prevents the free radical from oxidizing another compound by extracting a hydrogen atom and an electron from that compound and propagating a free-radical chain reaction. The radical form of vitamin E generated is relatively stable and actually donates another electron and proton to a second free radical, forming oxidized vitamin E (see Fig. 25.14).
- The answer is B.** The Fenton reaction is the nonenzymatic donation of an electron from Fe^{2+} to H_2O_2 to produce Fe^{3+} , the hydroxyl radical, and hydroxide ion. Only Fe^{2+} or Cu^{1+} can be utilized in this reaction; thus, the other answers are incorrect.
- The answer is E.** Histones coat nuclear DNA and protect it from damage by radicals. Mitochondrial DNA lacks histones, so when radicals are formed, the DNA can be easily oxidized. Answers A and B are nonsensical; SOD reduces radical concentrations, so the fact that it is present in the mitochondria should help to protect the DNA from damage, not enhance it; and glutathione also protects against radical damage, and if the nucleus lacks it, then one would expect higher levels of nuclear DNA damage, not reduced levels. ROS can diffuse across membranes, so answers C and D are incorrect. Other factors that increase mitochondrial DNA damage relative to nuclear DNA are the proximity of mitochondrial DNA to the membrane and the fact that most radical species are formed from coenzyme Q, which is found within the mitochondria.
- The answer is A.** The familial form of chronic granulomatous disease is due to reduced activity of NADPH oxidase, which generates superoxide from oxygen during the respiratory burst in neutrophils, designed to destroy engulfed bacteria. Once superoxide is generated other oxygen radicals can be generated (such as hydrogen peroxide), but the generation of superoxide is the primary event. Hypochlorous acid is also generated during the respiratory burst, but the enzyme required is myeloperoxidase, which is not defective in chronic granulomatous disease. Nitric oxide is generated by nitric oxide synthase, which is not mutated in chronic granulomatous. Reduced glutathione is the protective form of glutathione, and can be generated using glutathione peroxidase, or glutathione reductase, neither of which is defective in chronic granulomatous disease.
- The answer is E.** The familial form of Lou Gehrig disease (amyotrophic lateral sclerosis) is due to an inherited mutation in superoxide dismutase (SOD). In the absence of SOD increased oxidative damage is

possible to the neurons, due to the accumulation of superoxide, the substrate for SOD. Catalase will reduce hydrogen peroxide levels, while glutathione peroxidase will convert reduced glutathione to oxidized glutathione, using as an electron donor hydrogen peroxide. Nitric oxide does not accumulate in Lou Gehrig disease. The hydroxy radical may accumulate due to the accumulation of superoxide, but the hydroxy radical is not the direct cause of the disease.

8. **The answer is E.** RNOS are involved in neurodegenerative diseases such as Parkinson disease and in chronic inflammatory diseases such as rheumatoid arthritis. While RNOS has a minor role in neutrophils (bacterial infections), ROS are strongly involved in fungal and viral infections as well as ischemic heart disease and infertility.
9. **The answer is C.** Most xenobiotics (such as alcohol, medications, and other chemicals) induce the cytochrome P450 family of enzymes to metabolize the xenobiotic. During the reactions catalyzed by this family of enzymes, free radicals are sometimes generated and released from the enzyme complex, which can lead to intracellular protein and lipid damage. The ingestion of alcohol, medications, and other chemicals does not increase the frequency of oxygen reacting with coenzyme Q, nor do they induce oxidases in peroxisomes, nor do they produce ionizing radiation. Hydrogen peroxide is not produced in the manufacturing of alcohol, most medications, or most chemicals.
10. **The answer is A.** Vitamins C and E and perhaps A act as antioxidants. Citrus fruits are high in vitamin C. Enriched bread is high in niacin and folate. Fortified dairy products are high in vitamin D (though not raw milk), and green, leafy vegetables are high in vitamin K and folate. Energy drinks usually have sugar, caffeine, and B vitamins.
11. **The answer is D.** The enzyme glutathione peroxidase will utilize reduced glutathione to donate electrons to hydrogen peroxide to generate two molecules of water. During the course of the reaction, the glutathione is oxidized, and the hydrogen peroxide is reduced. Glutathione peroxidase requires selenium (but not magnesium, copper, or iron) for activity. NADPH is not required for this reaction but is required to regenerate the reduced form of glutathione from the oxidized form of glutathione.
12. **The answer is B.** The protective form of glutathione is the reduced form; once glutathione is oxidized (and forms the disulfide between two glutathione molecules) it must be reduced by the enzyme glutathione reductase, using electrons provided by NADPH, to be converted back to the protective, reduced form of glutathione. Glutathione reductase does not utilize NADH or FAD(2H) as electron donors in this reaction. The oxidized forms of NAD(P) and FAD cannot donate electrons, and NADP⁺ is a product of the glutathione reductase reaction.
13. **The answer is A.** The patient is exhibiting the symptoms of Parkinson disease, which is due to the loss of ability to synthesize dopamine, along with an increased level of ROS in certain areas of the brain. The increased ROS leads to lipid peroxidation and the formation of malondialdehyde, which is released into the circulation. Malondialdehyde is a marker for increased ROS and oxidative stress. One would not expect the levels of fatty acids, glucose, or vitamins C and E to be elevated under these conditions.
14. **The answer is B.** Monoamine oxidase catalyzes the reaction of a monoamine (such as dopamine) to an aldehyde, plus ammonia and hydrogen peroxide. The enzyme requires molecular oxygen as an electron acceptor, leading to the production of hydrogen peroxide, which could then go on and generate other ROS. A monoamine oxidase inhibitor would directly reduce the production of hydrogen peroxide, and with a reduced level of hydrogen peroxide, there would be reduced levels of other ROS, and an overall reduced oxidative stress in the cells.
15. **The answer is C.** Nitric acid synthase (NOS) is the enzyme responsible for the synthesis of NO, and the reaction catalyzed by all isozymes of NOS (iNOS, eNOS, nNOS) is arginine + NADPH + O₂ yields NO, NADP⁺, and citrulline. The enzyme requires an iron-heme group, FAD, FMN, and tetrahydrobiopterin to aid in electron flow during the course of the reaction. Superoxide is not required to synthesize NO, nor is it a product of the nitric acid synthase reaction.

Formation and Degradation of Glycogen

Glycogen is the storage form of glucose found in most types of cells. It is composed of glucosyl units linked by α -1,4-glycosidic bonds, with α -1,6-branches occurring roughly every 8 to 10 glucosyl units (Fig. 26.1). The liver and skeletal muscle contain the largest glycogen stores.

FIGURE 26.1 Glycogen structure. Glycogen is composed of glucosyl units linked by α -1,4-glycosidic bonds and α -1,6-glycosidic bonds. The branches occur more frequently in the center of the molecule and less frequently in the periphery. The anomeric carbon that is not attached to another glucosyl residue (the reducing end) is attached to the protein glycogenin by a glycosidic bond. The hydrogen atoms have been omitted from this figure for clarity.

The formation of glycogen from glucose is an energy-requiring pathway that begins, like most of glucose metabolism, with the phosphorylation of glucose to **glucose 6-phosphate**. Glycogen synthesis from glucose 6-phosphate involves the formation of uridine diphosphate glucose (**UDP-glucose**) and the transfer of glucosyl units from UDP-glucose to the nonreducing ends of the glycogen chains by the enzyme **glycogen synthase**. Once the chains reach approximately 11 glucosyl units, a **branching enzyme** moves 6 to 8 units to form an α -(1,6)-branch.

Glycogenolysis, the pathway for glycogen degradation, is not the reverse of the biosynthetic pathway. The degradative enzyme **glycogen phosphorylase** removes glucosyl units one at a time from the nonreducing ends of the glycogen chains, converting them to **glucose 1-phosphate** without resynthesizing UDP-glucose or UTP. A **debranching enzyme** removes the glucosyl residues in α -1,6 linkages.

Liver glycogen serves as a source of **blood glucose**. To generate glucose, the glucose 1-phosphate produced from glycogen degradation is converted to glucose 6-phosphate. **Glucose 6-phosphatase**, an enzyme found only in liver and kidney, converts glucose 6-phosphate to free glucose, which then enters the blood.

Glycogen synthesis and degradation are regulated in liver by **hormonal changes** that signal the need for blood glucose (see Chapter 19). The body maintains fasting blood glucose levels at approximately 80 mg/dL to ensure that the brain and other tissues that are dependent on glucose for

the generation of adenosine triphosphate (ATP) have a continuous supply. The lack of dietary glucose, signaled by a decrease of the **insulin/glucagon ratio**, activates liver glycogenolysis and inhibits glycogen synthesis. **Epinephrine**, which signals an increased utilization of blood glucose and other fuels for exercise or emergency situations, also activates liver glycogenolysis. The hormones that regulate liver glycogen metabolism work principally through changes in the **phosphorylation** state of glycogen synthase in the biosynthetic pathway and glycogen phosphorylase in the degradative pathway.

In skeletal muscle, glycogen supplies glucose 6-phosphate for ATP synthesis in the glycolytic pathway. Muscle glycogen phosphorylase is stimulated during exercise by the increase of adenosine monophosphate (**AMP**), an **allosteric activator** of the enzyme, and also by phosphorylation. The phosphorylation is stimulated by **calcium** released during contraction, and by epinephrine, the fight-or-flight hormone. Glycogen synthesis is activated in resting muscles by the elevation of insulin after carbohydrate ingestion.

The neonate must rapidly adapt to an intermittent fuel supply after birth. Once the umbilical cord is clamped, the supply of glucose from the maternal circulation is interrupted. The combined effect of epinephrine and glucagon on the liver glycogen stores of the neonate rapidly restores glucose levels to normal.

THE WAITING ROOM

A newborn baby girl, **Gretchen C.**, was born after a 38-week gestation. Her 36-year-old mother developed a significant viral infection that resulted in a prolonged severe loss of appetite with nausea in the month preceding delivery, leading to minimal food intake. Fetal bradycardia (slower than normal fetal heart rate) was detected at the end of each uterine contraction of labor, a sign of possible fetal distress, and the baby was delivered emergently.

At birth, **Gretchen C.** was cyanotic (a bluish discoloration caused by a lack of adequate oxygenation of tissues) and limp. She responded to several minutes of assisted ventilation. Her Apgar score of 3 was low at 1 minute after birth but improved to a score of 7 at 5 minutes. The Apgar score is an objective estimate of the overall condition of the newborn, determined at both 1 and 5 minutes after birth. A score of 7, 8, or 9 is normal and fine. The highest score of 10 is less common.

Physical examination in the nursery at 10 minutes showed a thin, malnourished female newborn. Her body temperature was slightly low, her heart rate was rapid, and her respiratory rate of 55 breaths/minute was elevated. **Gretchen C.**'s birth weight was only 2,100 g, compared with a normal value of above 2,500 g. Her length was 47 cm, and her head circumference was 33 cm (low normal). The laboratory reported that **Gretchen C.**'s serum glucose level when she was unresponsive was 14 mg/dL. A glucose value below 40 mg/dL (2.5 mM) is considered to be abnormal in newborn infants.

At 5 hours of age, she was apneic (not breathing) and unresponsive. Ventilatory resuscitation was initiated, and a cannula was placed in the umbilical vein. Blood for a glucose level was drawn through this cannula, and 5 mL of a 20% glucose solution was injected. **Gretchen C.** slowly responded to this therapy.

Jim B.'s treadmill exercise and most other types of moderate exercise involving whole-body movement (running, skiing, dancing, tennis) increase the utilization of blood glucose and other fuels by skeletal muscles. The blood glucose is normally supplied by the stimulation of liver glycogenolysis and gluconeogenesis.

Jim B., a 19-year-old bodybuilder, was rushed to the hospital emergency room in a coma. One-half hour earlier, his mother had heard a loud crashing sound in the basement where **Jim B.** had been lifting weights and completing his daily workout on the treadmill. She found her son on the floor having severe jerking movements of all muscles (a grand mal seizure).

In the emergency room, the doctors learned that despite the objections of his family and friends, **Jim B.** regularly used androgens, other anabolic steroids, and insulin in an effort to bulk up his muscle mass.

On initial physical examination, he was comatose with occasional involuntary jerking movements of his

extremities. Foamy saliva dripped from his mouth. He had bitten his tongue and had lost bowel and bladder control at the height of the seizure.

The laboratory reported a serum glucose level of 18 mg/dL (extremely low). The intravenous infusion of 5% glucose (5 g of glucose per 100 mL of solution), which had been started earlier, was increased to 10%. In addition, 50 g glucose was given intravenously.

I. Structure of Glycogen

Glycogen, the storage form of glucose, is a branched glucose polysaccharide composed of chains of glucosyl units linked by α -1,4-bonds with α -1,6-branches every 8 to 10 residues (see Fig. 26.1). In a molecule of this highly branched structure, only one glucosyl residue has an anomeric carbon that is not linked to another glucose residue. This anomeric carbon at the beginning of the chain is attached to the protein glycogenin. The other ends of the chains are called **nonreducing ends** (see Chapter 5). The branched structure permits rapid degradation and rapid synthesis of glycogen because enzymes can work on several chains simultaneously from the multiple nonreducing ends.

Glycogen is present in tissues as polymers of very high molecular weight (10^7 to 10^8 Da) collected together in glycogen particles. The enzymes involved in glycogen synthesis and degradation and some of the regulatory enzymes are bound to the surface of the glycogen particles.

II. Function of Glycogen in Skeletal Muscle and Liver

Glycogen is found in most cell types, where it serves as a reservoir of glucosyl units for adenosine triphosphate (ATP) generation from glycolysis.

Glycogen is degraded mainly to **glucose 1-phosphate**, which is converted to **glucose 6-phosphate**. In skeletal muscle and other cell types, glucose 6-phosphate enters the glycolytic pathway (Fig. 26.2). Glycogen is an extremely important fuel source for skeletal muscle when ATP demands are high and when glucose 6-phosphate is used rapidly in anaerobic glycolysis. In many other cell types, the small glycogen reservoir serves a similar purpose; it is an emergency fuel source that supplies glucose for the generation of ATP in the absence of oxygen or during restricted blood flow. In general, glycogenolysis and glycolysis are activated together in these cells.

FIGURE 26.2 Glycogenolysis in skeletal muscle and liver. Glycogen stores serve different functions in muscle cells and liver. In the muscle and most other cell types, glycogen stores serve as a fuel source for the generation of adenosine triphosphate (ATP). In the liver, glycogen stores serve as a source of blood glucose.

Glycogen serves a very different purpose in liver than in skeletal muscle and other tissues (see Fig. 26.2). Liver glycogen is the first and immediate source of glucose for the maintenance of blood glucose levels. In the liver, the glucose 6-phosphate that is generated from glycogen degradation is hydrolyzed to glucose by **glucose 6-phosphatase**, an enzyme that is present only in the liver and kidneys. Glycogen degradation thus provides a readily mobilized source of blood glucose as dietary glucose decreases or as exercise increases the utilization of blood glucose by muscles.

The pathways of glycogenolysis and gluconeogenesis in the liver both supply blood glucose, and, consequently, these two pathways are activated together by glucagon. Gluconeogenesis, the synthesis of glucose from amino acids and other gluconeogenic precursors (discussed in detail in Chapter 28), also forms glucose 6-phosphate, so that glucose 6-phosphatase serves as a “gateway” to the blood for both pathways (see Fig. 26.2).

Regulation of glycogen synthesis serves to prevent futile cycling and waste of ATP. Futile cycling (or substrate cycling) refers to a situation in which a substrate is converted to a product through one pathway, and the product is converted back to the substrate through another pathway. Because the biosynthetic pathway is energy requiring, futile cycling results in a waste of high-energy phosphate bonds. Thus, glycogen synthesis is activated when glycogen degradation is inhibited, and vice versa.

III. Synthesis and Degradation of Glycogen

Glycogen synthesis, like almost all the pathways of glucose metabolism, begins with the phosphorylation of glucose to glucose 6-phosphate by hexokinase or, in the liver, glucokinase (Fig. 26.3). Glucose 6-phosphate is the precursor of glycolysis, the pentose phosphate pathway, and pathways for the synthesis of other sugars. In the pathway for glycogen synthesis, glucose 6-phosphate is converted to glucose 1-phosphate by phosphoglucomutase, a reversible reaction.

FIGURE 26.3 Scheme of glycogen synthesis and degradation. (S1) Glucose 6-phosphate is formed from glucose by hexokinase in most cells, and glucokinase in the liver. It is a metabolic branch point for the pathways of glycolysis, the pentose phosphate pathway, and glycogen synthesis. (S2) UDP-glucose (UDP-G) is synthesized from glucose 1-phosphate. UDP-glucose is the branch point for glycogen synthesis and other pathways that require the addition of carbohydrate units. (S3) Glycogen synthesis is catalyzed by glycogen synthase and the branching enzyme. (D1) Glycogen degradation is catalyzed by glycogen phosphorylase and a debrancher enzyme. (D2) Glucose 6-phosphatase in the liver (and, to a small extent, the kidney) generates free glucose from glucose 6-phosphate. ATP, adenosine triphosphate; P_i , inorganic phosphate; PP_i , pyrophosphate; UTP, uridine triphosphate.

Glycogen is both formed from and degraded to glucose 1-phosphate, but the biosynthetic and degradative pathways are separate and involve different enzymes (see Fig. 26.3). The biosynthetic pathway is an energy-requiring pathway; high-energy phosphate from UTP is used to activate the glucosyl residues to UDP-glucose (Fig. 26.4). In the degradative pathway, the glycosidic bonds between the glucosyl residues in glycogen are simply cleaved by the addition of phosphate to produce glucose 1-phosphate (or water to produce free glucose), and UDP-glucose is not resynthesized. The existence of separate pathways for the formation and degradation of

important compounds is a common theme in metabolism. Because the synthesis and degradation pathways use different enzymes, one can be activated while the other is inhibited.

FIGURE 26.4 Formation of UDP-glucose. The high-energy phosphate bond of UTP provides the energy for the formation of a high-energy bond in UDP-glucose. Pyrophosphate (PP_i), released by the reaction, is cleaved to two inorganic phosphate (P_i).

A. Glycogen Synthesis

Glycogen synthesis requires the formation of α -1,4-glycosidic bonds to link glucosyl residues in long chains and the formation of an α -1,6-branch every 8 to 10 residues (Fig. 26.5). Most of glycogen synthesis occurs through the lengthening of the polysaccharide chains of a pre-existing glycogen molecule (a glycogen primer) in which the reducing end of the glycogen is attached to the protein glycogenin. To lengthen the glycogen chains, glucosyl residues are added from UDP-glucose to the nonreducing ends of the chain by glycogen synthase. The anomeric carbon of each glucosyl residue is attached in an α -1,4-bond to the hydroxyl on carbon 4 of the terminal glucosyl residue. When the chain reaches approximately 11 residues in length, a 6- to 8-residue piece is cleaved by amylo-4:6-transferase (also known as branching enzyme) and reattached to a glucosyl unit by an α -1,6-bond. Both chains continue to lengthen until they are long enough to produce two new branches. This process continues, producing highly branched molecules. **Glycogen synthase**, the enzyme that attaches the glucosyl residues in α -1,4-bonds, is the regulated step in the pathway. Branching of glycogen serves two major roles: increased sites for synthesis and degradation and enhancing the solubility of the molecule.

FIGURE 26.5 Glycogen synthesis. See text for details. UDP, uridine diphosphate.

The synthesis of new glycogen primer molecules also occurs. Glycogenin, the protein to which glycogen is attached, glycosylates itself (autoglycosylation) by attaching the glucosyl residue of UDP-glucose to the hydroxyl side chain of a serine residue in the protein. The protein then extends the carbohydrate chain (using UDP-glucose as the substrate) until the glucosyl chain is long enough to serve as a substrate for glycogen synthase.

B. Glycogen Degradation

Glycogen is degraded by two enzymes, **glycogen phosphorylase** and the **debrancher enzyme** (Fig. 26.6). Glycogen degradation is a phosphorolysis reaction (breaking of a bond using a phosphate ion as a nucleophile). Enzymes that catalyze phosphorolysis reactions are named phosphorylase. Because more than one type of phosphorylase exists, the substrate usually is included in the name of the enzyme, such as glycogen phosphorylase or purine nucleoside phosphorylase.

○ } Glucose residue

◇ } linked α -1,4

● Glucose residue
linked α -1,6

FIGURE 26.6 Glycogen degradation. See text for details. P_i, inorganic phosphate.

The enzyme glycogen phosphorylase starts at the nonreducing end of a chain and successively cleaves glucosyl residues by adding phosphate to the anomeric carbon of the terminal glycosidic bond, thereby releasing glucose 1-phosphate and producing a free 4'-hydroxyl group on the glucose residue now at the end of the glycogen chain. However, glycogen phosphorylase cannot act on the glycosidic bonds of the four glucosyl residues closest to a branch point because the branching chain sterically hinders a proper fit into the catalytic site of the enzyme. The debrancher enzyme, which catalyzes the removal of the four residues closest to the branch point, has two catalytic activities: it acts as a transferase and as an α -1,6-glucosidase. As a transferase, the debrancher first removes a unit containing three glucose residues and adds it to the end of a longer chain by an α -1,4-glycosidic bond. The one glucosyl residue remaining at the α -1,6-branch is hydrolyzed by the amylo-1,6-glucosidase activity of the debrancher, resulting in the release of free glucose. Thus, one glucose and approximately seven to nine glucose 1-phosphate residues are released for every branch point.

Some degradation of glycogen also occurs within lysosomes when glycogen particles become surrounded by membranes that then fuse with the lysosomal membranes. A lysosomal α -glucosidase hydrolyzes this glycogen to glucose.

To confirm a diagnosis of phosphorylase deficiency (in either muscle or liver) DNA testing can be performed or a biopsy can be obtained, followed by a sensitive assay for phosphorylase activity within the biopsied tissue. There are a number of procedures to do this. The first is to incubate glycogen, inorganic phosphate, and a sample of the extracted biopsy tissue. If phosphorylase activity is present, glucose 1-phosphate will be produced. One can determine the amount of glucose 1-phosphate produced by converting it to glucose 6-phosphate (G6P), using the enzyme phosphoglucomutase. The G6P levels are then measured by the conversion of G6P to 6-phosphogluconate using the enzyme G6P dehydrogenase. G6P dehydrogenase requires NADP⁺, generating NADPH during the course of the reaction. The formation of NADPH can be followed spectrophotometrically as the absorbance at 340 nm will increase as NADPH is produced, and the increase in NADPH levels will be directly proportional to the amount of glucose 1-phosphate produced by phosphorylase. A second assay to measure phosphorylase activity utilizes radioactive glycogen as a substrate. The labeled glycogen is incubated with inorganic phosphate and sample extract, generating labeled glucose 1-phosphate. The radioactive glucose 1-phosphate is then separated from the glycogen and measured. A variation of this method is to use ³²P-labeled inorganic phosphate and measure the radioactive glucose 1-phosphate produced. A third assay for phosphorylase activity is to measure the reverse reaction (glycogen synthesis). Under appropriate conditions, the phosphorylase reaction can go backward, in which the glucose residue from glucose 1-phosphate is added to an existing glycogen chain, releasing inorganic phosphate. The phosphate produced, using this method, is then measured in a sensitive spectrophotometric assay.

Why do you think that a genetic deficiency in muscle glycogen phosphorylase (McArdle disease) is a mere inconvenience, whereas a deficiency of liver glycogen phosphorylase (Hers disease) can be lethal?

IV. Disorders of Glycogen Metabolism

A series of inborn errors of metabolism, the glycogen storage diseases, result from deficiencies in the enzymes of glycogenolysis (Table 26.1). The diseases are labeled I through XI, and O. Several disorders have different subtypes, as indicated in the legend to Table 26.1. Glycogen phosphorylase, the key regulatory enzyme of glycogen degradation, is encoded by different genes in the muscle and liver (tissue-specific isozymes), and thus a person may have a defect in one and not the other.

TABLE 26.1 Glycogen Storage Diseases

TYPE	ENZYME AFFECTED (GENE)	PRIMARY ORGAN INVOLVED	MANIFESTATIONS ^a
O	Glycogen synthase (GYS2)	Liver	Hypoglycemia, hyperketonemia, failure to thrive, early death
I ^b	Glucose 6-phosphatase (Von Gierke disease) (G6PC)	Liver	Enlarged liver and kidney, growth failure, severe fasting hypoglycemia, acidosis, lipemia, thrombocyte dysfunction
II	Lysosomal α -glucosidase (Pompe disease): may see clinical symptoms in childhood, juvenile, or adult life stages, depending on the nature of the mutation (GAA)	All organs with lysosomes	Infantile form: early-onset progressive muscle hypotonia, cardiac failure, death before age 2 years. Juvenile form: later-onset myopathy with variable cardiac involvement. Adult form: limb-girdle muscular dystrophy-like features. Glycogen deposits accumulate in lysosomes

III	Amylo-1,6-glucosidase (debrancher): form IIIa is the liver and muscle enzymes, form IIIb is a liver-specific form, and IIIc a muscle-specific form (AGL)	Liver, skeletal muscle, heart	Fasting hypoglycemia; hepatomegaly in infancy and some myopathic features. Glycogen deposits have short outer branches
IV	Amylo-4,6-glucosidase (branching enzyme) (Andersen disease) (GBE1)	Liver	Hepatosplenomegaly; symptoms may arise from a hepatic reaction to the presence of a foreign body (glycogen with long outer branches). Usually fatal
V	Muscle glycogen phosphorylase (McArdle disease) (expressed as either adult or infantile form) (PYGM)	Skeletal muscle	Exercise-induced muscular pain, cramps, and progressive weakness, sometimes with myoglobinuria
VI	Liver glycogen phosphorylase (Her disease) (PYGL)	Liver	Hepatomegaly, mild hypoglycemia; good prognosis
VII	Phosphofructokinase-I (Tarui syndrome) (PFKM)	Muscle, red blood cells	As in type V; in addition, enzymopathic hemolysis
IX ^c	Phosphorylase kinase (PHKA2; PHKB; PHKG2; PHKA1)	Liver and muscle	Similar to type VI for liver-specific subunits; muscle fatigue for muscle-specific subunits
X ^d	Phosphoglycerate mutase (PGAM2)	Muscle	Similar to type V
XII	Aldolas A (ALDOA)	Liver, red blood cells	Hepatosplenomegaly, hemolytic anemia

^aAll of these diseases except type O are characterized by increased glycogen deposits.

^bGlucose 6-phosphatase is composed of several subunits that also transport glucose, glucose 6-phosphate, phosphate, and pyrophosphate across the endoplasmic reticulum membranes. Therefore, there are two major subtypes of this disease, corresponding to defects in the different subunits. Type Ia is a lack of glucose 6-phosphatase activity; type Ib is a lack of glucose 6-phosphate translocase activity (the SLC37A4 gene), which transfers glucose 6-phosphate from the cytosol to the endoplasmic reticulum, where glucose 6-phosphatase is located.

^cGlycogen storage disease IX consists of a variety of subtypes. (IXa is the α -subunit of hepatic phosphorylase kinase; IXb is the common β -subunit for both liver and muscle phosphorylase kinase; IXc is the liver-specific γ -subunit, while IXd is the muscle-specific α -subunit.)

^dGlycogen storage disease 11 is the muscle-specific subunit of lactate dehydrogenase (LDHA) with symptoms similar to GSD10; GSD13 is the muscle predominant form of enolase (ENO3), with symptoms similar to GSD10; and GSD15 is the muscle form of glycogenin (GYG1), with symptoms of muscle weakness and carbohydrate accumulation in the heart, leading to arrhythmias.

A genetic defect of lysosomal glucosidase, called type II glycogen storage disease, or Pompe disease, leads to the accumulation of glycogen particles in large, membrane-enclosed residual bodies, which disrupt the function of liver and muscle cells. The disorder can be treated with enzyme replacement therapy (myozyme), which requires periodic enzyme infusions for the life of the patient. In the absence of treatment, the disorder is fatal.

V. Regulation of Glycogen Synthesis and Degradation

The regulation of glycogen synthesis in different tissues matches the function of glycogen in each tissue. Liver glycogen serves principally for the support of blood glucose during fasting or during extreme need (e.g., exercise), and the degradative and biosynthetic pathways are regulated principally by changes in the insulin/glucagon ratio and by blood glucose levels, which reflect the availability of dietary glucose (Table 26.2). Degradation of liver glycogen is also activated by epinephrine, which is released in response to exercise, hypoglycemia, or other stressful situations in which there is an immediate demand for blood glucose. In contrast, in skeletal muscles, glycogen is a reservoir of glucosyl units for the generation of ATP from glycolysis and glucose oxidation. As a consequence, muscle glycogenolysis is regulated principally by AMP, which signals a lack of ATP, and by Ca^{2+} released during contraction. Epinephrine, which is released in response to exercise and other stress situations, also activates skeletal muscle glycogenolysis. The glycogen stores of resting muscle decrease very little during fasting.

TABLE 26.2 Regulation of Liver and Muscle Glycogen Stores

STATE	REGULATORS	RESPONSE OF TISSUE
<i>Liver</i>		
Fasting	Blood: Glucagon ↑	Glycogen degradation ↑
	Insulin ↓	Glycogen synthesis ↓
	Tissue: cAMP ↑	
Carbohydrate meal	Blood: Glucagon ↓	Glycogen degradation ↓
	Insulin ↑	Glycogen synthesis ↑
	Glucose ↑	
	Tissue: cAMP ↓	
Exercise and stress	Blood: Epinephrine ↑	Glycogen degradation ↑
	Tissue: cAMP ↑	Glycogen synthesis ↓
	Ca ²⁺ -calmodulin ↑	
<i>Muscle</i>		
Fasting (rest)	Blood: Insulin ↓	Glycogen synthesis ↓
		Glucose transport ↓
Carbohydrate meal (rest)	Blood: Insulin ↑	Glycogen synthesis ↑
		Glucose transport ↑
Exercise	Blood: Epinephrine ↑	Glycogen synthesis ↓
	Tissue: AMP ↑	Glycogen degradation ↑
	Ca ²⁺ -calmodulin ↑	Glycolysis ↑
	cAMP ↑	

↑, increased compared with other physiologic states; ↓, decreased compared with other physiologic states.

 Muscle glycogen is used within the muscle to support exercise. Thus, an individual with McArdle disease (type V glycogen storage disease) experiences no symptoms except unusual fatigue and muscle cramps during exercise. These symptoms may be accompanied by myoglobinuria and release of muscle creatine kinase into the blood. Liver glycogen is the first reservoir for the support of blood glucose levels, and a deficiency in glycogen phosphorylase or any of the other enzymes of liver glycogen degradation can result in fasting hypoglycemia. The hypoglycemia is usually mild because patients can still synthesize glucose from gluconeogenesis (see Table 26.1).

A. Regulation of Glycogen Metabolism in Liver

Liver glycogen is synthesized after a carbohydrate meal when blood glucose levels are elevated and degraded as blood glucose levels decrease. When an individual eats a carbohydrate-containing meal, blood glucose levels immediately increase, insulin levels increase, and glucagon levels decrease (see Fig. 19.8). The increase of blood glucose levels and the rise of the insulin/glucagon ratio inhibit glycogen degradation and stimulate glycogen synthesis. The immediately increased transport of glucose into peripheral tissues and storage of blood glucose as glycogen helps to bring circulating blood glucose levels back to the normal 70- to 100-mg/dL range of the fasted state. As the length of time after a carbohydrate-containing meal increases, insulin levels decrease, and glucagon levels increase. The fall of the insulin/glucagon ratio results in inhibition of the biosynthetic pathway and activation of the degradative pathway. As a result, liver glycogen is rapidly degraded to glucose, which is released into the blood.

 Maternal blood glucose readily crosses the placenta to enter the fetal circulation. During the last 9 or 10 weeks of gestation, glycogen formed from maternal glucose is deposited in the fetal liver under the influence of the insulin-dominated hormonal milieu of that period. At birth, maternal glucose supplies cease, causing a temporary physiologic drop in glucose levels in the newborn's blood, even in normal healthy infants. This drop serves as one of the signals for glucagon release from the newborn's pancreas, which, in turn, stimulates glycogenolysis. As a result, the glucose levels in the newborn return to normal.

Healthy full-term babies have adequate stores of liver glycogen to survive short periods (12 hours) of caloric deprivation provided other aspects of fuel metabolism are normal. Because **Gretchen C.**'s mother was markedly anorexic during the critical period when the fetal liver is normally synthesizing glycogen from glucose supplied in the maternal blood, **Gretchen**

C.'s liver glycogen stores were below normal. Thus, because fetal glycogen is the major source of fuel for the newborn in the early hours of life, **Gretchen C.** became profoundly hypoglycemic within 5 hours of birth because of her low levels of stored carbohydrate.

Although glycogenolysis and gluconeogenesis are activated together by the same regulatory mechanisms, glycogenolysis responds more rapidly, with a greater outpouring of glucose. A substantial proportion of liver glycogen is degraded within the first few hours after eating (30% after 4 hours) (Table 26.3). The rate of glycogenolysis decreases significantly in a prolonged fast as the liver glycogen supplies dwindle. Liver glycogen stores are therefore a rapidly rebuilt and degraded store of glucose, ever responsive to small and rapid changes of blood glucose levels.

TABLE 26.3 Effect of Fasting on Liver Glycogen Content in the Human

LENGTH OF FAST (h)	GLYCOGEN CONTENT ($\mu\text{mol/g}$ liver)	RATE OF GLYCOGENOLYSIS ($\mu\text{mol/kg}\cdot\text{min}$)
0	300	—
2	260	4.3
4	216	4.3
24	42	1.7
64	16	0.3

 A patient was diagnosed as an infant with type III glycogen storage disease, a deficiency of debrancher enzyme (see Table 26.1). The patient had hepatomegaly (an enlarged liver) and experienced bouts of mild hypoglycemia. To diagnose the disease, glycogen was obtained from the patient's liver by biopsy after the patient had fasted overnight and compared with normal glycogen. The glycogen samples were treated with a preparation of commercial glycogen phosphorylase and commercial debrancher enzyme. The amounts of glucose 1-phosphate and glucose produced in the assay were then measured. The ratio of glucose 1-phosphate to glucose for the normal glycogen sample was 9:1, and the ratio for the patient was 3:1. Can you explain these results?

1. Nomenclature of Enzymes Metabolizing Glycogen

Both glycogen phosphorylase and glycogen synthase will be covalently modified to regulate their activity. When activated by covalent modification, glycogen phosphorylase is referred to as **glycogen phosphorylase a** (remember **a** for active); when the covalent modification is removed and the enzyme is inactive, it is referred to as **glycogen phosphorylase b**. Glycogen synthase, when it is not covalently modified, is active, and can be designated **glycogen synthase a** or **glycogen synthase I** (the **I** stands for independent of modifiers for activity). When glycogen synthase is covalently modified, it is inactive, in the form of **glycogen synthase b** or **glycogen synthase D** (for dependent on a modifier for activity).

 With a deficiency of debrancher enzyme but normal levels of glycogen phosphorylase, the glycogen chains of the patient could be degraded in vivo only to within four residues of the branch point. When the glycogen samples were treated with the commercial preparation containing normal enzymes, one glucose residue was released for each α -1,6-branch. However, in the patient's glycogen sample, with the short outer branches, three glucose 1-phosphates and one glucose residue were obtained for each α -1,6-branch. Normal glycogen has 8 to 10 glucosyl residues per branch and thus gives a ratio of approximately 9 mol glucose 1-phosphate to 1 mol glucose.

2. Regulation of Liver Glycogen Metabolism by Insulin and Glucagon

Insulin and glucagon regulate liver glycogen metabolism by changing the phosphorylation state of glycogen phosphorylase in the degradative pathway and glycogen synthase in the biosynthetic pathway. An increase of glucagon and decrease of insulin during the fasting state initiates a cAMP-directed phosphorylation cascade, which results in the phosphorylation of glycogen phosphorylase to an active enzyme and the phosphorylation of glycogen synthase to an inactive enzyme (Fig. 26.7). As a consequence, glycogen degradation is stimulated, and glycogen synthesis is inhibited.

FIGURE 26.7 Regulation of glycogen synthesis and degradation in the liver. (1) Glucagon binding to the serpentine glucagon receptor or epinephrine binding to a serpentine β -receptor in the liver activates adenylate cyclase, via G-proteins, which synthesizes cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). (2) cAMP binds to protein kinase A (cAMP-dependent protein kinase), thereby activating the catalytic subunits. (3) Protein kinase A activates phosphorylase kinase by phosphorylation. (4) Phosphorylase kinase adds a phosphate to specific serine residues on glycogen phosphorylase b, thereby converting it to the active glycogen phosphorylase a. (5) Protein kinase A also phosphorylates glycogen synthase, thereby decreasing its activity. (6) As a result of the inhibition of glycogen synthase and the activation of glycogen phosphorylase, glycogen is degraded to glucose 1-phosphate. The *red dashed lines* denote reactions that are decreased in the livers of fasting individuals. ADP, adenosine diphosphate; GTP, guanosine triphosphate; P_i , inorganic phosphate; UDP, uridine diphosphate.

3. Activation of a Phosphorylation Cascade by Glucagon

Glucagon regulates glycogen metabolism through its intracellular second messenger cAMP and protein kinase A (see Chapter 19). Glucagon, by binding to its cell membrane receptor, transmits a signal through G-proteins that activates adenylate cyclase, causing cAMP levels to increase (see Fig. 26.7). cAMP binds to the regulatory subunits of protein kinase A, which dissociate from the catalytic subunits. The catalytic subunits of protein kinase A are activated by the dissociation and phosphorylate the enzyme phosphorylase kinase, activating it. Phosphorylase kinase is the protein kinase that converts the inactive liver glycogen phosphorylase b to the active glycogen phosphorylase a by transferring a phosphate from ATP to a specific serine residue on the phosphorylase subunits. The addition of the phosphate triggers a conformational change in the enzyme, thereby activating it. As a result of the activation of glycogen phosphorylase, glycogenolysis is stimulated.

4. Inhibition of Glycogen Synthase by Glucagon-Directed Phosphorylation

When glycogen degradation is activated by the cAMP-stimulated phosphorylation cascade, glycogen synthesis is simultaneously inhibited. The enzyme glycogen synthase is also phosphorylated by protein kinase A, but this

phosphorylation results in a less active form, glycogen synthase b.

The phosphorylation of glycogen synthase is far more complex than glycogen phosphorylase. Glycogen synthase has multiple phosphorylation sites and is acted on by up to 10 different protein kinases. Phosphorylation by protein kinase A does not, by itself, inactivate glycogen synthase. Instead, phosphorylation by protein kinase A facilitates the subsequent addition of phosphate groups by other kinases, and these inactivate the enzyme. A term that has been applied to changes of activity resulting from multiple phosphorylations is “hierarchical” or “synergistic” phosphorylation; the phosphorylation of one site makes another site more reactive and easier to phosphorylate by a different protein kinase.

Most of the enzymes that are regulated by phosphorylation have multiple phosphorylation sites. Glycogen phosphorylase, which has only one serine per subunit and can be phosphorylated only by phosphorylase kinase, is the exception. For some enzymes, the phosphorylation sites are antagonistic, and phosphorylation initiated by one hormone counteracts the effects of other hormones. For other enzymes, the phosphorylation sites are synergistic, and phosphorylation at one site stimulated by one hormone can act synergistically with phosphorylation at another site.

5. Regulation by Protein Phosphatases

At the same time that protein kinase A and phosphorylase kinase are adding phosphate groups to enzymes, the protein phosphatases that remove this phosphate are inhibited. Protein phosphatases remove the phosphate groups, bound to serine or other residues of enzymes, by hydrolysis. Hepatic protein phosphatase 1 (hepatic PP-1), one of the major protein phosphatases involved in glycogen metabolism, removes phosphate groups from phosphorylase kinase, glycogen phosphorylase, and glycogen synthase. During fasting, hepatic PP-1 is inactivated by several mechanisms. One is dissociation from the glycogen particle, such that the substrates are no longer available to the phosphatase. A second is the binding of inhibitor proteins, such as the protein called **inhibitor-1**, which, when phosphorylated by a glucagon (or epinephrine)-directed mechanism, binds to and inhibits phosphatase action. Insulin indirectly activates hepatic PP-1 through its own signal transduction cascade initiated at the insulin-receptor tyrosine kinase.

Protein phosphatase 1 will bind to proteins that target the phosphatase to glycogen particles. There are four such targeting proteins: G_M , G_L , R6, and R5/PTG (protein targeting to glycogen). G_M is found in the heart and skeletal muscle, G_L is found primarily in the liver, while R5/PTG and R6 are found in most tissues. The targeting subunits all bind to the same hydrophobic site on PP-1, leading to just one targeting subunit bound per PP-1 molecule. The targeting subunits allow for compartmentalized activation of PP-1 under the appropriate conditions, whereas other tissues, or cellular compartments, may still express an inhibited PP-1. Regulation of the phosphatase involves complex interactions between the target enzymes, the targeting subunits, the phosphatase, and protein inhibitor 1, and will not be considered further.

Most of the enzymes that are regulated by phosphorylation also can be converted to the active conformation by allosteric effectors. Glycogen synthase b, the less active form of glycogen synthase, can be activated by the accumulation of glucose 6-phosphate above physiological levels. The activation of glycogen synthase by glucose 6-phosphate may be important in individuals with glucose 6-phosphatase deficiency, a disorder known as type I or von Gierke glycogen storage disease (see Table 26.1). When glucose 6-phosphate produced from gluconeogenesis accumulates in the liver, it activates glycogen synthesis even though the individual may be hypoglycemic and have low insulin levels. Glucose 1-phosphate is also elevated, resulting in the inhibition of glycogen phosphorylase. As a consequence, large glycogen deposits accumulate in certain tissues, including the liver, and hepatomegaly occurs.

6. Insulin in Liver Glycogen Metabolism

Insulin is antagonistic to glucagon in the degradation and synthesis of glycogen. The glucose level in the blood is the signal that controls the secretion of insulin and glucagon. Glucose stimulates insulin release and suppresses glucagon release; after a high-carbohydrate meal, one increases while the other decreases. However, insulin levels in the blood change to a greater degree with the fasting–feeding cycle than do the glucagon levels, and thus insulin is considered the principal regulator of glycogen synthesis and degradation. The role of insulin in glycogen metabolism is often overlooked because the mechanisms by which insulin reverses all of the effects of glucagon on individual metabolic enzymes is still under investigation. In addition to the activation of hepatic PP-1 through the insulin-receptor tyrosine kinase phosphorylation cascade, insulin may activate the phosphodiesterase that converts cAMP to AMP, thereby decreasing cAMP levels and inactivating protein kinase A. Regardless of the mechanisms involved, insulin is able to reverse all of the effects of glucagon and is the most important hormonal regulator of blood glucose levels.

An inability of liver and muscle to store glucose as glycogen contributes to the hyperglycemia in patients, such as **Dianna** with type 1 diabetes mellitus and in patients, such as **Deborah S.**, with type 2 diabetes mellitus. The absence of insulin in type 1 diabetes mellitus patients and the high levels of glucagon result in decreased activity of glycogen synthase. Glycogen synthesis in skeletal muscles of type 1 patients is also limited by the lack of insulin-stimulated glucose transport. Insulin resistance in type 2 patients has the same effect.

An injection of insulin suppresses glucagon release and alters the insulin/glucagon ratio. The result is rapid uptake of glucose into skeletal muscle and rapid conversion of glucose to glycogen in skeletal muscle and liver.

7. Blood Glucose Levels and Glycogen Synthesis and Degradation

When an individual eats a high-carbohydrate meal, glycogen degradation immediately stops. Although the changes in insulin and glucagon levels are relatively rapid (10 to 15 minutes), the direct inhibitory effect of rising glucose levels on glycogen degradation is even more rapid. Glucose, as an allosteric effector, inhibits liver glycogen phosphorylase a by stimulating dephosphorylation of this enzyme. As insulin levels rise and glucagon levels fall, cAMP levels decrease and protein kinase A reassociates with its inhibitory subunits and becomes inactive. The protein phosphatases are activated, and phosphorylase a and glycogen synthase D are dephosphorylated. The collective result of these effects is rapid inhibition of glycogen degradation, and rapid activation of glycogen synthesis.

8. Epinephrine and Calcium in the Regulation of Liver Glycogen

Epinephrine, the fight-or-flight hormone, is released from the adrenal medulla in response to neural signals reflecting an increased demand for glucose. To flee from a dangerous situation, skeletal muscles use increased amounts of blood glucose to generate ATP. As a result, liver glycogenolysis must be stimulated. In the liver, epinephrine stimulates glycogenolysis through two different types of receptors, the α - and β -agonist receptors.

a. Epinephrine Acting at β -Receptors

Epinephrine, acting at the β -receptors, transmits a signal through G-proteins to adenylate cyclase, which increases cAMP and activates protein kinase A. Hence, regulation of glycogen degradation and synthesis in liver by epinephrine and glucagon are similar (see Fig. 26.7).

In the neonate, the release of epinephrine during labor and birth normally contributes to restoring blood glucose levels. Unfortunately, **Gretchen C.** did not have adequate liver glycogen stores to support a rise in her blood glucose levels.

b. Epinephrine Acting at α -Receptors

Epinephrine also binds to α -receptors in the hepatocyte. This binding activates glycogenolysis and inhibits glycogen synthesis principally by increasing the Ca^{2+} levels in the liver. The effects of epinephrine at the α -agonist receptor are mediated by the phosphatidylinositol biphosphate (PIP_2)- Ca^{2+} signal transduction system, one of the principal intracellular second messenger systems employed by many hormones (Fig. 26.8) (see Chapter 10).

FIGURE 26.8 Regulation of glycogen synthesis and degradation by epinephrine and Ca^{2+} . (1) The effect of epinephrine binding to α -agonist receptors in liver transmits a signal via G-proteins to phospholipase C, which hydrolyzes phosphatidylinositol bisphosphate (PIP_2) to diacylglycerol (DAG) and IP_3 . (2) IP_3 stimulates the release of Ca^{2+} from the endoplasmic reticulum. (3) Ca^{2+} binds to the modifier protein calmodulin, a subunit of a calmodulin-dependent protein kinase, as well as the calmodulin subunit of phosphorylase kinase, which activates both kinases. Both Ca^{2+} and DAG activate protein kinase C. (4) These three kinases phosphorylate glycogen synthase at different sites and decrease its activity. (5) Phosphorylase kinase phosphorylates glycogen phosphorylase b to the active form. It therefore activates glycogenolysis as well as inhibiting glycogen synthesis. GTP, guanosine triphosphate.

In the PIP_2 - Ca^{2+} signal transduction system, the signal is transferred from the epinephrine receptor to membrane-bound phospholipase C by G-proteins. Phospholipase C hydrolyzes PIP_2 to form diacylglycerol (DAG) and inositol trisphosphate (IP_3). IP_3 stimulates the release of Ca^{2+} from the endoplasmic reticulum. Ca^{2+} and DAG activate protein kinase C. The amount of calcium bound to one of the calcium-binding proteins, calmodulin, is also increased.

Calcium/calmodulin associates as a subunit with a number of enzymes and modifies their activities. Calmodulin is a subunit of phosphorylase kinase, and when it binds calcium the enzyme is partially activated (full activity requires both calcium binding and phosphorylation by protein kinase A). Phosphorylase kinase then phosphorylates glycogen phosphorylase b, thereby activating glycogen degradation. Calcium/calmodulin is also a modifier protein that activates one of the glycogen synthase kinases (calcium/calmodulin synthase kinase). Protein kinase C, calcium/calmodulin synthase kinase, and phosphorylase kinase all phosphorylate glycogen synthase at different serine residues on the enzyme, thereby inhibiting glycogen synthase and thus glycogen synthesis.

The effect of epinephrine in the liver, therefore, enhances or is synergistic with the effects of glucagon. Epinephrine release during bouts of hypoglycemia or during exercise can stimulate hepatic glycogenolysis and inhibit glycogen synthesis very rapidly.

B. Regulation of Glycogen Synthesis and Degradation in Skeletal Muscle

The regulation of glycogenolysis in skeletal muscle is related to the availability of ATP for muscular contraction. Skeletal muscle glycogen produces glucose 1-phosphate and a small amount of free glucose. Glucose 1-phosphate is converted to glucose 6-phosphate, which is committed to the glycolytic pathway; the absence of glucose 6-phosphatase in skeletal muscle prevents the conversion of the glucosyl units from glycogen to blood glucose. Skeletal muscle glycogen is therefore degraded only when the demand for ATP

generation from glycolysis is high. The highest demands occur during anaerobic glycolysis, which requires more moles of glucose for each ATP produced than oxidation of glucose to CO₂ (see Chapter 24). Anaerobic glycolysis occurs in tissues that have fewer mitochondria, a higher content of glycolytic enzymes, and higher levels of glycogen, or fast-twitch glycolytic fibers. It occurs most frequently at the onset of exercise—before vasodilation occurs to bring in blood-borne fuels. The regulation of skeletal muscle glycogen degradation therefore must respond very rapidly to the need for ATP, indicated by the increase in AMP.

The regulation of skeletal muscle glycogen synthesis and degradation differs from that in liver in several important respects:

1. Glucagon has no effect on muscle, and thus glycogen levels in muscle do not vary with the fasting/feeding state.
2. AMP is an allosteric activator of the muscle isozyme of glycogen phosphorylase, but not liver glycogen phosphorylase (Fig. 26.9).

FIGURE 26.9 Activation of muscle glycogen phosphorylase during exercise. Glycogenolysis in skeletal muscle is initiated by muscle contraction, neural impulses, and epinephrine. (1) Adenosine monophosphate (AMP) produced from the degradation of adenosine triphosphate (ATP) during muscular contraction allosterically activates glycogen phosphorylase b. (2) The neural impulses that initiate contraction release Ca²⁺ from the sarcoplasmic reticulum. The Ca²⁺ binds to calmodulin, which is a subunit of phosphorylase kinase, leading to the activation of phosphorylase kinase. (3) Phosphorylase kinase is also activated through phosphorylation by protein kinase A. The formation of cyclic AMP (cAMP) and the resultant activation of protein kinase A are initiated by the binding of epinephrine to plasma membrane receptors. ADP, adenosine diphosphate; P_i, inorganic phosphate.

3. The effects of Ca²⁺ in muscle result principally from the release of Ca²⁺ from the sarcoplasmic reticulum after neural stimulation and not from epinephrine-stimulated uptake.
4. Glucose is not a physiological inhibitor of glycogen phosphorylase a in muscle.
5. Glycogen is a stronger feedback inhibitor of muscle glycogen synthase than of liver glycogen synthase, resulting in a smaller amount of stored glycogen per gram weight of muscle tissue.

However, the effects of epinephrine-stimulated phosphorylation by protein kinase A on skeletal muscle glycogen degradation and glycogen synthesis are similar to those occurring in liver (see Fig. 26.7).

Muscle glycogen phosphorylase is a genetically distinct isoenzyme of liver glycogen phosphorylase and contains an amino acid sequence that has a purine nucleotide-binding site. When AMP binds to this site, it changes the conformation at the catalytic site to a structure very similar to that in the phosphorylated enzyme. Thus, hydrolysis of ATP to ADP and the consequent increase of AMP generated by adenylate kinase during muscular contraction can directly stimulate glycogenolysis to provide fuel for the glycolytic pathway. AMP also stimulates glycolysis by activating phosphofructokinase 1, so this one effector activates both glycogenolysis and glycolysis. The activation of the calcium/calmodulin subunit of phosphorylase kinase by the Ca^{2+} released from the sarcoplasmic reticulum during muscle contraction also provides a direct and rapid means of stimulating glycogen degradation.

Jim B. gradually regained consciousness with continued infusions of high-concentration glucose titrated to keep his serum glucose level between 120 and 160 mg/dL. Although he remained somnolent and moderately confused over the next 12 hours, he was eventually able to tell his physicians that he had self-injected approximately 25 units of regular (short-acting) insulin every 6 hours while eating a high-carbohydrate diet for the last 2 days preceding his seizure. Normal subjects under basal conditions secrete an average of 40 U of insulin daily. He had last injected insulin just before exercising. An article in a bodybuilding magazine that he had read recently cited the anabolic effects of insulin on increasing muscle mass. He had purchased the insulin and necessary syringes from the same underground drug source from whom he regularly bought his anabolic steroids.

Normally, muscle glycogenolysis supplies the glucose required for the kinds of high-intensity exercise that require anaerobic glycolysis, such as weightlifting. **Jim B.**'s treadmill exercise also uses blood glucose, which is supplied by liver glycogenolysis. The high serum insulin levels, resulting from the injection he gave himself just before his workout, activated both glucose transport into skeletal muscle and glycogen synthesis, while inhibiting glycogen degradation. His exercise, which would continue to use blood glucose, could normally be supported by breakdown of liver glycogen. However, glycogen synthesis in his liver was activated, and glycogen degradation was inhibited by the insulin injection.

CLINICAL COMMENTS

Gretchen C.'s hypoglycemia illustrates the importance of glycogen stores in the neonate. At birth, the fetus must make two major adjustments in the way fuels are used: it must adapt to using a greater variety of fuels than were available in utero, and it must adjust to intermittent feeding. In utero, the fetus receives a relatively constant supply of glucose from the maternal circulation through the placenta, producing a level of glucose in the fetus that approximates 75% of maternal blood levels. With regard to the hormonal regulation of fuel utilization in utero, fetal tissues function in an environment dominated by insulin, which promotes growth. During the last 10 weeks of gestation, this hormonal milieu leads to glycogen formation and storage. At birth, the infant's diet changes to one containing greater amounts of fat and lactose (galactose and glucose in equal ratio), presented at intervals rather than in a constant fashion. At the same time, the neonate's need for glucose is relatively larger than that of the adult because the newborn's ratio of brain to liver weight is greater. Thus, the infant has even greater difficulty maintaining glucose homeostasis than the adult.

At the moment that the umbilical cord is clamped, the normal neonate is faced with a metabolic problem: The high insulin levels of late fetal existence must be quickly reversed to prevent hypoglycemia. This reversal is accomplished through the secretion of the counterregulatory hormones epinephrine and glucagon. Glucagon release is triggered by the normal decline of blood glucose after birth. The neural response that stimulates the release of both glucagon and epinephrine is activated by the anoxia, cord clamping, and tactile stimulation that are part of a normal delivery. These responses have been referred to as the "normal sensor function" of the neonate.

Within 3 to 4 hours of birth, these counterregulatory hormones reestablish normal serum glucose levels in the newborn's blood through their glycogenolytic and gluconeogenic actions. The failure of **Gretchen C.**'s normal "sensor function" was partly the result of maternal malnutrition, which resulted in an inadequate deposition of glycogen in **Gretchen C.**'s liver before birth. The consequence was a serious degree of postnatal hypoglycemia.

The ability to maintain glucose homeostasis during the first few days of life also depends on the activation of gluconeogenesis and the mobilization of fatty acids. Fatty acid oxidation in the liver not only promotes gluconeogenesis (see Chapter 28), it also generates ketone bodies. The neonatal brain has an enhanced capacity to use ketone bodies relative to that of infants (4-fold) and adults (40-fold). This ability is consistent with the

relatively high-fat content of breast milk.

Jim B. attempted to build up his muscle mass with androgens and with insulin. The anabolic (nitrogen-retaining) effects of androgens on skeletal muscle cells enhance muscle mass by increasing amino acid flux into muscle and by stimulating protein synthesis. Exogenous insulin has the potential to increase muscle mass by similar actions and also by increasing the content of muscle glycogen.

The most serious side effect of exogenous insulin administration is the development of severe hypoglycemia, such as occurred in **Jim B.**'s case. The immediate adverse effect relates to an inadequate flow of fuel (glucose) to the metabolizing brain. When hypoglycemia is extreme, the patient may suffer a seizure and, if the hypoglycemia worsens, irreversible brain damage may occur. If prolonged, the patient will lapse into a coma and die.

BIOCHEMICAL COMMENTS

Glycogen Synthase Kinase 3 (GSK-3). It should be clear that the regulation of glycogen metabolism is quite complex. Recent work has indicated that certain enzymes involved in regulating glycogen synthase activity also have far-reaching effects on other aspects of cell metabolism, such as cell structure, motility, growth, and survival.

The best example of this is glycogen synthase kinase 3 (GSK-3). The enzyme was first identified as being an inhibitor of glycogen synthase. GSK-3 refers to two isozymes, GSK-3 α and GSK-3 β . GSK-3 has been identified as a kinase that can phosphorylate >60 different proteins, including a large number of transcription factors. GSK-3 activity is also itself regulated by phosphorylation.

GSK-3 activity is reduced by phosphorylation of a serine residue near its amino terminal. PKA, Akt, casein kinase II (CKII), and protein kinase C can all catalyze this inhibitory phosphorylation event. GSK-3 is most active on protein substrates that have already been phosphorylated by other kinases (the substrates are said to be primed for further phosphorylation events). For example, GSK-3 will add phosphates to glycogen synthase but only after glycogen synthase had been phosphorylated by CKII.

GSK-3 binds to a number of proteins that sequester GSK-3 in certain pathways. This includes the Wnt signaling pathway, disruption of which is a significant component of colon cancer, the patched-smoothed signal transduction pathway (see Chapter 17), and the phosphorylation of microtubule-associated proteins, which leads to altered cell motility. Activation of GSK-3 has also been linked to apoptosis, although GSK-3 activity is also required for cell survival.

One of the effects of insulin is to phosphorylate GSK-3, via activation of Akt, rendering the GSK-3 inactive. Loss of activity of GSK-3 will lead to activation of glycogen synthase activity, and the pathways of energy storage. In animal models of type 2 diabetes, there is a loss of inhibitory control of GSK-3, leading to greater-than-normal GSK-3 activity, which antagonizes insulin action (promoting insulin resistance, a hallmark of type 2 diabetes). Studies in rats have shown that inhibitors of GSK-3 lowered blood glucose levels and stimulated glucose transport into muscles of insulin-resistant animals. Inappropriate stimulation of GSK-3 has also been implicated in Alzheimer disease.

Current research concerning GSK-3 is geared toward understanding all of the roles of GSK-3 in cell growth and survival, and to decipher its actions in the multitude of multiprotein complexes with which it is associated. Inhibitors of GSK-3 are being examined as possible agents to treat diabetes, but interpretation of results is difficult due to the multitude of roles GSK-3 plays within cells. It is possible that in the future such drugs will be available to treat type 2 diabetes.

KEY CONCEPTS

- ◆ Glycogen is the storage form of glucose, composed of glucosyl units linked by α -1,4-glycosidic bonds with α -1,6-branches occurring about every 8 to 10 glucosyl units.
- ◆ Glycogen synthesis requires energy.
- ◆ Glycogen synthase transfers a glucosyl residue from the activated intermediate UDP-glucose to the nonreducing ends of existing glycogen chains during glycogen synthesis. The branching enzyme creates α -1,6-linkages in the glycogen chain.

- ◆ Glycogenolysis is the degradation of glycogen. Glycogen phosphorylase catalyzes a phosphorolysis reaction, utilizing exogenous inorganic phosphate to break α -1,4-linkages at the ends of glycogen chains, releasing glucose 1-phosphate. The debranching enzyme hydrolyzes the α -1,6-linkages in glycogen, releasing free glucose.
- ◆ Liver glycogen supplies blood glucose.
- ◆ Glycogen synthesis and degradation are regulated in the liver by hormonal changes that signify either a deficiency of or an excess of blood glucose.
- ◆ Lack of dietary glucose, signaled by a decrease of the insulin/glucagon ratio, activates liver glycogenolysis and inhibits glycogen synthesis. Epinephrine also activates liver glycogenolysis.
- ◆ Glucagon and epinephrine release lead to phosphorylation of glycogen synthase (inactivating it) and glycogen phosphorylase (activating it).
- ◆ Glycogenolysis in muscle supplies glucose 6-phosphate for ATP synthesis in the glycolytic pathway.
- ◆ Muscle glycogen phosphorylase is allosterically activated by AMP, as well as by phosphorylation.
- ◆ Increases in sarcoplasmic Ca^{2+} stimulates phosphorylation of muscle glycogen phosphorylase.
- ◆ Diseases discussed in this chapter are summarized in Table 26.4.

TABLE 26.4 Diseases Discussed in Chapter 26

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Newborn hypoglycemia	Both	Poor maternal nutrition may lead to inadequate glycogen levels in the newborn, resulting in hypoglycemia during the early fasting period after birth, in addition to some genetic disorders affecting glycogen and gluconeogenesis.
Insulin overdose	Environmental	Insulin taken without carbohydrate ingestion will lead to severe hypoglycemia, due to stimulation of glucose uptake by peripheral tissues, leading to insufficient glucose in the circulation for proper functioning of the nervous system.
Glycogen storage diseases	Genetic	These have been summarized in Table 26.1. Affect storage and use of glycogen, with different levels of severity, from mild to fatal.

REVIEW QUESTIONS—CHAPTER 26

- Under conditions of glucagon release, the degradation of liver glycogen normally produces which one of the following?
 - More glucose than glucose 1-phosphate
 - More glucose 1-phosphate than glucose
 - Equal amounts of glucose and glucose 1-phosphate
 - Neither glucose nor glucose 1-phosphate
 - Only glucose 1-phosphate
- A patient has large deposits of liver glycogen, which, after an overnight fast, had shorter-than-normal branches. This abnormality could be caused by a defective form of which one of the following proteins or activities?
 - Glycogen phosphorylase
 - Glucagon receptor
 - Glycogenin
 - Amylo-1,6-glucosidase
 - Amylo-4,6-transferase
- An adolescent patient with a deficiency of muscle phosphorylase was examined while exercising her forearm by squeezing a rubber ball. Compared with a normal person performing the same exercise, this patient would exhibit which one of the following?
 - Exercise for a longer time without fatigue
 - Have increased glucose levels in blood drawn from her forearm
 - Have decreased lactate levels in blood drawn from her forearm
 - Have lower levels of glycogen in biopsy specimens from her forearm muscle

- E. Hyperglycemia
- In a glucose tolerance test, an individual in the basal metabolic state ingests a large amount of glucose. If the individual is normal, this ingestion should result in which one of the following?
 - An enhanced glycogen synthase activity in the liver
 - An increased ratio of glycogen phosphorylase a to glycogen phosphorylase b in the liver
 - An increased rate of lactate formation by red blood cells
 - An inhibition of protein phosphatase I activity in the liver
 - An increase of cAMP levels in the liver
 - Consider a type 1 diabetic who has neglected to take insulin for the past 72 hours and has not eaten much as well. Which one of the following best describes the activity level of hepatic enzymes involved in glycogen metabolism under these conditions?

	Glycogen Synthase	Phosphorylase Kinase	Glycogen Phosphorylase
A	Active	Active	Active
B	Active	Active	Inactive
C	Active	Inactive	Inactive
D	Inactive	Inactive	Inactive
E	Inactive	Active	Inactive
F	Inactive	Active	Active

- Assume that an individual carries a mutation in muscle protein kinase A such that the protein is refractory to high levels of cAMP. Glycogen degradation in the muscle would occur, then, under which one of the following conditions?
 - High levels of intracellular calcium
 - High levels of intracellular glucose
 - High levels of intracellular glucose 6-phosphate
 - High levels of intracellular glucose 1-phosphate
 - High levels of intracellular magnesium
- Without a steady supply of glucose to the bloodstream, a patient would become hypoglycemic, and if blood glucose levels get low enough, experience seizures or even a coma. Which one of the following is necessary for the maintenance of normal blood glucose?
 - Muscle glucose 6-phosphatase
 - Liver glucose 6-phosphatase
 - Glycogen in the heart
 - Glycogen in the brain
 - Glycogen in the muscle
- Glycogen is the storage form of glucose, and its synthesis and degradation is carefully regulated. Which one statement below correctly describes glycogen synthesis and/or degradation?
 - UDP-glucose is produced in both the synthesis and degradation of glycogen
 - Synthesis requires the formation of α -1,4 branches every 8 to 10 residues
 - Energy, in the form of ATP, is used to produce UDP-glucose
 - Glycogen is both formed from and degrades to glucose 1-phosphate
 - The synthesis and degradation of glycogen use the same enzymes, so are reversible processes
- Mutations in various enzymes can lead to the glycogen storage diseases. Which one statement is true of the glycogen storage diseases?

- A. All except type O are fatal in infancy or childhood
 - B. All except type O involve the liver
 - C. All except type O produce hepatomegaly
 - D. All except type O produce hypoglycemia
 - E. All except type O produce increased glycogen deposits
0. A 7.5-pound baby was delivered at 40 weeks gestation by normal spontaneous vaginal delivery. At one hour, the baby's blood glucose level was determined to be 50 mg/dL and at two hours postbirth was 80 mg/dL. These glucose numbers indicate which process listed below?
- A. Maternal malnutrition
 - B. Glycogen storage disease
 - C. Normal physiological change
 - D. Insulin was given to the baby
 - E. IV Dextrose 50 was given to the baby
1. A number of glycogen storage diseases result from mutations in glycolytic enzymes (such as phosphoglycerate mutase and enolase). Such mutations lead to enhanced glycogen deposition due to which one of the following?
- A. A stimulation of gluconeogenesis
 - B. Enhanced lactate formation, which activates glycogen synthase
 - C. An elevation of glucose 6-phosphate levels due to the glycolytic block
 - D. Enhanced glucose uptake due to the glycolytic block
 - E. Inhibition of glycogen phosphorylase due to the binding of glycolytic intermediates
2. An individual exhibits muscle cramping while exercising, and analysis of the blood indicates low lactate formation after vigorous exercise. This individual could have an inactivating mutation in which of the following enzymes? Choose the one best answer.

	Muscle PFK- I	Liver PFK- I	Muscle Glycogen Phosphorylase	Liver Glycogen Phosphorylase
A	Yes	No	Yes	Yes
B	Yes	Yes	No	No
C	Yes	No	Yes	No
D	No	Yes	No	Yes
E	No	No	Yes	No
F	No	Yes	No	Yes

Questions 13 and 14 are based on the following case: A person with type-1 diabetes injected themselves with pre-meal insulin but then got distracted and forgot to eat dinner. A few hours later, the person was sweating and fainted. The paramedics were called to help treat the patient.

3. Upon arrival, the paramedics injected the patient with which one of the following?
- A. Insulin
 - B. Cortisol
 - C. Dopamine
 - D. Glucagon
 - E. Iron
4. The patient fainted due to which one of the following?
- A. Stimulation of glycogenolysis in the liver

- B. Increased GLUT4 transporters in the membranes of muscle and adipose tissue
 - C. Increased GLUT2 transporters in the membranes of liver tissue
 - D. A stimulation of existing GLUT1 proteins in neurons
 - E. A reduction in number of existing GLUT1 proteins in neurons
5. Allosteric inactivation of liver glycogen phosphorylase occurs via which of the following molecules?
Choose the one best answer.

	Glucose	Glucose 6-Phosphate	Calcium Ion	cAMP
A	No	Yes	Yes	No
B	No	No	Yes	No
C	No	Yes	Yes	Yes
D	Yes	No	No	Yes
E	Yes	Yes	No	Yes
F	Yes	No	No	No

ANSWERS TO REVIEW QUESTIONS

1. **The answer is B.** Glycogen phosphorylase produces glucose 1-phosphate; the debranching enzyme hydrolyzes branch points and thus releases free glucose. Ninety percent of the glycogen contains α -(1,4)-bonds, and only 10% are α -(1,6)-bonds, so more glucose 1-phosphate will be produced than glucose.
2. **The answer is D.** If, after fasting, the branches were shorter than normal, glycogen phosphorylase must be functional and capable of being activated by glucagon (thus, A and B are incorrect). The branching enzyme (amylo-4,6-transferase) is also normal because branch points are present within the glycogen (thus, E is incorrect). Because glycogen is also present, glycogenin is present to build the carbohydrate chains, indicating that C is incorrect. If the debranching activity is abnormal (the amylo-1,6-glucosidase), glycogen phosphorylase would break the glycogen down up to four residues from branch points and would then stop. With no debranching activity, the resultant glycogen would contain the normal number of branches, but the branched chains would be shorter than normal.
3. **The answer is C.** The patient has McArdle disease, a glycogen storage disease caused by a deficiency of muscle glycogen phosphorylase. Because she cannot degrade glycogen to produce energy for muscle contraction, she becomes fatigued more readily than a normal person (thus, A is incorrect), the glycogen levels in her muscle will be higher than normal as a result of the inability to degrade them (thus, D is incorrect), and her blood lactate levels will be lower because of the lack of glucose for entry into glycolysis. She will, however, draw on the glucose in her circulation for energy, so her forearm blood glucose levels will be decreased (thus, B is incorrect), and because the liver is not affected, blood glucose levels can be maintained by liver glycogenolysis (thus, E is incorrect).
4. **The answer is A.** After ingestion of glucose, insulin levels rise, cAMP levels within the cell drop (thus, E is incorrect), and protein phosphatase I is activated (thus, D is incorrect). Glycogen phosphorylase is converted to glycogen phosphorylase b by the phosphatase (thus, B is incorrect), and glycogen synthase is activated by the phosphatase. Red blood cells continue to use glucose at their normal rate; thus lactate formation will remain the same (thus, C is incorrect).
5. **The answer is F.** In the absence of insulin, glucagon-stimulated activities predominate. This leads to the activation of protein kinase A, the phosphorylation and inactivation of glycogen synthase, the phosphorylation and activation of phosphorylase kinase, and the phosphorylation and activation of glycogen phosphorylase.
6. **The answer is A.** Calcium activates a calmodulin subunit in phosphorylase kinase, which will allow

phosphorylase kinase to phosphorylate, and activate, glycogen phosphorylase. Glucose is an allosteric inhibitor of glycogen phosphorylase a in liver but has no effect in muscle. Glucose 1-phosphate has no effect on muscle phosphorylase, whereas glucose 6-phosphate is an allosteric inhibitor of muscle glycogen phosphorylase a. The levels of magnesium have no effect on muscle glycogen phosphorylase activity. Normally, glucagon or epinephrine would activate the cAMP-dependent protein kinase, but this is not occurring under these conditions.

7. **The answer is B.** Glycogen in the liver provides glucose for the circulation. Glycogen in the heart, brain, or muscle cannot provide glucose for the circulation. In the liver, glucose 6-phosphatase hydrolyzes glucose 6-phosphate to glucose, which is released into the bloodstream. The liver generates glucose 6-phosphate from either glycogen degradation or gluconeogenesis. Muscle does not contain glucose 6-phosphatase.
8. **The answer is D.** Glycogen is both formed from and degrades to glucose 1-phosphate. A high-energy phosphate bond from UTP is required to produce UDP-glucose in glycogen synthesis but UDP-glucose is not resynthesized when glycogen is degraded. The pathways of glycogen synthesis and degradation utilize different enzymes and are not reversible reactions. In this way, the pathways can be regulated independently.
9. **The answer is E.** Type O glycogen storage disease is due to a reduced level of liver glycogen synthase activity, so in this disease, very little liver glycogen is formed so glycogen deposits would not be found in the liver. All of the other glycogen storage diseases are characterized by glycogen deposits. Not all are fatal, some are mild, and some have an adult-onset form. Some glycogen storage disorders involve the liver and whereas others involve the muscle. Only those involving the liver will produce hepatomegaly and hypoglycemia.
10. **The answer is C.** At birth, maternal glucose supply to the baby ceases, causing a temporary physiological drop in glucose even in normal healthy infants. This drop signals glycogenolysis in the newborn liver, returning the blood glucose to normal levels. Exogenous insulin would precipitously drop the blood glucose into hypoglycemic levels and an exogenous bolus of dextrose would raise blood glucose levels above normal levels. This physiological drop does not necessarily mean maternal malnutrition or evidence of a glycogen storage disease.
11. **The answer is C.** As glycolysis proceeds in cells with a mutation in a glycolytic enzyme the substrate for the defective enzyme will accumulate. As an example, if the defective enzyme is phosphoglycerate mutase (glycogen storage disease 10) 3-phosphoglycerate would accumulate, leading to the accumulation of glyceraldehyde 3-phosphate, dihydroxyacetone phosphate, and fructose 1,6-bisphosphate. The high levels of fructose 1,6-bisphosphate would block PFK-1 activity, and glucose 6-phosphate levels will accumulate. The increase in glucose 6-phosphate levels will allosterically activate glycogen synthase D, leading to excessive glycogen synthesis and deposition with the affected tissue. Since the defective glycolytic enzymes related to glycogen storage diseases are also required for gluconeogenesis, there would be an inhibition of gluconeogenesis, rather than a stimulation (answer choice A is incorrect). Since glycolysis is impaired, due to the mutation, lactate formation would be reduced, not enhanced (answer choice B is incorrect). The regulation of glucose transporters is not affected by the rate of glycolysis (answer choice D is incorrect). Glycogen phosphorylase is not regulated by glycolytic intermediates, rather by energy charge in the muscle, or glucose in the liver (answer choice E is incorrect).
12. **The answer is C.** The patient has a defect in metabolizing glucose to lactate in the muscle, so mutations in liver enzymes will not lead to a reduction in circulating lactate levels (so neither mutations in liver PFK-1 or liver glycogen phosphorylase can be correct). Defects in the muscle enzymes listed, PFK-1, or glycogen phosphorylase, would result in a reduced rate of glycolysis, and a reduction in lactate production. Mutations in either of those enzymes lead to a glycogen storage disease (type 5 for muscle glycogen phosphorylase, and type 7 for muscle PFK-1).
13. **The answer is D.** The patient has become severely hypoglycemic due to insulin stimulating glucose uptake into the muscle and fat cells, despite the patient not eating, and supplying the blood with dietary glucose. Since the individual has a high insulin:glucagon ratio after the injection, the liver is not exporting glucose, but is rather synthesizing glycogen and degrading glucose for fatty acid biosynthesis. A combination of the increased tissue uptake of glucose, the liver not exporting glucose, and the lack of dietary carbohydrates, has led to the severe hypoglycemia. Injecting glucagon can reverse the insulin:glucagon ratio, and allow the liver to export glucose to stabilize blood glucose levels. Injecting insulin will make the problem worse while injecting dopamine or cortisol or iron will not stimulate the liver to export glucose to manage the hypoglycemia.

14. **The answer is B.** The injection of insulin has stimulated the muscle and adipose tissue to increase the amount of GLUT4 transporters in their plasma membranes. The increase of GLUT4 transporters in the muscle and adipose tissue results in a lowering of blood glucose levels such that glucose transport into neurons is significantly reduced, due to the glucose levels falling below the K_m values for the GLUT1 transporters. Insulin injection does not alter the number or activity of GLUT1 or GLUT2 transporters. An increase in glycogenolysis would increase blood glucose levels, but glycogenolysis is inhibited by insulin, and stimulated by glucagon.
15. **The answer is F.** Glucose is an allosteric inhibitor of liver glycogen phosphorylase and is the only allosteric inhibitor of this enzyme. There are no allosteric activators of liver glycogen phosphorylase. Calcium ions will activate phosphorylase kinase, which will then activate glycogen phosphorylase, but that is via a covalent modification, not allosteric activation.

Pentose Phosphate Pathway and the Synthesis of Glycosides, Lactose, Glycoproteins, and Glycolipids

Glucose is used in a number of pathways other than glycolysis and glycogen synthesis. The **pentose phosphate pathway** (also known as the hexose monophosphate shunt, HMP shunt) consists of both **oxidative** and **nonoxidative** components (Fig. 27.1). In the oxidative pathway, glucose 6-phosphate is oxidized to **ribulose 5-phosphate** (ribulose 5-P), CO_2 , and **NADPH**. Ribulose 5-phosphate, a pentose, can be converted to **ribose 5-phosphate** (ribose 5-P) for nucleotide biosynthesis. The NADPH is used for reductive pathways, such as **fatty acid biosynthesis**, **detoxification** of drugs by monooxygenases, and the **glutathione defense system** against injury by reactive oxygen species (ROS).

FIGURE 27.1 Overview of the pentose phosphate pathway. The pentose phosphate pathway generates reduced nicotinamide adenine dinucleotide phosphate (NADPH) for reactions that require reducing equivalents (electrons) or ribose 5-phosphate for nucleotide biosynthesis. Glucose 6-phosphate is a substrate for both the pentose phosphate pathway and glycolysis. The five-carbon sugar intermediates of the pentose phosphate pathway are reversibly interconverted to intermediates of glycolysis. The portion of glycolysis that is not part of the pentose phosphate pathway is shown in red. ATP, adenosine triphosphate.

In the nonoxidative phase of the pathway, ribulose 5-phosphate is converted to ribose 5-phosphate and to intermediates of the glycolytic pathway. This portion of the pathway is reversible; therefore, ribose 5-phosphate can also be formed from intermediates of glycolysis. One of the enzymes involved in these sugar interconversions, **transketolase**, uses **thiamin pyrophosphate** as a coenzyme.

The sugars produced by the pentose phosphate pathway enter glycolysis as fructose 6-phosphate and glyceraldehyde 3-phosphate, and their further metabolism in the glycolytic pathway generates NADH, adenosine triphosphate (ATP), and pyruvate. The overall equation for the conversion of glucose 6-phosphate to fructose 6-phosphate and glyceraldehyde 3-phosphate through both the oxidative and nonoxidative reactions of the pentose phosphate pathway is

As had been seen previously in glycogen synthesis, several pathways for interconversion of sugars or the formation of sugar derivatives use activated sugars attached to nucleotides. Both uridine diphosphate (**UDP**)-**glucose** and **UDP-galactose** are used for **glycosyltransferase** reactions in many systems. Lactose, for example, is synthesized from UDP-galactose and glucose in the mammary gland. UDP-glucose also can be oxidized to form UDP-glucuronate, which is used to form **glucuronide derivatives** of bilirubin and xenobiotic compounds. Glucuronide derivatives are generally more readily excreted in urine or bile than the parent compound.

In addition to serving as fuel, carbohydrates are often found in **glycoproteins** (carbohydrate chains attached to proteins) and **glycolipids** (carbohydrate chains attached to lipids). **Nucleotide sugars** are used to donate sugar residues for the formation of the glycosidic bonds in both glycoproteins and glycolipids. These carbohydrate groups have many different types of functions.

Glycoproteins contain short chains of carbohydrates (oligosaccharides) that are usually branched. These oligosaccharides are generally composed of glucose, galactose, and their amino derivatives. In addition, mannose, L-fucose, and N-acetylneuraminic acid (NANA) are frequently present. The carbohydrate chains grow by the sequential addition of sugars to a **serine** or **threonine** residue of the protein. Nucleotide sugars are the precursors. Branched carbohydrate chains also may be attached to the amide nitrogen of **asparagine** in the protein. In this case, the chains are synthesized on **dolichol phosphate** and subsequently transferred to the protein. Glycoproteins are found in mucus, in the blood, in compartments within the cell (such as lysosomes), in the extracellular matrix, and embedded in the cell membrane with the carbohydrate portion extending into the extracellular space.

Many glycolipids belong to the class of **sphingolipids**. They are synthesized from nucleotide sugars that add monosaccharides sequentially to the hydroxymethyl group of the lipid ceramide (related to sphingosine). They often contain branches of N-acetylneuraminic acid produced from cytidine monophosphate (CMP)-NANA. They are found in the cell membrane with the carbohydrate portion extruding from the cell surface. These carbohydrates, as well as some of the carbohydrates of glycoproteins, serve as **cell recognition factors**.

 Blood typing in a clinical lab utilizes antibodies that recognize either the A antigen, the B antigen, or the Rh(D) antigen. Each antigen is distinctive, in part, because of the different carbohydrate chains attached to the protein. The blood sample is mixed with each antibody individually. If cell clumping (agglutination) occurs, the red blood cells are expressing the carbohydrate that is recognized by the antibody (recall from Chapter 7 that antibodies are bivalent; the agglutination occurs because one arm of the antibody binds to antigen on one cell, while the other arm binds to antigen on a second cell, thereby bringing the cells together). If neither the A nor B antibodies cause agglutination, the blood type is O, indicating a lack of either antigen.

THE WAITING ROOM

 After **Al M.** had been released from the hospital due to thiamin deficiency, he continued to struggle with abstaining from alcohol and injured his arm after falling down in the street while intoxicated. His friends took him to the hospital when he developed a fever of 101.5°F 2 days after hurting his arm. One of the physicians noticed that one of the lacerations on **Al M.**'s arm was red and swollen with some pus drainage. The pus was cultured and gram-positive cocci were found and identified as *Staphylococcus aureus*. Because his friends stated that he had an allergy to penicillin, and the concern over methicillin-resistant *S. aureus*, **Al M.** was started on a course of the antibiotic combination of trimethoprim and sulfamethoxazole (TMP/sulfa). To his friend's knowledge, he had never been treated with a sulfa drug previously.

On the third day of therapy with TMP/sulfa for his infection, **Al M.** was slightly jaundiced. His hemoglobin level had fallen by 3.5 g/dL from its value at admission, and his urine was red-brown because of the presence of free hemoglobin. **Al M.** had apparently suffered acute hemolysis (lysis or destruction of some of his red blood cells) induced by his infection and exposure to the sulfa drug.

 To help support herself through medical school, **Edna R.** works evenings in a hospital blood bank. She is responsible for assuring that compatible donor blood is available to patients who need blood transfusions. As part of her training, **Edna R.** has learned that the external surfaces of all blood cells

contain large numbers of antigenic determinants. These determinants are often glycoproteins or glycolipids that differ from one individual to another. As a result, all blood transfusions expose the recipient to many foreign immunogens. Most of these, fortunately, do not induce antibodies, or they induce antibodies that elicit little or no immunological response. For routine blood transfusions, therefore, tests are performed only for the presence of antigens that determine whether the patient's blood type is A, B, AB, or O, and Rh(D)-positive or Rh(D)-negative.

Jay S.'s psychomotor development has become progressively more abnormal (see Chapter 14). At 2 years of age, he is obviously severely developmentally delayed and nearly blind. His muscle weakness has progressed to the point that he cannot sit up or even crawl. As the result of a weak cough reflex, he is unable to clear his normal respiratory secretions and has had recurrent respiratory infections.

I. The Pentose Phosphate Pathway

The **pentose phosphate pathway** is essentially a scenic bypass route around the first stage of glycolysis that generates NADPH and ribose 5-phosphate (as well as other pentose sugars). Glucose 6-phosphate is the common precursor for both pathways. The oxidative first stage of the pentose phosphate pathway generates 2 mol of NADPH per mole of glucose 6-phosphate oxidized. The second stage of the pentose phosphate pathway generates ribose 5-P and converts unused intermediates to fructose 6-P and glyceraldehyde 3-P in the glycolytic pathway (see Fig. 27.1). All cells require NADPH for reductive detoxification, and most cells require ribose 5-P for nucleotide synthesis. Consequently, the pathway is present in all cells. The enzymes reside in the cytosol, as do the enzymes of glycolysis.

A. Oxidative Phase of the Pentose Phosphate Pathway

In the oxidative first phase of the pentose phosphate pathway, glucose 6-phosphate undergoes an oxidation and decarboxylation to a pentose sugar, ribulose 5-phosphate (Fig. 27.2). The first enzyme of this pathway, glucose 6-phosphate dehydrogenase, oxidizes the aldehyde at carbon 1 and reduces NADP^+ to NADPH. The gluconolactone that is formed is rapidly hydrolyzed to 6-phosphogluconate, a sugar acid with a carboxylic acid group at carbon 1. The next oxidation step releases this carboxyl group as CO_2 , with the electrons being transferred to NADP^+ . This reaction is mechanistically very similar to the one catalyzed by isocitrate dehydrogenase in the TCA cycle. Thus, 2 mol of NADPH per mole of glucose 6-phosphate are formed from this portion of the pathway.

Glucose 6-phosphate

6-Phosphoglucono- δ -lactone

6-Phosphogluconate

Ribulose 5-phosphate

FIGURE 27.2 Oxidative portion of the pentose phosphate pathway. Carbon 1 of glucose 6-phosphate is oxidized to an acid and then released as CO₂ in an oxidation followed by a decarboxylation reaction. Each of the oxidation steps generates a reduced nicotinamide adenine dinucleotide phosphate (NADPH).

NADPH, rather than NADH, is generally used in the cell in pathways that require the input of electrons for reductive reactions because the ratio of NADPH/NADP⁺ is much greater than the NADH/NAD⁺ ratio. The NADH generated from fuel oxidation is rapidly oxidized back to NAD⁺ by NADH dehydrogenase in the electron transport chain, so the level of NADH in the cell is very low.

M The transketolase activity of red blood cells can be used to measure thiamin nutritional status and diagnose the presence of thiamin deficiency. The activity of transketolase is measured in the presence and absence of added thiamin pyrophosphate. If the thiamin intake of a patient is adequate, the addition of thiamin pyrophosphate does not increase the activity of transketolase because it already contains bound thiamin pyrophosphate. If the patient is thiamin-deficient, transketolase activity will be low, and adding thiamin pyrophosphate will greatly stimulate the reaction. **Al M.** was diagnosed in Chapter 24 as having beriberi heart disease resulting from thiamin deficiency, by direct measurement of thiamin, which is the more commonly used test now.

NADPH can be generated from a number of reactions in the liver and other tissues, but not red blood cells. For example, in tissues with mitochondria, an energy-requiring transhydrogenase located near the complexes of the electron transport chain can transfer reducing equivalents from NADH to NADP⁺ to generate NADPH.

NADPH, however, cannot be oxidized directly by the electron transport chain, and the ratio of NADPH to NADP⁺ in cells is >1. The reduction potential of NADPH, therefore, can contribute to the energy needed for biosynthetic processes and provide a constant source of reducing power for detoxification reactions.

The ribulose 5-phosphate formed from the action of the two oxidative steps is isomerized to produce ribose 5-phosphate (a ketose-to-aldose conversion, similar to fructose 6-phosphate being isomerized to glucose 6-phosphate). The ribose 5-phosphate can then enter the pathway for nucleotide synthesis, if needed, or it can be converted to glycolytic intermediates, as described below for the nonoxidative phase of the pentose phosphate pathway. The pathway through which the ribose 5-phosphate travels is determined by the needs of the cell at the time of its synthesis.

Q How does the net energy yield from the metabolism of 3 mol of glucose 6-phosphate through the pentose phosphate pathway to pyruvate compare with the yield of 3 mol of glucose 6-phosphate through glycolysis?

B. Nonoxidative Phase of the Pentose Phosphate Pathway

The nonoxidative reactions of this pathway are *reversible reactions* that allow intermediates of glycolysis (specifically, glyceraldehyde 3-P and fructose 6-P) to be converted to five-carbon sugars (such as ribose 5-P), and vice versa. The needs of the cell determine in which direction this pathway proceeds. If the cell has produced ribose 5-P but does not need to synthesize nucleotides, then the ribose 5-P is converted to glycolytic intermediates. If the cell still requires NADPH, the ribose 5-P is converted back into glucose 6-P using nonoxidative reactions (see below). And finally, if the cell already has a high level of NADPH but needs to produce nucleotides, the oxidative reactions of the pentose phosphate pathway are inhibited, and the glycolytic intermediates fructose 6-P and glyceraldehyde 3-P are used to produce the five-carbon sugars using exclusively the nonoxidative phase of the pentose phosphate pathway.

1. Conversion of Ribulose 5-Phosphate to Glycolytic Intermediates

The nonoxidative portion of the pentose phosphate pathway consists of a series of rearrangement and transfer reactions that first convert ribulose 5-phosphate to ribose 5-phosphate and xylulose 5-phosphate, and then the ribose 5-phosphate and xylulose 5-phosphate are converted to intermediates of the glycolytic pathway. The enzymes involved are an epimerase, an isomerase, transketolase, and transaldolase.

The epimerase and isomerase convert ribulose 5-phosphate to two other five-carbon sugars (Fig. 27.3). The isomerase converts ribulose 5-phosphate to ribose 5-phosphate. The epimerase changes the stereochemical position of one hydroxyl group (at carbon 3), converting ribulose 5-phosphate to xylulose 5-phosphate.

Ribose 5-phosphate

Isomerase

Ribulose 5-phosphate

Epimerase

Xylulose 5-phosphate

FIGURE 27.3 Ribulose 5-phosphate can be epimerized (to xylulose 5-phosphate, shown in *red*) or isomerized (to ribose 5-phosphate, shown in the *yellow box*).

The net energy yield from 3 mol of glucose 6-phosphate metabolized through the pentose phosphate pathway and then the last portion of the glycolytic pathway is 6 mol of NADPH, 3 mol of CO₂, 5 mol of NADH, 8 mol of ATP, and 5 mol of pyruvate. In contrast, the metabolism of 3 mol of glucose 6-phosphate through glycolysis is 6 mol of NADH, 9 mol of ATP, and 6 mol of pyruvate.

Transketolase transfers two-carbon fragments of keto sugars (sugars with a keto group at carbon 2) to other sugars. Transketolase picks up a two-carbon fragment from xylulose 5-phosphate by cleaving the carbon-carbon bond between the keto group and the adjacent carbon, thereby releasing glyceraldehyde 3-phosphate (Fig. 27.4). The two-carbon fragment is covalently bound to thiamin pyrophosphate, which transfers it to the aldehyde carbon of another sugar, forming a new ketose. The role of thiamin pyrophosphate here is thus very similar to its role in the oxidative decarboxylation of pyruvate and α -ketoglutarate (see Chapter 24, Section I.B). Two reactions in the pentose phosphate pathway use transketolase: In the first, the two-carbon keto fragment from xylulose 5-phosphate is transferred to ribose 5-phosphate to form sedoheptulose 7-phosphate; and in the other, a two-carbon keto fragment (usually derived from xylulose 5-phosphate) is transferred to erythrose 4-phosphate to form fructose 6-phosphate.

Sedoheptulose 7-phosphate

FIGURE 27.4 Two-carbon units transferred by transketolase. Transketolase cleaves the bond next to the keto group and transfers the two-carbon keto fragment to an aldehyde. Thiamin pyrophosphate carries the two-carbon fragment, forming a covalent bond with the carbon of the keto group.

Transaldolase transfers a three-carbon keto fragment from sedoheptulose 7-phosphate to glyceraldehyde 3-phosphate to form erythrose 4-phosphate and fructose 6-phosphate (Fig. 27.5). The aldol cleavage occurs between the two hydroxyl carbons adjacent to the keto group (on carbons 3 and 4 of the sugar). This reaction is similar to the aldolase reaction in glycolysis, and the enzyme uses an active amino group, from the side chain of lysine, to catalyze the reaction.

Fructose 6-phosphate

FIGURE 27.5 Transaldolase transfers a three-carbon fragment that contains an alcohol group next to a keto group.

The net result of the metabolism of 3 mol of ribulose 5-phosphate in the pentose phosphate pathway is the formation of 2 mol of fructose 6-phosphate and 1 mol of glyceraldehyde 3-phosphate, which then continue through the glycolytic pathway with the production of NADH, ATP, and pyruvate. Because the pentose phosphate pathway begins with glucose 6-phosphate and feeds back into the glycolytic pathway, it is sometimes called the **hexose monophosphate shunt** (a shunt or a pathway for glucose 6-phosphate). The reaction sequence starting from glucose 6-phosphate and involving both the oxidative and nonoxidative phases of the pathway is shown in Figure 27.6.

FIGURE 27.6 A balanced sequence of reactions in the pentose phosphate pathway. The interconversion of sugars in the pentose phosphate pathway results in the conversion of three glucose 6-phosphate to six reduced nicotinamide adenine dinucleotide phosphate (NADPH), three CO₂, two fructose 6-phosphate, and one glyceraldehyde 3-phosphate.

2. Generation of Ribose 5-Phosphate from Intermediates of Glycolysis

The reactions catalyzed by the epimerase, isomerase, transketolase, and transaldolase are all reversible reactions under physiological conditions. Thus, ribose 5-phosphate required for purine and pyrimidine nucleotide synthesis can be generated from intermediates of the glycolytic pathway, as well as from the oxidative phase of the pentose phosphate pathway. The sequence of reactions that generate ribose 5-phosphate from intermediates of glycolysis is as follows:

C. Role of the Pentose Phosphate Pathway in Generation of NADPH

In general, the oxidative phase of the pentose phosphate pathway is the major source of NADPH in cells. NADPH provides the reducing equivalents for biosynthetic reactions and for oxidation–reduction reactions involved in protection against the toxicity of ROS (see Chapter 25). The glutathione-mediated defense against oxidative stress is common to all cell types (including red blood cells), and the requirement for NADPH to maintain levels of reduced glutathione probably accounts for the universal distribution of the pentose phosphate pathway among different types of cells. Figure 27.7 illustrates the importance of this pathway in maintaining the membrane integrity of the red blood cells. NADPH is also used for anabolic pathways, such as fatty acid synthesis, cholesterol synthesis, and fatty acid chain elongation (Table 27.1). It is the source of reducing equivalents for cytochrome P450 hydroxylation of aromatic compounds, steroids, alcohols, and drugs. The highest concentrations of glucose 6-phosphate dehydrogenase are found in phagocytic cells, where NADPH oxidase uses NADPH to form superoxide from molecular oxygen. The superoxide then generates hydrogen peroxide, which kills the micro-organisms taken up by the phagocytic cells (see Chapter 25).

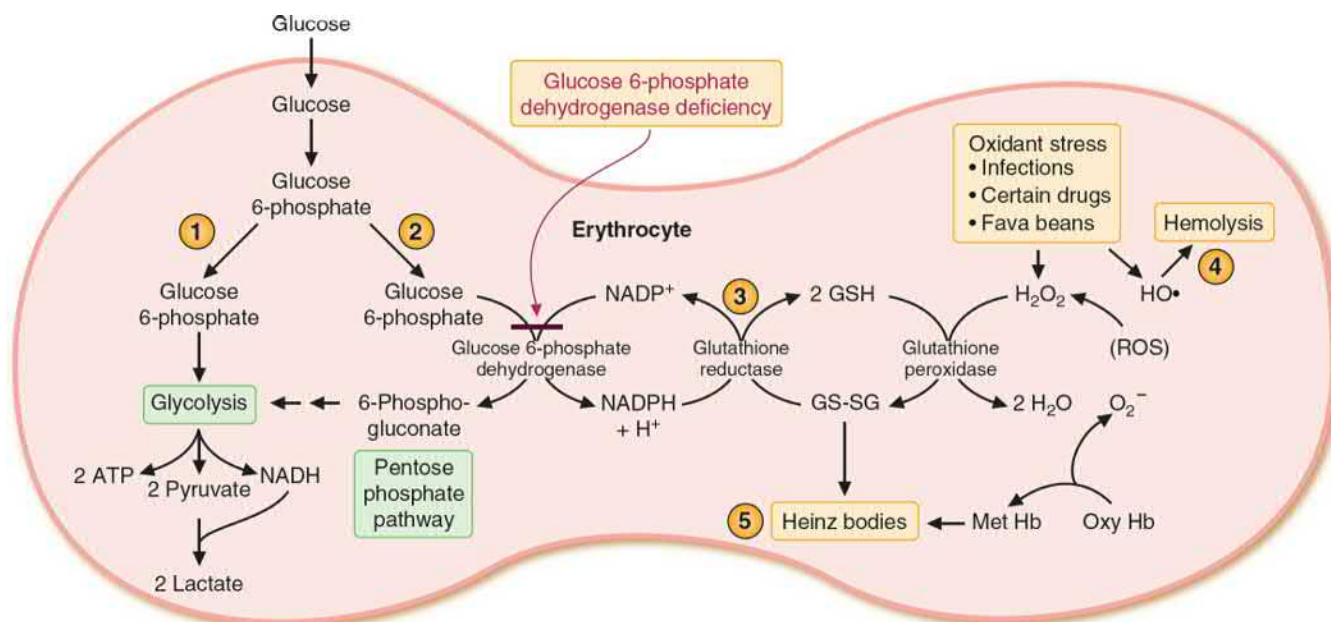

FIGURE 27.7 Hemolysis caused by reactive oxygen species (ROS). (1) Maintenance of the integrity of the erythrocyte membrane depends on its ability to generate adenosine triphosphate (ATP) and reduced nicotinamide adenine dinucleotide (NADH) from glycolysis. (2) NADPH is generated by the pentose phosphate pathway. (3) NADPH is used for the reduction of oxidized glutathione (GSSG) to reduced glutathione (GSH). Glutathione is necessary for the removal of hydrogen peroxide (H_2O_2) and lipid peroxides generated by ROS. (4) In the erythrocytes of healthy individuals, the continuous generation of superoxide ion from the nonenzymatic oxidation of hemoglobin provides a source of ROS. The glutathione defense system is compromised by glucose 6-phosphate dehydrogenase deficiency, infections, certain drugs, and the purine glycosides of fava beans. (5) As a consequence, Heinz bodies, aggregates of cross-linked hemoglobin, form on the cell membranes and subject the cell to mechanical stress as it tries to go through small capillaries. The action of the ROS on the cell membrane as well as mechanical stress from the lack of deformability result in hemolysis. Met Hb, methemoglobin; Oxy Hb, oxyhemoglobin.

Doctors suspected that the underlying factor in the destruction of **Al M.**'s red blood cells was an X-linked defect in the gene that codes for glucose 6-phosphate dehydrogenase. The red blood cell is dependent on this enzyme for a source of NADPH to maintain reduced levels of glutathione, one of its major defenses against oxidative stress (see Chapter 25). Glucose 6-phosphate dehydrogenase deficiency is the most common known enzymopathy, affecting approximately 7% of the world's population and about 2% of the U.S. population. Most glucose 6-phosphate dehydrogenase-deficient individuals are asymptomatic but can undergo an episode of hemolytic anemia if they are exposed to certain drugs, to certain types of infections, or if they ingest fava beans. When questioned, **Al M.** replied that he did not know what a fava bean was and had no idea whether he was sensitive to them.

The entry of glucose 6-phosphate into the pentose phosphate pathway is controlled by the cellular concentration of NADPH. NADPH is a strong product inhibitor of glucose 6-phosphate dehydrogenase, the first enzyme of the pathway. As NADPH is oxidized in other pathways, the product inhibition of glucose 6-phosphate dehydrogenase is relieved, and the rate of the enzyme is accelerated to produce more NADPH.

In the liver, the synthesis of fatty acids from glucose is a major route of NADPH reoxidation. The synthesis of liver glucose 6-phosphate dehydrogenase, like the key enzymes of glycolysis and fatty acid synthesis, is induced by the increased insulin:glucagon ratio after a high-carbohydrate meal. A summary of the possible routes that glucose 6-P may follow using the pentose phosphate pathway is presented in Table 27.2.

TABLE 27.2 Cellular Needs Dictate the Direction of the Pentose Phosphate Pathway Reactions	
CELLULAR NEED	DIRECTION OF PATHWAY
NADPH only	Oxidative reactions produce NADPH; nonoxidative reactions convert ribulose 5-P to glucose 6-P to produce more NADPH.
NADPH + ribose 5-P	Oxidative reactions produce NADPH and ribulose 5-P; the isomerase converts ribulose 5-P to ribose 5-P.
Ribose 5-P only	Only the nonoxidative reactions. High NADPH inhibits glucose 6-P dehydrogenase, so transketolase and transaldolase are used to convert fructose 6-P and glyceraldehyde 3-P to ribose 5-P.
NADPH and pyruvate	Both the oxidative and nonoxidative reactions are used. The oxidative reactions generate NADPH and ribulose 5-P. The nonoxidative reactions convert the ribulose 5-

II. Interconversions Involving Nucleotide Sugars

Activated sugars attached to nucleotides are converted to other sugars, oxidized to sugar acids, and joined to proteins, lipids, or other sugars through **glycosidic bonds**.

A. Reactions of UDP-Glucose

Uridine diphosphate (UDP)-glucose is an activated sugar nucleotide that is a precursor of glycogen and lactose; UDP-glucuronate and glucuronides; and the carbohydrate chains in proteoglycans, glycoproteins, and glycolipids (Fig. 27.8). Both proteoglycans and glycosaminoglycans are discussed further in Chapter 47. In the synthesis of many of the carbohydrate portions of these compounds, a sugar is transferred from the nucleotide sugar to an alcohol or other nucleophilic group to form a glycosidic bond (Fig. 27.9). The use of UDP as a leaving group in this reaction provides the energy for the formation of the new bond. The enzymes that form glycosidic bonds are sugar transferases (e.g., glycogen synthase is a glucosyltransferase). Transferases are also involved in the formation of the glycosidic bonds in bilirubin glucuronides, proteoglycans, and lactose.

FIGURE 27.8 An overview of uridine diphosphate (UDP)-glucose metabolism. The activated glucose moiety of UDP-glucose can be attached by a glycosidic bond to other sugars, as in glycogen or the sugar oligosaccharide and polysaccharide side chains of proteoglycans, glycoproteins, and glycolipids. UDP-glucose also can be oxidized to UDP-glucuronate, or epimerized to UDP-galactose, a precursor of lactose. UTP, uridine triphosphate.

FIGURE 27.9 Glycosyltransferases. These enzymes transfer sugars from nucleotide sugars to nucleophilic amino acid residues on proteins, such as the hydroxyl group of serine or the amide group of asparagine. Other transferases transfer specific sugars from a nucleotide sugar to a hydroxyl group of other sugars. The bond formed between the anomeric carbon of the sugar and the nucleophilic group of another compound is a glycosidic bond. UDP, uridine diphosphate.

What is the difference in structure between 6-phosphogluconate and glucuronic acid?

B. UDP-Glucuronate: A Source of Negative Charges

One of the major routes of UDP-glucose metabolism is the formation of **UDP-glucuronate**, which serves as a precursor of other sugars and of glucuronides (Fig. 27.10). Glucuronate is formed by the oxidation of the alcohol on carbon 6 of glucose to an acid (through two oxidation states) by a NAD^+ -dependent dehydrogenase (Fig. 27.11). Glucuronate is also present in the diet and can be formed from the degradation of inositol (the sugar alcohol that forms inositol trisphosphate [IP_3]), an intracellular second messenger for many hormones.

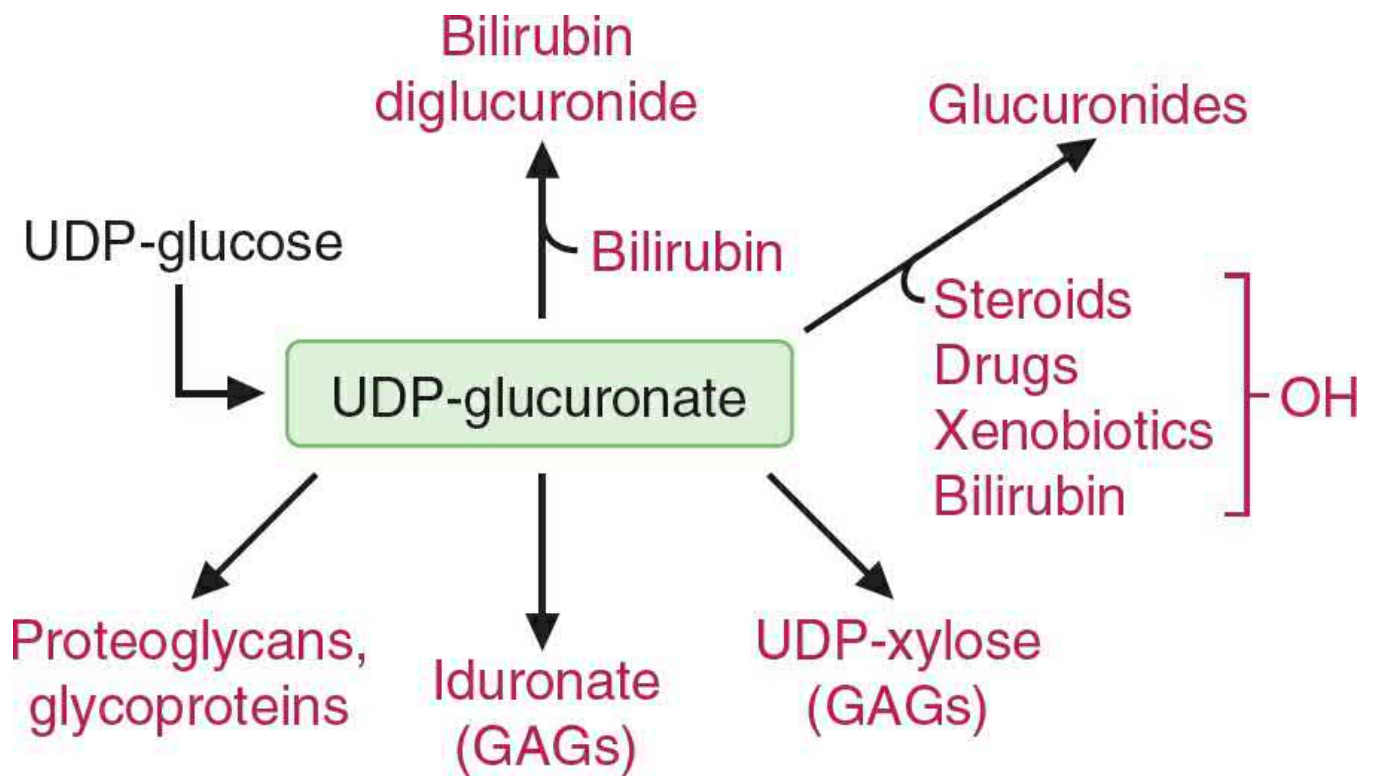

FIGURE 27.10 Metabolic routes of uridine diphosphate (UDP)-glucuronate. UDP-glucuronate is formed from UDP-glucose (shown in *black*). Glucuronate from UDP-glucuronate is incorporated into glycosaminoglycans (GAGs), where certain of the glucuronate residues are converted to iduronate (see Chapter 47). UDP-glucuronate is a precursor of UDP-xylose, another sugar residue incorporated into glycosaminoglycans. Glucuronate is also transferred to the carboxyl groups of bilirubin or the alcohol groups of steroids, drugs, and xenobiotics to form glucuronides. The “-ide” in the name glucuronide denotes that these compounds are glycosides. Xenobiotics are pharmacologically, endocrinologically, or toxicologically active substances not produced endogenously and, therefore, are foreign to an organism. Drugs are an example of xenobiotics.

UDP-glucose

UDP-glucuronate

Glucuronide

└─┬─> Bile or urine

FIGURE 27.11 Formation of glucuronate and glucuronides. A glycosidic bond is formed between the anomeric hydroxyl of glucuronate (at carbon 1) and the hydroxyl group of a nonpolar compound. The negatively charged carboxyl group of the glucuronate increases the water solubility and allows otherwise nonpolar compounds to be excreted in the urine or bile. The hydrogen atoms have been omitted from the figure for clarity. UDP, uridine diphosphate.

A failure of the liver to transport, store, or conjugate bilirubin results in the accumulation of unconjugated bilirubin in the blood. Jaundice (or icterus), the yellowish tinge to the skin and the whites of the eyes (sclerae) experienced by **Erin G.** (see Chapter 22), occurs when plasma becomes supersaturated with bilirubin (>2 to 2.5 mg/dL), and the excess diffuses into tissues. When bilirubin levels are measured in the blood (see Chapter 6), one can either measure indirect bilirubin (this is the nonconjugated form of bilirubin, which is bound to albumin), direct bilirubin (the conjugated, water-soluble form), or total bilirubin (the sum of the direct and indirect levels). If total bilirubin levels are high, then a determination of direct and indirect bilirubin is needed to appropriately determine a cause for the elevation of total bilirubin.

C. Glucuronides: A Source of Negative Charges

The function of glucuronate in the excretion of bilirubin, drugs, xenobiotics, and other compounds containing a hydroxyl group is to add negative charges and increase their solubility. Bilirubin is a degradation product of heme that is formed in the reticuloendothelial system and is only slightly soluble in plasma. It is transported to the liver bound to albumin. In the liver, glucuronate residues are transferred from UDP-glucuronate to two carboxyl groups on bilirubin, sequentially forming bilirubin monoglucuronide and bilirubin diglucuronide, the “conjugated” forms of bilirubin (Fig. 27.12). The more soluble bilirubin diglucuronide (as compared with unconjugated bilirubin) is then actively transported into the bile for excretion.

FIGURE 27.12 Formation of bilirubin diglucuronide. A glycosidic bond is formed between the anomeric hydroxyl of glucuronate and the carboxylate groups of bilirubin. The addition of the hydrophilic carbohydrate group and the negatively charged carboxyl group of the glucuronate increases the water solubility of the conjugated bilirubin and allows the otherwise insoluble bilirubin to be excreted in the urine or bile. The hydrogen atoms on the sugars have been omitted from the figure for clarity.

Many xenobiotics, drugs, steroids, and other compounds with hydroxyl groups and low solubility in water are converted to glucuronides in a similar fashion by glucuronyltransferases present in the endoplasmic reticulum and cytoplasm of the liver and kidney (Table 27.3). This is one of the major conjugation pathways for the excretion of these compounds.

TABLE 27.3 Examples of Compounds Degraded and Excreted as Urinary Glucuronides
Estrogen (female sex hormone)
Progesterone (steroid hormone)
Triiodothyronine (thyroid hormone)
Acetylaminofluorene (xenobiotic carcinogen)

Meprobamate (drug for sleep)

Morphine (painkiller)

6-Phosphogluconate is produced by the first oxidative reaction in the pentose phosphate pathway, in which carbon 1 of glucose is oxidized to a carboxylate. In contrast, glucuronic acid is oxidized at carbon 6 to the carboxylate form.

Glucuronate, once formed, can reenter the pathways of glucose metabolism through reactions that eventually convert it to D-xylulose 5-phosphate, an intermediate of the pentose phosphate pathway. In most mammals other than humans, an intermediate of this pathway is the precursor of ascorbic acid (vitamin C). Humans, however, are deficient in this pathway and cannot synthesize vitamin C.

Many full-term newborns develop jaundice, termed neonatal jaundice. It is usually caused by an increased destruction of red blood cells after birth (the fetus has an unusually large number of red blood cells) and an immature bilirubin conjugating system in the liver. This leads to elevated levels of nonconjugated bilirubin, which is deposited in hydrophobic (fat) environments. If bilirubin levels reach a certain threshold at the age of 48 hours, the newborn is a candidate for phototherapy, in which the child is placed under lamps or on a "biliblanket" that emit light between the wavelengths of 425 and 475 nm. Bilirubin absorbs this light, undergoes chemical changes, and becomes more water-soluble. Usually, within a week of birth, the newborn's liver can handle the load generated from red blood cell turnover.

D. Synthesis of UDP-Galactose and Lactose from Glucose

Lactose is synthesized from UDP-galactose and glucose (Fig. 27.13). However, galactose is not required in the diet for lactose synthesis, because galactose can be synthesized from glucose.

FIGURE 27.13 Lactose synthesis. Lactose is a disaccharide composed of galactose and glucose. Uridine diphosphate (UDP)-

galactose for the synthesis of lactose in the mammary gland is usually formed from the epimerization of UDP-glucose. Lactose synthase catalyzes the attack of the C4 alcohol group of glucose on the anomeric carbon of the galactose, releasing UDP, and forming a glycosidic bond. Lactose synthase is composed of a galactosyltransferase and α -lactalbumin, which is a regulatory subunit. PP_i , pyrophosphate; UTP, uridine triphosphate.

High concentrations of galactose 1-phosphate inhibit phosphoglucomutase, the enzyme that converts glucose 6-phosphate to glucose 1-phosphate. How can this inhibition account for the hypoglycemia and jaundice that accompany galactose 1-phosphate uridylyltransferase deficiency?

1. Conversion of Glucose to Galactose

Galactose and glucose are **epimers**; they differ only in the stereochemical position of one hydroxyl group, at carbon 4. Thus, the formation of UDP-galactose from UDP-glucose is an **epimerization** (Fig. 27.14). The epimerase does not actually transfer the hydroxyl group; it oxidizes the hydroxyl to a ketone by transferring electrons to NAD^+ , and then donates electrons back to re-form the alcohol group on the other side of the carbon.

UDP-glucose

UDP-glucose
4-epimerase
(NAD⁺)

UDP-galactose

FIGURE 27.14 Epimerization of uridine diphosphate (UDP)-glucose to UDP-galactose. The epimerization of glucose to galactose occurs on UDP-sugars. The epimerase uses nicotinamide adenine dinucleotide (NAD⁺) to oxidize the alcohol to a ketone and then reduces the ketone back to an alcohol. The reaction is reversible; glucose being converted to galactose forms galactose for lactose synthesis, and galactose being converted to glucose is part of the pathway for the metabolism of dietary galactose. The hydrogen atoms have been omitted for clarity.

2. Lactose Synthesis

Lactose is unique in that it is synthesized only in the mammary gland of the adult female for short periods during lactation. Lactose synthase, an enzyme present in the endoplasmic reticulum of the lactating mammary gland, catalyzes the last step in lactose biosynthesis, the transfer of galactose from UDP-galactose to glucose (see Fig. 27.13). Lactose synthase has two protein subunits, a galactosyltransferase and α -lactalbumin. α -Lactalbumin is a modifier protein synthesized after parturition (childbirth) in response to the hormone prolactin. This enzyme subunit lowers the K_m of the galactosyltransferase for glucose from 1,200 to 1 mM, thereby increasing the rate of lactose synthesis. In the absence of α -lactalbumin, galactosyltransferase transfers galactosyl units to glycoproteins.

The inhibition of phosphoglucomutase by galactose 1-phosphate results in hypoglycemia by interfering with both the formation of UDP-glucose (the glycogen precursor) and the degradation of glycogen back to glucose 6-phosphate. Ninety percent of glycogen degradation leads to glucose 1-phosphate, which can only be converted to glucose 6-phosphate by phosphoglucomutase. When phosphoglucomutase activity is inhibited, less glucose 6-P production occurs, and hence, less glucose is available for export. Thus, the stored glycogen is only approximately 10% efficient in raising blood glucose levels, and hypoglycemia results. UDP-glucose levels are reduced because glucose 1-phosphate is required to synthesize UDP-glucose, and in the absence of phosphoglucomutase activity, glucose 6-phosphate (derived from either the glucokinase reaction or gluconeogenesis) cannot be converted to glucose 1-phosphate. This prevents the formation of UDP-glucuronate, which is necessary to convert bilirubin to the diglucuronide form for transport into the bile. Bilirubin accumulates in tissues, giving them a yellow color (jaundice).

E. Formation of Sugars for Glycolipid and Glycoprotein Synthesis

The transferases that produce the oligosaccharide and polysaccharide side chains of glycolipids and attach sugar residues to proteins are specific for the sugar moiety and for the donating nucleotide (e.g., UDP, CMP, or GDP). Some of the sugar nucleotides used for **glycoprotein**, **proteoglycan** (see Chapter 47), and **glycolipid** formation are listed in Table 27.4. They include the derivatives of glucose and galactose that we have already discussed, as well as acetylated amino sugars and derivatives of mannose. The reason for the large variety of sugars attached to proteins and lipids is that they have relatively specific and different functions, such as targeting a protein toward a membrane; providing recognition sites on the cell surface for other cells, hormones, or viruses; or acting as lubricants or molecular sieves (see Chapter 47).

TABLE 27.4 Examples of Sugar Nucleotides That Are Precursors for Transferase Reactions

GDP-mannose

The pathways for the utilization and formation of many of these sugars are summarized in Figure 27.15. Note that many of the steps are reversible so that glucose and other dietary sugars enter a common pool from which the diverse sugars can be formed.

FIGURE 27.15 Pathways for the interconversion of sugars. All of the different sugars found in glycosaminoglycans, gangliosides, and other compounds in the body can be synthesized from glucose. Dietary glucose, fructose, galactose, mannose, and other sugars enter a common pool from which other sugars are derived. The activated sugar is transferred from the nucleotide sugar, shown in *yellow boxes*, to form a glycosidic bond with another sugar or amino acid residue. The *green box* next to each nucleotide sugar lists some of the compounds that contain the sugar. Iduronic acid, in the upper right corner of the diagram, is formed only after glucuronic acid is incorporated into a glycosaminoglycan (which is discussed in more detail in Chapter 47). Acetyl CoA, acetyl coenzyme A; CMP, cytidine monophosphate; GDP, guanosine diphosphate; UDP, uridine diphosphate.

A pregnant woman who was extremely lactose-intolerant asked her physician if she would still be able to breastfeed her infant even though she could not drink milk or dairy products. What advice should she be given?

The amino sugars are all derived from glucosamine 6-phosphate. To synthesize glucosamine 6-phosphate, an amino group is transferred from the amide of glutamine to fructose 6-phosphate (Fig. 27.16). Amino sugars, such as glucosamine, can then be *N*-acetylated by an acetyltransferase. *N*-acetyltransferases are present in the endoplasmic reticulum and cytosol and provide another means of chemically modifying sugars, metabolites, drugs, and xenobiotic compounds. Individuals may vary greatly in their capacity for acetylation reactions.

FIGURE 27.16 The formation of *N*-acetyl-glucosamine 6-phosphate. The amino sugar is formed by a transfer of the amino group from the amide of glutamine to a carbon of the sugar. The amino group is acetylated by the transfer of an acetyl group from acetyl coenzyme A (acetyl CoA). The hydrogen atoms from the sugar have been omitted for clarity. CoASH, coenzyme A; Fructose 6-P, fructose 6-phosphate; Glucosamine 6-P, glucosamine 6-phosphate.

Mannose is found in the diet in small amounts. Like galactose, it is an epimer of glucose, and mannose and glucose are interconverted by epimerization reactions at carbon 2. The interconversion can take place either at the level of fructose 6-phosphate to mannose 6-phosphate or at the level of the derivatized sugars (see Fig. 27.15). *N*-acetylmannosamine is the precursor of *N*-acetylneuraminic acid (NANA, a sialic acid) and GDP-mannose is the precursor of GDP-fucose (see Fig. 27.15). The negative charge on NANA is obtained by the addition of a three-carbon carboxyl moiety from phosphoenolpyruvate.

Although the lactose in dairy products is a major source of galactose, the ingestion of lactose is not required for lactation. UDP-galactose in the mammary gland is derived principally from the epimerization of glucose. Dairy products are, however, a major dietary source of Ca^{2+} , so breastfeeding mothers need increased Ca^{2+} from another source.

III. Glycoproteins

A. Structure and Function

Glycoproteins contain short carbohydrate chains covalently linked to either serine/threonine or asparagine residues in the protein. These oligosaccharide chains are often branched, and they do not contain repeating disaccharides (Fig. 27.17). Most proteins in the blood are glycoproteins. They serve as hormones, antibodies, enzymes (including those of the blood clotting cascade), and as structural components of the extracellular matrix. Collagen contains galactosyl units and disaccharides composed of galactosyl-glucose attached to hydroxylysine residues (see Chapter 47). The secretions of mucus-producing cells, such as salivary mucin, are glycoproteins (Fig. 27.18).

FIGURE 27.17 An example of a branched glycoprotein. Fuc, fucose; Gal, Galactose; GlcNAc, *N*-acetylglucosamine; Man, mannose; NANA, *N*-acetylneuraminic acid.

Salivary mucin

—●— = Sialic acid

—●— = *N*-Acetylglucosamine

FIGURE 27.18 Structure of salivary mucin. The sugars form hydrogen bonds with water. Sialic acid provides a negatively charged carboxylate group. The protein is extremely large, and the negatively charged sialic acids extend the carbohydrate chains (by charge repulsion) so the molecules occupy a large space. All of the salivary glycoproteins contain *O*-linked sugars. *N*-Acetylneuraminic acid (NANA) is a sialic acid.

Although most glycoproteins are secreted from cells, some are segregated in lysosomes, where they serve as the lysosomal enzymes that degrade various types of cellular and extracellular material. Other glycoproteins are produced like secretory proteins, but hydrophobic regions of the protein remain attached to the cell membrane, and the carbohydrate portion extends into the extracellular space (also see Chapter 15, Section I). These glycoproteins serve as receptors for compounds such as hormones, as transport proteins, and as cell attachment and cell–cell recognition sites. Bacteria and viruses also bind to these sites.

By identifying the nature of antigenic determinants on the surface of the donor's red blood cells, **Edna R.** is able to classify the donor's blood as belonging to certain specific blood groups. These antigenic determinants are located in the oligosaccharides of the glycoproteins and glycolipids of the cell membranes. The most important blood group in humans is the ABO group, which comprises two antigens, A and B. Individuals with the A antigen on their cells belong to blood group A. Those with B belong to group B, and those with both A and B belong to group AB. The absence of both the A and B antigens

results in blood type O (see Fig. 27.23).

Blood Type

Type O

Type A

Type B

FIGURE 27.23 Structures of the blood group substances. Note that these structures are the same except that type A has *N*-acetylgalactosamine (GalNAc) at the nonreducing end, type B has galactose (Gal), and type O has neither. R is either a protein or the lipid ceramide. Each antigenic determinant is boxed. Fuc, fucose; Gal, galactose; GlcNAc, *N*-acetylglucosamine.

B. Synthesis

The protein portion of glycoproteins is synthesized on ribosomes attached to the endoplasmic reticulum (ER). The carbohydrate chains are attached to the protein in the lumen of the ER and the Golgi complex. In some cases, the initial sugar is added to a serine or a threonine residue in the protein, and the carbohydrate chain is extended by the sequential addition of sugar residues to the nonreducing end. As seen in Table 27.4, UDP-sugars are the precursors for the addition of four of the seven sugars that are usually found in glycoproteins—glucose, galactose, *N*-acetylglucosamine, and *N*-acetylgalactosamine. GDP-sugars are the precursors for the addition of mannose and L-fucose, and CMP-NANA is the precursor for NANA. Dolichol phosphate (Fig.

27.19) (which is synthesized from isoprene units, as is discussed in Chapter 32) is involved in transferring branched sugar chains to the amide nitrogen of asparagine residues. Sugars are removed and added as the glycoprotein moves from the ER through the Golgi complex (Fig. 27.20). As discussed in Chapter 10, the carbohydrate chain is used as a targeting marker for lysosomal enzymes.

FIGURE 27.19 Structure of dolichol phosphate. In humans, the isoprene unit (in *brackets*) is repeated approximately 17 times ($n \approx 17$).

FIGURE 27.20 Action of dolichol phosphate in synthesizing the high-mannose form of oligosaccharides **(A)** and the processing of these carbohydrate groups **(B)**. Transfer of the branched oligosaccharide from dolichol phosphate to a protein in the lumen of the rough endoplasmic reticulum (RER) (step 1) and processing of the oligosaccharide (steps 2–11). Steps 1 through 4 occur in the RER. The glycoprotein is transferred in vesicles to the Golgi complex, where further modifications of the oligosaccharides occur (steps 5–11). (Part **B** modified with permission from Kornfeld R, Kornfeld S. Assembly of asparagine-linked oligosaccharides. *Annu Rev Biochem.* 1985;54:631–664. © 1985 by Annual Reviews, Inc.; permission conveyed through Copyright Clearance Center, Inc.)

I-cell (inclusion cell) disease is a rare condition in which lysosomal enzymes lack the mannose phosphate marker that targets them to lysosomes. The enzyme that is deficient in I-cell disease is a phosphotransferase located in the Golgi apparatus (Fig. 27.21). The phosphotransferase has the unique ability to recognize lysosomal proteins because of their three-dimensional structure, such that they can all be appropriately tagged for transport to the lysosomes. Consequently, as a result of the lack of mannose phosphate, lysosomal enzymes are secreted from the cells. Because lysosomes lack their normal complement of enzymes, undegraded molecules accumulate within the nonfunctional lysosomes inside these cells, forming inclusion bodies.

FIGURE 27.21 Synthesis of mannose 6-phosphate on the oligosaccharide of lysosomal proteins. The pathway for

phosphorylating a mannose residue within the protein-attached oligosaccharide requires two steps. The first is a transfer of *N*-acetylglucosamine phosphate to the mannose residue, and the second is the release of *N*-acetylglucosamine from the intermediate product, leaving the phosphate behind on the mannose residue. NAcGlc, *N*-acetylglucosamine; UDP, uridine diphosphate; UMP, uridine monophosphate.

IV. Glycolipids

A. Function and Structure

Glycolipids are derivatives of the lipid sphingosine. These **sphingolipids** include the **cerebrosides** and the **gangliosides** (Fig. 27.22; see also Chapter 5, Fig. 5.20). They contain ceramide, with carbohydrate moieties attached to its hydroxymethyl group.

Ceramide — Galactose

Ganglioside

Ceramide

FIGURE 27.22 Structures of cerebrosides and gangliosides. In these glycolipids, sugars are attached to ceramide (shown below the glycolipids). The boxed portion of ceramide is sphingosine, from which the name “sphingolipids” is derived. GalNAc, *N*-acetylgalactosamine; NANA, *N*-acetylneuraminic acid.

Glycolipids are involved in intercellular communication. Oligosaccharides of identical composition are present in both the glycolipids and glycoproteins associated with the cell membrane, where they serve as cell recognition factors. For example, carbohydrate residues in these oligosaccharides are the antigens of the ABO blood group substances (Fig. 27.23).

B. Synthesis

Cerebrosides are synthesized from ceramide and UDP-glucose or UDP-galactose. They contain a single sugar (a monosaccharide). Gangliosides contain oligosaccharides produced from UDP-sugars and CMP-NANA, which is the precursor for the *N*-acetylneuraminic acid residues that branch from the linear chain. The synthesis of the sphingolipids is described in more detail in Chapter 31. Defects in the degradation of sphingolipids lead to the sphingolipidoses (also known as the gangliosidosis), as outlined in Table 27.5.

DISEASE	ENZYME DEFICIENCY	ACCUMULATED LIPID ^a
Fucosidosis	α -Fucosidase	Cer–Glc–Gal–GalNAc–Gal: Fuc H-isoantigen
Generalized gangliosidosis	G _{M1} - β -galactosidase	Cer–Glc–Gal(NeuAc)–GalNAc:Gal G _{M1} ganglioside

^aThe colon indicates the bond which cannot be broken due to the enzyme deficiency associated with the disease.

The blood group substances are oligosaccharide components of glycolipids and glycoproteins found in most cell membranes. Those located on red blood cells have been studied extensively. A single genetic locus with two alleles determines an individual's blood type. These genes encode glycosyltransferases involved in the synthesis of the oligosaccharides of the blood group substances.

Most individuals can synthesize the H substance, an oligosaccharide that contains a fucose linked to a galactose at the nonreducing end of the blood group substance (see Fig. 27.23). Type A individuals produce an *N*-acetylgalactosamine transferase (encoded by the *A* gene) that attaches *N*-acetylgalactosamine to the galactose residue of the H substance. Type B individuals produce a galactosyltransferase (encoded by the *B* gene) that links galactose to the galactose residue of the H substance. Type AB individuals have both alleles and produce both transferases. Thus, some of the oligosaccharides of their blood group substances contain *N*-acetylgalactosamine and some contain galactose. Type O individuals produce a defective transferase, and, therefore, they do not attach either *N*-acetylgalactosamine or galactose to the H substance. Thus, individuals of blood type O have only the H substance.

Sphingolipids are produced in the Golgi complex. Their lipid component becomes part of the membrane of the secretory vesicle that buds from the *trans* face of the Golgi. After the vesicle membrane fuses with the cell membrane, the lipid component of the glycolipid remains in the outer layer of the cell membrane, and the

carbohydrate component extends into the extracellular space. Sometimes the carbohydrate component is used as a recognition signal for foreign proteins; for example, cholera toxin (which affected **Dennis V.**; see Chapter 10) binds to the carbohydrate portion of the GM1 ganglioside to allow its catalytic subunit to enter the cell.

CLINICAL COMMENTS

Al M. The wound culture, sent on the second day of **Al M.**'s admission for acute alcohol intoxication, grew *Staphylococcus aureus*. This organism can be resistant to a variety of antibiotics, so TMP/sulfa treatment was initiated. Unfortunately, it appeared that **Al M.** had suffered an acute hemolysis (lysis or destruction of some of his red blood cells), probably induced by exposure to the sulfa drug and his infection with *S. aureus*. The hemoglobin that escaped from the lysed red blood cells was filtered by his kidneys and appeared in his urine.

By mechanisms that are not fully delineated, certain drugs (such as sulfa drugs and antimalarials), a variety of infectious agents, and exposure to fava beans can cause red blood cell destruction in individuals with an X-linked genetic deficiency of glucose 6-phosphate dehydrogenase. Presumably, these patients cannot generate enough reduced NADPH to defend against the ROS. Although erythrocytes lack most of the other enzymatic sources of NADPH for the glutathione antioxidant system, they do have the defense mechanisms provided by the antioxidant vitamins E and C and catalase. Thus, individuals who are not totally deficient in glucose 6-phosphate dehydrogenase remain asymptomatic unless an additional oxidative stress, such as an infection, generates additional oxygen radicals.

Some drugs, such as the antimalarial primaquine and the sulfonamide that **Al M.** is taking, affect the ability of red blood cells to defend against oxidative stress. Fava beans, which look like fat string beans and are sometimes called broad beans, contain the purine glycosides vicine and isouramil. These compounds react with glutathione. It has been suggested that cellular levels of reduced glutathione (GSH) decrease to such an extent that critical sulfhydryl groups in some key proteins cannot be maintained in reduced form.

The highest prevalence rates for glucose 6-phosphate dehydrogenase deficiency are found in tropical Africa and Asia, in some areas of the Middle East and the Mediterranean, and in Papua New Guinea. The geographic distribution of this deficiency is similar to that of sickle cell trait and is probably also related to the relative resistance it confers against the malaria parasite.

Because individuals with this deficiency are asymptomatic unless they are exposed to an "oxidant challenge," the clinical course of the hemolytic anemia is usually self-limited if the causative agent is removed. However, genetic polymorphism accounts for a substantial variability in the severity of the disease. Severely affected patients may have a chronic hemolytic anemia and other sequelae even without known exposure to drugs, infection, and other causative factors. In such patients, neonatal jaundice is also common and can be severe enough to cause death.

Al M.'s antibiotic was changed and his infection and symptoms caused by the lack of glucose 6-phosphate dehydrogenase deficiency abated.

Edna R. determined that a patient's blood type was AB. The new surgical resident was eager to give this patient a blood transfusion and, because AB blood is rare and an adequate amount was not available in the blood bank, he requested type A blood. Should **Edna R.** give him type A blood for his patient?

Edna R. During her stint in the hospital blood bank, **Edna R.** learned that the importance of the ABO blood group system in transfusion therapy is based on two principles (Table 27.6). (1) Antibodies to A and to B antigens occur naturally in the blood serum of persons whose red blood cell surfaces lack the corresponding antigen (i.e., individuals with A antigens on their red blood cells have B antibodies in their serum, and vice versa). These antibodies may arise as a result of previous exposure to cross-reacting antigens in bacteria and foods or to blood transfusions. (2) Antibodies to A and B are usually present in high titers and are capable of activating the entire complement system. As a result, these antibodies may cause intravascular destruction of a large number of incompatible red blood cells given inadvertently during a blood transfusion. Individuals with type AB blood have both A and B antigens and do not produce antibodies to either. Hence, they are "universal" recipients. They can safely receive red blood cells from individuals of A, B, AB, or O blood type. (However, they cannot safely receive serum from these individuals, because it contains antibodies to A or B antigens.) Those with type O blood do not have either antigen. They are "universal" donors; that is, their red cells can safely be infused into type A, B, O, or AB

individuals. (However, their serum contains antibodies to both A and B antigens and cannot be given safely to recipients with those antigens.)

TABLE 27.6 Characteristics of the ABO Blood Groups

RED CELL TYPE	O	A	B	AB
Possible genotypes	OO	AA or AO	BB or BO	AB
Antibodies in serum	Anti-A and B	Anti-B	Anti-A	None
Frequency (in Caucasians)	45%	40%	10%	5%
Can accept blood types	O	A, O	B, O	A, B, AB, O

The second important red blood cell group is the Rh group. It is important because one of its antigenic determinants, the D antigen, is a very potent immunogen, stimulating the production of a large number of antibodies. The unique carbohydrate composition of the glycoproteins that constitute the antigenic determinants on red blood cells in part contributes to the relative immunogenicity of the A, B, and Rh(D) red blood cell groups in human blood.

The patient could safely receive type A blood cells from another person because he has both A and B antigens on his own cells and does not have antibodies in his serum to either type A or B cells. However, he should not be given type A serum (or type A whole blood) because type A serum contains antibodies to type B antigens, which are present in his cells.

Jay S. Tay–Sachs disease, the problem afflicting **Jay S.**, is an autosomal recessive disorder that is rare in the general population (1 in 300,000 births), but its prevalence in Jews of Eastern European (Ashkenazi) extraction (who make up 90% of the Jewish population in the United States) is much higher (1 in 3,600 births). One in 28 Ashkenazi Jews carries this defective gene. Its presence can be discovered by measuring the serum hexosaminidase A enzymatic activity or by recombinant DNA techniques.

Carriers of the affected gene have a reduced but functional level of this enzyme that normally hydrolyzes a specific bond between an *N*-acetyl-*D*-galactosamine and a *D*-galactose residue in the polar head of the ganglioside.

No effective therapy is available. Enzyme replacement has met with little success because of the difficulties in getting the enzyme across the blood–brain barrier.

Tay–Sachs disease, which is one of the gangliosidoses, is a multifaceted disorder. The sphingolipidoses, which include Fabry and Gaucher diseases, affect mainly the brain, the skin, and the reticuloendothelial system (e.g., liver and spleen). In these diseases, complex lipids accumulate. Each of these lipids contains a ceramide as part of its structure (see Table 27.5). The rate at which the lipid is synthesized is normal. However, the lysosomal enzyme required to degrade it is not very active, either because it is made in deficient quantities as a result of a mutation in a gene that specifically codes for the enzyme or because a critical protein required to activate the enzyme is deficient. Because the lipid cannot be degraded, it accumulates and causes degeneration of the affected tissues, with progressive malfunction, such as the psychomotor deficits that occur as a result of the central nervous system involvement seen in most of these storage diseases.

BIOCHEMICAL COMMENTS

Biochemistry of Tay–Sachs disease. Hexosaminidase A, the defective enzyme in Tay–Sachs disease, is actually composed of two subunits, an α - and a β -chain. The stoichiometry is currently considered to be $\alpha\beta$ (a dimer). The α -subunit is coded for by the *HexA* gene, whereas the β -subunit is coded for by the *HexB* gene. In Tay–Sachs disease, the α -subunit is defective, and hexosaminidase A activity is lost. However, the β -subunit can form active dimers in the absence of the α -subunit, and this activity, named hexosaminidase B, is able to cleave the glycolipid globoside and retains activity in children with Tay–Sachs disease. Thus, children with Tay–Sachs disease accumulate the ganglioside GM2, but not globoside (Fig. 27.24).

FIGURE 27.24 Substrate specificities of hexosaminidase A, B, and the function of the activator protein. Defects in the β -subunit inactivate both *HexA* and *HexB* activities, leading to GM2 and globoside accumulation. A defect in Sandhoff activator protein also leads to GM2 accumulation, as *HexA* activity is reduced. Defects in the α -subunit inactivate only *HexA* activity, such that *HexB* activity toward globoside is unaffected. Gal, galactose; Glc, glucose; NAcGal, N-acetylgalactosamine.

Mutation of the *HexB* gene, and production of a defective β -subunit, leads to inactivation of both hexosaminidase A and B activity. Such a mutation leads to Sandhoff disease. Both activities are lost because both activities require a functional β -subunit. The clinical course of this disease is similar to Tay-Sachs but with an accelerated timetable because of the initial accumulation of both GM2 and globoside in the lysosomes.

A third type of mutation also can lead to disease symptoms similar to those of Tay-Sachs disease. Children were identified with Tay-Sachs symptoms, but when both hexosaminidase A and B activities were measured in a test tube, they were normal. This disease, ultimately named Sandhoff activator disease, is caused by a mutation in a protein that is needed to activate hexosaminidase A activity. In the absence of the activator, hexosaminidase A activity is minimal, and GM2 initially accumulates in lysosomes. This mutation has no effect on hexosaminidase B activity.

When a glycolipid cannot be degraded because of an enzymatic mutation, it accumulates in residual bodies (vacuoles that contain material that lysosomal enzymes cannot digest). Normal cells contain a small number of residual bodies, but in diseases of lysosomal enzymes, large numbers of residual bodies accumulate within the cell, eventually interfering with normal cell function.

In 70% of the cases of Tay-Sachs disease in persons of Ashkenazi Jewish background, exon 11 of the gene for the α -chain of hexosaminidase A contains a mutation. The normal gene sequence encodes a protein with the amino acids Arg-Ile-Ser-Tyr-Gly-Pro-Asp in this region, as shown below:

The mutant DNA sequence for this area is

A four-base insertion (underlined) occurs in the mutated gene, which alters the reading frame of the protein and also introduces a premature stop codon farther down the protein, so no functional α -subunit can be produced.

KEY CONCEPTS

- ◆ The pentose phosphate pathway consists of both oxidative and nonoxidative reactions.
- ◆ The oxidative steps of the pentose phosphate pathway generate NADPH and ribulose 5-phosphate from glucose 6-phosphate.
 - ◆ Ribulose 5-phosphate is converted to ribose 5-phosphate for nucleotide biosynthesis.
 - ◆ NADPH is utilized as reducing power for biosynthetic pathways.
- ◆ The nonoxidative steps of the pentose phosphate pathway reversibly convert five-carbon sugars to fructose 6-phosphate and glyceraldehyde 3-phosphate.
- ◆ The needs of the cell dictate whether the cell will utilize the oxidative reactions of the pentose phosphate pathway, the nonoxidative reactions, or both sets of reactions.
- ◆ Reactions between sugars or the formation of sugar derivatives utilize sugars activated by attachment to nucleotides (a nucleotide sugar).
- ◆ UDP-glucose and UDP-galactose are substrates for many glycosyltransferase reactions.
- ◆ Lactose is formed from UDP-galactose and glucose.
- ◆ UDP-glucose is oxidized to UDP-glucuronate, which forms glucuronide derivatives of various hydrophobic compounds, making them more readily excreted in urine or bile than the parent compound.
- ◆ Glycoproteins and glycolipids contain various types of carbohydrate residues.
- ◆ The carbohydrates in glycoproteins can be either *O*-linked or *N*-linked and are synthesized in the ER and the Golgi apparatus.
- ◆ For *O*-linked carbohydrates, the carbohydrates are added sequentially (via nucleotide sugar precursors), beginning with a sugar linked to the hydroxyl group of the amino acid side chains of serine or threonine.
- ◆ For *N*-linked carbohydrates, the branched carbohydrate chain is first synthesized on dolichol phosphate and then transferred to the amide nitrogen of an asparagine residue of the protein.
- ◆ Glycolipids belong to the class of sphingolipids that add carbohydrate groups to the base ceramide one at a time from nucleotide sugars.
- ◆ Defects in the degradation of glycosphingolipids lead to a class of lysosomal diseases known as the sphingolipidoses.
- ◆ Table 27.7 summarizes the diseases discussed in this chapter.

TABLE 27.7 Diseases Discussed in Chapter 27

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Blood transfusions	Environmental/Genetic	Blood typing is dependent on antigens on the cell surface, particularly the carbohydrate content of the antigen.
Tay–Sachs disease	Genetic	Lack of hexosaminidase A activity, leading to an accumulation of GM2 in the lysosomes
Sandhoff disease	Genetic	Lack of both hexosaminidase A and B activity, leading to an accumulation of GM2 and globoside in the lysosomes
Jaundice	Both	Lack of ability to conjugate bilirubin with glucuronic acid in the liver
Sphingolipidoses	Genetic	Defects in ganglioside and sphingolipid degradation, as summarized in Table 27.5
Glucose 6-phosphate dehydrogenase deficiency	Genetic, X-linked	Lack of glucose 6-phosphate dehydrogenase activity leads to hemolytic anemia in the presence of strong oxidizing agents.

REVIEW QUESTIONS—CHAPTER 27

1. Which one of the following best describes a mother with galactosemia caused by a deficiency of galactose 1-phosphate uridylyl transferase?
 - A. She can convert galactose to UDP-galactose for lactose synthesis during lactation.

- B. She can form galactose 1-phosphate from galactose.
 - C. She can use galactose as a precursor to glucose production.
 - D. She can use galactose to produce glycogen.
 - E. She will have lower-than-normal levels of serum galactose after drinking milk.
2. The immediate carbohydrate precursors for glycolipid and glycoprotein synthesis are which of the following?
 - A. Sugar phosphates
 - B. Sugar acids
 - C. Sugar alcohols
 - D. Nucleotide sugars
 - E. Acyl-sugars
 3. A newborn is diagnosed with neonatal jaundice. In this patient, the bilirubin produced lacks which one of the following carbohydrates?
 - A. Glucose
 - B. Gluconate
 - C. Glucuronate
 - D. Galactose
 - E. Galactitol
 4. The nitrogen donor for the formation of amino sugars is which one of the following?
 - A. Ammonia
 - B. Asparagine
 - C. Glutamine
 - D. Adenine
 - E. Dolichol
 5. Which one of the following glycolipids would accumulate in a patient with Sandhoff disease?
 - A. GM1
 - B. Lactosylceramide
 - C. Globoside
 - D. Glucocerebroside
 - E. GM3
 6. A defect in which one of the following enzymes would severely affect an individual's ability to specifically metabolize galactose?
 - A. UDP-glucose pyrophosphorylase
 - B. Hexokinase
 - C. Glucose 6-phosphate dehydrogenase
 - D. Triose kinase
 - E. Pyruvate carboxylase
 7. A woman, shortly after giving birth to her first child, was discovered to be unable to synthesize lactose. Analysis of various glycoproteins in her serum indicated that there was no defect in the carbohydrate chains, nor was the carbohydrate content of her cell surface glycolipids altered. This woman may have a mutation in which one of the following enzymes or class of enzymes?
 - A. A glucosyl transferase
 - B. A galactosyl transferase
 - C. Lactase
 - D. α -Lactalbumin
 - E. A lactosyl transferase
 8. A 27-year-old man of Mediterranean descent developed hemolytic anemia after being prescribed a drug that is a potent oxidizing agent. The anemia results from which one of the following?
 - A. A lowered concentration of oxidized glutathione
 - B. A lowered concentration of reduced glutathione
 - C. Increased production of NADPH
 - D. A reduction of hydrogen peroxide levels
 - E. An increase in the production of glucose 6-phosphate
 9. A patient's blood is being typed by exposing it to either type A or type B antibodies. Which result would be expected if the patient had type AB blood?
 - A. No reaction to A antibodies

- B. No reaction to B antibodies
 - C. No reaction to either A or B antibodies
 - D. Reaction to both A and B antibodies
 - E. A reaction to A antibodies, but not to B antibodies
0. Inherited defects in the pentose phosphate shunt pathway could lead to which one of the following?
- A. Ineffective oxidative phosphorylation due to dysfunctional mitochondria.
 - B. An inability to carry out reductive detoxification.
 - C. An inability to produce fructose 6-phosphate and glyceraldehyde 3-phosphate for five-carbon sugar biosynthesis.
 - D. An inability to generate NADH for biosynthetic reactions.
 - E. An inability to generate NADH to protect cells from ROS.
1. A chronic alcohol use abuser (for over 10 years) was found unconscious on the sidewalk after having a two-week binge in which the only calories the individual ingested were from alcohol. Blood glucose levels were 31 mg/dL, and the patient was placed on an iv-glucose drip. After a few hours, the patient regained consciousness but was still intoxicated. After talking to the patient, it was determined that their diet over the past 10 years consisted primarily of alcohol and small amounts of protein, with no nutritional supplements. Which enzyme activities would you expect to be reduced in this patient at the time of initial treatment?

	Pyruvate Dehydrogenase	Isocitrate Dehydrogenase	Glycer-aldehyde 3-phosphate Dehydrogenase	Trans-ketolase	Transaldolase
A	Yes	No	No	Yes	No
B	Yes	Yes	No	No	No
C	Yes	No	No	Yes	Yes
D	No	Yes	Yes	No	Yes
E	No	No	Yes	Yes	Yes
F	No	Yes	Yes	No	No

2. An individual of Mediterranean descent gets ill after eating fava beans, so he has learned to remove these from his diet. Which enzymes would be required in this individual's liver to synthesize ribose 5-phosphate from glucose 6-phosphate? Choose the one best answer.

	Phospho- glucomu- tase	Glycer- aldehyde 3-phosphate Dehydroge- nase	Glucose 6-phos- phate Dehydroge- nase	Tran- sketo- lase	C3- epimerase
A	No	No	No	Yes	No
B	No	No	No	Yes	Yes
C	Yes	Yes	No	Yes	No
D	Yes	Yes	Yes	No	Yes
E	No	No	Yes	No	No
F	No	Yes	Yes	No	Yes

3. A child of Ashkenazi Jewish descent had been progressing normally for their first 6 months of life but then started to regress developmentally, losing motor skills, displaying vision problems, overall weakness, and an exaggerated startle response. Genetic analysis indicated that each parent was heterozygous for an inactivating mutation in the *HexB* gene. The child does have, however, the ability to degrade which of the following glycolipids? Choose the one best answer.

	Globoside	GM₂	Galactosylceramide	Sphingomyelin
A	Yes	Yes	No	No
B	Yes	No	Yes	Yes
C	Yes	Yes	No	No
D	No	No	Yes	No
E	No	Yes	No	Yes
F	No	No	Yes	Yes

4. Azaserine is a powerful drug, highly toxic, which inhibits virtually all reactions that utilize glutamine as a nitrogen donor. Which one of the following substrates would no longer be able to accept a nitrogen group in the presence of azaserine?
- Glucose 1-phosphate
 - Glucose 6-phosphate
 - Fructose 1-phosphate
 - Fructose 6-phosphate
 - Mannose 1-phosphate
 - Mannose 6-phosphate
5. A one-year-old child, at birth, was small and displayed hypotonia. The child's growth curve was below normal, and normal developmental milestones were late, especially the ability to sit and stand. The child's mobility was hindered by joint deformities. During the diagnosis process, fibroblasts were obtained from the

child and cultured in the laboratory. It was found that these fibroblasts secreted lysosomal enzymes instead of targeting them to the lysosomes. The lysosomes in the cells were dark and resembled inclusion bodies. The mutated enzyme in this child is best classified as which one of the following?

- A. A hydrolase
- B. A dehydrogenase
- C. A transamidase
- D. An isomerase
- E. A phosphotransferase

ANSWERS TO REVIEW QUESTIONS

1. **The answer is B.** Galactose metabolism requires the phosphorylation of galactose to galactose 1-phosphate, which is then converted to UDP-galactose (which is the step that is defective in the patient), and then epimerized to UDP-glucose. Although the mother cannot convert galactose to lactose because of the enzyme deficiency, she can make UDP-glucose from glucose 6-phosphate, and once she has made UDP-glucose she can epimerize it to form UDP-galactose and can synthesize lactose (thus, A is incorrect). However, because of her enzyme deficiency, the mother cannot convert galactose 1-phosphate to UDP-galactose or UDP-glucose, so the dietary galactose cannot be used for glycogen synthesis or glucose production (thus, C and D are incorrect). After ingesting milk, the galactose levels will be elevated in the serum because of the metabolic block in the cells (thus, E is incorrect).
2. **The answer is D.** Nucleotide sugars, such as UDP-glucose, UDP-galactose, and CMP-sialic acid, donate sugars to the growing carbohydrate chain. The other activated sugars listed do not contribute to glycolipid or glycoprotein synthesis.
3. **The answer is C.** Bilirubin is conjugated with glucuronic acid residues to enhance its solubility. Glucuronic acid is glucose oxidized at position 6; gluconic acid is glucose oxidized at position 1 and is generated by the HMP shunt pathway. The activated form of glucuronic acid is UDP-glucuronate.
4. **The answer is C.** Glutamine donates the amide nitrogen to fructose 6-phosphate to form glucosamine 6-phosphate. None of the other nitrogen-containing compounds (A, B, and D) donate their nitrogen to carbohydrates. Dolichol contains no nitrogen and is the carrier for carbohydrate chain synthesis of *N*-linked glycoproteins.
5. **The answer is C.** Sandhoff disease is a deficiency of both hexosaminidase A and B activity, resulting from loss of activity of the β -subunit in both of these enzymes. The degradative step at which amino sugars need to be removed from the glycolipids would be defective, such that globoside and GM2 accumulate in this disease. The other answers are incorrect; GM1 does contain an amino sugar, but it is converted to GM2 before the block in Sandhoff disease is apparent.
6. **The answer is A.** Galactose is phosphorylated by galactokinase and the galactose 1-phosphate formed reacts with UDP-glucose to form glucose 1-phosphate and UDP-galactose. The enzyme that catalyzes this reaction is galactose 1-phosphate uridylyl transferase. UDP-glucose is absolutely required for further galactose metabolism. UDP-glucose is formed from UTP and glucose 1-phosphate by the enzyme UDP-glucose pyrophosphorylase, so a deficiency in this enzyme would lead to reduced galactose metabolism, due to a lack of UDP-glucose. Galactose is phosphorylated by galactokinase, not by hexokinase. Glucose 6-phosphate dehydrogenase is not required for galactose metabolism; it converts glucose 6-phosphate to 6-phosphogluconate in the first step of the HMP shunt pathway. Triose kinase is also not required for galactose metabolism, as this enzyme converts glyceraldehyde to glyceraldehyde 3-phosphate. Pyruvate carboxylase is also not required for galactose metabolism, as it converts pyruvate to oxaloacetate.
7. **The answer is D.** Lactose synthase is composed of two subunits: a galactosyl transferase and α -lactalbumin. In the absence of α -lactalbumin, the galactosyl transferase is active in glycoprotein and glycolipid synthesis, but relatively inactive for lactose synthesis. At birth, α -lactalbumin is induced and alters the specificity of the galactosyl transferase such that lactose can now be synthesized. Since glycoprotein and glycolipid synthesis was normal, the mutation could not be in the galactosyl transferase subunit. Lactase is the enzyme that digests lactose in the intestine, and a lactosyl transferase enzyme, if such an enzyme did exist, would not answer the question, as it would require lactose as a substrate. A glucosyl transferase is not required for lactose synthesis (lactose synthase is).
8. **The answer is B.** The patient has glucose 6-phosphate dehydrogenase deficiency, and cannot generate NADPH from glucose 6-phosphate. In the red blood cells, which lack mitochondria, this is the only

pathway through which NADPH can be generated. In the absence of NADPH, the molecule which protects against oxidative damage (glutathione) is oxidized preferentially to protect membrane lipids and proteins. There is only limited glutathione in the membrane, so once it is oxidized it needs to be converted back to reduced glutathione (the protective form). The enzyme which does this, glutathione reductase, requires NADPH to supply the electrons to reduce the oxidized glutathione. In the absence of NADPH, the glutathione cannot be reduced, and the protection offered by reduced glutathione is eliminated, leading to membrane damage and cell lysis. Since the life of a red cell is so short (120 days in circulation) there is usually sufficient glutathione to protect the cell in the absence of an exogenous oxidizing agent. However, once such an agent is present (such as a drug) the red cells are easily lysed, leading to the anemia. The hemolytic anemia is not due to a lowering of hydrogen peroxide levels, nor an increase in the production of glucose 6-phosphate.

9. **The answer is D.** A type AB person would carry both the A and B antigens, so the blood cells would bind to antibodies directed against either the type A antigen, or the type B antigen. Type O blood, which does not express either the type A or type B antigens, would not react with either antibody. Type A blood would react to antibodies to antigen A, but not to antigen B. Type B blood would react to antibodies to antigen B, but not to antibodies directed against antigen A.
10. **The answer is B.** The pentose phosphate pathway is operative in the cytosol of all cells since all cells require NADPH for reductive detoxification. NADPH is also used for fatty acid synthesis and detoxification of medications. NADPH does not donate electrons to complex I of the electron transfer chain, so oxidative phosphorylation would not be impaired. Fructose 6-phosphate and glyceraldehyde 3-phosphate can be generated via glycolysis; the pentose phosphate pathway is not required for their synthesis. NADPH is used for both biosynthetic reactions and to protect cells from ROS, not NADH (which is generated via glycolysis).
11. **The answer is A.** Individuals with chronic alcohol abuse are at risk for a thiamin deficiency (vitamin B1), due to both the poor diet of the individual and ethanol's inhibition of thiamin absorption in the small intestine. In the patient described in the question, the thiamin deficiency will negatively affect the activities of pyruvate dehydrogenase and transketolase. Isocitrate dehydrogenase, glyceraldehyde 3-phosphate dehydrogenase, and transaldolase do not require thiamin for activity.
12. **The answer is B.** The individual has glucose 6-phosphate dehydrogenase deficiency, and cannot catalyze the oxidative steps of the HMP shunt pathway. Due to this enzyme defect, the individual can synthesize ribose 5-phosphate from glucose 6-phosphate using the reactions of the nonoxidative portion of the HMP shunt pathway. This entails glucose 6-phosphate being converted to fructose 6-phosphate (phosphoglucosmutase is not required), some fructose 6-phosphate being phosphorylated by PFK-1 to generate fructose 1,6-bisphosphate, and aldolase splitting fructose 1,6-bisphosphate to glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. The dihydroxyacetone phosphate can be converted to glyceraldehyde 3-phosphate by triose phosphate isomerase. Fructose 6-phosphate and glyceraldehyde 3-phosphate will then be substrates for transketolase (so glyceraldehyde 3-phosphate dehydrogenase is not required for this reaction sequence), which will generate erythrose 4-phosphate and xylulose 5-phosphate. The xylulose 5-phosphate is epimerized (by C3-epimerase) to ribulose 5-phosphate, which is isomerized to ribose 5-phosphate.
13. **The answer is F.** The child has Sandhoff disease and produces a dysfunctional hexosaminidase β -subunit (the product of the *HexB* gene). This is an autosomal recessive disorder and the child has inherited the mutation from both his mother and father. The β -subunit is utilized for both Hexosaminidase A activity (which cleaves GM2, and is a dimer of one α and one β -subunit), and Hexosaminidase B activity (which cleaves globoside, and is a dimer of β -subunits). The lack of hexosaminidase A or B activity will not interfere with the degradation of galactosylceramide or sphingomyelin.
14. **The answer is D.** Amino sugars are synthesized from fructose 6-phosphate, which reacts with glutamine to form glucosamine 6-phosphate and glutamate. The other sugars listed do not react with glutamine to form amide sugars—all amide sugars are derived from glucosamine 6-phosphate.
15. **The answer is E.** The child has I-cell disease, which is due to the lack of an enzyme in the ER, *N*-acetylglucosamine phosphotransferase, which adds an *N*-acetylglucosamine phosphate to a mannose residue on the carbohydrate portion of enzymes destined for the lysosomes. A second enzyme then removes the *N*-acetylglucosamine from the molecule, leaving the phosphate behind so the carbohydrate chain now has a mannose 6-phosphate on it. The mannose 6-phosphate receptor then binds the glycoproteins expressing mannose 6-phosphate and transfers them to the lysosomes. In the absence of this signal, the proteins are secreted from the cell. The enzyme is a phosphotransferase, and would not be

considered a hydrolase (hydrolyzing a bond with water), a dehydrogenase (catalyzing an oxidation–reduction reaction), an amidase (nitrogen is not being added to the mannose), or an isomerase (there is no isomerization of the substrate occurring during this reaction).

Gluconeogenesis and Maintenance of Blood Glucose Levels

During fasting, many of the reactions of glycolysis are reversed as the liver produces glucose to maintain blood glucose levels. This process of **glucose production** is called **gluconeogenesis**.

Gluconeogenesis, which occurs primarily in the liver, is the pathway for the synthesis of glucose from compounds other than carbohydrates. In humans, the major precursors of glucose are **lactate**, **glycerol**, and **amino acids**, particularly **alanine**. Except for three key sequences, the reactions of gluconeogenesis are reversals of the steps of glycolysis (Fig. 28.1). The sequences of gluconeogenesis that do not use enzymes of glycolysis involve the irreversible, regulated steps of glycolysis. These three sequences are the conversion of (1) pyruvate to phosphoenolpyruvate (PEP), (2) fructose 1,6-bisphosphate to fructose 6-phosphate (fructose 6-P), and (3) glucose 6-phosphate (glucose 6-P) to glucose.

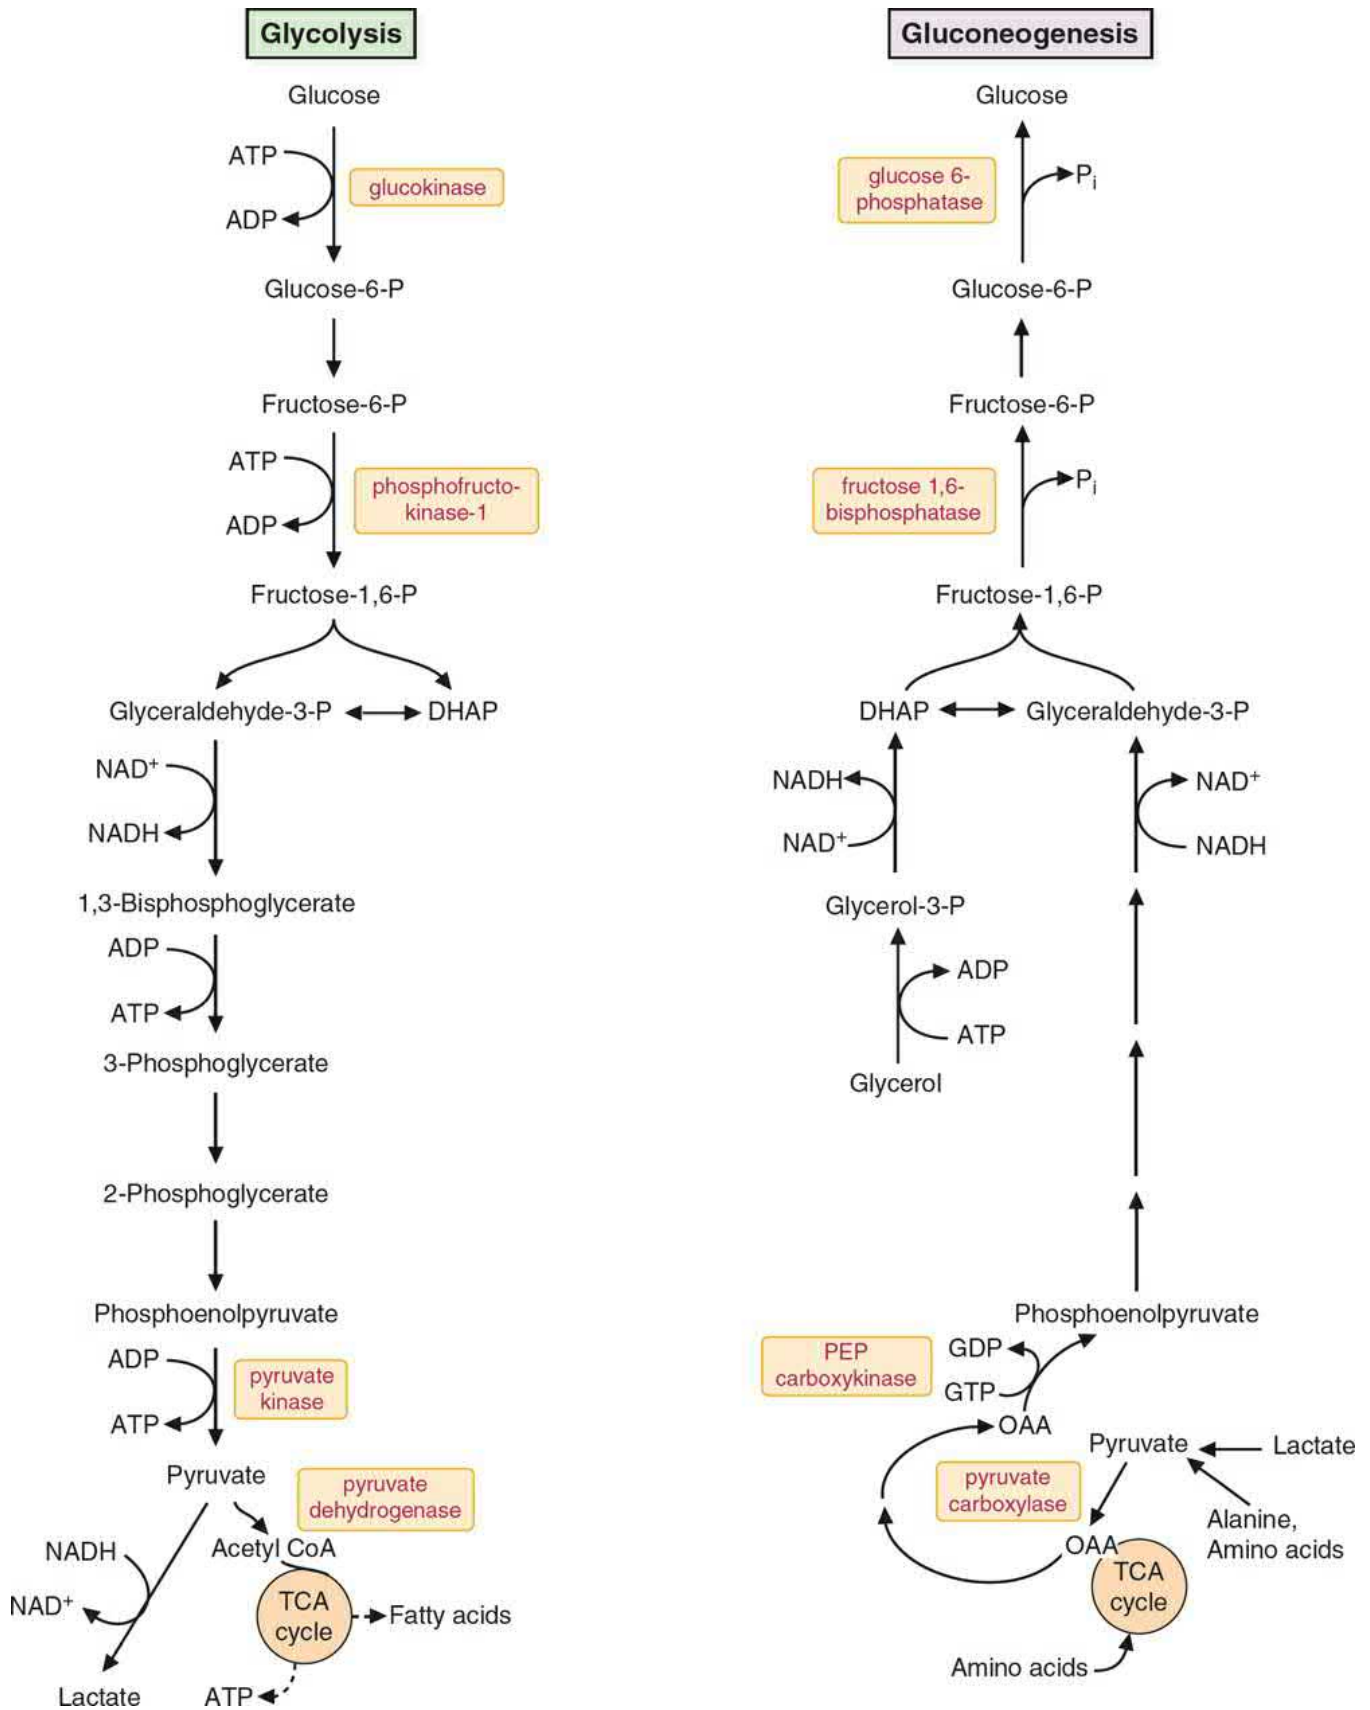

FIGURE 28.1 Glycolysis and gluconeogenesis in the liver. The gluconeogenic pathway is almost the reverse of the glycolytic pathway, except for three reaction sequences. At these three steps, the reactions are catalyzed by different enzymes. The energy requirements of these reactions differ, and one pathway can be activated while the other is inhibited. The steps for which enzyme names are indicated are the irreversible steps of those pathways. All other steps are reversible, although for clarity this is not indicated in the figure. Acetyl CoA, acetyl coenzyme A; ADP, adenosine diphosphate; ATP, adenosine triphosphate; DHAP, dihydroxyacetone phosphate; fructose-1,6-P, fructose 1,6-bisphosphate; fructose-6-P, fructose 6-phosphate; GDP, guanosine diphosphate; glucose-6-P, glucose 6-phosphate; glyceraldehyde-3-P, glyceraldehyde 3-

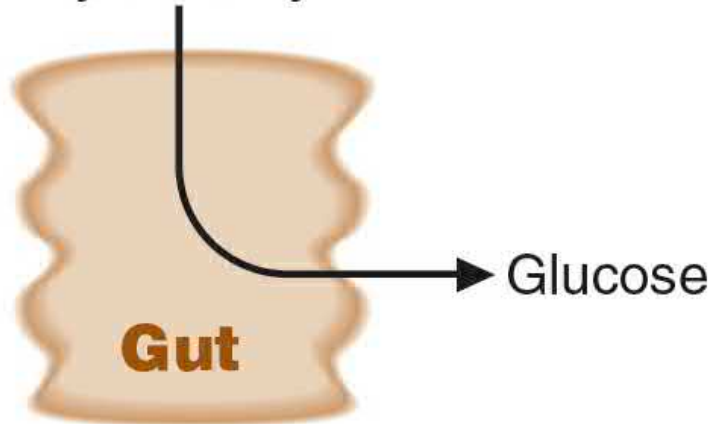

phosphate; glycerol-3-P, glycerol 3-phosphate; GTP, guanosine triphosphate; NAD, nicotinamide adenine dinucleotide; OAA, oxaloacetate; PEP, phosphoenolpyruvate; Pi, inorganic phosphate; TCA, tricarboxylic acid.

Some tissues of the body, such as the brain and red blood cells, cannot synthesize glucose on their own but depend on glucose for energy. On a long-term basis, most tissues also require glucose for other functions, such as synthesis of the ribose moiety of nucleotides or the carbohydrate portion of glycoproteins and glycolipids. Therefore, to survive, humans must have mechanisms for maintaining blood glucose levels.

After a meal containing carbohydrates, blood glucose levels rise (Fig. 28.2). Some of the glucose from the diet is stored in the liver as **glycogen**. After 2 or 3 hours of fasting, this glycogen begins to be degraded by the process of **glycogenolysis**, and glucose is released into the blood. As glycogen stores decrease, **adipose triacylglycerols** are also degraded, providing **fatty acids** as an alternative fuel and glycerol for the synthesis of glucose by gluconeogenesis. Amino acids are also released from the muscle to serve as gluconeogenic precursors.

Fed

Dietary carbohydrate

Fasting

Starved

FIGURE 28.2 Sources of blood glucose in the fed, fasting, and starved states. RBC, red blood cells.

During an overnight fast, blood glucose levels are maintained by both glycogenolysis and gluconeogenesis. However, after approximately 30 hours of fasting, liver glycogen stores are mostly depleted. Subsequently, gluconeogenesis is the only source of blood glucose.

Changes in the metabolism of glucose that occur during the switch from the fed to the fasting state are regulated by the hormones **insulin** and **glucagon**. Insulin is elevated in the fed state, and glucagon is elevated during fasting. Insulin stimulates the **transport** of glucose into certain cells such as those in muscle and adipose tissue. Insulin also alters the activity of key enzymes that regulate metabolism, stimulating the storage of fuels. Glucagon counters the effects of insulin, stimulating the release of stored fuels and the conversion of lactate, amino acids, and glycerol to glucose.

Blood glucose levels are maintained not only during fasting but also during exercise, when muscle cells take up glucose from the blood and oxidize it for energy. During exercise, the liver supplies glucose to the blood by the processes of glycogenolysis and gluconeogenesis.

THE WAITING ROOM

Al M., who suffers from alcohol use disorder, was brought to the emergency department by his landlady, who stated that he had been drinking heavily for the past week. During this time, his appetite had gradually diminished, and he had not eaten any food for the past 3 days. He was confused, combative, tremulous, and sweating profusely. His speech was slurred. His heart rate was rapid (110 beats/minute). As his blood pressure was being determined, he had a grand mal seizure. His blood glucose, drawn just before the onset of the seizure, was 28 mg/dL or 1.6 mM (reference range for overnight fasting blood glucose, 70 to 100 mg/dL or 3.9 to 5.6 mM). His blood ethanol level drawn at the same time was 295 mg/dL (intoxication level, i.e., “confused” stage, 150 to 300 mg/dL).

Emma W. presented to the emergency department 3 days after being discharged from the hospital following a 7-day admission for a severe asthma exacerbation. During her last admission, she was intubated and required high-dose intravenous methylprednisolone (a synthetic anti-inflammatory glucocorticoid) for the first 4 days of her stay. After 3 additional days on oral prednisone, she was discharged on substantial pharmacologic doses of this steroid and instructed to return to her physician’s office in 5 days. She presented now with marked polyuria (increased urination), polydipsia (increased thirst), and muscle weakness. Her blood glucose was 275 mg/dL or 15 mM (reference range, 70 to 100 mg/dL or 3.9 to 5.6 mM).

Dianne A. took her morning insulin, but then did not feel well, so did not eat and took a nap. When her friend came over later, she was unresponsive. The friend called an ambulance, and **Dianne A.** was rushed to the hospital emergency department in a coma. Her pulse and blood pressure at admission were normal. Her skin was flushed and slightly moist. Her respirations were slightly slow.

Ann R. continues to resist efforts on the part of her psychiatrist and family physician to convince her to increase her caloric intake. Her body weight varies between 97 and 99 lb, far below the desirable weight for a woman who is 5 ft 7 in tall. In spite of her severe diet, her fasting blood glucose levels range from 55 to 70 mg/dL. She denies having any hypoglycemic symptoms.

Otto S. has complied with his calorie-restricted diet and aerobic exercise program. He has lost another 7 lb and is closing in on his goal of weighing 154 lb. He notes increasing energy during the day, and he remains alert during lectures and assimilates the lecture material noticeably better than he did before starting his weight loss and exercise program. He jogs for 45 minutes each morning before breakfast.

I. Glucose Metabolism in the Liver

Glucose serves as a fuel for most tissues of the body. It is the major fuel for certain tissues such as the brain and

red blood cells. After a meal, food is the source of blood glucose. The liver oxidizes glucose and stores the excess as glycogen. The liver also uses the pathway of glycolysis to convert glucose to pyruvate, which provides carbon for the synthesis of fatty acids. Glycerol 3-phosphate, produced from glycolytic intermediates, combines with fatty acids to form triacylglycerols, which are secreted into the blood in very-low-density lipoprotein (VLDL; explained further in Chapter 31). During fasting, the liver releases glucose into the blood, so that glucose-dependent tissues do not suffer from a lack of energy. Two mechanisms are involved in this process: glycogenolysis and gluconeogenesis. Hormones, particularly insulin and glucagon, dictate whether glucose flows through glycolysis or whether the reactions are reversed and glucose is produced via gluconeogenesis.

The measurement of ketones (acetoacetate and β -hydroxybutyrate, see Chapter 3) in the blood and urine can indicate the level of starvation, or the presence of diabetic ketoacidosis (DKA). There are several methods to detect ketones. One is the use of reagent strips for urine (based on the reaction of sodium nitroprusside with acetoacetate), but this method does not detect the major blood ketone (β -hydroxybutyrate). A cyclic enzymatic method has been developed to overcome this, in which blood or plasma samples are incubated with acetoacetate decarboxylase, which removes all acetoacetate from the sample (converting it to acetone and carbon dioxide). Once this has been accomplished, β -hydroxybutyrate dehydrogenase is then incubated with the sample, along with thionicotinamide adenine dinucleotide (thio-NAD⁺). The thio-NAD⁺ is converted to thio-NADH, generating a colored product and acetoacetate. Thio-NADH absorbs light at 405 nm, in the visible range, as compared to NADH, which absorbs at 340 nm, in the ultraviolet range. The use of thio-NAD⁺ allows clinical laboratory instrumentation to be used. The acetoacetate is then recycled back to β -hydroxybutyrate, in which NADH is converted to NAD⁺. The β -hydroxybutyrate produced is then cycled back to acetoacetate, generating more thio-NADH. The cycling enhances the sensitivity of the assay. Once equilibrium is reached, one can calculate, from the change in absorbance per minute, the concentration of the β -hydroxybutyrate in the sample.

II. Gluconeogenesis

Gluconeogenesis, the process by which glucose is synthesized from noncarbohydrate precursors, occurs mainly in the liver under fasting conditions. Under the more extreme conditions of starvation, the kidney cortex also may produce glucose. For the most part, the glucose produced by the kidney cortex is used by the kidney medulla, but some may enter the bloodstream.

Starting with pyruvate, most of the steps of gluconeogenesis are simply reversals of those of glycolysis (Fig. 28.3). In fact, these pathways differ at only three points. Enzymes involved in catalyzing these steps are regulated so that either glycolysis or gluconeogenesis predominates, depending on physiologic conditions.

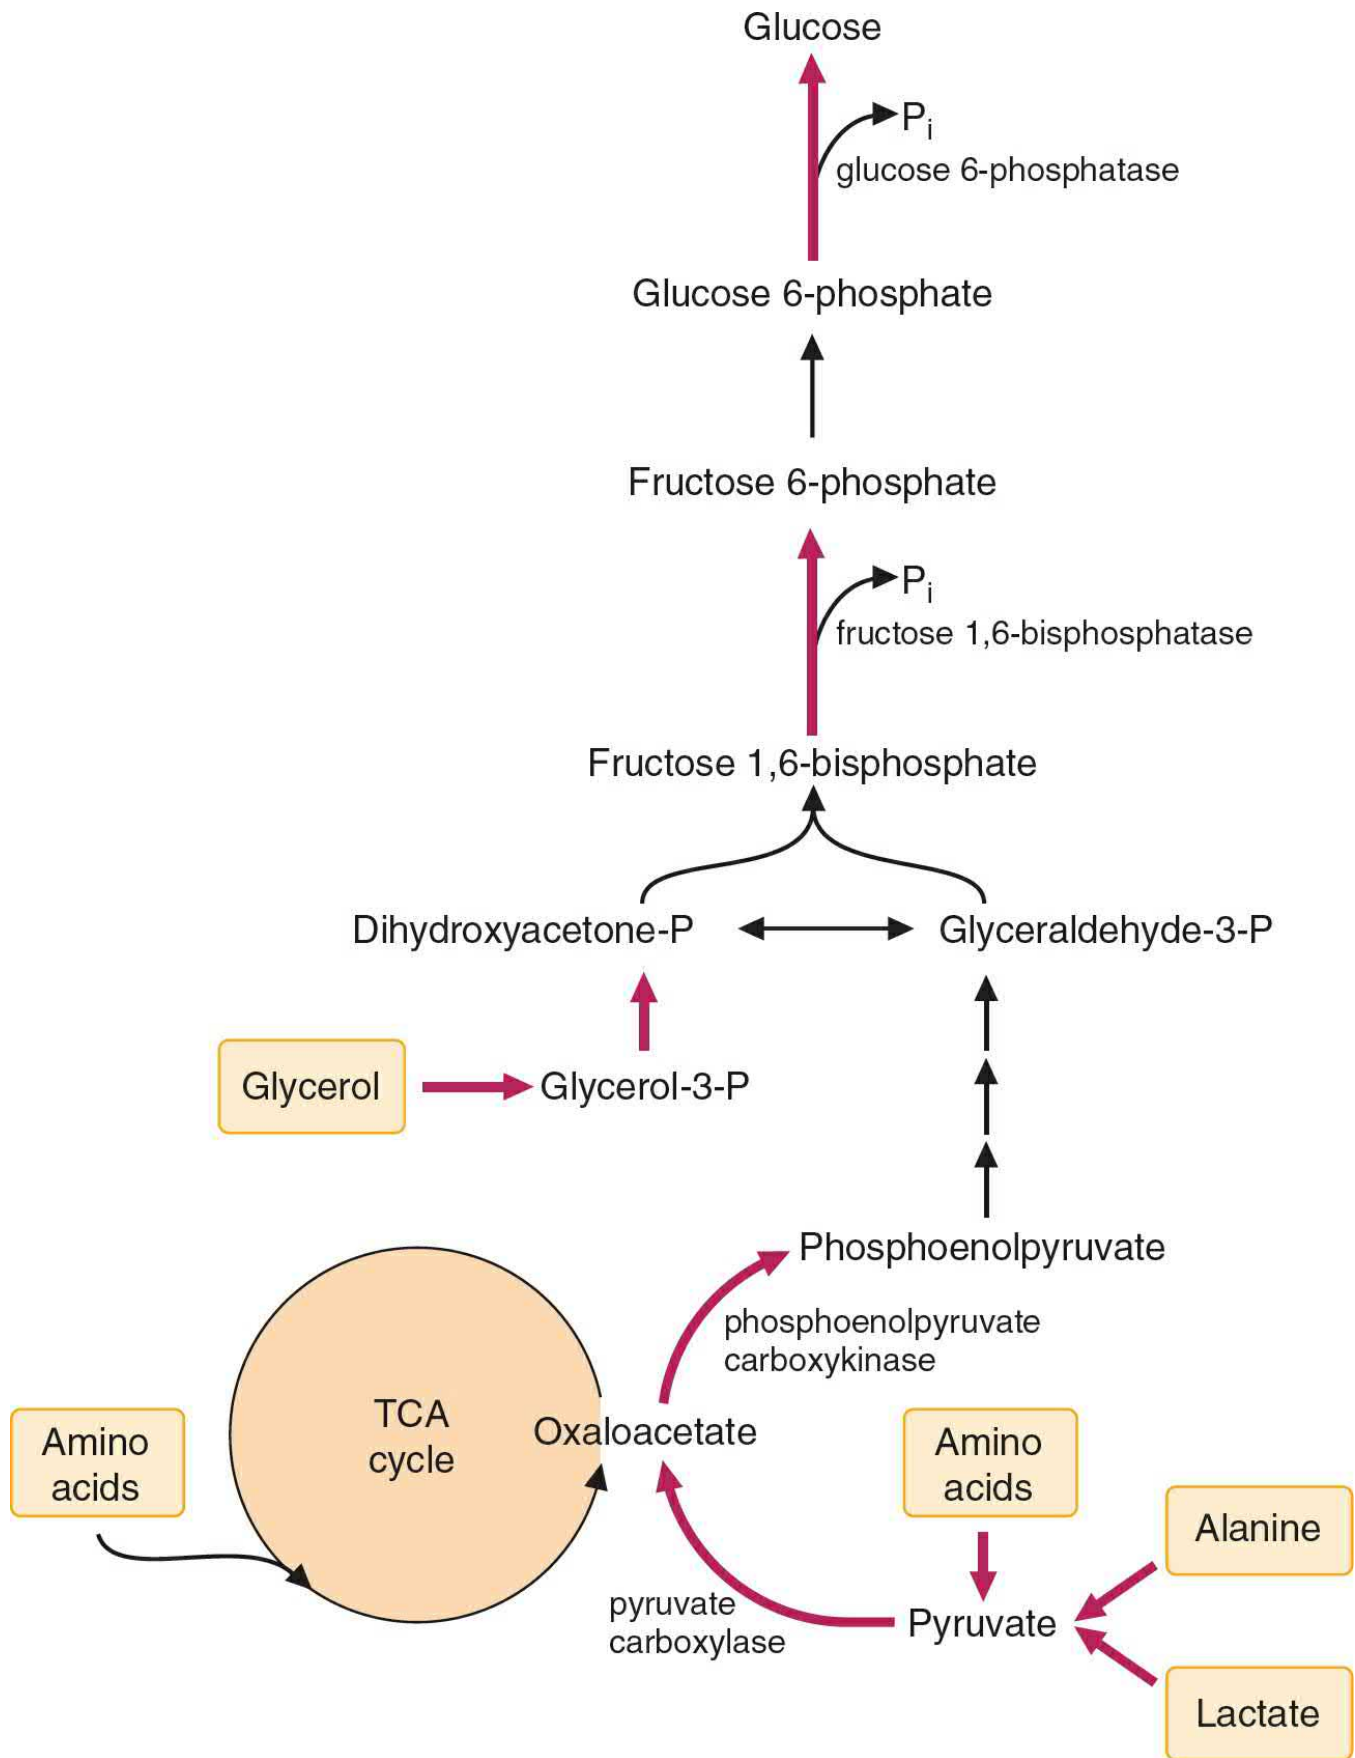

FIGURE 28.3 Key reactions of gluconeogenesis. The precursors are amino acids (particularly alanine), lactate, and glycerol. *Heavy red arrows* indicate steps that differ from those of glycolysis. Dihydroxyacetone-P, dihydroxyacetone phosphate; glyceraldehyde-3-P, glyceraldehyde 3-phosphate; glycerol-3-P, glycerol 3-phosphate; P_i, inorganic phosphate; TCA, tricarboxylic acid.

Most of the steps of gluconeogenesis use the same enzymes that catalyze the process of glycolysis. The flow of carbon, of course, is in the reverse direction. Three reaction sequences of gluconeogenesis differ from the corresponding steps of glycolysis. They involve the conversion of pyruvate to phosphoenolpyruvate (PEP) and the reactions that remove phosphate from fructose 1,6-bisphosphate to form fructose 6-phosphate (fructose 6-P) and from glucose 6-phosphate (glucose 6-P) to form glucose (see Fig. 28.3). The conversion of pyruvate to PEP is catalyzed during gluconeogenesis by a series of enzymes instead of the single enzyme used for glycolysis. The reactions that remove phosphate from fructose 1,6-bisphosphate and from glucose 6-P each use single enzymes that differ from the corresponding enzymes of glycolysis. Although phosphate is added during glycolysis by kinases, which use adenosine triphosphate (ATP), it is removed during gluconeogenesis by phosphatases that release inorganic phosphate (P_i) via hydrolysis reactions.

Comatose patients in DKA have the smell of acetone (a derivative of the ketone body acetoacetate) on their breath. In addition, DKA patients have deep, relatively rapid respirations typical of acidotic patients (Kussmaul respirations). These respirations result from an acidosis-induced stimulation of the respiratory center in the brain. More CO_2 is exhaled in an attempt to reduce the amount of acid in the body: $H^+ + HCO_3^- \rightarrow H_2CO_3 \rightarrow H_2O + CO_2$ (exhaled). These signs are not observed in a hypoglycemic coma.

The hyperglycemia of DKA also causes osmotic diuresis (i.e., glucose entering the urine carries water with it), which, in turn, causes a contraction of blood volume. Volume depletion may be aggravated by vomiting, which is common in patients with DKA. DKA may cause dehydration (dry skin), low blood pressure, and a rapid heartbeat. These respiratory and hemodynamic alterations are not seen in patients with hypoglycemic coma. The flushed, wet skin of hypoglycemic coma is in contrast to the dry skin observed in DKA.

A. Precursors for Gluconeogenesis

The three major carbon sources for gluconeogenesis in humans are lactate, glycerol, and amino acids, particularly alanine. Lactate is produced by anaerobic glycolysis in tissues such as exercising muscle or red blood cells, as well as by adipocytes during the fed state. Glycerol is released from adipose stores of triacylglycerol, and amino acids come mainly from amino acid pools in muscle, where they may be obtained by degradation of muscle protein. Alanine, the major gluconeogenic amino acid, is produced in the muscle from other amino acids and from glucose (see Chapter 37). Because ethanol metabolism only gives rise to acetyl coenzyme A (acetyl CoA), the carbons of ethanol cannot be used for gluconeogenesis.

B. Formation of Gluconeogenic Intermediates from Carbon Sources

The carbon sources for gluconeogenesis form pyruvate, intermediates of the tricarboxylic acid (TCA) cycle, or intermediates that are common to both glycolysis and gluconeogenesis.

DM should be suspected if a venous plasma glucose level drawn regardless of when food was last eaten (a “random” sample of blood glucose) is “unequivocally elevated” (i.e., >200 mg/dL), particularly in a patient who manifests the classic signs and symptoms of chronic hyperglycemia (polydipsia, polyuria, blurred vision, headaches, rapid weight loss, sometimes accompanied by nausea and vomiting). To confirm the diagnosis, the patient can fast overnight (10 to 16 hours), and the blood glucose measurement should be repeated. Values of <100 mg/dL are considered normal. Values ≥ 126 mg/dL are indicative of DM. The level of glycosylated hemoglobin (HbA_{1c}) can also be measured to make the diagnosis, and if $>6.5\%$ is diagnostic for DM. The levels of HbA_{1c} can also gauge the extent of hyperglycemia over the past 8 to 12 weeks and is used to guide treatment. Values of fasting blood glucose between 100 and 125 mg/dL are designated impaired fasting glucose (IFG) (or prediabetes), and further testing should be performed to determine whether these individuals will eventually develop overt DM. Individuals with blood glucose levels in this range have been defined as “prediabetes.” The determination that fasting blood glucose levels >126 mg/dL, or a percentage of glycosylated hemoglobin of $>6.5\%$, is diagnostic for DM is based on data indicating that at these levels of glucose or glycosylated hemoglobin patients begin to develop complications of DM, specifically retinopathy.

The renal tubular transport maximum in the average healthy subject is such that glucose will not appear in the urine until the blood glucose level is >180 mg/dL. As a result, reagent tapes (Tes-Tape or Dextrostix) designed to detect the presence of glucose in the urine are not sensitive enough to establish a diagnosis of early DM.

1. Lactate, Amino Acids, and Glycerol

Pyruvate is produced in the liver from the gluconeogenic precursors lactate and alanine. Lactate dehydrogenase oxidizes lactate to pyruvate, generating reduced nicotinamide adenine dinucleotide (NADH; Fig. 28.4A), and alanine aminotransferase converts alanine to pyruvate (see Fig. 28.4B).

FIGURE 28.4 Metabolism of gluconeogenic precursors. **A.** Conversion of lactate to pyruvate. **B.** Conversion of alanine to pyruvate. In this reaction, alanine aminotransferase transfers the amino group of alanine to α -ketoglutarate to form glutamate. The coenzyme for this reaction, pyridoxal phosphate, accepts and donates the amino group. **C.** Conversion of glycerol to DHAP. α -kg, α -ketoglutarate; DHAP, dihydroxyacetone phosphate; NAD, nicotinamide adenine dinucleotide.

Although alanine is the major gluconeogenic amino acid, other amino acids, such as serine, serve as carbon sources for the synthesis of glucose because they also form pyruvate, the substrate for the initial step in the process. Some amino acids form intermediates of the TCA cycle (see Chapter 23), which can enter the gluconeogenic pathway.

The carbons of glycerol are gluconeogenic because they form dihydroxyacetone phosphate (DHAP), a glycolytic intermediate (see Fig. 28.4C).

Glucocorticoids are naturally occurring steroid hormones. In humans, the major glucocorticoid is cortisol.

Glucocorticoids are produced in the adrenal cortex in response to various types of stress (see Chapter 41). One of their actions is to stimulate the degradation of muscle protein. Thus, increased amounts of amino acids become available as substrates for gluconeogenesis. **Emma W.** noted muscle weakness, a result of the muscle-degrading action of the synthetic glucocorticoid prednisone, which she was taking for its anti-inflammatory effects.

2. Propionate

Fatty acids with an odd number of carbon atoms, which are obtained mainly from vegetables in the diet, produce propionyl coenzyme A (propionyl CoA) from the three carbons at the ω -end of the chain (see Chapter 30). These carbons are relatively minor precursors of glucose in humans. Propionyl CoA is converted to methylmalonyl coenzyme A (methylmalonyl CoA), which is rearranged to form succinyl coenzyme A (succinyl CoA), a four-carbon intermediate of the TCA cycle that can be used for gluconeogenesis. The remaining carbons of an odd-chain fatty acid form acetyl CoA, from which no net synthesis of glucose occurs. In some species, propionate is a major source of carbon for gluconeogenesis. Ruminants can produce massive amounts of glucose from propionate. In cows, the cellulose in grass is converted to propionate by bacteria in the rumen. This substrate is then used to generate >5 lb of glucose each day by the process of gluconeogenesis. Propionate can also be formed from amino acid degradation in tissues (see Chapter 37).

β -Oxidation of fatty acids produces acetyl CoA (see Chapter 30). Because the pyruvate dehydrogenase reaction is thermodynamically and kinetically irreversible, acetyl CoA does not form pyruvate for gluconeogenesis. Therefore, if acetyl CoA is to produce glucose, it must enter the TCA cycle and be converted

to malate. For every two carbons of acetyl CoA that are converted to malate, two carbons are released as CO₂: one in the reaction catalyzed by isocitrate dehydrogenase and the other in the reaction catalyzed by α-ketoglutarate dehydrogenase. Therefore, there is no **net** synthesis of glucose from acetyl CoA.

In a fatty acid with 19 carbons, how many carbons (and which ones) have the capability to form glucose?

C. Pathway of Gluconeogenesis

Gluconeogenesis occurs by a pathway that reverses many, but not all, of the steps of glycolysis.

1. Conversion of Pyruvate to PEP

In glycolysis, PEP is converted to pyruvate by pyruvate kinase. In gluconeogenesis, a series of steps is required to accomplish the reversal of this reaction (Fig. 28.5). Pyruvate is carboxylated by pyruvate carboxylase to form oxaloacetate (OAA). This enzyme, which requires biotin, is the catalyst of an anaplerotic (refilling) reaction of the TCA cycle (see Chapter 23). In gluconeogenesis, this reaction replenishes the OAA that is used for the synthesis of glucose (Fig. 28.6).

FIGURE 28.5 Conversion of pyruvate to PEP in the liver. Follow the *shaded circled numbers* on the diagram, starting with the precursors alanine and lactate. The first step is the conversion of alanine and lactate to pyruvate. Pyruvate then enters the mitochondria and is converted to OAA (*circle 2*) by pyruvate carboxylase. Pyruvate dehydrogenase has been inactivated by both the NADH and acetyl CoA generated from fatty acid oxidation, which allows OAA production for gluconeogenesis. The OAA formed in the mitochondria is converted to either malate or aspartate to enter the cytoplasm via the malate/aspartate shuttle. In the cytoplasm, the malate or aspartate is converted back into OAA (*circle 3*), and phosphoenolpyruvate carboxykinase converts it to PEP (*circle 4*). The PEP formed is not converted to pyruvate, because pyruvate kinase has been inactivated by phosphorylation by the cAMP-dependent protein kinase under these conditions. The *white circled numbers* are alternative routes for exit of carbon from the mitochondrion using the malate/aspartate shuttle. Acetyl CoA, acetyl coenzyme A; ADP, adenosine diphosphate; ATP, adenosine triphosphate; FA, fatty acid; GDP, guanosine diphosphate; GTP, guanosine triphosphate; OAA, oxaloacetate; PEP, phosphoenolpyruvate; P_i, inorganic phosphate; PK, pyruvate kinase; TG, triacylglycerol

Pyruvate

Oxaloacetate

FIGURE 28.6 Conversion of pyruvate to oxaloacetate. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i , inorganic phosphate.

A Only the three carbons at the ω -end of an odd-chain fatty acid that form propionyl CoA are converted to glucose. The remaining 16 carbons of a fatty acid with 19 carbons form acetyl CoA, which does not form any net glucose.

The CO_2 that was added to pyruvate to form OAA is released in the reaction catalyzed by phosphoenolpyruvate carboxykinase (PEPCK), which generates PEP (Fig. 28.7A). For this reaction, guanosine triphosphate (GTP) provides a source of energy as well as the phosphate group of PEP. Pyruvate carboxylase is found in mitochondria. In various species, PEPCK is located either in the cytosol or in mitochondria, or it is distributed between these two compartments. In humans, the enzyme is distributed about equally in each compartment.

FIGURE 28.7 Generation of PEP from gluconeogenic precursors. **A.** Conversion of OAA to PEP, using PEPCK. **B.** Interconversion of OAA and malate. **C.** Transamination of aspartate to form OAA. Note that the cytosolic reaction is the reverse of the mitochondrial reaction as shown in Figure 28.5. GDP, guanosine diphosphate; GTP, guanosine triphosphate; NAD, nicotinamide adenine dinucleotide; OAA, oxaloacetate; PEP, phosphoenolpyruvate; PEPCK, phosphoenolpyruvate carboxykinase.

Excessive ethanol metabolism blocks the production of gluconeogenic precursors. Cells have limited amounts of NAD, which exist either as NAD^+ or as NADH. As the levels of NADH rise, those of NAD^+ fall, and the ratio of the concentrations of NADH and NAD^+ ($[\text{NADH}]/[\text{NAD}^+]$) increases. In the presence of ethanol, which is very rapidly oxidized in the liver, the $[\text{NADH}]/[\text{NAD}^+]$ ratio is much higher than it is in the normal fasting liver (see Chapter 33). High levels of NADH drive the lactate dehydrogenase reaction toward lactate. Therefore, lactate cannot enter the gluconeogenic pathway, and pyruvate that is generated from alanine is converted to lactate. Because glycerol is oxidized by NAD^+ during its conversion to DHAP, the conversion of glycerol to glucose is also inhibited when NADH levels are elevated. Consequently, the major precursors lactate, alanine, and glycerol are not used for gluconeogenesis under conditions in which alcohol metabolism is high.

OAA, generated from pyruvate by pyruvate carboxylase or from amino acids that form intermediates of the TCA cycle, does not readily cross the mitochondrial membrane. It is either decarboxylated to form PEP by the mitochondrial PEPCK or it is converted to malate or aspartate (see Fig. 28.7B and C). The conversion of OAA to malate requires NADH. PEP, malate, and aspartate can be transported into the cytosol.

After malate or aspartate traverses the mitochondrial membrane (acting as a carrier of OAA) and enters the cytosol, it is reconverted to OAA by reversal of the reactions given previously (see Fig. 28.7B and C). The conversion of malate to OAA generates NADH. Whether OAA is transported across the mitochondrial membrane as malate or aspartate depends on the need for reducing equivalents in the cytosol. NADH is required to reduce 1,3-bisphosphoglycerate to glyceraldehyde 3-phosphate during gluconeogenesis.

OAA, produced from malate or aspartate in the cytosol, is converted to PEP by the cytosolic PEPCK (see Fig. 28.7A).

2. Conversion of PEP to Fructose 1,6-Bisphosphate

The remaining steps of gluconeogenesis occur in the cytosol (Fig. 28.8). Starting with PEP as a substrate, the steps of glycolysis are reversed to form glyceraldehyde 3-phosphate. For every two molecules of glyceraldehyde 3-phosphate that are formed, one is converted to DHAP. These two triose phosphates, DHAP and glyceraldehyde 3-phosphate, condense to form fructose 1,6-bisphosphate by a reversal of the aldolase reaction. Because glyceral forms DHAP, it enters the gluconeogenic pathway at this level.

FIGURE 28.8 Conversion of phosphoenolpyruvate and glycerol to glucose. Gluconeogenic reactions are indicated by the red arrows. Glucokinase is inactive because of the low levels of glucose in the cell (below the K_m for glucokinase), whereas PFK-1 is inactive because of the low concentration of the allosteric activators AMP and fructose 2,6-bisphosphate, coupled to high concentrations of ATP, an allosteric inhibitor. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; F-2,6-P, fructose 2,6-bisphosphate; NAD, nicotinamide adenine dinucleotide; PFK-1, phosphofruktokinase-1; P_i , inorganic phosphate.

3. Conversion of Fructose 1,6-Bisphosphate to Fructose 6-P

The enzyme fructose 1,6-bisphosphatase releases inorganic phosphate from fructose 1,6-bisphosphate to form fructose 6-P. This is not a reversal of the phosphofructokinase-1 (PFK-1) reaction; ATP is not produced when the phosphate is removed from the 1-position of fructose 1,6-bisphosphate because that is a low-energy phosphate bond. Rather, inorganic phosphate is released in this hydrolysis reaction. In the next reaction of gluconeogenesis, fructose 6-P is converted to glucose 6-P by the same isomerase used in glycolysis (phosphoglucoisomerase).

4. Conversion of Glucose 6-P to Glucose

Glucose 6-phosphatase hydrolyzes P_i from glucose 6-P, and free glucose is released into the blood. As with fructose 1,6-bisphosphatase, this is not a reversal of the glucokinase reaction, because the phosphate bond in glucose 6-P is a low-energy bond, and ATP is not generated at this step.

Glucose 6-phosphatase is located in the membrane of the endoplasmic reticulum. It is used not only in gluconeogenesis, but also to produce blood glucose from the breakdown of liver glycogen.

AI M. had not eaten for 3 days, so he had no dietary source of glucose, and his liver glycogen stores were essentially depleted. He was solely dependent on gluconeogenesis to maintain his blood glucose levels. One of the consequences of ethanol ingestion and the subsequent rise in NADH levels is that the major carbon sources for gluconeogenesis cannot readily be converted to glucose (the high NADH/NAD⁺ ratio favors lactate formation from pyruvate, malate formation from OAA, and glycerol 3-phosphate formation from DHAP). Intermediates of the TCA cycle derived from amino acids are converted to malate, which enters the cytosol and is converted to OAA, which proceeds through gluconeogenesis to form glucose. When excessive amounts of ethanol are ingested, elevated NADH levels inhibit the conversion of malate to OAA in the cytosol. As a result, when **AI M.** drank a lot of alcohol, he became hypoglycemic. His blood glucose level was 28 mg/dL.

D. Regulation of Gluconeogenesis

Although gluconeogenesis occurs during fasting, it is also stimulated during prolonged exercise, by a high-protein diet, and under conditions of stress. The factors that promote the overall flow of carbon from pyruvate to glucose include the availability of substrate and changes in the activity or amount of certain key enzymes of glycolysis and gluconeogenesis.

1. Availability of Substrate

Gluconeogenesis is stimulated by the flow of its major substrates (glycerol, lactate, and amino acids) from peripheral tissues to the liver. Glycerol is released from adipose tissue whenever the levels of insulin are low and the levels of glucagon or the “stress” hormones, epinephrine and cortisol (a glucocorticoid), are elevated in the blood (see Chapter 19). Lactate is produced by muscle during exercise and by red blood cells. Amino acids are released from muscle whenever insulin is low or when cortisol is elevated. Amino acids are also available for gluconeogenesis when the dietary intake of protein is high and intake of carbohydrate is low.

2. Activity or Amount of Key Enzymes

The following three sequences in the pathway of gluconeogenesis are regulated:

1. Pyruvate → PEP
2. Fructose 1,6-bisphosphate → fructose 6-P
3. Glucose 6-P → glucose

These steps correspond to those in glycolysis that are catalyzed by regulatory enzymes. The enzymes involved in these steps of gluconeogenesis differ from those that catalyze the reverse reactions in glycolysis. The net flow of carbon, whether from glucose to pyruvate (glycolysis) or from pyruvate to glucose (gluconeogenesis), depends on the relative activity or amount of these glycolytic or gluconeogenic enzymes (Fig. 28.9 and Table 28.1).

TABLE 28.1 Regulation of Enzymes of Glycolysis and Gluconeogenesis in Liver

ENZYME	MECHANISM
A. Glycolytic enzymes	

Pyruvate kinase	Activated by F 1,6-BP Inhibited by ATP, alanine
	Inhibited by phosphorylation (glucagon and epinephrine lead to an increase in cAMP levels, which activates protein kinase A)
Phosphofructokinase-1	Activated by F 2,6-BP, AMP Inhibited by ATP, citrate
Glucokinase	High K_m for glucose Induced by insulin
B. Gluconeogenic enzymes	
Pyruvate carboxylase	Activated by acetyl CoA
Phosphoenolpyruvate carboxykinase	Induced (increase in gene transcription) by glucagon, epinephrine, glucocorticoids Repressed (decrease in gene transcription) by insulin
Glucose 6-phosphatase	Induced (increase in gene transcription) during fasting
Fructose 1,6-bisphosphatase	Inhibited by F 2,6-BP, AMP Induced (increase in gene transcription) during fasting

Acetyl CoA, acetyl coenzyme A; AMP, adenosine monophosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; F 1,6-BP, fructose 1,6-bisphosphate; F 2,6-BP, fructose 2,6-bisphosphate.

Glycolysis

Gluconeogenesis

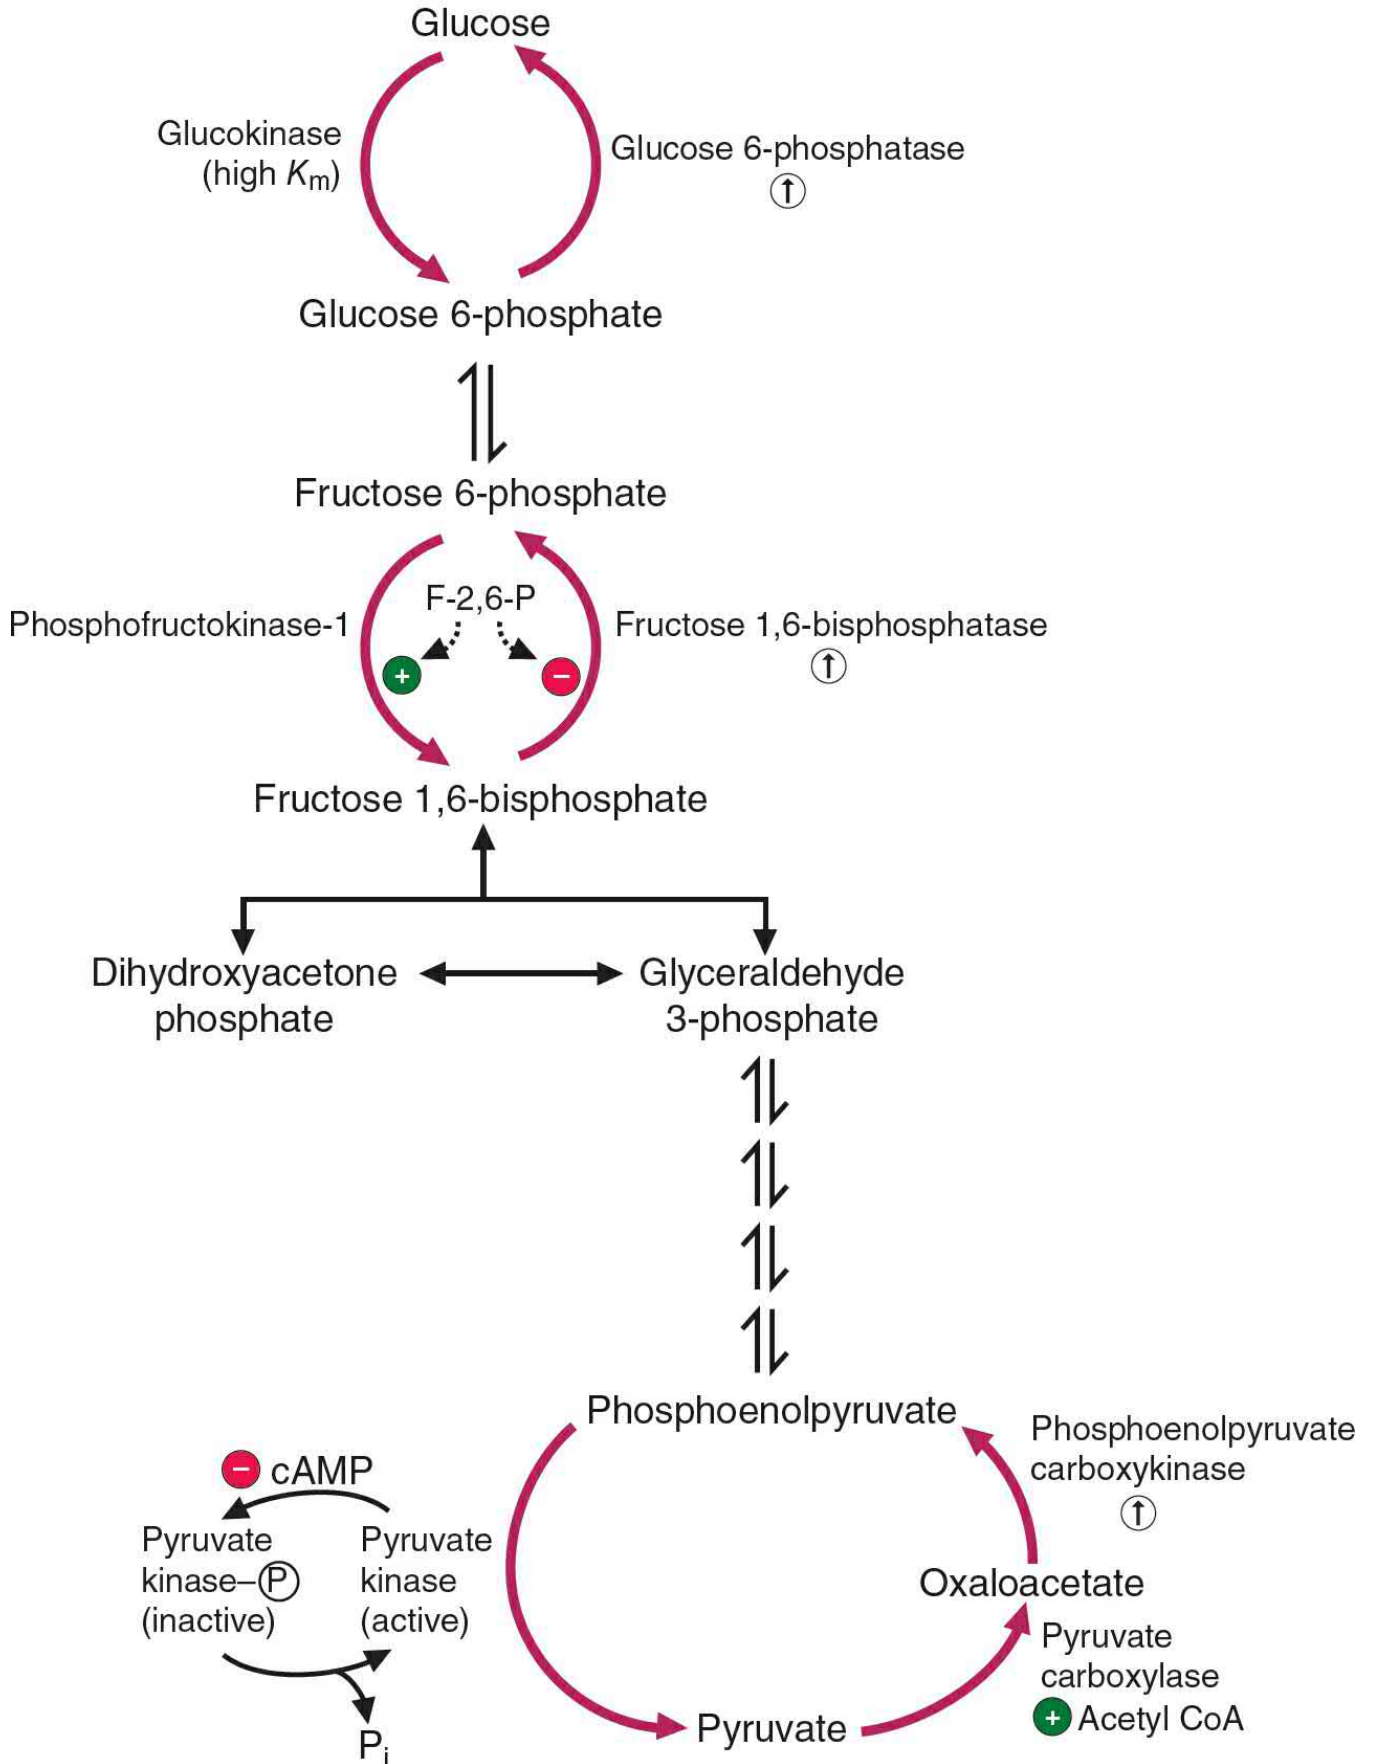

FIGURE 28.9 Liver enzymes involved in regulating the substrate cycles of glycolysis and gluconeogenesis. Heavy arrows

indicate the three substrate cycles. Acetyl CoA, acetyl coenzyme A; cAMP, cyclic adenosine monophosphate; F-2,6-P, fructose 2,6-bisphosphate; P_i, inorganic phosphate; ⊕, activated by; ⊖, inhibited by; †, inducible enzyme.

3. Conversion of Pyruvate to PEP

Pyruvate, a key substrate for gluconeogenesis, is derived from lactate and amino acids, particularly alanine. Pyruvate is not converted to acetyl CoA under conditions that favor gluconeogenesis because pyruvate dehydrogenase is relatively inactive. Instead, pyruvate is converted to OAA by pyruvate carboxylase. Subsequently, OAA is converted to PEP by PEPCK. The following is a description of activity states of enzymes under which PEP will be used to form glucose rather than pyruvate.

- **Pyruvate dehydrogenase is inactive.** Under conditions of fasting, insulin levels are low and glucagon levels are elevated. Consequently, fatty acids and glycerol are released from the triacylglycerol stores of adipose tissue. Fatty acids travel to the liver, where they undergo β -oxidation, producing acetyl CoA, NADH, and ATP (see Chapter 30). As a consequence, the concentration of adenosine diphosphate (ADP) decreases. These changes result in the phosphorylation of pyruvate dehydrogenase to the inactive form. Therefore, pyruvate is not converted to acetyl CoA.
- **Pyruvate carboxylase is active.** Acetyl CoA, which is produced by oxidation of fatty acids, activates pyruvate carboxylase. Therefore, pyruvate, derived from lactate or alanine, is converted to OAA. Acetyl CoA levels, then, reciprocally regulate pyruvate dehydrogenase and pyruvate carboxylase. High levels of acetyl CoA inhibit pyruvate dehydrogenase while activating pyruvate carboxylase.
- **PEPCK is induced.** OAA produces PEP in a reaction catalyzed by PEPCK. Cytosolic PEPCK is an inducible enzyme, which means that the quantity of the enzyme in the cell increases because of increased transcription of its gene and increased translation of its messenger RNA (mRNA). The major inducer is cyclic adenosine monophosphate (cAMP), which is increased by hormones that activate adenylate cyclase. Adenylate cyclase produces cAMP from ATP. Glucagon is the hormone that causes cAMP to rise during fasting, whereas epinephrine acts during exercise or stress. cAMP activates protein kinase A, which phosphorylates a set of specific transcription factors (cAMP response element-binding protein [CREB]) that stimulate transcription of the PEPCK gene (see Chapter 15 and Fig. 15.17). Increased synthesis of mRNA for PEPCK results in increased synthesis of the enzyme. Cortisol, the major human glucocorticoid, also induces PEPCK but through a different regulatory site on the PEPCK promoter.
- **Pyruvate kinase is inactive.** When glucagon is elevated, liver pyruvate kinase is phosphorylated and inactivated by a mechanism that involves cAMP and protein kinase A. Therefore, PEP is not reconverted to pyruvate. Rather, it continues along the pathway of gluconeogenesis. If PEP were reconverted to pyruvate, these substrates would simply cycle, causing a net loss of energy with no net generation of useful products. The inactivation of pyruvate kinase prevents such futile cycling and promotes the net synthesis of glucose.

The mechanism of action of steroid hormones on glucose homeostasis differs from that of glucagon or epinephrine (see Chapters 15 and 19). Glucocorticoids are steroid hormones that stimulate gluconeogenesis, in part because they induce the synthesis of PEPCK. **Emma W.** had elevated levels of blood glucose because she was being treated with large pharmacologic doses of prednisone, a potent synthetic glucocorticoid.

4. Conversion of Fructose 1,6-Bisphosphate to Fructose 6-P

The carbons of PEP reverse the steps of glycolysis, forming fructose 1,6-bisphosphate. Fructose 1,6-bisphosphatase acts on this bisphosphate to release inorganic phosphate and produce fructose 6-P. A futile substrate cycle is prevented at this step because, under conditions that favor gluconeogenesis, the concentrations of the compounds that activate the glycolytic enzyme PFK-1 are low. These same compounds, fructose 2,6-bisphosphate (whose levels are regulated by insulin and glucagon) and AMP, are allosteric inhibitors of fructose 1,6-bisphosphatase. When the concentrations of these allosteric effectors are low, PFK-1 is less active, fructose 1,6-bisphosphatase is more active, and the net flow of carbon is toward fructose 6-P and, thus, toward glucose. The synthesis of fructose 1,6-bisphosphatase is also induced during fasting.

5. Conversion of Glucose 6-P to Glucose

Glucose 6-phosphatase catalyzes the conversion of glucose 6-P to glucose, which is released from the liver cell (Fig. 28.10). The glycolytic enzyme glucokinase, which catalyzes the reverse reaction, is relatively inactive during gluconeogenesis. Glucokinase, which has a high $S_{0.5}$ (K_m) for glucose (see Chapter 9, Fig. 9.4), is not

very active during fasting because the blood glucose level is lower (~5 mM) than the $S_{0.5}$ of the enzyme.

Blood

- Transport proteins
- Glucose 6-phosphatase

FIGURE 28.10 Location and function of glucose 6-phosphatase. Glucose 6-P travels on a transporter into the ER, where it is hydrolyzed by glucose 6-phosphatase to glucose and inorganic phosphate (P_i). These products travel back to the cytosol on transporters. ER, endoplasmic reticulum; G-1-P, glucose 1-phosphate; glucose 6-P, glucose 6-phosphate; P_i , inorganic phosphate.

Glucokinase is also an inducible enzyme. The concentration of the enzyme increases in the fed state, when blood glucose and insulin levels are elevated, and decreases in the fasting state, when glucose and insulin are

low.

E. Energy Is Required for the Synthesis of Glucose

During the gluconeogenic reactions, 6 mol of high-energy phosphate bonds are cleaved. Two moles of pyruvate are required for the synthesis of 1 mol of glucose. As 2 mol of pyruvate are carboxylated by pyruvate carboxylase, 2 mol of ATP are hydrolyzed. PEPCK requires 2 mol of GTP (the equivalent of 2 mol of ATP) to convert 2 mol of OAA to 2 mol of PEP. An additional 2 mol of ATP are used when 2 mol of 3-phosphoglycerate are phosphorylated, forming 2 mol of 1,3-bisphosphoglycerate. Energy in the form of reducing equivalents (NADH) is also required for the conversion of 1,3-bisphosphoglycerate to glyceraldehyde 3-phosphate. Under fasting conditions, the energy required for gluconeogenesis is obtained from β -oxidation of fatty acids. Defects in fatty acid oxidation can lead to hypoglycemia in part because of reduced fatty acid-derived energy production within the liver.

III. Changes in Blood Glucose Levels after a Meal

After a high-carbohydrate meal, blood glucose rises from a fasting level of approximately 70 to 100 mg/dL (~5 mM) to a level of approximately 120 to 140 mg/dL (8 mM) within a period of 30 minutes to 1 hour (Fig. 28.11). The concentration of glucose in the blood then begins to decrease, returning to the fasting range by approximately 2 hours after the meal (see also Chapter 19).

FIGURE 28.11 Blood glucose concentrations at various times after a meal.

Blood glucose levels increase as dietary glucose is digested and absorbed. The values go no higher than approximately 140 mg/dL in a normal, healthy person because tissues take up glucose from the blood, storing it for subsequent use and oxidizing it for energy. After the meal is digested and absorbed, blood glucose levels decline because cells continue to metabolize glucose.

If blood glucose levels continued to rise after a meal, the high concentration of glucose would cause the release of water from tissues as a result of the osmotic effect of glucose. Tissues would become dehydrated and their function would be affected. If hyperglycemia becomes severe, a hyperosmolar coma could result from dehydration of the brain.

Conversely, if blood glucose levels continued to drop after a meal, tissues that depend on glucose would suffer from a lack of energy. If blood glucose levels dropped abruptly, the brain would not be able to produce

an adequate amount of ATP. Light-headedness and dizziness would result, followed by drowsiness and, eventually, coma. Red blood cells would not be able to produce enough ATP to maintain the integrity of their membranes. Hemolysis of these cells would decrease the transport of oxygen to the tissues of the body. Eventually, all tissues that rely on oxygen for energy production would fail to perform their normal functions. If the problem were severe enough, death could result.

Devastating consequences of glucose excess or insufficiency are normally avoided because the body is able to regulate its blood glucose levels. As the concentration of blood glucose approaches the normal fasting range of 70 to 100 mg/dL roughly 2 hours after a meal, the process of glycogenolysis is activated in the liver. Liver glycogen is the primary source of blood glucose during the first few hours of fasting. Subsequently, gluconeogenesis begins to play a role as an additional source of blood glucose. The carbon for gluconeogenesis, a process that occurs in the liver, is supplied by other tissues. Exercising muscle and red blood cells provide lactate through glycolysis, muscle also provides amino acids by degradation of protein, and glycerol is released from adipose tissue as triacylglycerol stores are mobilized.

Even during a prolonged fast, blood glucose levels do not decrease dramatically. After 5 to 6 weeks of starvation, blood glucose levels decrease to only approximately 65 mg/dL (Table 28.2).

TABLE 28.2 Blood Glucose Levels at Various Stages of Fasting

STAGE OF FASTING	GLUCOSE (mg/dl)
Glucose, 700 g/d IV	100
Fasting, 12 hour	80
Starvation, 3 day	70
Starvation, 5–6 weeks	65

IV, intravenous.

Source: Ruderman NB, Aoki TT, Cahill GF Jr. Gluconeogenesis and its disorders in man. In: Hanson RW, Mehlerman MA, eds. *Gluconeogenesis: Its Regulation in Mammalian Species*. John Wiley & Sons; 1976:517.

When **Dianne A.** inadvertently injected insulin without eating, she caused an acute reduction in her blood glucose levels 1 to 2 hours later. Had she been awake, she would have first experienced symptoms caused by hypoglycemia-induced hyperactivity of her sympathetic nervous system (e.g., sweating, tremulousness, palpitations). Eventually, as her hypoglycemia became more profound, she would have experienced symptoms of “neuroglycopenia” (inadequate glucose supply to the brain), such as confusion, speech disturbances, emotional instability, possible seizure activity, and, finally, coma.

Ann R., who is recovering from anorexia nervosa, and whose intake of glucose and of glucose precursors has been severely restricted, has not developed any of these manifestations. Her lack of hypoglycemic symptoms can be explained by the very gradual reduction of her blood glucose levels as a consequence of near-starvation and her ability to maintain blood glucose levels within an acceptable fasting range through hepatic gluconeogenesis. In addition, lipolysis of adipose triacylglycerols produces fatty acids, which are used as fuel and converted to ketone bodies by the liver. The oxidation of fatty acids and ketone bodies by the brain and muscle reduces the need for blood glucose.

In **Dianne A.’s** case, the excessive dose of insulin inhibited lipolysis and ketone body synthesis, so these alternative fuels were not available to spare blood glucose. The rapidity with which hypoglycemia was induced could not be compensated for quickly enough by hepatic glycogenolysis and gluconeogenesis, which are inhibited by the insulin, and hypoglycemia ensued.

An immediate fingerstick revealed that **Dianne A.’s** capillary blood glucose level was <20 mg/dL. An intravenous infusion of a 50% solution of glucose was started, and her blood glucose level was determined frequently. When **Dianne A.** regained consciousness, the intravenous solution was eventually changed to 10% glucose. After 6 hours, her blood glucose levels stayed in the upper-normal range, and she was able to tolerate oral feedings. By the next morning, her previous diabetes treatment regimen could be reestablished. The reasons that she had developed hypoglycemic coma were explained to her, and she was discharged to the care of her family doctor.

A. Blood Glucose Levels in the Fed State

The major factors involved in regulating blood glucose levels are the blood glucose concentration itself and hormones, particularly insulin and glucagon.

As blood glucose levels rise after a meal, the increased glucose concentration stimulates the β -cells of the pancreas to release insulin (Fig. 28.12). Certain amino acids, particularly arginine and leucine, also stimulate insulin release from the pancreas.

Glucose meal

Protein meal

FIGURE 28.12 Blood glucose, insulin, and glucagon levels after a high-carbohydrate meal and after a high-protein meal. The meal occurred at the time indicated by the *down arrows*.

Blood levels of glucagon, which is secreted by the α -cells of the pancreas, may increase or decrease, depending on the content of the meal. Glucagon levels decrease in response to a high-carbohydrate meal, but they increase in response to a high-protein meal. After a typical mixed meal containing carbohydrate, protein, and fat, glucagon levels remain relatively constant, whereas insulin levels increase.

1. Fate of Dietary Glucose in the Liver

After a meal, the liver oxidizes glucose to meet its immediate energy needs. Any excess glucose is converted to stored fuels. Glycogen is synthesized and stored in the liver, and glucose is converted to fatty acids and to the glycerol moiety that reacts with the fatty acids to produce triacylglycerols. These triacylglycerols are packaged in VLDL (see Chapter 29) and transported to adipose tissue, where the fatty acids are stored in adipose triacylglycerols. The VLDL can also deliver triglycerides (fatty acids) to the muscle for immediate oxidation, if required.

Regulatory mechanisms control the conversion of glucose to stored fuels. As the concentration of glucose increases in the hepatic portal vein, the concentration of glucose in the liver may increase from the fasting level of 70 to 100 mg/dL (~ 5 mM) to a concentration of 180 to 360 mg/dL (10 to 20 mM). Consequently, the velocity of the glucokinase reaction increases because this enzyme has a high $S_{0.5}$ (K_m) for glucose (see Fig. 9.4). Glucokinase is also induced by a high-carbohydrate diet; the quantity of the enzyme increases in response to elevated insulin levels.

Insulin promotes the storage of glucose as glycogen by countering the effects of glucagon-stimulated phosphorylation. The response to insulin activates the phosphatases that dephosphorylate glycogen synthase (which leads to glycogen synthase activation) and glycogen phosphorylase (which leads to inhibition of the enzyme) (Fig. 28.13A). Insulin also promotes the synthesis of the triacylglycerols that are released from the liver into the blood as VLDL. The regulatory mechanisms for this process are described in Chapter 31.

FIGURE 28.13 Glucose metabolism in various tissues. **A.** Effect of insulin on glycogen synthesis and degradation and on VLDL synthesis in the liver. **B.** Glucose metabolism in resting muscle in the fed state. Transport of glucose into cells and synthesis of glycogen are stimulated by insulin. **C.** Glucose metabolism in adipose tissue in the fed state. DHAP, dihydroxyacetone phosphate; FA, fatty acids; glycerol-3-P, glycerol 3-phosphate; TG, triacylglycerols; VLDL, very-low-density lipoprotein; ⊕, stimulated by insulin; ⊖, inhibited by insulin.

2. Fate of Dietary Glucose in Peripheral Tissues

Almost every cell in the body oxidizes glucose for energy. Certain critical tissues, particularly the brain, other nervous system tissues, and red blood cells, depend especially on glucose for their energy supply. The brain requires approximately 150 g of glucose per day. In addition, approximately 40 g/day of glucose is required by other glucose-dependent tissues. Furthermore, all tissues require glucose for the pentose phosphate pathway, and many tissues use glucose for synthesis of glycoproteins and other carbohydrate-containing compounds.

Insulin stimulates the transport of glucose into adipose and muscle cells by promoting the recruitment of glucose transporters to the cell membrane (see Fig. 28.13C). Other tissues, such as the liver, brain, and red blood cells, have a different type of glucose transporter that is not as significantly affected by insulin.

In muscle, glycogen is synthesized after a meal by a mechanism similar to that in the liver (see Fig. 28.13B). Metabolic differences exist between these tissues (see Chapter 26), but, in essence, insulin stimulates glycogen synthesis in resting muscle as it does in the liver. A key difference between muscle and liver is that insulin greatly stimulates the transport of glucose into muscle cells but only slightly stimulates its transport into liver cells.

3. Return of Blood Glucose to Fasting Levels

After a meal has been digested and absorbed, blood glucose levels reach a peak and then begin to decline. The uptake of dietary glucose by cells, particularly those in the liver, muscle, and adipose tissue, lowers blood glucose levels. By 2 hours after a meal, blood glucose levels return to the normal fasting level of <100 mg/dL.

The pathophysiology leading to an elevation of blood glucose after a meal differs between patients with type 1 DM and those with type 2 DM. **Dianne A.**, who has type 1 disease, cannot secrete insulin adequately in response to a meal because of a defect in the β -cells of her pancreas. **Deborah S.**, however, has type 2 disease. In this form of the disorder, the cause of glucose intolerance is more complex, involving at least a delay in the release of relatively appropriate amounts of insulin after a meal combined with a degree of resistance to the actions of insulin in skeletal muscle and adipocytes. Excessive hepatic gluconeogenesis occurs even though blood glucose levels are elevated.

B. Blood Glucose Levels in the Fasting State

1. Changes in Insulin and Glucagon Levels

During fasting, as blood glucose levels decrease, insulin levels decrease and glucagon levels rise. These hormonal changes cause the liver to degrade glycogen by the process of glycogenolysis and to produce glucose by the process of gluconeogenesis so that blood glucose levels are maintained.

2. Stimulation of Glycogenolysis

Within a few hours after a high-carbohydrate meal, glucagon levels begin to rise. Glucagon binds to cell-surface receptors and activates adenylate cyclase, causing cAMP levels in liver cells to rise (see Fig. 26.7). cAMP activates protein kinase A, which participates in the phosphorylation and inactivation of glycogen synthase. Therefore, glycogen synthesis decreases.

At the same time, protein kinase A stimulates glycogen degradation by a two-step mechanism. Protein kinase A phosphorylates and activates phosphorylase kinase. This enzyme, in turn, phosphorylates and activates glycogen phosphorylase.

Glycogen phosphorylase catalyzes the phosphorolysis of glycogen, producing glucose 1-phosphate, which is converted to glucose 6-P. Dephosphorylation of glucose 6-P by glucose 6-phosphatase produces free glucose, which then enters the blood.

3. Stimulation of Gluconeogenesis

By 4 hours after a meal, the liver is supplying glucose to the blood not only by the process of glycogenolysis but also by the process of gluconeogenesis. Hormonal changes cause peripheral tissues to release precursors

that provide carbon for gluconeogenesis, specifically lactate, amino acids, and glycerol.

Regulatory mechanisms promote the conversion of gluconeogenic precursors to glucose (Fig. 28.14). These mechanisms prevent the occurrence of potential futile cycles, which would continuously convert substrates to products while consuming energy but producing no useful result.

FIGURE 28.14 Regulation of gluconeogenesis (*red arrows*) in the liver. cAMP, cyclic adenosine monophosphate; F-1,6-Pase, fructose 1,6-bisphosphatase; F-1,6-BP, fructose 1,6-bisphosphate; F-2,6-BP, fructose 2,6-bisphosphate; GK, glucokinase; G-6-Pase, glucose 6-phosphatase; OAA, oxaloacetate; PEPCK, phosphoenolpyruvate carboxykinase; PFK-1, phosphofructokinase-1; PK, pyruvate kinase.

These regulatory mechanisms inactivate the glycolytic enzymes pyruvate kinase, PFK-1, and glucokinase during fasting and promote the flow of carbon to glucose via gluconeogenesis. These mechanisms operate at the following three steps where glycolysis and gluconeogenesis differ:

1. Pyruvate (derived from lactate and alanine) is converted by the gluconeogenic pathway to PEP. PEP is not reconverted to pyruvate (a potentially futile cycle) because glucagon-stimulated phosphorylation inactivates pyruvate kinase. Therefore, PEP reverses the steps of glycolysis and forms fructose 1,6-bisphosphate.
2. Fructose 1,6-bisphosphate is converted to fructose 6-P by a bisphosphatase. Because the glycolytic enzyme PFK-1 is relatively inactive mainly as a result of low fructose 2,6-bisphosphate levels, fructose 6-P is not converted back to fructose 1,6-bisphosphate, and a second potential futile cycle is avoided. The low fructose 2,6-bisphosphate levels are attributable in part to the phosphorylation of PFK-2 by protein kinase A, which has been activated in response to glucagon. Fructose 6-P is converted to glucose 6-P.
3. Glucose 6-P is dephosphorylated by glucose 6-phosphatase, forming free glucose. Because glucokinase has a high $S_{0.5}$ (K_m) for glucose, and glucose concentrations are relatively low in liver cells during fasting, glucose is released into the blood. Therefore, the third potential futile cycle does not occur.
4. Enzymes that participate in gluconeogenesis, but not in glycolysis, are active under fasting conditions. Pyruvate carboxylase is activated by acetyl CoA, derived from oxidation of fatty acids. PEPCK, fructose 1,6-bisphosphatase, and glucose 6-phosphatase are induced; that is, the quantity of the enzymes increases. Fructose 1,6-bisphosphatase is also active because levels of fructose 2,6-bisphosphate, an inhibitor of the enzyme, are low.

4. Stimulation of Lipolysis

The hormonal changes that occur during fasting stimulate the breakdown of adipose triacylglycerols (see Chapters 3, 31, and 41). Consequently, fatty acids and glycerol are released into the blood (Fig. 28.15). Glycerol serves as a source of carbon for gluconeogenesis. Fatty acids become the major fuel of the body and are oxidized to CO_2 and H_2O by various tissues, which enables these tissues to decrease their use of glucose. Fatty acids are also oxidized to acetyl CoA in the liver to provide energy for gluconeogenesis. In a prolonged fast, acetyl CoA is converted to ketone bodies, which enter the blood and serve as an additional fuel source for the muscle and the brain.

FIGURE 28.15 Tissue interrelationships during fasting. (1) Blood glucose levels drop, decreasing insulin and raising blood glucagon levels. (2) Glycogenolysis is induced in the liver to raise blood glucose levels. (3) The brain uses the glucose released by the liver, as do the RBCs (4). (5) Adipose tissues are induced to release free fatty acids and glycerol from stored triglycerides. (6) The muscle and liver use fatty acids for energy. (7) The liver converts fatty acid–derived acetyl CoA to ketone bodies for export, which the muscles (8) and brain can use for energy. (9) Protein turnover is induced in muscle, and amino acids leave the muscle and travel to the liver for use as gluconeogenic precursors. (10) The high rate of amino acid metabolism in the liver generates urea, which travels to the kidney for excretion. (11) RBCs produce lactate, which returns to the liver as a substrate for gluconeogenesis. (12) The glycerol released from adipose tissue is used by the liver for gluconeogenesis. AA, amino acids; Acetyl CoA, acetyl coenzyme A; ATP, adenosine triphosphate; FA, fatty acids; KB, ketone bodies; RBC, red blood cell; TCA, tricarboxylic acid; TG, triacylglycerols.

C. Blood Glucose Levels during Prolonged Fasting (Starvation)

During prolonged fasting, several changes occur in fuel utilization. These changes cause tissues to use less glucose than they use during a brief fast and to use predominantly fuels derived from adipose triacylglycerols (i.e., fatty acids and their derivatives, the ketone bodies). Therefore, blood glucose levels do not decrease drastically. In fact, even after 5 to 6 weeks of starvation, blood glucose levels are still in the range of 65 mg/dL (Fig. 28.16; see Table 28.2).

FIGURE 28.16 Changes in blood fuels during fasting. The units for fatty acids, glucose, and ketone bodies are millimolar (on left) and for urinary nitrogen and ammonia are grams/day (on right). (Modified from Linder MC, ed. *Nutritional Biochemistry and Metabolism with Clinical Applications*. 2nd ed. Appleton & Lange; 1991:103.)

The major change that occurs in starvation is a dramatic elevation of blood ketone body levels after 3 to 5 days of fasting (see Fig. 28.16). At these levels, the brain and other nervous tissues begin to use ketone bodies and, consequently, they oxidize less glucose, requiring roughly one-third as much glucose (~40 g/day) as under normal dietary conditions. As a result of reduced glucose utilization, the rate of gluconeogenesis in the liver decreases, as does the production of urea (see Fig. 28.16). Because in this stage of starvation, amino acids, obtained from the degradation of existing proteins, are the major gluconeogenic precursor, reducing glucose requirements in tissues reduces the rate of protein degradation and hence the rate of urea formation. Protein from muscle and other tissues is, therefore, spared, because there is less need for amino acids for gluconeogenesis.

Body protein, particularly muscle protein, is not primarily a storage form of fuel in the same sense as glycogen or triacylglycerol; proteins have many functions besides fuel storage. For example, proteins function as enzymes, as structural proteins, and in muscle contraction. If tissue protein is degraded to too great an extent, body function can be severely compromised. If starvation continues and no other problems, such as infections, occur, a starving individual usually dies because of severe protein loss that causes malfunction of major organs, such as the heart. Therefore, the increase in ketone body levels that results in the sparing of body protein allows individuals to survive for extended periods without ingesting food.

D. Summary of Sources of Blood Glucose

Immediately after a meal, dietary carbohydrates serve as the major source of blood glucose (Fig. 28.17). As blood glucose levels return to the fasting range within 2 hours after a meal, glycogenolysis is stimulated and begins to supply glucose to the blood. Subsequently, glucose is also produced by gluconeogenesis.

FIGURE 28.17 Sources of blood glucose in fed, fasting, and starved states. Note that the scale changes from hours to days. (From Ruderman NB, Aoki TT, Cahill GF Jr. Gluconeogenesis and its disorders in man. In: Hanson RW, Mehlman MA, eds. *Gluconeogenesis: Its Regulation in Mammalian Species*. John Wiley & Sons; 1976:518.)

During a 12-hour fast, glycogenolysis is the major source of blood glucose. Thus, it is the major pathway by which glucose is produced in the basal state (after a 12-hour fast). However, by approximately 16 hours of fasting, glycogenolysis and gluconeogenesis contribute equally to the maintenance of blood glucose.

By 30 hours after a meal, liver glycogen stores are substantially depleted. Subsequently, gluconeogenesis is the primary source of blood glucose.

The mechanisms that cause fats to be used as the major fuel and that allow blood glucose levels to be maintained during periods of food deprivation result in the conservation of body protein and, consequently, permit survival during prolonged fasting for periods often exceeding 1 month or more.

Otto S. is able to jog for 45 minutes before eating breakfast without developing symptoms of hypoglycemia in spite of enhanced glucose utilization by skeletal muscle during exercise. He maintains his blood glucose level in an adequate range through hepatic glycogenolysis and gluconeogenesis.

E. Blood Glucose Levels during Exercise

During exercise, mechanisms very similar to those that are used during fasting operate to maintain blood glucose levels. The liver maintains blood glucose levels through both glucagon- and epinephrine-induced

glycogenolysis and gluconeogenesis. The use of fuels by muscle during exercise, including the uptake and use of blood glucose, is discussed in Chapter 45. Recall that muscle glycogen is not used to maintain blood glucose levels; muscle cells lack glucose 6-phosphatase, so glucose cannot be produced from glucose 6-P for export.

CLINICAL COMMENTS

Al M. The chronic excessive ingestion of ethanol concurrent with a recent reduction in nutrient intake caused **Al M.**'s blood glucose level to decrease to 28 mg/dL. This degree of hypoglycemia caused the release of a number of “counterregulatory” hormones into the blood, including glucagon, growth hormone, cortisol, and epinephrine (adrenaline).

Some of the patient's signs and symptoms are primarily the result of an increase in adrenergic nervous system activity after a rapid decrease in blood glucose. The subsequent increase in epinephrine levels in the blood leads to tremulousness, excessive sweating, and rapid heart rate. Other manifestations arise when the brain has insufficient glucose, hence the term “neuroglycopenic symptoms.” **Al M.** was confused, combative, had slurred speech, and eventually had a grand mal seizure. If he was not treated quickly by intravenous glucose administration, **Al M.** might have lapsed into a coma. Permanent neurologic deficits and even death may result if severe hypoglycemia is not corrected in 6 to 10 hours.

Emma W. The elevation in blood glucose that occurred in **Emma W.**'s case was primarily a consequence of the large pharmacologic doses of a glucocorticoid that she received in an effort to reduce the intrabronchial inflammation characteristic of an asthma exacerbation. Although the development of hyperglycemia in this case could be classified as a “secondary” form of diabetes mellitus (DM) (because of the activation of liver glucose export by the drug), most patients treated with glucocorticoids do not develop glucose intolerance. **Emma W.**, therefore, may have a predisposition to the eventual development of “primary” DM.

In hyperglycemia, increased amounts of glucose enter the urine, causing large amounts of water to be excreted. This “osmotic diuresis” is responsible for the increased volume of urine (polyuria) noted by the patient. Because of increased urinary water loss, the effective circulating blood volume is reduced. Therefore, less blood reaches volume-sensitive receptors in the central nervous system, which then trigger the sensation of thirst, causing increased drinking activity (polydipsia).

A diabetic diet and the tapering of her steroid dose over a period of several weeks gradually returned **Emma W.**'s blood glucose level to the normal range.

Dianne A. and Deborah S. Chronically elevated levels of glucose in the blood may contribute to the development of the microvascular complications of DM, such as diabetic retinal damage, kidney damage, and nerve damage, in addition to atherosclerosis of the coronary, cerebral, and peripheral arteries (macrovascular). The precise mechanism by which long-term hyperglycemia induces these vascular changes is not fully established.

One postulated mechanism proposes that nonenzymatic glycation of proteins in vascular tissue alters the structure and functions of these proteins. A protein that is exposed to chronically increased levels of glucose will covalently bind glucose, a process called **glycation**. This process is not regulated by enzymes (see Chapter 9). These nonenzymatically glycated proteins slowly form cross-linked protein adducts (often called advanced glycation end products) within the microvasculature and macrovasculature.

By cross-linking vascular matrix proteins and plasma proteins, chronic hyperglycemia may cause narrowing of the luminal diameter of the microvessels in the retina (causing diabetic retinopathy), the renal glomeruli (causing diabetic nephropathy), and the microvessels supplying peripheral and autonomic nerve fibers (causing diabetic neuropathy). The same process has been postulated to accelerate atherosclerotic change in the macrovasculature, particularly in the brain (causing strokes), the coronary arteries (causing heart attacks), and the peripheral arteries (causing peripheral arterial insufficiency and possibly gangrene). The abnormal lipid metabolism associated with poorly controlled DM also may contribute to the accelerated atherosclerosis associated with this metabolic disorder (see Chapters 31 and 32).

The publication of the Diabetes Control and Complications Trial followed by the United Kingdom Prospective Diabetes study were the first large human studies to show that maintaining long-term controlled blood glucose levels in patients with diabetes, such as **Dianne A.** and **Deborah S.** (who has type 2 diabetes), favorably affects the course of microvascular complications. More recent studies have confirmed this, and

although it is thought that controlling blood sugar decreases macrovascular complications, this has been more difficult to demonstrate in human studies.

BIOCHEMICAL COMMENTS

Warburg effect. In the early 1920s, Otto Warburg analyzed the processes of fermentation (anaerobic glycolysis) and respiration (aerobic metabolism) in tumor cells. Warburg surprisingly found that tumor cells, even in the presence of oxygen, exhibited enhanced glucose uptake and lactate production when compared to nontumor cells. This result indicates that despite the presence of oxygen in the system, tumor cells were producing lactate at an enhanced rate, a process coined aerobic glycolysis. The tumor cells used this pathway in preference to converting pyruvate to acetyl CoA, and then oxidizing the acetyl CoA through the TCA cycle and generating energy via oxidative phosphorylation. The significance of this finding (termed the Warburg effect) is still being explored today, almost 100 years after the initial discovery.

There have been several explanations for the Warburg effect, and it is likely that the ideas presented below will change over the next few years. Nevertheless, at this time, enhanced glycolysis in tumor cells, when compared to normal cells, could provide for the following:

1. Generate ATP at the fastest rate for cellular proliferation, despite aerobic glycolysis being significantly less efficient in generating ATP than oxidative phosphorylation. It has been estimated that starting with 1 mol of glucose, oxidative phosphorylation can generate 30 to 32 mol of ATP, whereas aerobic glycolysis, with an 85% to 5% split between glycolysis and oxidative phosphorylation, can generate 4 mol of ATP. The key is that ATP generation by glycolysis is significantly more rapid than by oxidative phosphorylation.
2. Generation of glycolytic intermediates for anabolic pathways to enhance the growth of the tumor cells. Serine, for example, is generated from 3-phosphoglycerate, and once serine is produced, one-carbon carriers can be synthesized to enhance purine and pyrimidine biosynthesis.
3. Generation of NADPH for biosynthetic pathways using the hexose monophosphate (HMP) shunt reactions and converting glucose 6-P to NADPH and ribulose 5-phosphate. The ribulose 5-phosphate is used for nucleotide biosynthesis, which reduces the amount of glucose available for energy generation.
4. Generate lactic acid, which acidifies the tumor microenvironment and promotes cellular migration and metastasis.
5. Reduce acetyl CoA production, thereby altering epigenetic regulation of gene expression (reduced ability to acetylate histones) and favoring the expression of isozymes promoting cellular proliferation.

The molecular changes that occur to allow the Warburg effect to occur have not yet been worked out. Various studies have implicated changes in expression of the transcription factor hypoxia-inducible factor-1 (HIF-1), altered expression of the two key isozymes of pyruvate kinase, and mitochondrial dysfunction because of oxygen being used to generate reactive oxygen species (ROS) instead of being used as the terminal acceptor in the electron transfer chain. The role of aberrant tyrosine kinases in phosphorylating key glycolytic enzymes has also been postulated to play a role in promoting aerobic glycolysis in tumor cells. Further work is needed before a molecular description of the Warburg effect will be available.

KEY CONCEPTS

- ◆ The process of glucose production is termed gluconeogenesis. Gluconeogenesis occurs primarily in the liver.
- ◆ The major precursors for glucose production are lactate, glycerol, and amino acids.
- ◆ The gluconeogenic pathway uses the reversible reactions of glycolysis, plus additional reactions to bypass the irreversible steps.
 - ◆ Pyruvate carboxylase (pyruvate to OAA) and PEPCK (OAA to PEP) bypass the pyruvate kinase step.
 - ◆ Fructose 1,6-bisphosphatase (fructose 1,6-bisphosphate to fructose 6-P) bypasses the PFK-1 step.
 - ◆ Glucose 6-phosphatase (glucose 6-P to glucose) bypasses the glucokinase step.
- ◆ Gluconeogenesis and glycogenolysis are carefully regulated so that blood glucose levels can be maintained at a constant level during fasting. The regulation of triglyceride metabolism is also linked to the regulation of blood glucose levels.

◆ Table 28.3 summarizes the diseases discussed in this chapter.

TABLE 28.3 Diseases Discussed in Chapter 28

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Ethanol-induced hypoglycemia	Environmental	Ethanol, combined with poor nutrition, leads to hypoglycemia because of excessive ethanol metabolism altering the NADH/NAD ⁺ ratio in the liver.
Asthma	Both	A treatment to reduce bronchoconstriction is inhalation/administration of glucocorticoids. Systemic treatments stimulate gluconeogenesis, and can lead to hyperglycemia.
Insulin overdose	Environmental	Hypoglycemia as a result of insulin overdose because of insulin stimulation of glucose transport into muscle and fat cells
Anorexia nervosa	Both	The use of ketone bodies as an alternative energy source during prolonged fasting preserves muscle protein as reduced levels of glucose are now required by the nervous system.
Weight loss	Environmental	Maintenance of blood glucose levels during dieting occurs because of glycogenolysis and gluconeogenesis.
Type I diabetes/DKA	Environmental	Excessive production of ketone bodies in a type 1 diabetic whose insulin levels are too low, coupled with hyperglycemia; rarely observed in type 2 diabetes

DKA, diabetic ketoacidosis; NAD, nicotinamide adenine dinucleotide.

REVIEW QUESTIONS—CHAPTER 28

1. A common intermediate in the conversion of glycerol and lactate to glucose is which one of the following?
 - A. Pyruvate
 - B. OAA
 - C. Malate
 - D. Glucose 6-P
 - E. PEP
2. A patient presented with a bacterial infection that produced an endotoxin that inhibits PEPCK. In this patient, then, under these conditions, glucose production from which of the following precursors would be inhibited?
 - A. Alanine
 - B. Glycerol
 - C. Even-chain-number fatty acids
 - D. PEP
 - E. Galactose
3. Which one of the following is most likely to occur in a normal individual after ingesting a high-carbohydrate meal?
 - A. Only insulin levels decrease.
 - B. Only insulin levels increase.
 - C. Only glucagon levels increase.
 - D. Both insulin and glucagon levels decrease.
 - E. Both insulin and glucagon levels increase.
4. A patient arrives at the hospital in an ambulance. She is currently in a coma. Before lapsing into the coma, her symptoms included vomiting, dehydration, low blood pressure, and a rapid heartbeat. She also had relatively rapid respirations, resulting in more carbon dioxide being exhaled. These symptoms are consistent with which one of the following conditions?
 - A. The patient lacks a pancreas.
 - B. Ketoalkalosis

- C. Hypoglycemic coma
 - D. DKA
 - E. Insulin shock in a diabetic patient
5. Assume that an individual had a glucagon-secreting pancreatic tumor (glucagonoma). Which one of the following is most likely to result from hyperglucagonemia?
 - A. Weight loss
 - B. Hypoglycemia
 - C. Increased muscle protein synthesis
 - D. Decreased lipolysis
 - E. Increased liver glycolytic rate
 6. A patient is rushed to the emergency department after a fainting episode. Blood glucose levels were extremely low; insulin levels were normal, but there was no detectable C-peptide. The cause of the fainting episode may be because of which one of the following?
 - A. An insulin-producing tumor
 - B. An overdose of insulin
 - C. A glucagon-producing tumor
 - D. An overdose of glucagon
 - E. An overdose of epinephrine
 7. A marathon runner reaches the last mile of the race, but becomes dizzy, light-headed, and confused. These symptoms arise because of which one of the following?
 - A. Reduction of GLUT4 transporters
 - B. Reduced blood glucose levels for GLUT2 transport
 - C. Inhibition of GLUT5 transporters
 - D. Reduced blood glucose levels for GLUT1 transport
 - E. Lack of induction of GLUT4 transporters
 8. A patient went on a 3-day “cleansing” fast but did continue to consume water and vitamins. What is this patient’s source of fuel to maintain blood glucose levels under these conditions?
 - A. Fatty acids
 - B. Glycerol
 - C. Liver glycogen stores
 - D. Muscle glycogen stores
 - E. Ketone bodies
 9. A patient with type 1 diabetes, who has forgotten to take insulin before a meal, will have difficulty assimilating blood glucose into which one of the following tissues?
 - A. Brain
 - B. Adipose
 - C. Red blood cell
 - D. Liver
 - E. Intestine
 0. A patient told her doctor that a friend told her that if she only ate carbohydrates and proteins and no fats, she would no longer store fats in adipose tissue. The doctor told the patient her friend was misinformed and then should further respond to this statement via which one of the following?
 - A. Dietary glucose is converted into fatty acids but not glycerol by the liver.
 - B. Dietary glucose is converted by the liver into fatty acids and glycerol.
 - C. Dietary glucose is converted into glycerol but not fatty acids by the liver.
 - D. Low-density protein (LDL) transports the dietary converted products from the liver to the adipose tissue.
 - E. LDL transports the dietary converted products to the muscle tissue for oxidation.
 1. Pyruvate entering the mitochondria can undergo a number of possible fates, which is primarily dependent on which one of the following metabolites?
 - A. Acetyl CoA
 - B. OAA
 - C. Citrate
 - D. NADH
 - E. α -Ketoglutarate
 2. Eggs contain the protein avidin, which binds extremely tightly to biotin such that avidin can inhibit biotin-requiring reactions. In the presence of avidin, gluconeogenesis would be impaired starting with which one of

the following compounds?

- A. Glycerol
 - B. Galactose
 - C. Fructose
 - D. Lactate
 - E. OAA
3. An individual has initiated a prolonged fast of seven days. Measurement of blood metabolites, from day 1 of the fast, as compared to day 7 of the fast, would indicate a significant decrease in which one of the following?
- A. Glucose
 - B. Fatty acids
 - C. Ketone bodies
 - D. Lactate
 - E. Urea
4. In the absence of appropriate enzyme regulation, a futile cycle (substrate cycling) would occur at which step of the gluconeogenic pathway?
- A. Lactate dehydrogenase
 - B. Fructose 1,6-bisphosphatase
 - C. Glyceraldehyde 3-phosphate dehydrogenase
 - D. Enolase
 - E. Phosphoglycerate kinase
5. An inactivating mutation in galactose 1-phosphate uridylyltransferase leads to fasting hypoglycemia because of a reduction in which one of the following pathways?
- A. Gluconeogenesis
 - B. Glycogen synthesis
 - C. Glycogenolysis
 - D. Glycolysis
 - E. Nucleotide-sugar production

ANSWERS TO REVIEW QUESTIONS

1. **The answer is D.** Glycerol is converted to glycerol 3-phosphate, which is oxidized to form glyceraldehyde 3-phosphate. The glyceraldehyde 3-phosphate formed then follows the gluconeogenic pathway to glucose. Lactate is converted to pyruvate, which is then carboxylated to form OAA. The OAA is decarboxylated to form PEP and then run through gluconeogenesis to glucose. Because glycerol enters the gluconeogenic pathway at the glyceraldehyde 3-phosphate step and lactate at the PEP step, the only compounds in common between these two starting points are the steps from glyceraldehyde 3-phosphate to glucose. Of the choices listed in the question, only glucose 6-P is in that part of the pathway.
2. **The answer is A.** PEPCK converts OAA to PEP. In combination with pyruvate carboxylase, it is used to bypass the pyruvate kinase reaction. Thus, compounds that enter gluconeogenesis between PEP and OAA (such as lactate, alanine, or any TCA cycle intermediate) must use PEPCK to produce PEP. Glycerol enters gluconeogenesis as glyceraldehyde 3-phosphate, bypassing the PEPCK step. Galactose is converted to glucose 1-phosphate, then glucose 6-P, also bypassing the PEPCK step. Even-chain fatty acids can only give rise to acetyl CoA, which cannot be used to synthesize glucose.
3. **The answer is B.** High blood glucose levels signal the release of insulin from the pancreas; glucagon levels either stay the same or decrease slightly.
4. **The answer is D.** The hyperglycemia in an untreated diabetic creates osmotic diuresis, which means that excessive water is lost through urination. This can lead to a contraction of blood volume, leading to low blood pressure and a rapid heartbeat. It also leads to dehydration. The rapid respirations result from acidosis-induced stimulation of the respiratory center of the brain, in order to reduce the amount of acid in the blood. Ketone bodies have accumulated, leading to DKA (thus, B is incorrect). A patient in a hypoglycemic coma (which can be caused by excessive insulin administration) does not exhibit dehydration, low blood pressure, or rapid respirations; in fact, the patient will sweat profusely as a result of epinephrine release (thus, C and E are incorrect). Answer A is incorrect because lack of a pancreas would be fatal.

5. **The answer is A.** The high levels of glucagon will antagonize the effects of insulin, and will lead to hyperglycemia, as glucagon stimulates glucose export from the liver by stimulating glycogenolysis and gluconeogenesis. Because of the overriding effects of glucagon, blood glucose cannot enter muscle and fat cells, and fat oxidation is stimulated to provide energy for these tissues. This leads to a loss of stored triglyceride, which, in turn, leads to weight loss. Insulin is required to stimulate protein synthesis in muscles (glucagon does not have this effect), and glucagon signals export of glucose from the liver, which means that the rate of glycolysis is suppressed in hepatic cells under these conditions. Glucagon also stimulates lipolysis in adipocytes to provide fatty acids as an energy source for muscle and liver.
6. **The answer is B.** The key to answering this question correctly relates to the absence of detectable C-peptide levels in the blood. An overproduction of insulin by the β -cells of the pancreas can lead to hypoglycemia severe enough to cause loss of consciousness, but because there was no detectable C-peptide in the blood, the loss of consciousness was most likely the result of the administration of exogenous insulin that lacks the C-peptide (see Chapter 19). An overdose of glucagon (either through injection or a glucagon-producing tumor), or epinephrine, would promote glucose release by the liver and not lead to hypoglycemia. Insulin levels were normal because of the rapid turnover of the injected insulin, which has a half-life of about 5 minutes.
7. **The answer is D.** GLUT1 is the carrier for glucose across the blood–brain barrier (as well as red blood cells). When blood glucose levels drop below the K_m for this transporter, then the nervous system does not receive sufficient glucose to keep functioning properly—hence, the signs of hypoglycemia. The GLUT2 and GLUT5 transporters are not responsible for glucose entry into the nervous system (the liver and pancreas use GLUT2, whereas GLUT5 primarily transports fructose, not glucose). GLUT4 transporters are insulin-responsive transporters, expressed primarily in the muscle and fat cells. During exercise, the muscle upregulates GLUT4 transporters such that the muscle can use blood glucose as an energy source. Increased glucose uptake by the muscle contributes to the hypoglycemia that ensues, such that blood glucose levels are now below the K_m value for the GLUT1 transporters.
8. **The answer is A.** During a fast, liver glycogen stores are exhausted after about 30 hours, so the only pathway via which the liver can produce glucose is by gluconeogenesis. Gluconeogenesis requires energy, which is provided by fatty acid oxidation. Glycerol is a substrate for gluconeogenesis, but it is not oxidized to provide energy for gluconeogenesis. Muscle glycogen stores can provide glucose 1-phosphate for use by the muscle, but the glucose produced from muscle glycogen cannot enter the blood to be used by any other tissue. The liver will produce ketone bodies from fatty acid oxidation, but the liver does not express the CoA transferase needed to metabolize ketone bodies.
9. **The answer is B.** Insulin stimulates the transport of glucose into adipose and muscle cells by promoting the recruitment of GLUT4 glucose transporters to the cell membrane. Liver, brain, intestine, and red blood cells have different types of glucose transporters that are not significantly affected by insulin.
10. **The answer is B.** The liver can convert dietary glucose into fatty acids and glycerol to produce triacylglycerols, which are packaged into VLDL for transport to adipose tissue (for storage) or to the muscle for immediate oxidation if necessary. A low-fat diet, if excessive in overall calories, will lead to triglyceride formation and storage of the triglyceride in adipose tissue.
11. **The answer is A.** When pyruvate enters the mitochondria, its two major fates are to be converted to acetyl CoA via pyruvate dehydrogenase or to OAA, using the enzyme pyruvate carboxylase. Pyruvate dehydrogenase and pyruvate carboxylase are reciprocally regulated by the levels of acetyl CoA; acetyl CoA inhibits pyruvate dehydrogenase, while activating pyruvate carboxylase. NADH is an inhibitor of pyruvate dehydrogenase, but does not activate pyruvate carboxylase. OAA, citrate, and α -ketoglutarate are not allosteric effectors of either pyruvate dehydrogenase or pyruvate carboxylase.
12. **The answer is D.** Avidin will block the pyruvate carboxylase reaction, which converts pyruvate to OAA. The conversion of glycerol, galactose, fructose, and OAA to glucose does not require the participation of pyruvate carboxylase, but the conversion of lactate to glucose does (lactate to pyruvate, which is then converted to OAA using pyruvate carboxylase). Glycerol enters gluconeogenesis at the DHAP step, bypassing the need for the conversion of pyruvate to OAA. Galactose is converted to glucose 1-phosphate, which is isomerized to glucose 6-P, and then dephosphorylated to produce glucose. Fructose is converted to fructose 1-phosphate, then split into DHAP and glyceraldehyde. The glyceraldehyde is phosphorylated to glyceraldehyde 3-phosphate, which condenses with DHAP to form fructose 1,6-bisphosphate. The fructose 1,6-bisphosphate then follows the gluconeogenic pathway to glucose.
13. **The answer is E.** As the individual's fast progresses, the liver will begin to synthesize ketone bodies from fatty acid oxidation as an alternative energy source for the nervous system. As the nervous system begins

to use ketone bodies for energy, the body's need for glucose slightly decreases (from 5 mM to 3.5 mM). As all the glycogen stores were used up about 30 hours into the fast, all of the glucose being exported to the circulation is from gluconeogenesis. Substrates for gluconeogenesis include lactate, glycerol, and amino acids obtained from protein turnover in the muscle. As the body's need for glucose diminishes, the use of amino acids as a carbon source for gluconeogenesis also decreases, thereby sparing muscle protein during the fast. As urea is produced during the metabolism of the amino acids to provide carbons for gluconeogenesis, urea production decreases as the length of the fast increases. Fatty acid and ketone body levels increase during the fast, whereas lactate levels (produced by red blood cells) remain relatively constant.

14. **The answer is B.** The enzymes lactate dehydrogenase, glyceraldehyde 3-phosphate dehydrogenase, enolase, and phosphoglycerate kinase are all reversible enzymes that are not regulated, in either glycolysis or gluconeogenesis. The fructose 1,6-bisphosphatase reaction converts fructose 1,6-bisphosphate to fructose 6-P, thereby bypassing the irreversible PFK-1 reaction. If both fructose 1,6-bisphosphatase and PFK-1 were active at the same time, a futile cycle would develop, as fructose 6-P would be recycled (substrate cycling) at the expense of ATP, for as soon as fructose 6-P is synthesized from fructose 1,6-bisphosphate, PFK-1 would convert the fructose 6-P to fructose 1,6-bisphosphate at the expense of ATP. This cycle would continue, both glycolysis and gluconeogenesis would be impaired, and energy levels in the cell would drop.
15. **The answer is C.** Classical galactosemia is the result of an inactivating mutation in galactose 1-phosphate uridylyltransferase. The enzyme uses galactose 1-phosphate and UDP-glucose as substrates and generates glucose 1-phosphate and UDP-galactose as products. When defective galactose 1-phosphate accumulates and blocks the activity of glycogen phosphorylase (because of phosphate depletion) and to a lesser extent phosphoglucomutase (as a substrate analog to glucose 1-phosphate, a substrate/product of the enzyme). Phosphoglucomutase activity is necessary to obtain glucose from glycogen (glycogen to glucose 1-phosphate, to glucose 6-P, to glucose), so the process of glycogenolysis is inhibited when galactose 1-phosphate uridylyltransferase activity is reduced. The reduced glycogen phosphorylase activity also impedes the process of glycogenolysis. The accumulation of galactose 1-phosphate has no effect on the pathways of glycolysis, gluconeogenesis, and only slightly on glycogen synthesis (as glucose 6-P accumulates, it can displace the galactose 1-phosphate from phosphoglucomutase and allow glucose 6-P conversion to glucose 1-phosphate, for UDP-glucose synthesis).

SECTION
V

Lipid Metabolism

Most of the lipids found in the body fall into the categories of fatty acids and triacylglycerols; glycerophospholipids and sphingolipids; eicosanoids; cholesterol, bile salts, and steroid hormones; and fat-soluble vitamins. These lipids have very diverse chemical structures and functions. However, they are related by a common property: their relative insolubility in water.

Fatty acids are a major fuel in the body. After eating, we store excess fatty acids and carbohydrates that are not oxidized as fat (triacylglycerols) in adipose tissue. Between meals, these fatty acids are released and circulate in blood bound to albumin (Fig. V.1). In muscle, liver, and other tissues, fatty acids are oxidized to acetyl coenzyme A (acetyl CoA) in the pathway of β -oxidation. NADH and FAD(2H) generated from β -oxidation are reoxidized by O_2 in the electron transport chain, thereby generating adenosine triphosphate (ATP). Small amounts of certain fatty acids are oxidized through other pathways that convert them to either oxidizable fuels or urinary excretion products (e.g., peroxisomal β -oxidation).

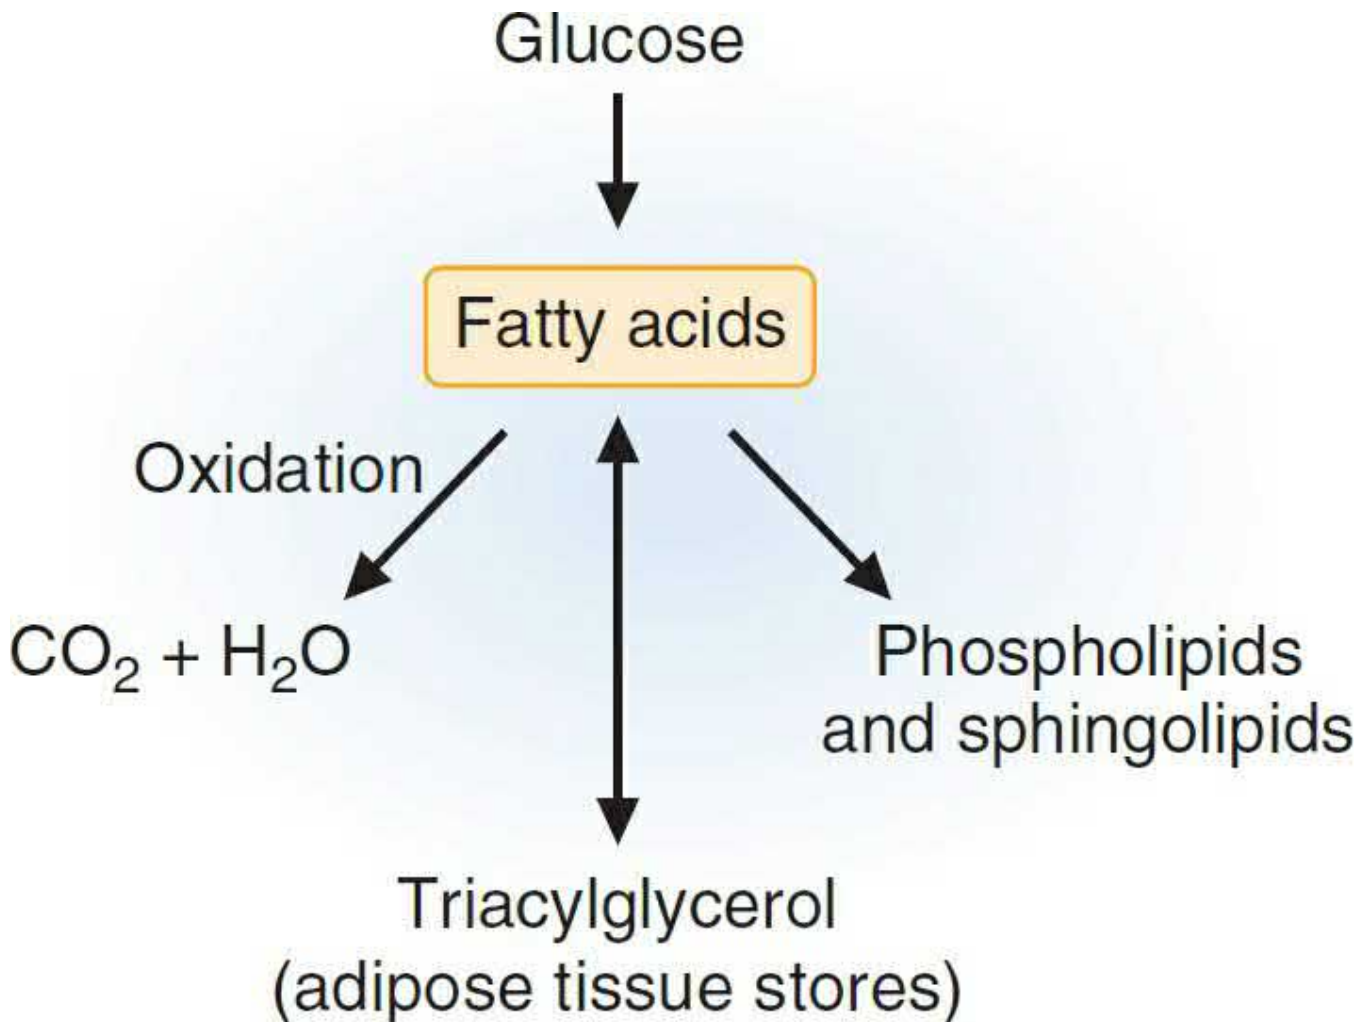

FIGURE V.1 Summary of fatty acid metabolism.

Not all acetyl CoA generated from β -oxidation enters the tricarboxylic acid (TCA) cycle. In the liver, acetyl CoA generated from β -oxidation of fatty acids can also be converted to the ketone bodies acetoacetate and β -

hydroxybutyrate. Ketone bodies are taken up by muscle and other tissues, which convert them back to acetyl CoA for oxidation in the TCA cycle. They become a major fuel for the brain during prolonged fasting.

Glycerophospholipids and sphingolipids, which contain esterified fatty acids, are found in membranes and in blood lipoproteins at the interfaces between the lipid components of these structures and the surrounding water. These membrane lipids form hydrophobic barriers between subcellular compartments and between cellular constituents and the extracellular milieu. Polyunsaturated fatty acids containing 20 carbons form the eicosanoids, which regulate many cellular processes (Fig. V.2).

FIGURE V.2 Summary of eicosanoid synthesis. EPA, eicosapentaenoic acid.

Cholesterol adds stability to the phospholipid bilayer of membranes. It serves as the precursor of the bile salts, detergent-like compounds that function in the process of lipid digestion and absorption (Fig. V.3). Cholesterol also serves as the precursor of the steroid hormones, which have many actions, including the regulation of metabolism, growth, and reproduction.

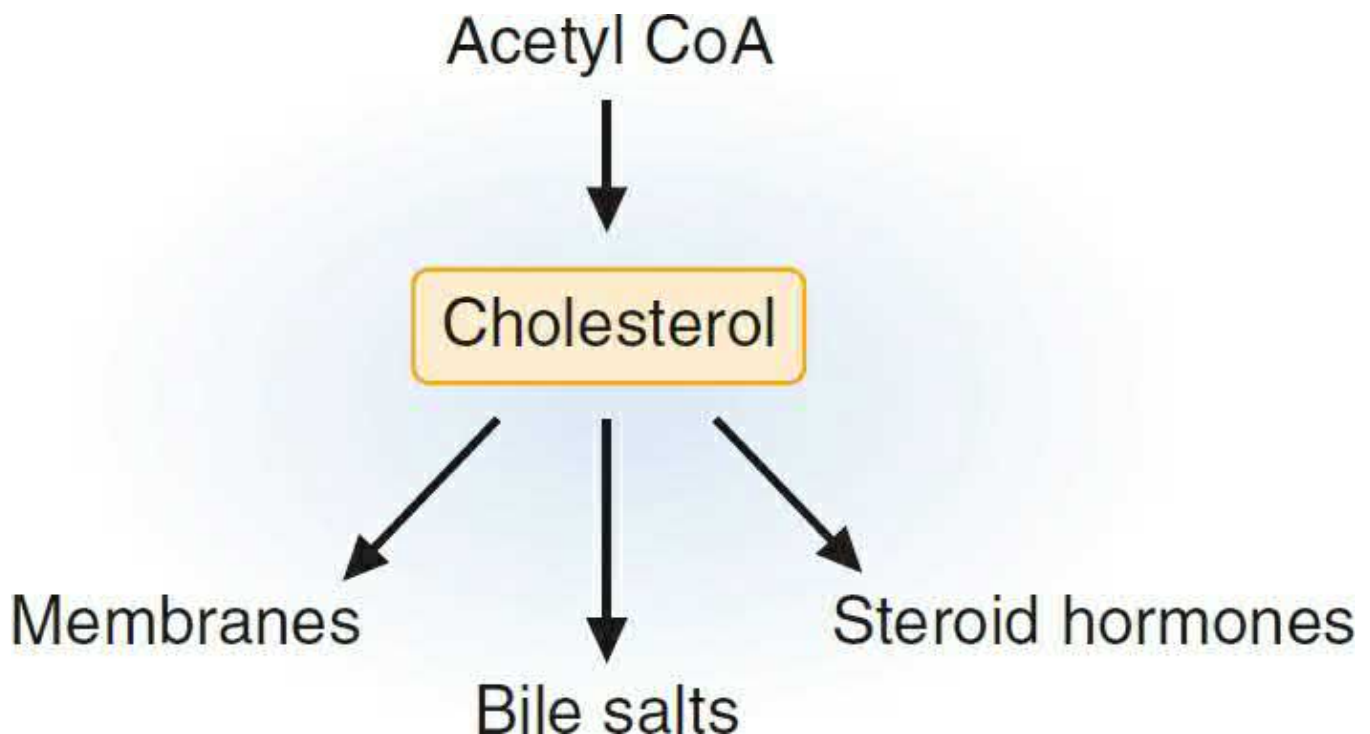

FIGURE V.3 Summary of cholesterol metabolism. Acetyl CoA, acetyl coenzyme A.

The fat-soluble vitamins are lipids that are involved in such varied functions as vision, growth, and differentiation (vitamin A), blood clotting (vitamin K), prevention of oxidative damage to cells (vitamin E), and calcium metabolism (vitamin D).

Triacylglycerols, the major dietary lipids, are digested in the lumen of the intestine (Fig. V.4). The initial digestive products, free fatty acids and 2-monoacylglycerol, are reconverted to triacylglycerols in intestinal epithelial cells, packaged in lipoproteins known as chylomicrons (so they can safely enter the circulation), and secreted into the lymph. Ultimately, chylomicrons enter the blood, serving as one of the major blood lipoproteins.

FIGURE V.4 Overview of triacylglycerol metabolism in the fed state. 2-MG, 2-monoacylglycerol; circled TG, triacylglycerols of VLDL and chylomicrons; CoA, coenzyme A; FA, fatty acid; LPL, lipoprotein lipase; TG, triacylglycerol; VLDL, very-low-density lipoprotein.

Very-low-density lipoprotein (VLDL) is produced in the liver, mainly from dietary carbohydrate. Lipogenesis is an insulin-stimulated process through which glucose is converted to fatty acids, which are subsequently esterified to glycerol to form the triacylglycerols that are packaged in VLDL and secreted from the liver. Thus, chylomicrons primarily transport dietary lipids, and VLDL transports endogenously synthesized lipids.

The triacylglycerols of chylomicrons and VLDL are digested by lipoprotein lipase (LPL), an enzyme found

attached to capillary endothelial cells (see Fig. V.4). The fatty acids that are released are taken up by muscle and many other tissues and oxidized to CO₂ and water to produce energy. After a meal, these fatty acids are taken up by adipose tissue and stored as triacylglycerols.

LPL converts chylomicrons to chylomicron remnants and VLDL to intermediate-density lipoprotein (IDL). These products, which have a relatively low triacylglycerol content, are taken up by the liver by the process of endocytosis and degraded by lysosomal action. IDL may also be converted to low-density lipoprotein (LDL) by further digestion of triacylglycerol. Endocytosis of LDL occurs in peripheral tissues as well as the liver (Table V.1) and is the major means of cholesterol transport and delivery to peripheral tissues.

TABLE V.1 Blood Lipoproteins

Chylomicrons
<ul style="list-style-type: none"> • Produced in intestinal epithelial cells from dietary fat • Carries TG in blood
VLDL
<ul style="list-style-type: none"> • Produced in liver mainly from dietary carbohydrate • Carries TG in blood
IDL
<ul style="list-style-type: none"> • Produced in blood (remnant of VLDL after TG digestion) • Endocytosed by liver or converted to LDL
LDL
<ul style="list-style-type: none"> • Produced in blood (remnant of IDL after TG digestion; end product of VLDL) • Contains high concentration of cholesterol and cholesterol esters • Endocytosed by liver and peripheral tissues
HDL
<ul style="list-style-type: none"> • Produced in liver and intestine • Exchanges proteins and lipids with other lipoproteins • Functions in the return of cholesterol from peripheral tissues to the liver

HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein; TG, triacylglycerol.

The principal function of high-density lipoprotein (HDL) is to transport excess cholesterol obtained from peripheral tissues to the liver and to exchange proteins and lipids with chylomicrons and VLDL. The protein exchange converts “nascent” particles to “mature” particles.

During fasting, fatty acids and glycerol are released from adipose triacylglycerol stores (Fig. V.5). The glycerol travels to the liver and is used for gluconeogenesis. Only the liver contains glycerol kinase, which is required for glycerol metabolism. The fatty acids form complexes with albumin in the blood and are taken up by muscle, kidney, and other tissues, where adenosine triphosphate (ATP) is generated by their oxidation to CO₂ and water. Liver also converts some of the carbon to ketone bodies, which are released into the blood. Ketone bodies are oxidized for energy in muscle, kidney, and other tissues during fasting, and in the brain during prolonged starvation.

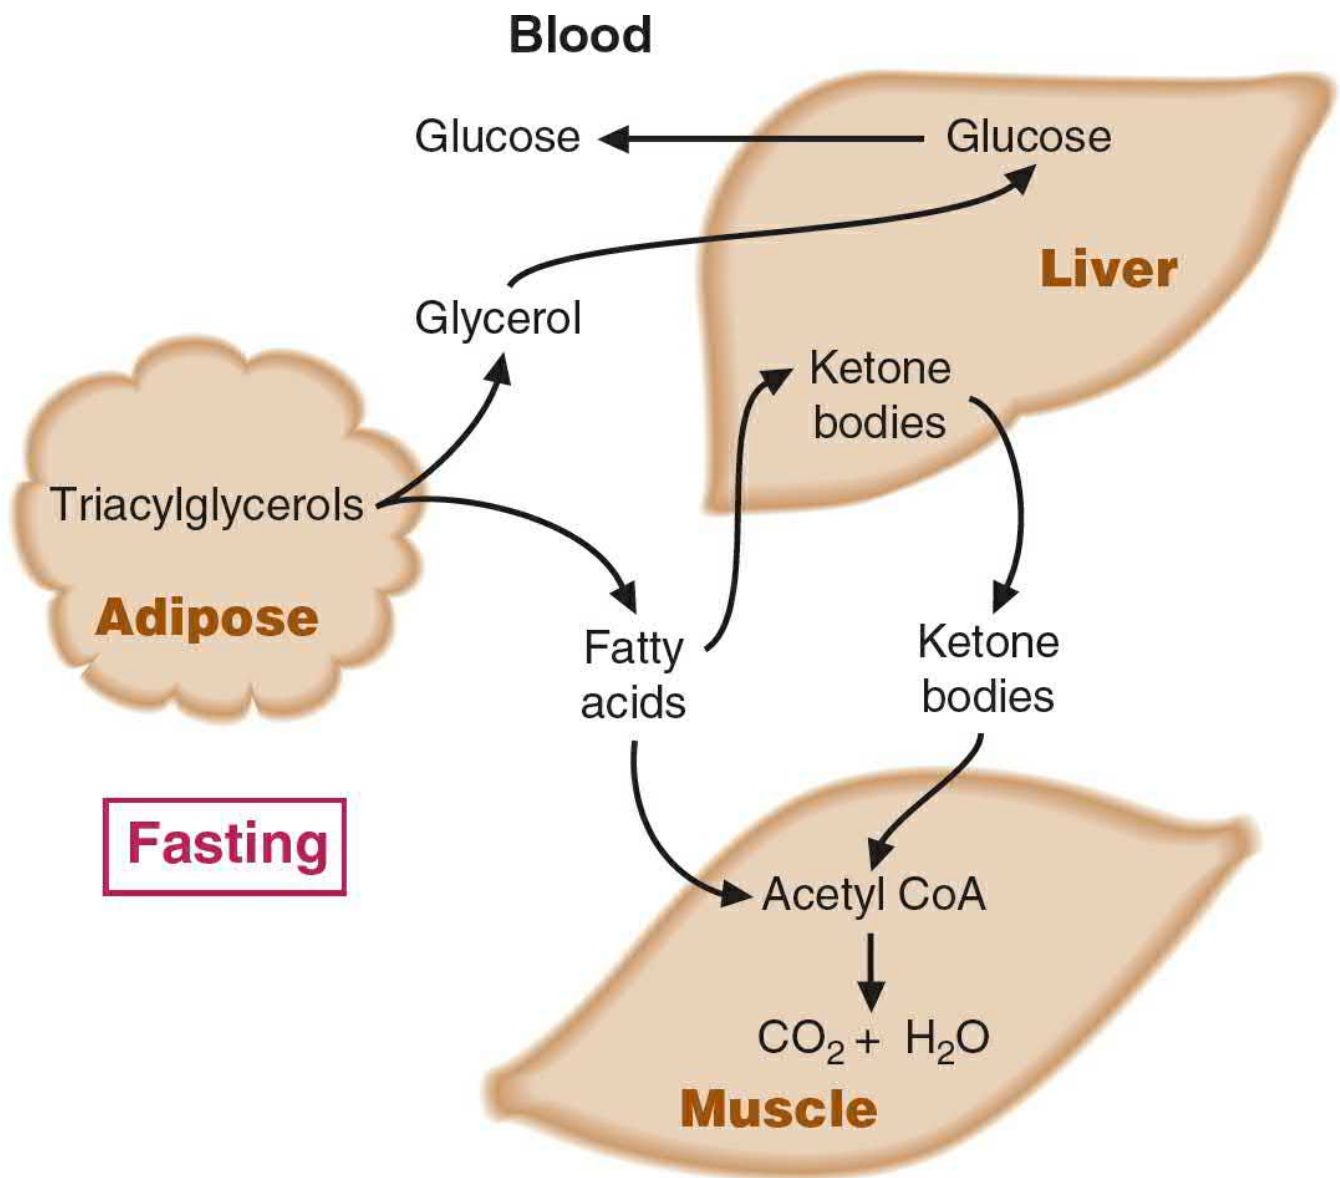

FIGURE V.5 Overview of triacylglycerol metabolism during fasting. Acetyl CoA, acetyl coenzyme A.

Digestion and Transport of Dietary Lipids

Triacylglycerols are the major fat in the human diet, consisting of three **fatty acids** esterified to a **glycerol** backbone. Limited digestion of these lipids occurs in the mouth (**lingual lipase**) and stomach (**gastric lipase**) because of the low solubility of the substrate. In the intestine, however, the fats are emulsified by **bile salts** that are released from the gallbladder. This increases the available surface area of the lipids for **pancreatic lipase and colipase** to bind and to digest the triglycerides. Degradation products are **free fatty acids** and **2-monoacylglycerol**. When partially digested food enters the intestine, the hormone **cholecystokinin** is secreted by the intestine, which signals the gallbladder to contract and release bile acids, and the pancreas to release digestive enzymes.

In addition to triacylglycerols, phospholipids, cholesterol, and cholesterol esters (cholesterol esterified to fatty acids) are present in the foods we eat. Phospholipids are hydrolyzed in the intestinal lumen by **phospholipase A₂**, and cholesterol esters are hydrolyzed by **cholesterol esterase**. Both of these enzymes are secreted from the pancreas.

The products of enzymatic digestion (free fatty acids, glycerol, **lysophospholipids**, and cholesterol) form **micelles** with bile acids in the intestinal lumen. The micelles interact with the enterocyte membrane and allow diffusion of the lipid-soluble components across the enterocyte membrane into the cell. The bile acids, however, do not enter the enterocyte at this time. They remain in the intestinal lumen, travel farther down, and are then reabsorbed and sent back to the liver by the **enterohepatic circulation**. This allows the bile salts to be used multiple times in fat digestion.

The lymph system is a network of vessels that surround interstitial cavities in the body. Cells secrete various compounds into the lymph, and the lymph vessels transport these fluids away from the interstitial spaces in the body tissues and into the bloodstream. In the case of the intestinal lymph system, the lymph enters the bloodstream through the thoracic duct. These vessels are designed so that under normal conditions the contents of the blood cannot enter the lymphatic system. The lymph fluid is similar in composition to that of the blood but lacks the cells found in blood.

The intestinal epithelial cells resynthesize triacylglycerol from free fatty acids and 2-monoacylglycerol and package them with a protein, **apolipoprotein B-48**, phospholipids, and cholesterol esters into a soluble **lipoprotein particle** known as a **chylomicron**. The chylomicrons are secreted into the **lymph** and eventually end up in the circulation, where they can distribute dietary lipids to all tissues of the body.

Once they are in the circulation, the newly released (“nascent”) chylomicrons interact with another lipoprotein particle, **high-density lipoprotein (HDL)**, and acquire two **apolipoproteins** from HDL, **apolipoprotein CII (apoCII)** and **apolipoprotein E (apoE)**. This converts the nascent chylomicron into a “mature” chylomicron. The apoCII on the mature chylomicron activates the enzyme **lipoprotein lipase (LPL)**, which is located on the inner surface of the capillary endothelial cells of muscle and adipose tissue. The LPL digests the triglyceride in the chylomicron, producing free fatty acids and glycerol. The fatty acids enter the adjacent organs either for energy production (muscle) or for fat storage (adipocyte). The glycerol that is released is metabolized in the liver.

As the chylomicron loses triglyceride, its density increases and it becomes a **chylomicron remnant**, which is taken up by the liver by receptors that recognize apoE. In the liver, the chylomicron remnant is degraded into its component parts for further disposition by the liver.

THE WAITING ROOM

Will S. has had several episodes of mild back and lower extremity pain over the last year, probably caused by minor sickle cell crises. He then developed abdominal pain in the right upper quadrant. He states that the pain is not like his usual crisis pain. Intractable vomiting began 12 hours after the onset of these new symptoms and he then went to the emergency department.

On physical examination, his body temperature is slightly elevated and his heart rate is rapid. The whites of his eyes (the sclerae) are slightly jaundiced (or icteric, a yellow discoloration caused by the accumulation of bilirubin pigment). He is exquisitely tender to pressure over his right upper abdomen.

The emergency department physician suspects that **Will S.** is not in sickle cell crisis but instead has acute cholecystitis (gallbladder inflammation). His hemoglobin level is low at 7.6 mg/dL (reference range, 12 to 16 mg/dL), but is unchanged from his baseline 3 months earlier. His serum total bilirubin level is 2.3 mg/dL (reference range, 0.2 to 1.0 mg/dL), and his direct (conjugated) bilirubin level is 0.9 mg/dL (reference range, 0 to 0.2 mg/dL).

Intravenous fluids were started, he was not allowed to take anything by mouth and symptomatic therapy was started for pain and nausea. He was sent for an ultrasonographic (ultrasound) study of his upper abdomen.

Al M. has continued to drink alcohol and to eat poorly. After a particularly heavy intake of vodka, a steady severe pain began in his upper midabdomen. This pain spread to the left upper quadrant and eventually radiated to his midback. He began vomiting nonbloody material and was brought to the hospital emergency department with fever, a rapid heartbeat, and a mild reduction in blood pressure. On physical examination, he was dehydrated and tender to pressure over the upper abdomen. His vomitus and stool were both negative for occult blood.

Blood samples were sent to the laboratory for a variety of hematologic and chemical tests, including a measurement of serum lipase, one of the digestive enzymes that is normally secreted from the exocrine pancreas through the pancreatic ducts into the lumen of the small intestine.

Amylase is produced only in the salivary glands and the acinar cells of the pancreas, whereas lipase is produced only in the pancreas. An elevated serum amylase, coupled with an elevated lipase, was used to diagnose pancreatitis in the past, but now only serum lipase is used. Serum lipase levels increase at the same rate as does serum amylase levels, but they stay elevated longer, and are more specific for pancreatitis than is serum amylase levels. For example, salivary gland lesions, such as mumps, can also increase serum amylase levels. The assay for serum lipase is more difficult than amylase (and has been more difficult to automate for the clinical laboratory), but currently a number of assays can be performed to determine lipase levels. Two such assays will be described here. The first involves incubating the serum sample with a known amount of triglyceride. The serum lipase will generate two free fatty acids and 2-monoacylglycerol for each triglyceride. Monoacylglycerol lipase is then added (to convert the 2-monoacylglycerol to free glycerol), as is glycerol kinase (to convert glycerol to glycerol 3-phosphate) and glycerol 3-phosphate oxidase (which converts molecular oxygen and glycerol 3-phosphate to dihydroxyacetone phosphate and hydrogen peroxide). The H_2O_2 generated can be determined colorimetrically using an appropriate chromogen and horseradish peroxidase. The amount of glycerol produced is dependent on the lipase activity. A second assay for lipase is turbidimetric (based on light scattering). The triglyceride sample does not easily go into solution, so when the assay is started, the solution is cloudy (turbid). As the lipase hydrolyzes the fatty acids from the triacylglycerol, the turbidity decreases, and this can be measured and compared to a standard curve generated with known lipase amounts.

I. Digestion of Triacylglycerols

Triacylglycerols are the major fat in the human diet because they are the major storage lipid in the plants and animals that constitute our food supply. Triacylglycerols contain a glycerol backbone to which three fatty acids are esterified (Fig. 29.1). The main route for digestion of triacylglycerols involves hydrolysis to fatty acids and 2-monoacylglycerol in the lumen of the intestine. However, the route depends to some extent on the chain length of the fatty acids. Lingual and gastric **lipases** are produced by cells at the back of the tongue and in the stomach, respectively. These lipases preferentially hydrolyze short- and medium-chain fatty acids (containing 12 or fewer carbon atoms) from dietary triacylglycerols. Therefore, they are most active in infants and young children who drink relatively large quantities of cow's milk, which contains triacylglycerols with a high percentage of short- and medium-chain fatty acids.

FIGURE 29.1 Structure of a triacylglycerol. The glycerol moiety is *highlighted*, and its carbons are *numbered*.

Currently, 38% of the calories (kcal) in the typical American diet come from fat. The content of fat in the diet increased from the early 1900s until the 1960s and then it decreased as we became aware of the unhealthy effects of a high-fat diet. According to current recommendations, fat should provide no >30% of the total calories of a healthy diet.

A. Action of Bile Salts

Dietary fat leaves the stomach and enters the small intestine, where it is emulsified (suspended in small particles in the aqueous environment) by bile salts (Fig. 29.2). The bile salts are amphipathic compounds (containing both hydrophobic and hydrophilic components), synthesized in the liver (see Chapter 32 for the pathway) and secreted via the gallbladder into the intestinal lumen. The contraction of the gallbladder and secretion of pancreatic enzymes are stimulated by the gut hormone **cholecystokinin**, which is secreted by the intestinal cells when stomach contents enter the intestine. Bile salts act as detergents, binding to the globules of dietary fat as they are broken up by the peristaltic action of the intestinal muscle. This emulsified fat, which has an increased surface area compared with unemulsified fat, is attacked by digestive enzymes from the pancreas (Fig. 29.3).

FIGURE 29.2 Structure of a bile salt. The bile salts are derived from cholesterol and retain the cholesterol ring structure. They differ from cholesterol in that the rings in bile salts contain more hydroxyl groups and a polar side chain and lack a C5–C6 double bond.

FIGURE 29.3 Digestion of triacylglycerols in the intestinal lumen. Prior to reaching the intestine, lingual lipase (mouth) and gastric lipase (stomach) have begun digestion of the triacylglycerol. 2-MG, 2-monoacylglycerol; bs, bile salts; FA, fatty acid; TG, triacylglycerol.

 The mammary gland produces milk, which is the major source of nutrients for the breastfed human infant. The fatty acid composition of human milk varies, depending on the diet of the mother. However, long-chain fatty acids predominate, particularly palmitic, oleic, and linoleic acids. Although the amount of fat contained in human milk and cow's milk is similar, cow's milk contains more short- and medium-chain fatty acids and does not contain the long-chain, polyunsaturated fatty acids found in human milk that are important in brain development. Although the concentrations of pancreatic lipase and bile salts are low in the intestinal lumen of the newborn infant, the fat of human milk is still readily absorbed. This is true because lingual and gastric lipases produced by the infant partially compensate for the lower levels of pancreatic lipase. The human mammary gland also produces lipases that enter the milk. One of these lipases, which requires lower levels of bile salts than pancreatic lipase, is not inactivated by stomach acid and

functions in the intestine for a number of hours.

B. Action of Pancreatic Lipase

The major enzyme that digests dietary triacylglycerols is a lipase produced in the pancreas. **Pancreatic lipase** is secreted along with another protein, **colipase**, in response to the release of cholecystokinin from the intestine. The peptide hormone **secretin** is also released by the small intestine in response to acidic materials (such as the partially digested materials from the stomach, which contains HCl) entering the duodenum. Secretin signals the liver, pancreas, and certain intestinal cells to secrete bicarbonate. Bicarbonate raises the pH of the contents of the intestinal lumen into a range (pH ~6) that is optimal for the action of all of the digestive enzymes of the intestine.

AI M.'s serum levels of pancreatic lipase were elevated—a finding consistent with a diagnosis of acute pancreatitis. The elevated level of this enzyme in the blood is the result of its escape from the inflamed exocrine cells of the pancreas into the surrounding pancreatic veins. The cause of this inflammatory pancreatic process in this case was related to the toxic effect of acute and chronic excessive alcohol ingestion.

Bile salts inhibit pancreatic lipase activity by coating the substrate and not allowing the enzyme access to it. The colipase binds to the dietary fat and to the lipase, relieving the bile salt inhibition and allowing triglyceride to enter the active site of the lipase. This enhances lipase activity. Pancreatic lipase hydrolyzes fatty acids of all chain lengths from positions 1 and 3 of the glycerol moiety of the triacylglycerol, producing free fatty acids and 2-monoacylglycerol—that is, glycerol with a fatty acid esterified at position 2 (Fig. 29.4). The pancreas also produces **esterases** that remove fatty acids from compounds (such as cholesterol esters) and **phospholipase A₂** (which is released in its zymogen form and is activated by trypsin) that digests phospholipids to a free fatty acid and a lysophospholipid (see Fig. 29.4B and C).

A**B****C**

FIGURE 29.4 Action of pancreatic enzymes on fatty acid digestion. **A.** Action of pancreatic lipase. FAs are cleaved from positions 1 and 3 of the triacylglycerol, and a monoacylglycerol with a fatty acid at position 2 is produced. **B.** Action of pancreatic cholesterol esterase. **C.** Action of phospholipase A_2 . FA, fatty acid.

II. Absorption of Dietary Lipids

The fatty acids and 2-monoacylglycerols produced by digestion are packaged into **micelles**, tiny microdroplets that are emulsified by bile salts (see Fig. 29.3). For bile salt micelles to form, the concentration of bile salts in the intestinal lumen must reach 5 to 15 mM (the critical micelle concentration [CMC]). Below this concentration the bile salts are soluble; above it, micelles will form. Other dietary lipids, such as cholesterol, lysophospholipids, and fat-soluble vitamins, are also packaged in micelles. The micelles travel through a layer of water (the unstirred water layer) to the microvilli on the surface of the intestinal epithelial cells, where the fatty acids, 2-monoacylglycerols, and other dietary lipids are absorbed, but the bile salts are left behind in the lumen of the gut.

The bile salts are extensively resorbed when they reach the ileum. Greater than 95% of the bile salts are recirculated, traveling through the enterohepatic circulation to the liver, which secretes them into the bile for storage in the gallbladder and ejection into the intestinal lumen during another digestive cycle (Fig. 29.5).

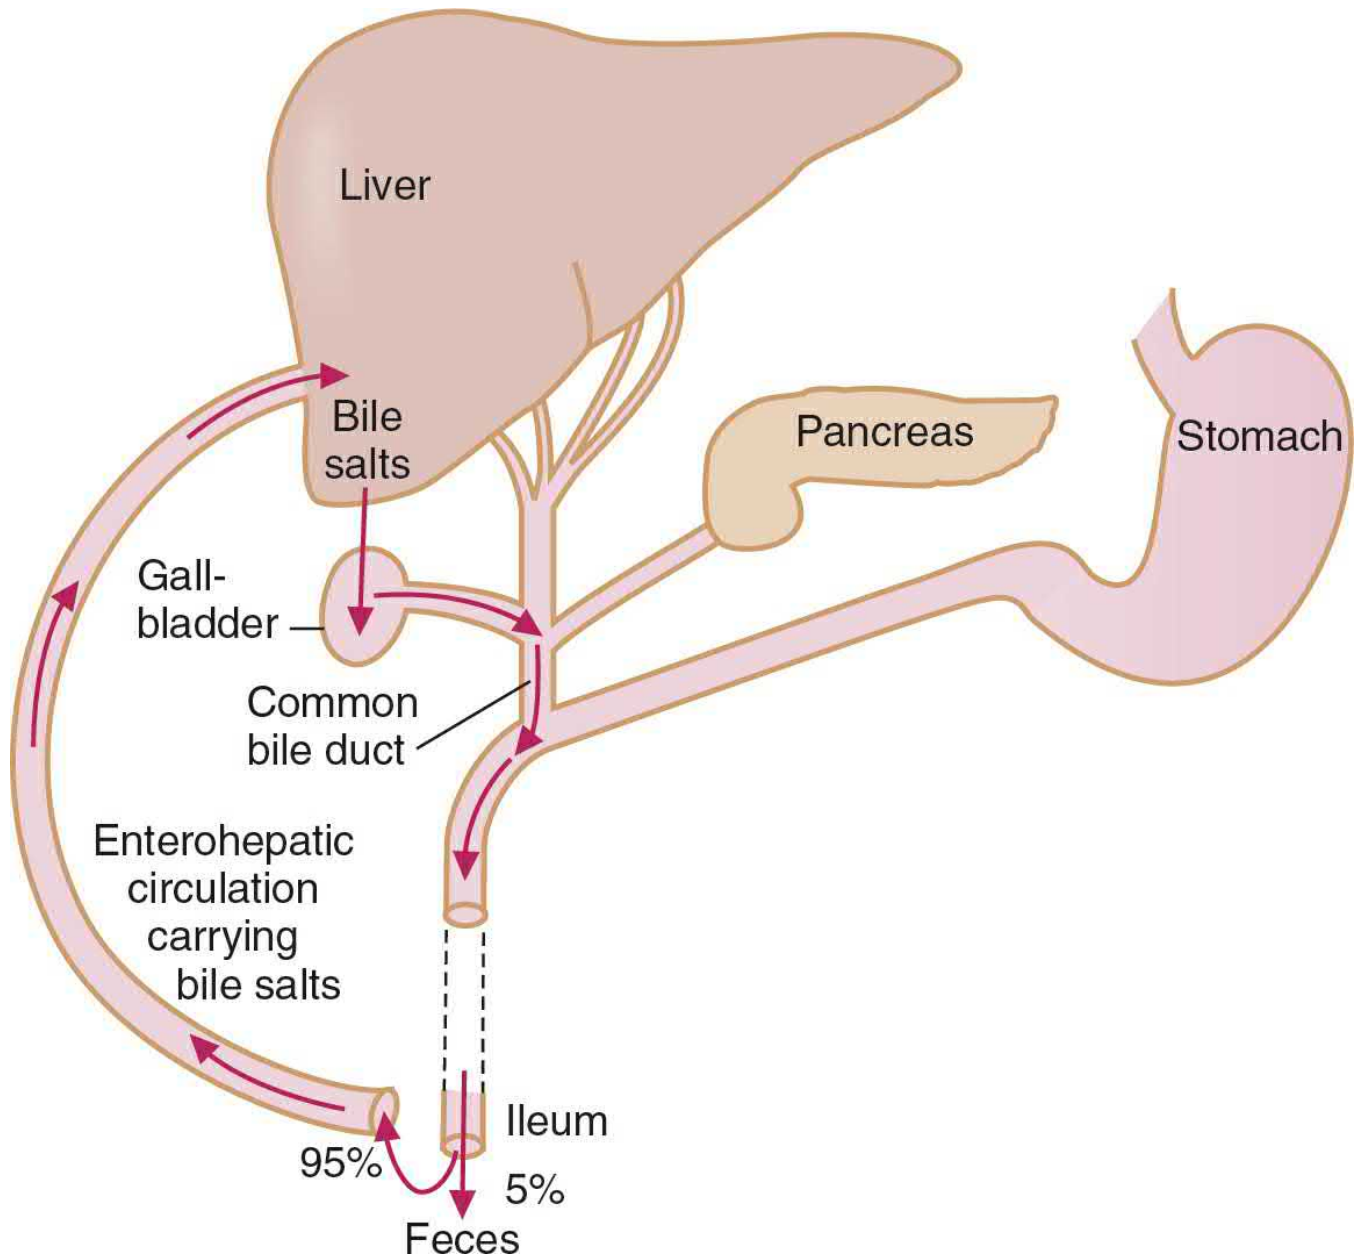

FIGURE 29.5 Recycling of bile salts. Bile salts are synthesized in the liver, stored in the gallbladder, secreted into the small intestine, resorbed in the ileum, and returned to the liver via the enterohepatic circulation. Under normal circumstances, 5% or less of luminal bile acids are excreted in the stool.

 In patients such as **Will S.** who have severe and recurrent episodes of increased red blood cell destruction (hemolytic anemia), greater than normal amounts of the red cell pigment heme must be processed by the liver and spleen. In these organs, heme (derived from hemoglobin) is degraded to bilirubin, which is excreted by the liver in the bile. If large quantities of bilirubin are presented to the liver as a consequence of acute hemolysis, the capacity of the liver to conjugate it, that is, convert it to the water-soluble bilirubin diglucuronide, can be overwhelmed. As a result, a greater percentage of the bilirubin entering the hepatic biliary ducts in patients with hemolysis is in the less water-soluble forms. In the gallbladder, these relatively insoluble particles tend to precipitate as gallstones that are rich in calcium bilirubinate. In some patients, one or more stones may leave the gallbladder through the cystic duct and enter the common bile duct. Most pass harmlessly into the small intestine and are later excreted in the stool. Larger stones, however, may become entrapped in the lumen of the cystic or common bile duct, where they cause varying degrees of obstruction to bile flow (cholestasis) with associated ductal spasm, producing pain. If adequate amounts of bile salts do not enter the intestinal lumen, dietary fats cannot readily be emulsified and digested.

Short- and medium-chain fatty acids (C₄ to C₁₂) do not require bile salts for their absorption. They are absorbed directly into intestinal epithelial cells. Because they do not need to be packaged to increase their solubility, they enter the portal blood (rather than the lymph) and are transported to the liver bound to serum albumin.

III. Synthesis of Chylomicrons

Within the intestinal epithelial cells, the fatty acids and 2-monoacylglycerols are condensed by enzymatic reactions in the smooth endoplasmic reticulum (ER) to form triacylglycerols. The fatty acids are activated to fatty acyl coenzyme A (fatty acyl CoA) by the same process used for activation of fatty acids before β -oxidation (see Chapter 30). A fatty acyl CoA then reacts with 2-monoacylglycerol to form diacylglycerol, which reacts with another fatty acyl CoA to form triacylglycerol (Fig. 29.6). The reactions for triacylglycerol synthesis in intestinal cells differ from those in liver and adipose cells in that 2-monoacylglycerol is an intermediate in triacylglycerol synthesis in intestinal cells, whereas phosphatidic acid is the necessary intermediate in other tissues.

FIGURE 29.6 Resynthesis of triacylglycerols in intestinal epithelial cells. FAs, produced by digestion, are activated in intestinal epithelial cells and then esterified to the 2-monoacylglycerol produced by digestion. The triacylglycerols are packaged in nascent chylomicrons and secreted into the lymph. AMP, adenosine monophosphate; ATP, adenosine triphosphate; CoA, coenzyme A; FA, fatty acid.

Triacylglycerols, owing to their insolubility in water, are packaged in lipoprotein particles. If triacylglycerols entered the blood directly, they would coalesce, impeding blood flow. Intestinal cells package triacylglycerols together with proteins and phospholipids in **chylomicrons**, which are lipoprotein particles that do not readily coalesce in aqueous solutions (Fig. 29.7). Chylomicrons also contain cholesterol and fat-soluble vitamins, but their major component is triglyceride derived from the diet (Fig. 29.8). The protein constituents of the lipoproteins are known as apolipoproteins.

FIGURE 29.7 Example of the structure of a blood lipoprotein. VLDL is depicted. Lipoproteins contain phospholipids and proteins on the surface, with their hydrophilic regions interacting with water. Hydrophobic molecules are in the interior of the lipoprotein. The hydroxyl group of cholesterol is near the surface. In cholesterol esters, the hydroxyl group is esterified to a fatty acid. Cholesterol esters are found in the interior of lipoproteins and are synthesized by reaction of cholesterol with an activated fatty acid (see Chapter 32). VLDL, very-low-density lipoprotein.

FIGURE 29.8 Composition of a typical chylomicron. Although the composition varies to some extent, the major component is TG. C, cholesterol; CE, cholesterol ester; PL, phospholipid; TG, triacylglycerol.

When he was finally able to tolerate a full diet, **Al M.**'s stools became bulky, glistening, yellow-brown, and foul-smelling. They floated on the surface of the toilet water. What caused this problem?

The major apolipoprotein associated with chylomicrons as they leave the intestinal cells is B-48. The B-48 apolipoprotein is structurally and genetically related to the B-100 apolipoprotein synthesized in the liver that serves as a major protein of another lipid carrier, **very-low-density lipoprotein (VLDL)**. These two apolipoproteins are encoded by the same gene. In the intestine, the primary transcript of this gene undergoes RNA editing (see Fig. 15.19). A stop codon is generated that causes a protein to be produced in the intestine that is 48% of the size of the protein produced in the liver; hence, the designations B-48 and B-100.

Because the fat-soluble vitamins (A, D, E, and K) are absorbed from micelles along with the long-chain fatty acids and 2-monoacylglycerols, prolonged obstruction of the duct that carries exocrine secretions from the pancreas and the gallbladder into the intestine (via the common duct) could lead to a deficiency of these metabolically important substances.

The protein component of the lipoproteins is synthesized on the rough ER. Lipids, which are synthesized in the smooth ER, are complexed with the proteins to form the chylomicrons.

Al M.'s stool changes are characteristic of steatorrhea (fat-laden stools caused by malabsorption of dietary fats), in this case caused by a lack of pancreatic secretions, particularly pancreatic lipase, which normally digests dietary fat. Steatorrhea also may be caused by insufficient production or secretion of bile salts. Therefore, **Will S.** might also develop this condition.

IV. Transport of Dietary Lipids in the Blood

By the process of exocytosis, nascent chylomicrons are secreted by the intestinal epithelial cells into the chyle

of the lymphatic system and enter the blood through the thoracic duct. Nascent chylomicrons begin to enter the blood within 1 to 2 hours after the start of a meal; as the meal is digested and absorbed, they continue to enter the blood for many hours. Initially, the particles are called nascent (newborn) chylomicrons. As they accept proteins from **high-density lipoprotein** (HDL) within the lymph and the blood, they become “mature” chylomicrons. HDL is the lipoprotein particle with the highest concentration of proteins and lowest concentration of triacylglycerol (see Chapter 32 for further discussion of HDL and other lipoprotein particles found in the body).

HDL transfers proteins to the nascent chylomicrons, particularly apoE and apoCII (Fig. 29.9). ApoE is recognized by membrane receptors, particularly those on the surface of liver cells, allowing apoE-bearing lipoproteins to enter these cells by endocytosis for subsequent digestion by lysosomes. ApoCII acts as an activator of LPL, the enzyme on capillary endothelial cells, primarily within muscle and adipose tissue, that digests the triacylglycerols of the chylomicrons and VLDL in the blood.

Blood

FIGURE 29.9 Transfer of proteins from HDL to chylomicrons. Newly synthesized chylomicrons (nascent chylomicrons) mature as they receive apoCII and apoE from HDL. HDL functions in the transfer of these apolipoproteins and also in transfer of cholesterol from peripheral tissues to the liver (see Table V.1 in the introduction to Section V). apoCII, apolipoprotein CII; apoE, apolipoprotein E; HDL, high-density lipoprotein.

Olestra is an artificial fat substitute designed to allow individuals to obtain the taste and food consistency of fat without the calories from fat. The structure of Olestra is shown below and consists of a sucrose molecule to which fatty acids are esterified to the hydroxyl groups.

Olestra = octa-acyl sucrose
 R = fatty acyl group

The fatty acids attached to sucrose are resistant to hydrolysis by pancreatic lipase, so Olestra passes through the intestine intact and is eliminated in the feces. As a result, no useful calories can be obtained through the metabolism of Olestra, although in the mouth the sucrose portion of the molecule imparts a sweet taste. In addition, because Olestra has the ability to pass through the digestive system unimpeded, it can also carry essential fat-soluble vitamins with it. Therefore, foods prepared with Olestra are supplemented with these vitamins. Unfortunately, the side effects of cramping and diarrhea decreased the popularity of Olestra as a food additive. Olestra was approved by the Food and Drug Administration (FDA) in the United States in 1996 as a food additive and is still approved today, although other countries (e.g., Canada, European Union) have banned its use because of its side effects.

V. Fate of Chylomicrons

The triacylglycerols of the chylomicrons are digested by LPL attached to the proteoglycans in the basement membranes of endothelial cells that line the capillary walls (Fig. 29.10). LPL is produced by adipose cells, muscle cells (particularly cardiac muscle), and cells of the lactating mammary gland. The isozyme synthesized in adipose cells has a higher K_m than the isozyme synthesized in muscle cells. Therefore, adipose LPL is more active after a meal, when chylomicron levels are elevated in the blood. Insulin stimulates the synthesis and secretion of adipose LPL, so that after a meal, when triglyceride levels increase in circulation, LPL has been upregulated (through insulin release) to facilitate the hydrolysis of fatty acids from the triglyceride.

FIGURE 29.10 Fate of chylomicrons. Nascent chylomicrons are synthesized in intestinal epithelial cells, secreted into the lymph, pass into the blood, and become mature chylomicrons (see Fig. 29.9). On capillary walls in adipose tissue and muscle, LPL activated by apoCII digests the TG of chylomicrons to FAs and glycerol. FAs are oxidized in muscle or stored in adipose cells as TGs. The remnants of the chylomicrons are taken up by the liver by receptor-mediated endocytosis (through recognition of apoE on the remnant). Lysosomal enzymes within the hepatocyte digest the remnants, releasing the products into the cytosol. apoCII, apolipoprotein CII; apoE, apolipoprotein E; FA, fatty acid; LPL, lipoprotein lipase; TG, triacylglycerol.

The fatty acids released from triacylglycerols by LPL are not very soluble in water. They become soluble in blood by forming complexes with the protein albumin. The major fate of the fatty acids is storage as triacylglycerol in adipose tissue. However, these fatty acids also may be oxidized for energy in muscle and other tissues (see Fig. 29.10). The LPL in the capillaries of muscle cells has a lower K_m than adipose LPL. Thus, muscle cells can obtain fatty acids from blood lipoproteins whenever they are needed for energy, even if the concentration of the lipoproteins is low.

 Because of their high triacylglycerol content, chylomicrons are the least dense of the blood lipoproteins. When blood is collected from patients with certain types of hyperlipoproteinemias (high concentrations of lipoproteins in the blood) in which chylomicron levels are elevated and the blood is allowed to stand in the refrigerator overnight, the chylomicrons float to the top of the liquid and coalesce, forming a creamy layer.

 One manner in which individuals can lose weight is to inhibit the activity of pancreatic lipase. This results in reduced fat digestion and absorption and a reduced caloric yield from the diet. The drug Orlistat is a chemically synthesized derivative of lipstatin—a natural lipase inhibitor found in certain bacteria. The drug works in the intestinal lumen and forms a covalent bond with the active-site serine residues of both gastric and pancreatic lipase, thereby inhibiting their activities. Nondigested triglycerides are not absorbed by the intestine and are eliminated in the feces. Under normal use of the drug, approximately 30% of dietary fat absorption is inhibited. Because excessive nondigested fat in the intestines can lead to gastrointestinal distress related to excessive intestinal gas formation, individuals who take this drug need to follow a diet with reduced daily intake of fat, which should be evenly distributed among the meals of the day.

The glycerol released from chylomicron triacylglycerols by LPL may be used for triacylglycerol synthesis in the liver in the fed state.

The portion of a chylomicron that remains in the blood after LPL action is known as a **chylomicron remnant**. The remnant has lost many of the apoCII molecules bound to the mature chylomicron, which exposes apoE. This remnant binds to receptors on hepatocytes (the major cells of the liver), which recognize apoE, and is taken up by the process of endocytosis. Lysosomes fuse with the endocytic vesicles, and the chylomicron remnants are degraded by lysosomal enzymes. The products of lysosomal digestion (e.g., fatty acids, amino acids, glycerol, phosphate) can be reused by the cell.

Heparin is a complex polysaccharide (a glycosaminoglycan) that is a component of proteoglycans (see Chapter 47). Isolated heparin is frequently used as an anticoagulant, because it binds to antithrombin III (ATIII), and the activated ATIII then binds factors necessary for clotting and inhibits them from working. As LPL is bound to the capillary endothelium through binding to proteoglycans, heparin also can bind to LPL and dislodge it from the capillary wall. This leads to loss of LPL activity and an increase of triglyceride content in the blood.

CLINICAL COMMENTS

Will S. The upper abdominal ultrasound study showed a large gallstone lodged in **Will S.**'s cystic duct with dilation of this duct proximal to the stone. Intravenous (IV) fluids were continued, he was not allowed to take anything by mouth, antibiotics were started, and he was scheduled for a cholecystectomy.

Gallstones can also obstruct the common bile duct, which can cause bilirubin to flow back into the venous blood draining from the liver. As a consequence, serum bilirubin levels, particularly the direct (conjugated) fraction, increase. Tissues such as the sclerae of the eye take up this pigment, which causes them to become yellow (jaundiced, icteric). You can also see inflammation from a cystic duct obstruction and cholecystitis causing some obstruction of the common bile duct and mild elevation of bilirubin.

Al M. Alcohol excess may produce proteinaceous plugs in the small pancreatic ducts, causing back pressure injury and autodigestion of the pancreatic acini drained by these obstructed channels. This process causes one form of acute pancreatitis. **Al M.** had an episode of acute alcohol-induced pancreatitis superimposed on a more chronic alcohol-related inflammatory process in the pancreas—in other words, chronic pancreatitis. As a result of decreased secretion of pancreatic lipase through the pancreatic ducts and into the lumen of the small intestine, dietary fat was not absorbed at a normal rate, and steatorrhea (fat-rich stools) occurred. If abstinence from alcohol does not allow adequate recovery of the enzymatic secretory function of the pancreas, **Al M.** will have to take a commercial preparation of pancreatic enzymes with meals that contain even minimal amounts of fat.

BIOCHEMICAL COMMENTS

Microsomal Triglyceride Transfer Protein. The assembly of chylomicrons within the ER of the enterocyte requires the activity of **microsomal triglyceride transfer protein (MTP)**. The protein is a dimer of two nonidentical subunits. The smaller subunit (57 kDa) is protein disulfide isomerase (PDI, see Chapter 7, Section IX.A), whereas the larger subunit (97 kDa) contains the triglyceride transfer activity. MTP accelerates the transport of triglycerides, cholesterol esters, and phospholipids across membranes of subcellular organelles. The role of PDI in this complex is not known; the disulfide isomerase activity of this subunit is not needed for triglyceride transport to occur. The lack of triglyceride transfer activity leads to the disease **abetalipoproteinemia**. This disease affects both chylomicron assembly in the intestine and VLDL assembly in the liver. Both particles require a B apolipoprotein for their assembly (apoB-48 for chylomicrons, apoB-100 for VLDL), and MTP binds to the B apolipoproteins. For both chylomicron and VLDL assembly, a small apoB-containing particle is first produced within the lumen of the ER. The appropriate apoB is made on the rough endoplasmic reticulum (RER) and is inserted into the ER lumen during its synthesis (see Chapter 14, Section VIII). As the protein is being translated, lipid (a small amount of triglyceride) begins to associate with the protein, and the lipid association is catalyzed by MTP. This leads to the generation of small apoB-containing particles; these particles are not formed in patients with abetalipoproteinemia. Thus, it appears that MTP activity is necessary to transfer triacylglycerol formed within the ER to the apoB protein. The second stage of particle assembly is the fusion of the initial apoB particle with triacylglycerol droplets within the ER. The role of MTP in this second step is still under investigation; it may be required for the transfer of triacylglycerol from the cytoplasm to the lumen of the ER to form this lipid droplet. These steps are illustrated in Figure 29.11. In the absence of MTP activity, membrane-associated apoB is degraded.

FIGURE 29.11 A model of MTP action. MTP is required to transfer lipid to apoB-48 as it is synthesized and to transfer lipid from the cytoplasm to the ER lumen. ER, endoplasmic reticulum; MTP, microsomal triglyceride transfer protein; TG, triglyceride.

The symptoms of abetalipoproteinemia include lipid malabsorption (and its accompanying symptoms, such as steatorrhea and vomiting), which can result in caloric deficiencies and weight loss. Because lipid-soluble vitamin distribution occurs through chylomicron circulation, signs and symptoms of deficiencies in the lipid-soluble vitamins may be seen in these patients. The lack of vitamin E in such patients can lead to neurologic complications.

MTP inhibitors have been investigated and studied for their effect on circulating lipid and cholesterol levels. Although the inhibitors discovered to date are effective in lowering circulating lipid levels, they have the complication of potentially initiating severe hepatic steatosis (fatty liver), a serious complication which could lead to liver failure. The steatosis comes about by an accumulation of triglyceride in the liver owing to the inability to form VLDL and export the triglyceride from the liver. The accumulation of triglyceride within hepatocytes will eventually interfere with hepatic function and structure. Current research for MTP inhibitors is aimed toward reducing the severity of fat accumulation in the liver (e.g., by specifically targeting the intestinal MTP without affecting the hepatic MTP).

KEY CONCEPTS

- ◆ Triacylglycerols are the major fat source in the human diet.
- ◆ Lipases (lingual lipase in the saliva and gastric lipase in the stomach) perform limited digestion of triacylglycerol before food enters the intestine.
- ◆ As food enters the intestine, cholecystokinin is released, which signals the gallbladder to release bile acids and the exocrine pancreas to release digestive enzymes.
- ◆ Within the intestine, bile salts emulsify fats, which increase their accessibility to pancreatic lipase and colipase.
- ◆ Triacylglycerols are degraded to form free fatty acids and 2-monoacylglycerol by pancreatic lipase and colipase.
- ◆ Dietary phospholipids are hydrolyzed by pancreatic phospholipase A₂ in the intestine.
- ◆ Dietary cholesterol esters (cholesterol esterified to a fatty acid) are hydrolyzed by pancreatic cholesterol esterase in the intestine.
- ◆ Micelles, consisting of bile acids and the products of fat digestion, form within the intestinal lumen and interact with the enterocyte membrane. Lipid-soluble components diffuse from the micelle into the cell.
- ◆ Bile salts are resorbed farther down the intestinal tract and returned to the liver by the enterohepatic circulation.
- ◆ The intestinal epithelial cells resynthesize triacylglycerol and package them into nascent chylomicrons for release into the circulation.
- ◆ Once they are in the circulation, the nascent chylomicrons interact with HDL particles and acquire two

additional protein components, apoCII and apoE.

- ◆ ApoCII activates LPL on capillary endothelium of muscle and adipose tissue, which digests the triglycerides in the chylomicron. The fatty acids released from the chylomicron enter the muscle for energy production or the fat cell for storage. The glycerol released is metabolized only in the liver.
- ◆ As the chylomicron loses triglyceride, its density increases and it becomes a chylomicron remnant. Chylomicron remnants are removed from circulation by the liver through specific binding of the remnant to apoE receptors on the liver membrane.
- ◆ Once it is in the liver, the remnant is degraded and the lipids are recycled.
- ◆ Table 29.1 summarizes the diseases discussed in this chapter.

TABLE 29.1 Diseases Discussed in Chapter 29

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Sickle cell disease	Genetic	Cholecystitis may result as a consequence of sickle cell disease, which is caused by increased red cell destruction in the spleen and an inability of the liver to conjugate all of the bilirubin resulting from heme degradation. This can result in stone formation and blockage of the cystic duct.
Alcohol use disorder	Both	Pancreatitis may result from chronic alcohol abuse, leading to malabsorption problems within the intestine.
Abetalipoproteinemia	Genetic	Loss of MTP activity, leading to an inability to produce both chylomicrons and VLDL. Steatorrhea and fat-soluble vitamin deficiencies may result, as well as a deficiency in required dietary fatty acids.

MTP, microsomal triglyceride transfer protein; VLDL, very-low-density lipoprotein.

REVIEW QUESTIONS—CHAPTER 29

- Most of our dietary fats are incorporated into chylomicrons in the intestine. The most abundant component of chylomicrons is which one of the following?
 - ApoB-48
 - Triglyceride
 - Phospholipid
 - Cholesterol
 - Cholesterol ester
- In order for the lipids in chylomicrons to be used by the tissues of the body, the nascent chylomicrons need to be converted to mature chylomicrons. This conversion requires which one of the following?
 - Bile salts
 - 2-Monoacylglycerol
 - LPL
 - HDL
 - Lymphatic system
- Chylomicrons and VLDL contain similar and different apolipoproteins. The apoB-48 and apoB-100 are similar with respect to which one of the following?
 - They are synthesized from the same gene.
 - They are derived by alternative splicing of the same heterogeneous nuclear RNA (hnRNA).
 - ApoB-48 is a proteolytic product of apoB-100.
 - Both are found in mature chylomicrons.
 - Both are found in VLDLs.
- Bile salts must reach a particular concentration within the intestinal lumen before they are effective agents for lipid digestion. This is because of which one of the following?
 - The bile salt concentration must be equal to the triglyceride concentration.
 - The bile salt solubility in the lumen is a critical factor.
 - The ability of bile salts to bind lipase is concentration-dependent.
 - The bile salts cannot be reabsorbed in the ileum until they reach a certain concentration.
 - The bile salts do not activate lipase until they reach a particular concentration.

5. Type III hyperlipidemia can be caused by a deficiency of apoE. Analysis of the serum of patients with this disorder would exhibit which one of the following?
 - A. An absence of chylomicrons after eating
 - B. Above-normal levels of VLDL after eating
 - C. Normal triglyceride levels
 - D. Elevated triglyceride levels
 - E. Below-normal triglyceride levels
6. Pancreatitis can lead to a blockage of the pancreatic duct that, in turn, leads to steatorrhea. The steatorrhea is most likely caused by the absence of which one of the following?
 - A. Trypsin
 - B. Colipase
 - C. Pepsin
 - D. Cholesterol esterase
 - E. Amylase
7. A patient has been taking an experimental drug to reduce weight. The drug leads to significant steatorrhea and some night-blindness. A potential target of this drug is which one of the following?
 - A. LPL activity
 - B. Albumin synthesis
 - C. Glucagon release
 - D. Insulin release
 - E. Cholecystokinin release
8. A patient trying to lose weight is taking an over-the-counter “fat blocker” that supposedly blocks fat absorption from the gastrointestinal (GI) tract. If this supplement truly blocked fat absorption, for which vitamin below could the patient potentially develop a deficiency?
 - A. K
 - B. B₁
 - C. B₃
 - D. B₆
 - E. C
9. The absence of which hormone below would result in an inability to raise the pH of the partially digested food leaving the stomach, leading to an inability to digest lipids in the intestine?
 - A. Pancreatic lipase
 - B. Intestinal cholecystokinin
 - C. Pancreatic cholecystokinin
 - D. Intestinal secretin
 - E. Pancreatic secretin
10. Short- and medium-chain fatty acids in the diet follow which one of the following digestive sequences?
 - A. They are emulsified by bile acids.
 - B. They are packaged in micelles.
 - C. They enter the portal blood after intestinal absorption.
 - D. They enter the lymph after intestinal absorption.
 - E. They are formed by chylomicrons.
11. A child was diagnosed with abetalipoproteinemia and exhibited low levels of circulating lipoproteins containing either apoB-48 or apoB-100. As part of the child’s treatment plan, the diet was supplemented with which of the following? Choose the one best answer.
 - A. Folic acid and vitamin C
 - B. Vitamin K and vitamin C
 - C. Vitamin E and folic acid
 - D. Vitamin D and vitamin E
 - E. Folic acid and vitamin D

Questions 12 and 13 are based on the following case: An individual is homozygous for a mutation in *apoCII* such that the protein is unable to carry out its normal function.

2. One consequence of this mutation would be which of the following?
 - A. Decreased water-soluble vitamin uptake from the diet
 - B. Decreased fat-soluble vitamin uptake from the diet

- C. Inability to produce chylomicrons
 - D. Elevated serum triglyceride levels
 - E. Decreased serum triglyceride levels
3. The symptoms and laboratory findings exhibited by the patient would be most similar to an individual with a deficiency of which one of the following?
 - A. MTP
 - B. Pancreatic lipase
 - C. LPL
 - D. Phospholipase
 - E. Gastric lipase
 4. Children with cystic fibrosis often develop steatorrhea, with stool that floats in the toilet bowl. In order to treat this symptom of the disease, the children ingest capsules, composed of tiny coated beads surrounding pancreatic enzymes, that can aid in digesting a meal. The enzyme required to treat the steatorrhea would be which one of the following?
 - A. Phospholipase
 - B. Cholesterol esterase
 - C. Lipase
 - D. Protease
 - E. Amylase
 5. The key feature of bile salts that allow them to carry out their function is which one of the following?
 - A. Their ability to bind apoB-48
 - B. Their hydrophobic properties
 - C. Their amphipathic properties
 - D. Their ability to activate pancreatic lipase
 - E. Their ability to stimulate pancreatic enzyme secretion

ANSWERS TO REVIEW QUESTIONS

1. **The answer is B.** Chylomicrons transport dietary lipids, and >80% of the chylomicron is triglyceride. All other components are present at <10%; hence, all other answers are incorrect.
2. **The answer is D.** HDLs transfer apoCII and apoE to nascent chylomicrons to convert them to mature chylomicrons. Bile salts are required to emulsify dietary lipid, 2-monoacylglycerol is a digestion product of pancreatic lipase, lipoprotein lipase digests triglyceride from mature chylomicrons, and the lymphatic system delivers the nascent chylomicrons to the bloodstream.
3. **The answer is A.** Both apoB-48 and apoB-100 are derived from the same gene and from the same messenger RNA (mRNA); there is no difference in splicing between the two; thus, B is incorrect). However, RNA editing introduces a stop codon in the message such that B-48 stops protein synthesis approximately 48% along the message. Thus, proteolytic cleavage is not correct. B-48 is found only in chylomicrons, and B-100 is found only in VLDL particles.
4. **The answer is B.** The bile salts must be above their critical micelle concentration in order to form micelles with the components of lipase digestion, fatty acids, and 2-monoacylglycerol. In the absence of micelle formation, lipid absorption would not occur. The critical micelle concentration is independent of triglyceride concentration (thus, A is incorrect). Bile salts do not bind or activate lipase (thus, C and E are incorrect). The absorption of bile salts in the ileum is not related to digestion (thus, D is incorrect).
5. **The answer is D.** Nascent chylomicrons would be synthesized, which can only acquire apoCII from HDL (thus, A is incorrect). The chylomicrons would be degraded in part by LPL, leading to chylomicron remnant formation. However, the chylomicron remnants would remain in circulation because of the lack of apoE (thus, B is incorrect). Because these remnant particles still contain a fair amount of triglyceride, serum triglyceride levels will be elevated (thus, C and E are incorrect).
6. **The answer is B.** Lipase and colipase together are required to digest triglycerides from the diet. Both are secreted by the exocrine pancreas through the pancreatic duct into the common duct and then into the intestine. If colipase cannot make its way into the intestine, lipase is relatively inactive, and triglyceride digestion will not occur. Thus, the triglycerides are eliminated via the feces, leading to steatorrhea. The simultaneous reduction in other pancreatic exocrine secretions leading to an inability to digest proteins (lack of trypsin; pepsin is found in the stomach), or cholesterol esters (cholesterol esterase), or starch

- (amylase) does not lead to steatorrhea because the triglycerides account for the majority of fat in the diet.
7. **The answer is E.** The patient, when taking the drug, is not digesting fat or absorbing fat-soluble vitamins (the night-blindness is caused by a lack of vitamin A). This can occur because of mutations in lipase or colipase, or an inability to release cholecystokinin. In the absence of cholecystokinin, the digestive enzymes from the pancreas (including lipase and colipase) will not be secreted to the intestine, nor will bile acids be secreted from the gallbladder to the intestine. This would lead to inefficient triglyceride digestion and loss of triglyceride and lipid-soluble vitamins in the stools. Loss of LPL activity would lead to elevated triglyceride levels in the blood but not the stool. Loss of albumin synthesis would lead to problems in blood volume but would not lead to steatorrhea. Alterations in glucagon and insulin release do not affect triglyceride digestion in the intestine.
 8. **The answer is A.** Of those listed, only vitamin K is a fat-soluble vitamin, and the fat-soluble vitamins are absorbed along with the lipids in the intestine. The other fat-soluble vitamins are D, E, and A. Vitamin B₁ is thiamin, B₃ is niacin, and B₆ is pyridoxamine. All of the B vitamins, and vitamin C, are water-soluble, so their absorption into the intestinal epithelial cells would not be blocked by this drug.
 9. **The answer is D.** Intestinal cholecystokinin stimulates release of pancreatic lipase to digest triglyceride, along with other enzymes to digest carbohydrates and proteins. Intestinal secretin signals the liver, pancreas, and some intestinal cells to secrete bicarbonate. The pancreas does not produce cholecystokinin or secretin.
 10. **The answer is C.** Short- and medium-chain fatty acids do not require bile salts for their absorption and therefore do not go into micelles or the lymph. They are absorbed directly into intestinal epithelial cells and enter the portal blood, where they bind to serum albumin.
 11. **The answer is D.** Abetalipoproteinemia is caused by a mutation in the MTP such that chylomicrons and VLDL cannot be synthesized. In the absence of chylomicron synthesis, fat-soluble vitamin distribution throughout the body is impaired, particularly vitamins D and E. Chylomicrons carry the absorbed fat-soluble vitamins from the intestine to the rest of the body through the lymph and then the blood. Both folic acid and vitamin C are water-soluble vitamins whose absorption is not dependent on chylomicron synthesis. Vitamin K is a fat-soluble vitamin, but was paired with a water-soluble vitamin, which made the answer incorrect.
 12. **The answer is D.** ApoCII activates LPL such that the triglyceride in chylomicrons can be degraded into glycerol and three free fatty acids. In the absence of apoCII, chylomicrons (and VLDL) will not have their triglycerides hydrolyzed, and serum triglyceride levels will be constantly elevated. The lack of triglyceride hydrolysis will not interfere with fat-soluble vitamin delivery via chylomicrons. ApoCII is not involved in chylomicron assembly in the intestinal epithelial cells, rather its action is on the endothelial cell surface of blood vessels.
 13. **The answer is C.** As apoCII activates LPL, an LPL deficiency will also present with symptoms similar to an apoCII deficiency, namely elevated serum triglycerides. ApoCII does not interact with the other lipases presented as answer choices (pancreatic lipase, gastric lipase, or phospholipase). A lack of MTP activity results in reduced serum triglyceride levels as neither chylomicrons nor VLDL can be synthesized and released into the blood.
 14. **The answer is C.** Because of the defective cystic fibrosis transmembrane conductance regulator (CFTR), children with cystic fibrosis accumulate a mucous-like substance within their ducts owing to the inability to secrete chloride across the membrane. This includes the pancreatic duct, leading to difficulty in the pancreas secreting digestive enzymes into the intestinal lumen in response to cholecystokinin. The pancreatic enzyme that degrades triglyceride is lipase (in association with colipase). It is the accumulation of triglyceride in the stools that leads to steatorrhea, because of a very low density for the stool. Amylase digests starch, proteases degrade protein, cholesterol esterase converts cholesterol esters to cholesterol and a free fatty acid, and phospholipases remove a fatty acid from a phospholipid, generating a lysophospholipid.
 15. **The answer is C.** Bile salts work well in emulsifying lipids because of the presence of both a hydrophobic portion and a hydrophilic portion of the molecule; in other words, they are amphipathic. The hydrophobic portion of the bile acid can bind the hydrophobic triglyceride, whereas the hydrophilic portion is soluble in water and can present the triglyceride to lipase for digestion. Molecules without amphipathic properties would not be able to appropriately emulsify the dietary lipids for digestion. The bile acids actually inhibit lipoprotein lipase (colipase is required to relieve this inhibition), and the bile acids do not play a role in stimulating pancreatic enzyme secretion (that is the job of cholecystokinin).

Oxidation of Fatty Acids and Ketone Bodies

Fatty acids are a major fuel for humans and supply our energy needs between meals and during periods of increased demand, such as exercise. During overnight fasting, fatty acids become the major fuel for cardiac muscle, skeletal muscle, and liver. The liver converts fatty acids to ketone bodies (acetoacetate and β -hydroxybutyrate), which also serve as major fuels for tissues (e.g., the gut). The brain, which does not have a significant capacity for fatty acid oxidation, can use ketone bodies as a fuel during prolonged fasting.

The route of metabolism for a fatty acid depends somewhat on its chain length. Fatty acids are generally classified as **very-long-chain length fatty acids** (>C20), **long-chain fatty acids** (C12 to C20), **medium-chain fatty acids** (C6 to C12), and **short-chain fatty acids** (C4).

ATP is generated from oxidation of fatty acids in the pathway of β -oxidation. Between meals and during overnight fasting, **long-chain fatty acids** are released from adipose tissue triacylglycerols. They circulate through blood bound to **albumin** (Fig. 30.1). In cells, they are converted to **fatty acyl coenzyme A (fatty acyl CoA)** derivatives by **acyl CoA synthetases**. The activated acyl group is transported into the mitochondrial matrix bound to **carnitine**, where fatty acyl CoA is regenerated. In the pathway of **β -oxidation**, the fatty acyl group is sequentially oxidized to yield FAD(2H), NADH, and acetyl CoA. Subsequent oxidation of NADH and FAD(2H) in the electron transport chain, and oxidation of acetyl CoA to CO₂ in the tricarboxylic acid (TCA) cycle, generates ATP from oxidative phosphorylation.

FIGURE 30.1 Overview of mitochondrial long-chain fatty acid metabolism. (1) Fatty acid-binding proteins (FaBPs) transport

fatty acids across the plasma membrane and bind them in the cytosol. (2) Fatty acyl coenzyme A (Fatty acyl CoA) synthetase activates fatty acids to fatty acyl CoAs. (3) Carnitine transports the activated fatty acyl group into mitochondria. (4) β -Oxidation generates NADH, FAD(2H), and acetyl coenzyme A (acetyl CoA). (5) In the liver, acetyl CoA can be converted to ketone bodies. ATP, adenosine triphosphate; FAD(2H), reduced flavin adenine dinucleotide; GTP, guanosine triphosphate; NADH, nicotinamide adenine dinucleotide; TCA, tricarboxylic acid.

Many fatty acids have structures that require variations of this basic pattern. Long-chain fatty acids that are **unsaturated fatty acids** generally require additional isomerization and oxidation–reduction reactions to rearrange their double bonds during β -oxidation. Metabolism of water-soluble **medium-chain-length fatty acids** does not require carnitine and occurs only in the liver. **Odd-chain-length fatty acids** undergo β -oxidation to the terminal three-carbon **propionyl CoA**, which enters the TCA cycle as succinyl CoA.

Fatty acids that do not readily undergo mitochondrial β -oxidation are oxidized first by alternate routes that convert them to more suitable substrates or to urinary excretion products. **Excess fatty acids** may undergo microsomal ω -oxidation, which converts them to **dicarboxylic acids** that appear in urine. **Very-long-chain fatty acids** (both straight-chain and **branched fatty acids** such as phytanic acid) are whittled down to size in peroxisomes. **Peroxisomal α - and β -oxidation** generates hydrogen peroxide (H_2O_2), NADH, acetyl CoA, or propionyl CoA and a short- to medium-chain-length acyl CoA. The acyl CoA products are transferred to mitochondria to complete their metabolism.

In the liver, much of the acetyl CoA generated from fatty acid oxidation is converted to the ketone bodies, **acetoacetate** and **β -hydroxybutyrate**, which enter the blood (see Fig. 30.1). In other tissues, these ketone bodies are converted to acetyl CoA, which is oxidized in the TCA cycle. The liver synthesizes ketone bodies but cannot use them as a fuel.

The **rate of fatty acid oxidation** is linked to the rate of NADH, FAD(2H), and acetyl CoA oxidation and thus to the rate of oxidative phosphorylation and **ATP utilization**. Additional regulation occurs through **malonyl CoA**, which inhibits formation of the fatty acyl carnitine derivatives. Fatty acids and ketone bodies are used as fuel when their level increases in the blood, which is determined by hormonal regulation of adipose tissue **lipolysis**.

THE WAITING ROOM

Otto S. was disappointed that he did not place in his 5-km race and has decided that short-distance running is probably not right for him. After careful consideration, he decides to train for the marathon by running 12 miles three times per week. He is now 13 lb over his ideal weight, and he plans on losing this weight while studying for his Pharmacology finals. He considers a variety of dietary supplements to increase his endurance and selects one that contains carnitine, CoQ, pantothenate, riboflavin, and creatine.

Lola B. is a 16-year-old girl. Since age 14 months, she has experienced recurrent episodes of profound fatigue associated with vomiting and increased perspiration, which required hospitalization. These episodes occurred only if she fasted for more than 8 hours. Because her mother gave her food late at night and woke her early in the morning for breakfast, **Lola B.**'s physical and mental development had progressed normally.

On the day of admission for this episode, **Lola B.** had missed breakfast, and by noon, she was extremely fatigued, nauseated, and weak. She was unable to hold any food in her stomach and was rushed to the hospital, where an infusion of glucose was started intravenously. Her symptoms responded dramatically to this therapy.

Her initial serum glucose level was low, at 38 mg/dL (reference range for fasting serum glucose levels, 70 to 100 mg/dL). Her blood urea nitrogen (BUN) level was slightly elevated at 26 mg/dL (reference range, 8 to 25 mg/dL) because of vomiting, which led to a degree of dehydration. Her blood levels of liver transaminases were slightly elevated, although her liver was not palpably enlarged. Despite elevated levels of free fatty acids (4.3 mM) in the blood, which were later tested, blood ketone bodies were below normal.

Dianne A., a 27-year-old woman with type 1 diabetes mellitus, had been admitted to the hospital in a

ketoacidotic coma a year ago (see Chapter 4). She had been feeling drowsy and had been vomiting for 24 hours before that admission. At the time of admission, she was clinically dehydrated, her blood pressure was low, and her breathing was deep and rapid (Kussmaul breathing). Her pulse was rapid, and her breath had the odor of acetone. Her arterial blood pH was 7.08 (reference range, 7.36 to 7.44), and her blood ketone body levels were 15 mM (normal is approximately 0.2 mM for a person on a normal diet).

The liver transaminases measured in the blood are aspartate aminotransferase (AST), which was previously designated serum glutamate-oxaloacetate transaminase (SGOT), and alanine aminotransferase (ALT), which was previously designated serum glutamate pyruvate transaminase (SGPT). Elevation of these enzymes in the serum reflects damage to the liver cell plasma membrane. Transaminases catalyze the transfer of the nitrogen group of an amino acid to an acceptor α -ketoacid. For AST, aspartate donates the nitrogen to α -ketoglutarate, forming oxaloacetate (the corresponding α -ketoacid to aspartate) and glutamate. For ALT, alanine donates the nitrogen to α -ketoglutarate, forming pyruvate and glutamate. Transaminase activity is measured using a coupled reaction: Both oxaloacetate and pyruvate can be reduced by NADH to form, respectively, malate and lactate, in the presence of the appropriate secondary enzyme (malate dehydrogenase and lactate dehydrogenase). Thus, automated procedures that follow the loss of NADH in the reaction mix (by measuring the decrease in absorbance at 340 nm) can be utilized to measure the activity of AST and ALT in serum samples.

I. Fatty Acids as Fuels

The **fatty acids** oxidized as fuels are principally **long-chain fatty acids** released from adipose tissue triacylglycerol stores between meals, during overnight fasting, and during periods of increased fuel demand (e.g., during exercise). Adipose tissue triacylglycerols are derived from two sources: dietary lipids and triacylglycerols synthesized in the liver. The major fatty acids oxidized are the long-chain fatty acids, palmitate, oleate, and stearate because they are highest in dietary lipids and are also synthesized in the human.

Between meals, a decreased insulin level and increased levels of insulin counterregulatory hormones (e.g., glucagon) activate lipolysis and free fatty acids are transported to tissues bound to serum albumin. Within tissues, energy is derived from oxidation of fatty acids to acetyl CoA in the pathway of **β -oxidation**. Most of the enzymes involved in fatty acid oxidation are present as two or three isoenzymes, which have different but overlapping specificities for the chain length of the fatty acid. Metabolism of **unsaturated fatty acids**, **odd-chain-length fatty acids**, and **medium-chain-length fatty acids** requires variations of this basic pattern. The **acetyl CoA** produced from fatty acid oxidation is principally oxidized in the TCA cycle or converted to ketone bodies in the liver.

During **Otto S.**'s distance running (a moderate-intensity exercise), decreases in insulin and increases in insulin counterregulatory hormones, such as epinephrine and norepinephrine, increase adipose tissue lipolysis. Thus, his muscles are being provided with a supply of fatty acids in the blood that they can use as a fuel.

A. Characteristics of Fatty Acids Used as Fuels

Fat constitutes approximately 38% of the calories in the average North American diet. Of this, more than 95% of the calories are present as triacylglycerols (three fatty acids esterified to a glycerol backbone). During ingestion and absorption, dietary triacylglycerols are broken down into their constituents and then reassembled for transport to adipose tissue in chylomicrons (see Chapter 29). Thus, the fatty acid composition of adipose triacylglycerols varies with the type of food consumed.

Lola B. developed symptoms during fasting, when adipose tissue lipolysis was elevated. Under these circumstances, muscle tissue, liver, and many other tissues are oxidizing fatty acids as a fuel. After overnight fasting, approximately 60% to 70% of our energy supply is derived from the oxidation of fatty acids.

The most common dietary fatty acids are the saturated long-chain fatty acids palmitate (C16) and stearate (C18), the monounsaturated fatty acid oleate (C18:1), and the polyunsaturated essential fatty acid linoleate (C18:2) (to review fatty acid nomenclature, consult Chapter 5). Animal fat contains principally saturated and monounsaturated long-chain fatty acids, whereas vegetable oils contain linoleate and some longer-chain and polyunsaturated fatty acids. They also contain smaller amounts of branched-chain and odd-chain-length fatty acids. Medium-chain-length fatty acids are present principally in dairy fat (e.g., milk and butter), maternal milk, and vegetable oils.

Adipose tissue triacylglycerols also contain fatty acids synthesized in the liver, principally from excess calories ingested as glucose. The pathway of fatty acid synthesis generates palmitate, which can be elongated to

form stearate or unsaturated to form oleate. These fatty acids are assembled into triacylglycerols and transported to adipose tissue as the lipoprotein VLDL (very-low-density lipoprotein).

B. Transport and Activation of Long-Chain Fatty Acids

Long-chain fatty acids are hydrophobic and, therefore, water insoluble. In addition, they are toxic to cells because they can disrupt the hydrophobic bonding between amino acid side chains in proteins. Consequently, they are transported in the blood and in cells bound to proteins.

1. Cellular Uptake of Long-Chain Fatty Acids

During fasting and other conditions of metabolic need, long-chain fatty acids are released from adipose tissue triacylglycerols by lipases. They travel in the blood bound in the hydrophobic binding pocket of albumin, the major serum protein (see Fig. 30.1).

Fatty acids enter cells both by a saturable transport process and by diffusion through the lipid plasma membrane. A fatty acid-binding protein in the plasma membrane facilitates transport. An additional fatty acid-binding protein binds the fatty acid intracellularly and may facilitate its transport to the mitochondrion. The free fatty acid concentration in cells is, therefore, extremely low.

2. Activation of Long-Chain Fatty Acids

Fatty acids must be activated to acyl CoA derivatives before they can participate in β -oxidation and other metabolic pathways (Fig. 30.2). The process of activation involves an acyl CoA synthetase (also called a thiokinase) that uses ATP energy to form the fatty acyl CoA thioester bond. In this reaction, the β -bond of ATP is cleaved to form a fatty acyl adenosine monophosphate (AMP) intermediate and pyrophosphate (PP_i). Subsequent cleavage of PP_i helps to drive the reaction.

FIGURE 30.2 Activation of a fatty acid by a fatty acyl coenzyme A (fatty acyl CoA) synthetase. The fatty acid is activated by reacting with adenosine triphosphate (ATP) to form a high-energy fatty acyl adenosine monophosphate (AMP) and pyrophosphate. The AMP is then exchanged for coenzyme A (CoA). Pyrophosphate is cleaved by a pyrophosphatase. P_i , inorganic phosphate.

The acyl CoA synthetase that activates long-chain fatty acids, 12 to 20 carbons in length, is present in three locations in the cell: the endoplasmic reticulum, outer mitochondrial membranes, and peroxisomal membranes (Table 30.1). This enzyme has no activity toward C22 or longer fatty acids and little activity below C12. In contrast, the synthetase for activation of very-long-chain fatty acids is present in peroxisomes, and the medium-chain-length fatty acid-activating enzyme is present only in the mitochondrial matrix of liver and kidney cells.

TABLE 30.1 Chain-Length Specificity of Fatty Acid Activation and Oxidation Enzymes

ENZYME	CHAIN LENGTH	COMMENTS
Acyl CoA synthetases		
Very long chain	14–26	Found only in peroxisomes.
Long chain	12–20	Enzymes present in membranes of endoplasmic reticulum, mitochondria, and peroxisomes to facilitate different metabolic routes of acyl CoAs.
Medium chain	6–12	Exists as many variants, present only in mitochondrial matrix of kidney and liver. Also involved in xenobiotic metabolism.
Acetyl	2–4	Present in cytoplasm and possibly mitochondrial matrix.
Acyltransferases		
CPTI	12–16	Although maximum activity is for fatty acids 12–16 carbons long, it also acts on many smaller acyl CoA derivatives.
Medium chain (octanoylcarnitine transferase)	6–12	Substrate is medium-chain acyl CoA derivatives generated during peroxisomal oxidation.
Carnitine acetyltransferase	2	High level in skeletal muscle and heart to facilitate use of acetate as a fuel.
Acyl CoA dehydrogenases		
VLCAD	14–20	Present in inner mitochondrial membrane.
LCAD	12–18	Members of same enzyme family, which also includes acyl CoA dehydrogenases for carbon skeleton of branched-chain amino acids. Low expression of LCAD in humans; VLCAD is the predominant acyl CoA dehydrogenase for long-chain fatty acids.
MCAD	4–12	
SCAD	4–6	
Other enzymes		
Enoyl CoA hydratase, short chain	>4	Also called crotonase. Activity decreases with increasing chain length.
L-3-Hydroxyacyl CoA dehydrogenase, short chain	4–16	Activity decreases with increasing chain length.
Acetoacetyl CoA thiolase	4	Specific for acetoacetyl CoA.
Mitochondrial trifunctional protein	12–16	Complex of long-chain enoyl hydratase, L-3-hydroxyacyl CoA dehydrogenase, and a thiolase with broad specificity. Most active with longer chains.

CPTI, carnitine palmitoyltransferase 1; LCAD, long-chain acyl CoA dehydrogenase; MCAD, medium-chain acyl CoA dehydrogenase; SCAD, short-chain acyl CoA dehydrogenase; VLCAD, very-long-chain acyl CoA dehydrogenase.

3. Fates of Fatty Acyl Coenzyme A

Fatty acyl CoA formation, like the phosphorylation of glucose, is a prerequisite to metabolism of the fatty acid in the cell (Fig. 30.3). The multiple locations of the long-chain acyl CoA synthetase reflect the location of different metabolic routes taken by fatty acyl CoA derivatives in the cell (e.g., triacylglycerol and phospholipid synthesis in the endoplasmic reticulum, oxidation and plasmalogen synthesis in the peroxisome, and β -oxidation in mitochondria). In the liver and some other tissues, fatty acids that are not being used for energy generation are reincorporated (re-esterified) into triacylglycerols.

FIGURE 30.3 Major metabolic routes for long-chain fatty acyl coenzyme A_s (fatty acyl CoAs). Fatty acids are activated to acyl CoA compounds for degradation in mitochondrial β-oxidation, or incorporation into triacylglycerols or membrane lipids. When β-oxidation is blocked through an inherited enzyme deficiency, or metabolic regulation, excess fatty acids are diverted into triacylglycerol synthesis.

Several inherited diseases in the metabolism of carnitine or acylcarnitines have been described. These include defects in the following enzymes or systems: the transporter for carnitine uptake into muscle, CPTI, carnitine acylcarnitine translocase, and CPTII. Classical CPTII deficiency, the most common of these diseases (though still very rare), is characterized by adolescent to adult onset of recurrent episodes of acute myoglobinuria, with muscle pain and weakness, precipitated by prolonged exercise or fasting. During these episodes, the patient is weak, and may be somewhat hypoglycemic with diminished ketosis (hypoketosis), but metabolic decompensation is not severe. Lipid deposits are found in skeletal muscles. Both creatine phosphokinase (CPK) and long-chain acylcarnitines are elevated in the blood. CPTII levels in fibroblasts are approximately 25% of normal. The residual CPTII activity probably accounts for the mild effect on liver metabolism. In contrast, when CPTII deficiency presents in infants, CPTII levels are <10% of normal, the hypoglycemia and hypoketosis are severe, hepatomegaly occurs from the triacylglycerol deposits, and cardiomyopathy is also present.

4. Transport of Long-Chain Fatty Acids into Mitochondria

Carnitine serves as the carrier that transports activated long-chain fatty acyl groups across the inner mitochondrial membrane (Fig. 30.4). Carnitine acyltransferases are able to reversibly transfer an activated fatty acyl group from CoA to the hydroxyl group of carnitine to form an acylcarnitine ester. The reaction is reversible, so the fatty acyl CoA derivative can be regenerated from the carnitine ester.

Fatty acylcarnitine

FIGURE 30.4 Structure of fatty acylcarnitine. Carnitine palmitoyltransferases catalyze the reversible transfer of a long-chain fatty acyl group from the fatty acyl coenzyme A (fatty acyl CoA) to the hydroxyl group of carnitine. The atoms in the *green box* originate from the fatty acyl CoA.

Carnitine palmitoyltransferase I (CPTI; also called carnitine acyltransferase I, CATI), the enzyme that transfers long-chain fatty acyl groups from CoA to carnitine, is located on the outer mitochondrial membrane (Fig. 30.5). Fatty acylcarnitine crosses the inner mitochondrial membrane with the aid of a translocase. The fatty acyl group is transferred back to CoA by a second enzyme, carnitine palmitoyltransferase II (CPTII or CATII). The carnitine released in this reaction returns to the cytosolic side of the mitochondrial membrane by the same translocase that brings fatty acylcarnitine to the matrix side. Long-chain fatty acyl CoA, now located within the mitochondrial matrix, is a substrate for β -oxidation.

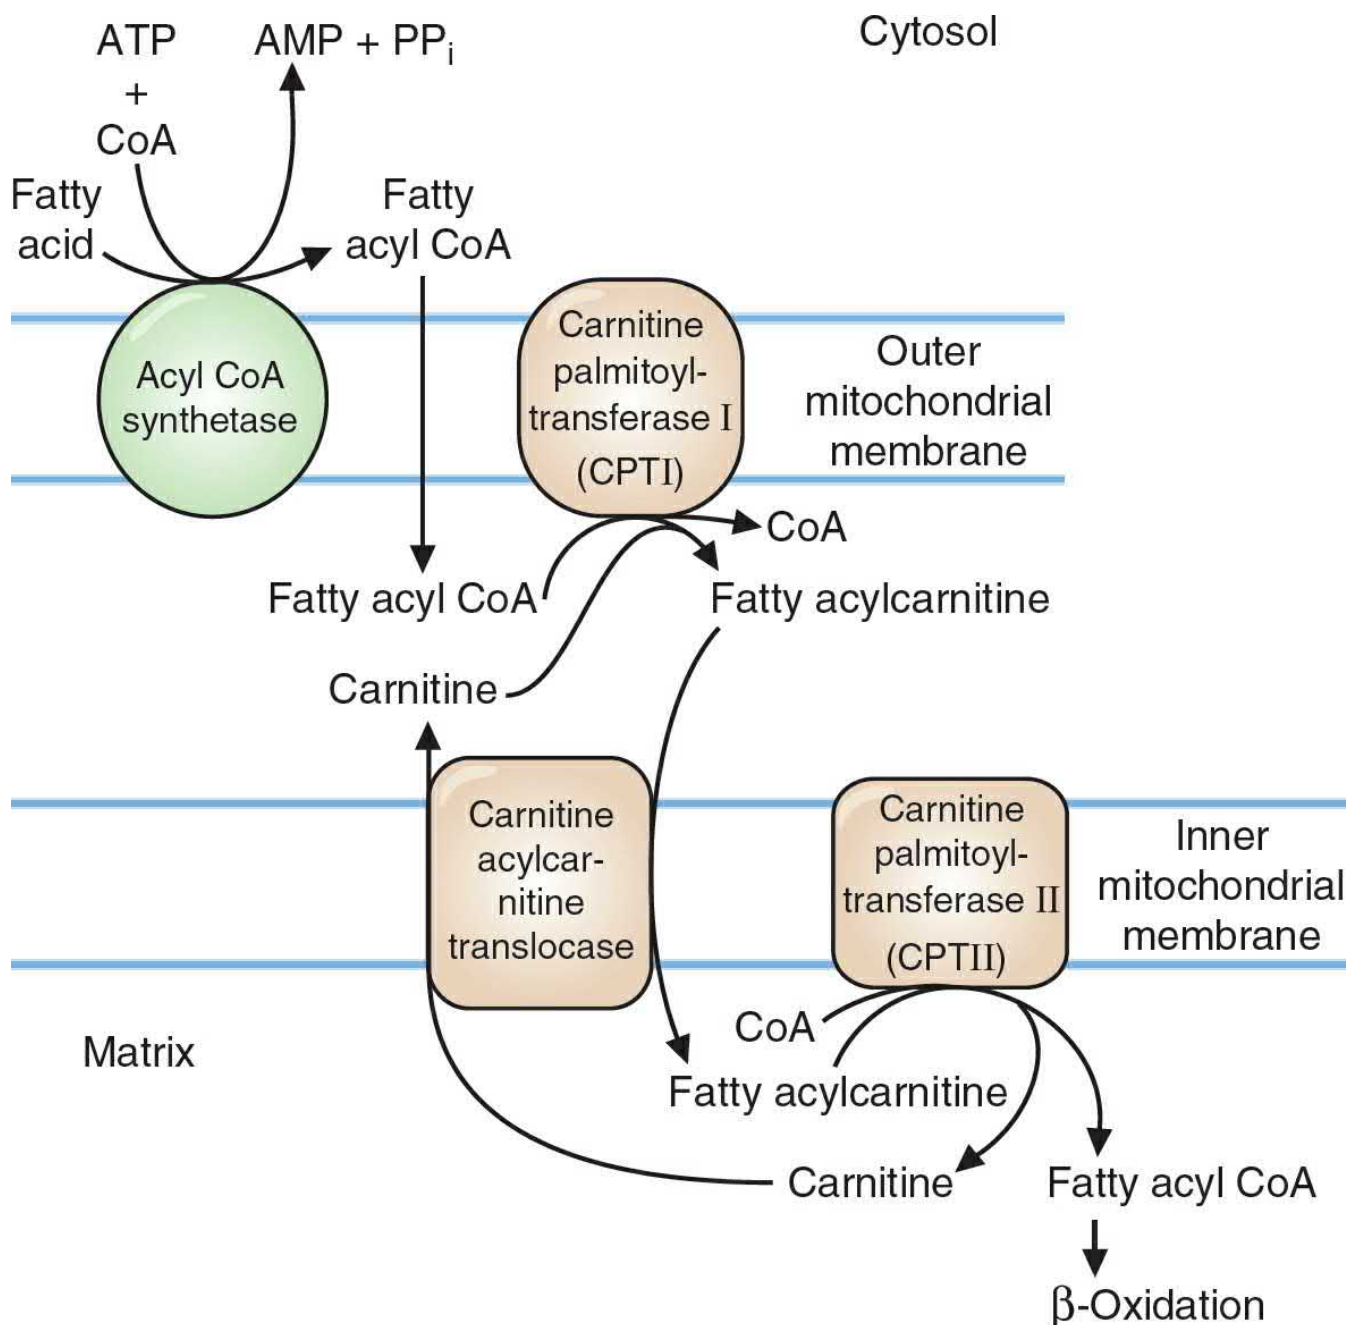

FIGURE 30.5 Transport of long-chain fatty acids into mitochondria. The fatty acyl coenzyme A (fatty acyl CoA) crosses the outer mitochondrial membrane. Carnitine palmitoyltransferase I (CPTI) in the outer mitochondrial membrane transfers the fatty acyl group to carnitine and releases CoASH. The fatty acyl carnitine is translocated into the mitochondrial matrix as carnitine moves out. Carnitine palmitoyltransferase II on the inner mitochondrial membrane transfers the fatty acyl group back to CoASH, to form fatty acyl CoA in the matrix. AMP, adenosine monophosphate; ATP, adenosine triphosphate; CoA, coenzyme A; PP_i, pyrophosphate.

Carnitine is obtained from the diet or synthesized from the side chain of lysine by a pathway that begins in skeletal muscle and is completed in the liver. The reactions use S-adenosylmethionine to donate methyl groups, and vitamin C (ascorbic acid) is also required for these reactions. Skeletal muscles have a high-affinity uptake system for carnitine, and most of the carnitine in the body is stored in skeletal muscle.

 **Otto S.**'s power supplement contains carnitine. However, his body can synthesize enough carnitine to meet his needs, and his diet contains carnitine. Carnitine deficiency has been found only in infants fed a soy-based formula that was not supplemented with carnitine. His other supplements likewise probably provide no benefit but are designed to facilitate fatty acid oxidation during exercise. Riboflavin is the vitamin precursor of FAD, which is required for acyl CoA dehydrogenases and electron transfer flavoproteins (ETFs). CoQ is synthesized in the body, but it is the recipient in the electron transport chain for electrons passed from complexes I and II and the ETFs. The results of studies looking at the effects of pantothenate (the precursor of CoA) on athletic performance have not been consistent.

C. β -Oxidation of Long-Chain Fatty Acids

The oxidation of fatty acids to acetyl CoA in the β -oxidation spiral conserves energy as FAD(2H) and NADH. FAD(2H) and NADH are oxidized in the electron transport chain, generating ATP from oxidative phosphorylation. Acetyl CoA is oxidized in the TCA cycle or converted to ketone bodies.

1. *The β -Oxidation Spiral*

The fatty acid β -oxidation pathway sequentially cleaves the fatty acyl group into two-carbon acetyl CoA units, beginning with the carboxyl end attached to CoA (Fig. 30.6). Before cleavage, the β -carbon is oxidized to a keto group in two reactions that generate NADH and FAD(2H); thus, the pathway is called β -oxidation. As each acetyl group is released, the cycle of β -oxidation and cleavage begins again, but each time, the fatty acyl group is two carbons shorter.

FIGURE 30.6 Overview of β -oxidation. Oxidation at the β -carbon is followed by cleavage of the α - β bond, releasing acetyl coenzyme A (acetyl CoA) and a fatty acyl coenzyme A (fatty acyl CoA) that is two carbons shorter than the original. The carbons cleaved to form acetyl CoA are shown in red. Successive spirals of β -oxidation completely cleave an even-chain fatty acyl CoA to acetyl CoA.

The β -oxidation pathway consists of four separate steps or reactions (Fig. 30.7).

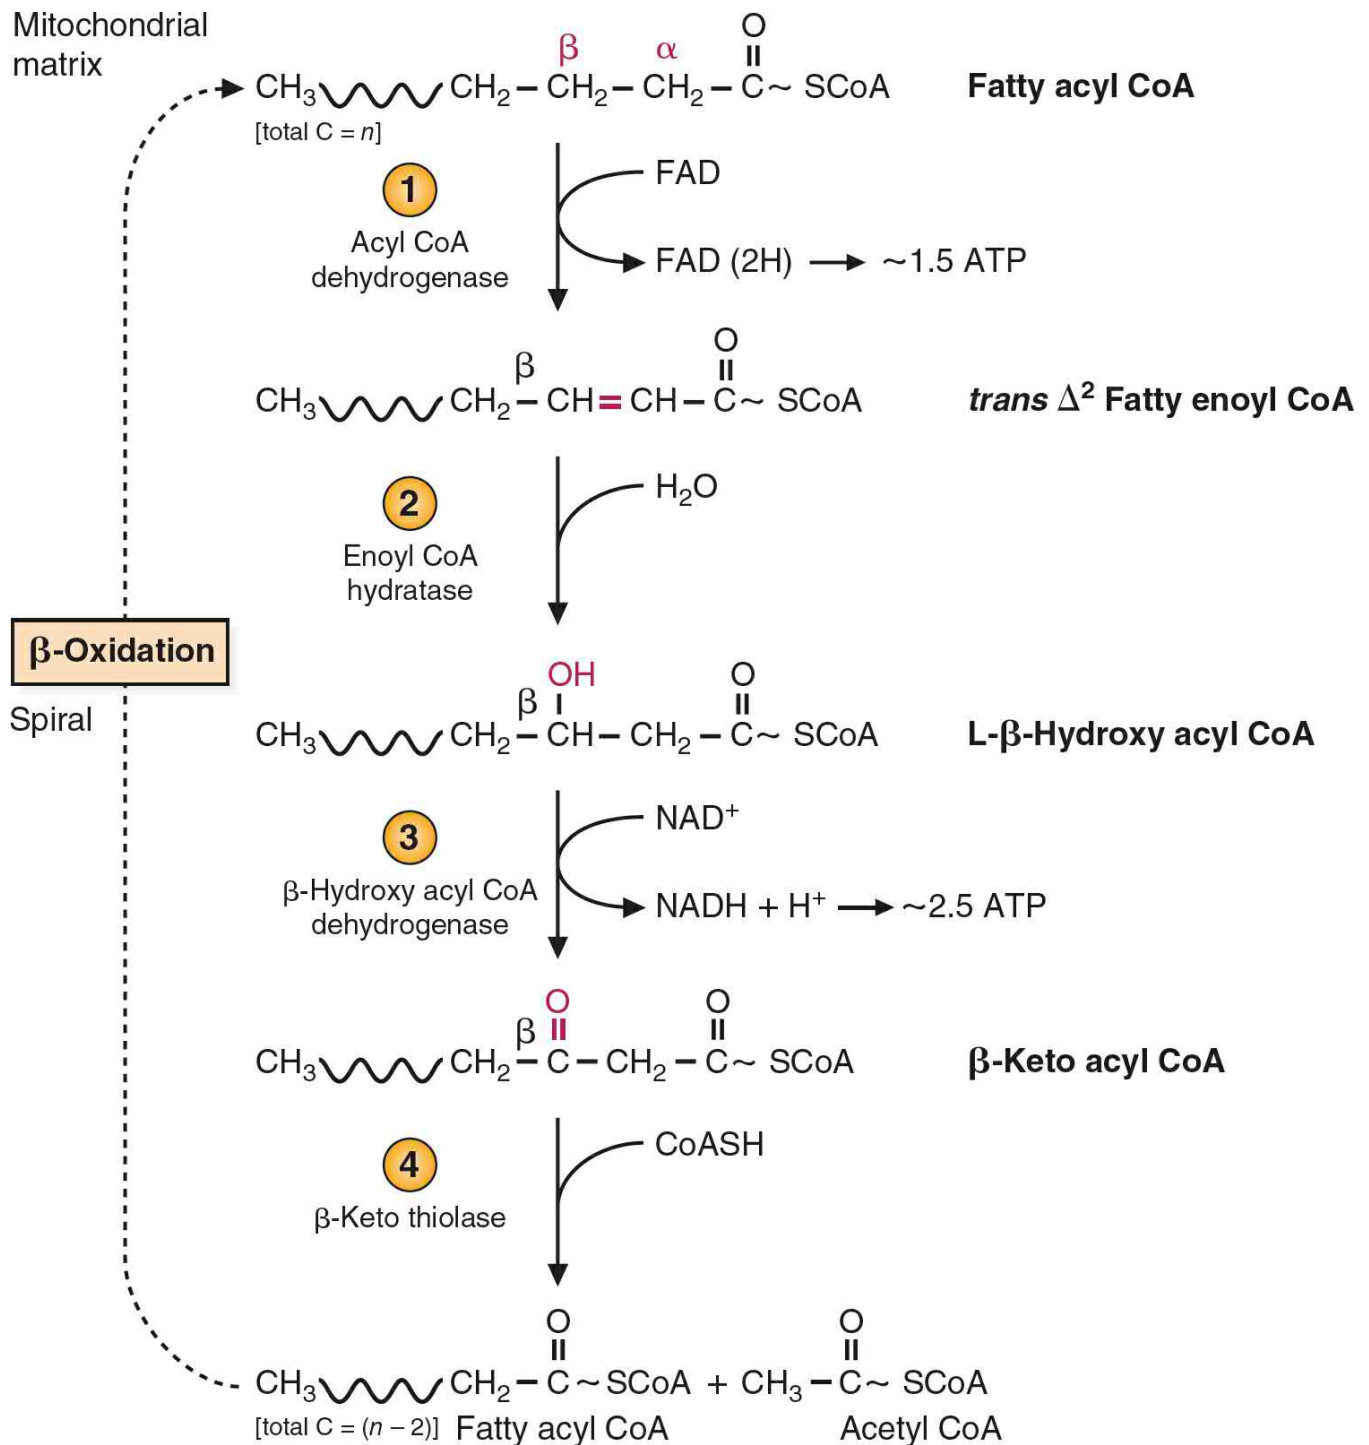

FIGURE 30.7 Steps of β -oxidation. The four steps are repeated until an even-chain fatty acid is completely converted to acetyl coenzyme A (acetyl CoA). The flavin adenine dinucleotide (FAD[2H]) and nicotinamide adenine dinucleotide (NADH) are reoxidized by the electron transport chain, producing adenosine triphosphate (ATP).

1. In the first step, a double bond is formed between the β - and α -carbons by an acyl CoA dehydrogenase that transfers electrons to FAD. The double bond is in the *trans* configuration (a Δ^2 -*trans* double bond).
2. In the next step, an -OH from water is added to the β -carbon, and an -H from water is added to the α -carbon. The enzyme is called an **enoyl CoA hydratase** (hydratases add the elements of water, and “-ene” in a name denotes a double bond).
3. In the third step of β -oxidation, the hydroxyl group on the β -carbon is oxidized to a ketone by a **hydroxyacyl CoA dehydrogenase**. In this reaction, as in the conversion of most alcohols to ketones, the electrons are transferred to NAD^+ to form NADH.
4. In the last reaction of the sequence, the bond between the β - and α -carbons is cleaved by a reaction that attaches CoASH to the β -carbon, and acetyl CoA is released. This is a thiolytic reaction (“lysis” refers to

breakage of the bond, and “thio” refers to the sulfur), catalyzed by enzymes called β -**ketothiolases**. The release of two carbons from the carboxyl end of the original fatty acyl CoA produces acetyl CoA and a fatty acyl CoA that is two carbons shorter than the original. It is of interest to note that the β -oxidation spiral uses the same reaction types seen in the TCA cycle in the conversion of succinate to oxaloacetate.

5. The enzyme activities that catalyze the last three steps of β -oxidation are all part of one protein complex, known as the **mitochondrial trifunctional protein** (TFP). The complex consists of eight proteins, four each of an α -subunit (encoded by the *HADHA* gene) and four each of a β -subunit (encoded by the *HADHB* gene). The MTP complex is associated with the inner mitochondrial membrane.

The shortened fatty acyl CoA repeats these four steps until all of its carbons are converted to acetyl CoA. β -Oxidation is thus a spiral rather than a cycle. In the last spiral, cleavage of the four-carbon fatty acyl CoA (butyryl CoA) produces two molecules of acetyl CoA. Thus, an even-chain fatty acid such as palmitoyl CoA, which has 16 carbons, is cleaved seven times, producing 7 FAD(2H), 7 NADH, and 8 molecules of acetyl CoA.

Specific mutations in the *HADHA* gene can lead to long-chain 3-hydroxyacyl CoA dehydrogenase deficiency, which results in the accumulation of 3-hydroxy-long-chain fatty acids. Most mutations in either the *HADHA* or *HADHB* gene lead to a loss of all three enzyme activities associated with the trifunctional protein. Mutations in the trifunctional protein lead to the accumulation of hydroxylated fatty acids, reduced energy production from fatty acid oxidation, hypoglycemic episodes during fasting or other high-energy-requiring situations, such as stress or fever. There are three clinical phenotypes of TFP deficiency. The first is the neonatal onset severe form, which results in death. The second is infantile onset, the intermediate form, and primarily affects the liver. The third is of late adolescent onset, the most-mild form, and exhibits as neuromyopathic symptoms.

Initial symptoms of the disease may include poor feeding, vomiting, lethargy, hypotonia, hepatomegaly, and cardiomyopathy. Lab tests would indicate elevated liver enzymes in the blood, elevated creatine kinase in the blood (muscle damage), a metabolic acidosis (usually caused by lactic acid), and fasting hypoglycemia.

2. Energy Yield of β -Oxidation

Like the FAD in all flavoproteins, FAD(2H) bound to the acyl CoA dehydrogenases is oxidized back to FAD without dissociating from the protein (Fig. 30.8). Electron transfer flavoproteins (ETFs) in the mitochondrial matrix accept electrons from the enzyme-bound FAD(2H) and transfer these electrons to ETF-QO (**e**lectron **t**ransfer **f**lavoprotein–**C**o**Q** oxidoreductase) in the inner mitochondrial membrane. ETF-QO, also a flavoprotein, transfers the electrons to CoQ in the electron transport chain. Oxidative phosphorylation thus generates approximately 1.5 ATP for each FAD(2H) produced in the β -oxidation spiral.

FIGURE 30.8 Transfer of electrons from acyl coenzyme A (acyl CoA) dehydrogenase to the electron transport chain. A flavin adenine dinucleotide (FAD) is tightly bound to each protein in these three electron transfer reactions. ETF, electron transfer flavoprotein; ETF-QO, electron transferring flavoprotein–coenzyme Q oxidoreductase.

The total energy yield from the oxidation of 1 mol of palmitoyl CoA to 8 mol of acetyl CoA is, therefore, 28 mol of ATP: 1.5 for each of the 7 FAD(2H), and 2.5 for each of the 7 NADH. To calculate the energy yield from oxidation of 1 mol of palmitate, two ATP need to be subtracted from the total because two high-energy phosphate bonds are cleaved when palmitate is activated to palmitoyl CoA.

What is the total ATP yield for the oxidation of 1 mol of palmitic acid to carbon dioxide and water?

3. Chain-Length Specificity in β -Oxidation

The four reactions of β -oxidation are catalyzed by sets of enzymes that are each specific for fatty acids with different chain lengths (see Table 30.1). The acyl CoA dehydrogenases, which catalyze the first step of the pathway, are part of an enzyme family that, in mammals, has three different ranges of specificity. The subsequent steps of the spiral use enzymes that are specific for long- or short-chain enoyl CoAs. Although these enzymes are structurally distinct, their specificities overlap to some extent. As the fatty acyl chains are shortened by consecutive cleavage of two carbon units, they are transferred from enzymes that act on longer chains to those that act on shorter chains. Medium- or short-chain fatty acyl CoA that may be formed from dietary fatty acids, or transferred from peroxisomes, enters the spiral at the enzyme that is most active for fatty acids of its chain length.

Palmitic acid is 16 carbons long, with no double bonds, so it requires seven oxidation spirals to be completely converted to acetyl CoA. After seven spirals, there are 7 FAD(2H), 7 NADH, and 8 acetyl CoA. Each NADH yields 2.5 ATP, each FAD(2H) yields 1.5 ATP, and each acetyl CoA yields 10 ATP as it is processed through the TCA cycle. This then yields $17.5 + 10.5 + 80 = 108$ ATP. However, activation of palmitic acid to palmitoyl CoA requires two high-energy bonds, so the net yield is $108 - 2$, or 106, mol of ATP.

4. Oxidation of Unsaturated Fatty Acids

Approximately one-half of the fatty acids in the human diet are unsaturated, containing *cis* double bonds, with oleate (C18:1, Δ^9) and linoleate (18:2, $\Delta^{9,12}$) being the most common. In β -oxidation of saturated fatty acids, a *trans* double bond is created between the second and third (α - and β -) carbons. For unsaturated fatty acids to undergo the β -oxidation spiral, their *cis* double bonds must be isomerized to *trans* double bonds that will end up between the second and third carbons during β -oxidation, or the double bond must be reduced. The process is illustrated for the polyunsaturated fatty acid linoleate in Figure 30.9. Linoleate is obtained from the diet and cannot be synthesized by the human; thus, it is considered an essential fatty acid. Therefore, only that portion of linoleate that is not needed for other processes will be oxidized. Linoleate undergoes β -oxidation until one double bond is between carbons 3 and 4 near the carboxyl end of the fatty acyl chain and the other is between carbons 6 and 7. An isomerase moves the double bond from the 3,4-position so that it is *trans* and in the 2,3-position, and β -oxidation continues. When a conjugated pair of double bonds is formed (two double bonds separated by one single bond) at positions 2 and 4, an NADPH-dependent reductase reduces the pair to one *trans* double bond at position 3. Then isomerization and β -oxidation resume.

FIGURE 30.9 Oxidation of linoleate. After three spirals of β -oxidation (*dashed lines*), there is now a 3,4-*cis* double bond and a 6,7-*cis* double bond. The 3,4-*cis* double bond is isomerized to a 2,3-*trans* double bond, which is in the proper configuration for the normal enzymes to act. One spiral of β -oxidation occurs, plus the first step of a second spiral. A reductase that uses reduced nicotinamide adenine dinucleotide phosphate (NADPH) now converts these two double bonds (between carbons 2 and 3 and between carbons 4 and 5) to one double bond between carbons 3 and 4 in a *trans* configuration. The isomerase (which can act on double bonds that are in either the *cis* or the *trans* configuration) moves this double bond to the 2,3-*trans* position, and β -oxidation can resume. CoA, coenzyme A.

After reviewing **Lola B.**'s previous hospital records, a specialist suspected that **Lola B.**'s medical problems were caused by a disorder in fatty acid metabolism. A battery of tests showed that **Lola B.**'s blood contained elevated levels of several partially oxidized medium-chain fatty acids, such as octanoic acid (8:0) and 4-decenoic acid (10:1, Δ^4). A urine specimen showed an increase in organic acid metabolites of medium-chain fatty acids containing 6 to 10 carbons, including medium-chain acylcarnitine derivatives. The profile of acylcarnitine species in the urine was characteristic of a genetically determined medium-chain acyl CoA dehydrogenase (MCAD) deficiency. In this disease, long-chain fatty acids are metabolized by β -oxidation to a medium-chain-length acyl CoA, such as octanoyl CoA. Because further oxidation of this compound is blocked in MCAD deficiency, the medium-chain acyl group is transferred back to carnitine. These acylcarnitines are water soluble and appear in blood and urine. The specific enzyme deficiency was demonstrated in cultured fibroblasts from **Lola B.**'s skin as well as in her circulating monocytic leukocytes.

In LCAD deficiency, fatty acylcarnitines accumulate in the blood. Those containing 14 carbons predominate. However, these do not appear in the urine.

In oleate (C18:1, Δ^9), there is only one double bond between carbons 9 and 10. It is handled by an isomerization reaction similar to that shown for the double bond at position 9 of linoleate.

5. Odd-Chain-Length Fatty Acids

Fatty acids that contain an odd number of carbon atoms undergo β -oxidation, producing acetyl CoA, until the last spiral, when five carbons remain in the fatty acyl CoA. In this case, cleavage by thiolase produces acetyl CoA and a three-carbon fatty acyl CoA, propionyl CoA (Fig. 30.10). Carboxylation of propionyl CoA yields methylmalonyl CoA, which is ultimately converted to succinyl CoA in a vitamin B₁₂-dependent reaction (Fig. 30.11). Propionyl CoA also arises from the oxidation of branched-chain amino acids.

FIGURE 30.10 Formation of propionyl coenzyme A (propionyl CoA) from odd-chain fatty acids. Successive spirals of β -oxidation cleave each of the bonds marked with *dashed lines*, producing acetyl CoA except for the three carbons at the ω -end,

which produce propionyl CoA.

L-Methylmalonyl CoA

Succinyl CoA

FIGURE 30.11 Conversion of propionyl coenzyme A (propionyl CoA) to succinyl coenzyme A (succinyl CoA). Succinyl CoA, an intermediate of the tricarboxylic acid (TCA) cycle, can form malate, which can be converted to glucose in the liver through the process of gluconeogenesis. Certain amino acids also form glucose by this route (see Chapter 37). ADP, adenosine diphosphate; ATP, adenosine triphosphate; CoA, coenzyme A; P_i, inorganic phosphate.

The propionyl CoA to succinyl CoA pathway is a major anaplerotic route for the TCA cycle and is used in the degradation of valine, isoleucine, and a number of other compounds. In the liver, this route provides precursors of oxaloacetate, which is converted to glucose. Thus, this small proportion of the odd-carbon-number fatty acid chain can be converted to glucose. In contrast, the acetyl CoA formed from β -oxidation of even-chain-number fatty acids in the liver either enters the TCA cycle, where it is principally oxidized to CO₂, or it is converted to ketone bodies.

D. Oxidation of Medium-Chain-Length Fatty Acids

Dietary medium-chain-length fatty acids are more water soluble than long-chain fatty acids and are not stored in adipose triacylglycerol. After a meal, they enter the blood and pass into the portal vein to the liver. In the liver, they enter the mitochondrial matrix by the monocarboxylate transporter and are activated to acyl CoA derivatives in the mitochondrial matrix (see Fig. 30.1). Medium-chain-length acyl CoAs, like long-chain acyl CoAs, are oxidized to acetyl CoA via the β -oxidation spiral. Medium-chain acyl CoAs also can arise from the peroxisomal oxidation pathway.

The medium-chain-length acyl CoA synthetase has a broad range of specificity for compounds of approximately the same size that contain a carboxyl group, such as drugs (salicylate, from aspirin metabolism, and valproate, which is used to treat epileptic seizures), or benzoate, a common component of plants. Once the drug CoA derivative is formed, the carboxyl group is conjugated with glycine to form a urinary excretion product. With certain disorders of fatty acid oxidation, medium- and short-chain fatty acylglycines may appear in the urine, together with acylcarnitines or dicarboxylic acids. Octanoylglycine, for example, will appear in the urine of a patient with medium-chain acyl CoA dehydrogenase (MCAD) deficiency.

E. Regulation of β -Oxidation

Fatty acids are used as fuels principally when they are released from adipose tissue triacylglycerols in response to hormones that signal fasting or increased demand. Many tissues, such as muscle and kidney, oxidize fatty acids completely to CO₂ and H₂O. In these tissues, the acetyl CoA produced by β -oxidation enters the TCA cycle. The FAD(2H) and the NADH from β -oxidation and the TCA cycle are reoxidized by the electron transport chain, and ATP is generated. The process of β -oxidation is regulated by the cells' requirements for energy (i.e., by the levels of ATP and NADH) because fatty acids cannot be oxidized any faster than NADH and FAD(2H) are reoxidized in the electron transport chain.

Fatty acid oxidation also may be restricted by the mitochondrial CoASH pool size. Acetyl CoASH units must enter the TCA cycle or another metabolic pathway to regenerate CoASH required for formation of the fatty acyl CoA derivative from fatty acylcarnitine.

An additional type of regulation occurs at carnitine palmitoyltransferase I (CPTI). Carnitine palmitoyltransferase I is inhibited by malonyl CoA, which is synthesized in the cytosol of many tissues by acetyl CoA carboxylase (Fig. 30.12). Acetyl CoA carboxylase is regulated by several different mechanisms, some of which are tissue-dependent. In skeletal muscles and liver, it is inhibited when it is phosphorylated by the AMP-activated protein kinase (AMP-PK). Thus, during exercise, when AMP levels increase, AMP-PK is activated, and phosphorylates acetyl CoA carboxylase, which becomes inactive. Consequently, malonyl CoA levels decrease, carnitine palmitoyltransferase I is activated, and the β -oxidation of fatty acids is able to restore ATP homeostasis and decrease AMP levels. In liver, in addition to the negative regulation by the AMP-PK, acetyl CoA carboxylase is activated by insulin-dependent mechanisms leading to elevated cytoplasmic citrate, an allosteric activator, which promotes the conversion of malonyl CoA to palmitate in the fatty acid synthesis pathway. Thus, in the liver, malonyl CoA inhibition of CPTI prevents newly synthesized fatty acids from being oxidized.

FIGURE 30.12 Regulation of β -oxidation. (1) Hormones control the supply of fatty acids in the blood. (2) Carnitine palmitoyltransferase I is inhibited by malonyl coenzyme A (malonyl CoA), which is synthesized by acetyl coenzyme A (acetyl CoA) carboxylase. AMP-PK is the AMP-activated protein kinase. (3) The rate of adenosine triphosphate (ATP) use controls the rate of the electron transport chain, which regulates the oxidative enzymes of β -oxidation and the tricarboxylic acid cycle (TCA) cycle. ADP, adenosine diphosphate; AMP, adenosine monophosphate; CoA, coenzyme A; FAD(2H), flavin adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide.

As **Otto S.** runs, his skeletal muscles increase their use of ATP and their rate of fuel oxidation. Fatty acid oxidation is accelerated by the increased rate of the electron transport chain. As ATP is used and AMP increases, the AMP-PK acts to facilitate fuel utilization and maintain ATP homeostasis. Phosphorylation of acetyl CoA carboxylase results in a decreased level of malonyl CoA and increased activity of CPT I. At the same time, AMP-PK facilitates the recruitment of glucose transporters into the plasma membrane of skeletal muscle, thereby increasing the rate of glucose uptake. AMP and hormonal signals also increase the supply of glucose 6-phosphate from glycogenolysis. Thus, his muscles are supplied with more fuel, and all the oxidative pathways are accelerated.

β -Oxidation is strictly an aerobic pathway, dependent on oxygen, a good blood supply, and adequate levels of mitochondria. Tissues that lack mitochondria, such as red blood cells, cannot oxidize fatty acids by β -oxidation. Fatty acids also do not serve as a significant fuel for the brain. They are not used by adipocytes, whose function is to store triacylglycerols to provide a fuel for other tissues. Those tissues that do not use fatty acids as a fuel, or use them only to a limited extent, use ketone bodies instead.

II. Alternative Routes of Fatty Acid Oxidation

Fatty acids that are not readily oxidized by the enzymes of β -oxidation enter alternative pathways of oxidation, including peroxisomal β - and α -oxidation and microsomal ω -oxidation. The function of these pathways is to convert as much as possible of the unusual fatty acids to compounds that can be used as fuels or biosynthetic precursors, and to convert the remainder to compounds that can be excreted in bile or urine. During prolonged fasting, fatty acids released from adipose triacylglycerols may enter the ω -oxidation or peroxisomal β -oxidation pathway, even though they have a normal composition. These pathways not only use fatty acids, they act on xenobiotic (a term used to cover all organic compounds that are foreign to an organism) carboxylic acids that are large hydrophobic molecules resembling fatty acids.

There are a number of theories as to why fatty acids are not a significant fuel for the brain. The first is restricted (slow) transport of fatty acids across the blood–brain barrier. A second is a reduced expression of the enzymes of β -oxidation in brain mitochondria as compared to mitochondria of other tissues. A third is that ATP generation by β -oxidation requires more oxygen than glucose oxidation, which could lead to localized hypoxia, and reduced ATP production as compared to glucose oxidation. The reduced rate of ATP production would lead to impaired neural function.

A. Peroxisomal Oxidation of Fatty Acids

A small proportion of our diet consists of very-long-chain fatty acids (20 or more carbons) or branched-chain fatty acids arising from degradative products of chlorophyll. Very-long-chain fatty acid synthesis also occurs within the body, especially in cells of the brain and nervous system, which incorporate them into the sphingolipids of myelin. These fatty acids are oxidized by **peroxisomal β - and α -oxidation pathways**, which are essentially chain-shortening pathways.

1. Very-Long-Chain Fatty Acids

Very-long-chain fatty acids of 24 to 26 carbons are oxidized exclusively in peroxisomes by a sequence of reactions similar to mitochondrial β -oxidation in that they generate acetyl CoA and NADH. However, the peroxisomal oxidation of straight-chain fatty acids stops when the chain reaches 4 to 6 carbons in length. Some of the long-chain fatty acids also may be oxidized by this route.

The long-chain fatty acyl CoA synthetase is present in the peroxisomal membrane, and the acyl CoA derivatives enter the peroxisome by a transporter that does not require carnitine. The first enzyme of peroxisomal β -oxidation is an oxidase, which donates electrons directly to molecular oxygen and produces hydrogen peroxide (H_2O_2) (Fig. 30.13). (In contrast, the first enzyme of mitochondrial β -oxidation is a dehydrogenase that contains FAD and transfers the electrons to the electron transport chain via ETF.) Thus, the first enzyme of peroxisomal oxidation is not linked to energy production. The three remaining steps of β -oxidation are catalyzed by the peroxisomal bifunctional enzyme (containing the enoyl CoA hydratase and hydroxyacyl CoA dehydrogenase activities), and thiolase, enzymes with activities similar to those found in mitochondrial β -oxidation but coded for by different genes. Thus, one NADH and one acetyl CoA are generated for each turn of the spiral. The peroxisomal β -oxidation spiral continues generating acetyl CoA until a medium-chain acyl CoA, which may be as short as butyryl CoA, is produced (Fig. 30.14).

FIGURE 30.13 Oxidation of fatty acids in peroxisomes. The first step of β -oxidation is catalyzed by a flavin adenine dinucleotide (FAD)-containing oxidase. The electrons are transferred from FAD(2H) to O_2 , which is reduced to hydrogen peroxide (H_2O_2). CoA, coenzyme A.

FIGURE 30.14 Chain shortening by peroxisomal β -oxidation. Very-long-chain fatty acyl CoAs and some long-chain fatty acyl coenzyme As (fatty acyl CoAs) are oxidized in peroxisomes through n cycles of β -oxidation to the stage of a short- to medium-chain fatty acyl CoA. These short- to medium-chain fatty acyl CoAs are converted to carnitine derivatives by COT or CAT in the peroxisomes. In the mitochondria, SCFA-carnitine is converted back to acyl CoA derivatives by either CPTII or CAT. CAC: carnitine acylcarnitine carrier; CAT, carnitine acetyltransferase; COT, carnitine octanoyltransferase; CPTI, carnitine palmitoyltransferase I; CPTII, carnitine palmitoyltransferase 2; IMM, inner mitochondrial membrane; MCFA, medium-chain fatty acyl; OMM, outer mitochondrial membrane; SCFA, short-chain fatty acyl; VLACS, very-long-chain acyl CoA synthetase; VLCFA, very-long-chain fatty acyl.

Within the peroxisome, the acetyl groups can be transferred from CoA to carnitine by an acylcarnitine transferase, or they can enter the cytosol. A similar reaction converts medium-chain-length acyl CoAs and the short-chain butyryl CoA to acyl carnitine derivatives. These acylcarnitines diffuse from the peroxisome to the mitochondria, pass through the outer mitochondrial membrane, and are transported through the inner mitochondrial membrane via the carnitine translocase system. They are converted back to acyl CoAs by carnitine acyltransferases appropriate for their chain length and enter the normal pathways for β -oxidation and acetyl CoA metabolism. The electrons from NADH and acetyl CoA can also pass from the peroxisome to the cytosol. The export of NADH-containing electrons occurs through use of a shuttle system similar to those described for NADH electron transfer into the mitochondria.

Peroxisomes are present in almost every cell type and contain many degradative enzymes, in addition to fatty acyl CoA oxidase, that generate hydrogen peroxide. H_2O_2 can generate toxic free radicals. Thus, these enzymes are confined to peroxisomes, where the H_2O_2 can be neutralized by the free-radical defense enzyme, catalase. Catalase converts H_2O_2 to water and O_2 (see Chapter 25).

Several inherited deficiencies of peroxisomal enzymes have been described. Zellweger syndrome, the most severe form of a group of related conditions called the Zellweger spectrum disorder, results from defective peroxisomal biogenesis. It leads to complex developmental and metabolic phenotypes that affect, principally, the liver and the brain. One of the metabolic characteristics of these diseases is an elevation of C26:0 and C26:1 fatty acid levels in plasma. Refsum disease is caused by a deficiency in a single peroxisomal enzyme, the phytanoyl CoA hydroxylase that carries out α -oxidation of phytanic acid. Symptoms include retinitis pigmentosa, cerebellar ataxia, and chronic polyneuropathy. Because phytanic acid is obtained solely from the diet, placing patients on a low-phytanic acid diet has resulted in marked improvement.

2. Long-Chain Branched-Chain Fatty Acids

Two of the most common branched-chain fatty acids in the diet are phytanic acid and pristanic acid, which are degradation products of chlorophyll and thus are consumed in green vegetables. Animals do not synthesize branched-chain fatty acids. These two multimethylated fatty acids are oxidized in peroxisomes to the level of a

branched C8 fatty acid, which is then transferred to mitochondria. The pathway thus is similar to that for the oxidation of straight very-long-chain fatty acids.

Phytanic acid, a multimethylated C20 fatty acid, is first oxidized to pristanic acid using the α -oxidation pathway (Fig. 30.15). Phytanic acid hydroxylase introduces a hydroxyl group on the α -carbon, which is then oxidized to a carboxyl group with release of the original carboxyl group as CO_2 . By shortening the fatty acid by one carbon, the methyl groups will appear on the α -carbon rather than the β -carbon during the β -oxidation spiral and so can no longer interfere with oxidation of the β -carbon. Peroxisomal β -oxidation thus can proceed normally, releasing propionyl CoA and acetyl CoA with alternate turns of the spiral. When a medium-chain length of approximately eight carbons is reached, the fatty acid is transferred to the mitochondrion as a carnitine derivative, and β -oxidation is resumed.

FIGURE 30.15 Oxidation of phytanic acid. A peroxisomal α -hydroxylase oxidizes the α -carbon, and its subsequent oxidation to a carboxyl group releases the carboxyl carbon as CO_2 . Subsequent spirals of peroxisomal β -oxidation alternately release propionyl and acetyl coenzyme A (acetyl CoA). At a chain length of approximately eight carbons, the remaining branched fatty acid is transferred to mitochondria as a medium-chain carnitine derivative.

B. β -Oxidation of Fatty Acids

Fatty acids also may be oxidized at the ω -carbon of the chain (the terminal methyl group) by enzymes in the endoplasmic reticulum (Fig. 30.16). The ω -methyl group is first oxidized to an alcohol by an enzyme that uses cytochrome P450, molecular oxygen, and NADPH. Dehydrogenases convert the alcohol group to a carboxylic acid. The dicarboxylic acids produced by ω -oxidation can undergo β -oxidation, forming compounds with 6 to 10 carbons that are water soluble. Such compounds may then enter the blood, be oxidized as medium-chain fatty acids, or be excreted in urine as medium-chain dicarboxylic acids.

FIGURE 30.16 ω -Oxidation of fatty acids converts them to dicarboxylic acids.

The pathways of peroxisomal α - and β -oxidation, and microsomal ω -oxidation, are not feedback-regulated. These pathways function to decrease levels of water-insoluble fatty acids or of xenobiotic compounds with a fatty acid-like structure that would become toxic to cells at high concentrations. Thus, their rate is regulated by the availability of substrate.

 Normally, ω -oxidation is a minor process. However, in conditions that interfere with β -oxidation (such as carnitine deficiency or deficiency in an enzyme of β -oxidation), ω -oxidation produces dicarboxylic acids in increased amounts. These dicarboxylic acids are excreted in the urine.

Lola B. was excreting dicarboxylic acids in her urine, particularly adipic acid (which has six carbons) and suberic acid (which has eight carbons):

Octanoylglycine was also found in the urine.

III. Metabolism of Ketone Bodies

Overall, fatty acids released from adipose triacylglycerols serve as the major fuel for the body during fasting. These fatty acids are completely oxidized to CO_2 and H_2O by some tissues. In the liver, much of the acetyl CoA generated from β -oxidation of fatty acids is used for synthesis of the ketone bodies acetoacetate and β -hydroxybutyrate, which enter the blood. In skeletal muscles and other tissues, these ketone bodies are converted back to acetyl CoA, which is oxidized in the TCA cycle with generation of ATP. An alternate fate of acetoacetate in tissues is the formation of cytosolic acetyl CoA.

A. Synthesis of Ketone Bodies

In the liver, ketone bodies are synthesized in the mitochondrial matrix from acetyl CoA generated from fatty acid oxidation (Fig. 30.17). The thiolase reaction of fatty acid oxidation, which converts acetoacetyl CoA to two molecules of acetyl CoA, is a reversible reaction, although formation of acetoacetyl CoA is not the favored direction. Therefore, when acetyl CoA levels are high, this reaction can generate acetoacetyl CoA for ketone body synthesis. The acetoacetyl CoA will react with acetyl CoA to produce 3-hydroxy-3-methylglutaryl CoA (HMG-CoA). The enzyme that catalyzes this reaction is HMG-CoA synthase. In the next reaction of the pathway, HMG-CoA lyase catalyzes the cleavage of HMG-CoA to form acetyl CoA and acetoacetate.

FIGURE 30.17 Synthesis of the ketone bodies acetoacetate, β -hydroxybutyrate, and acetone. The portion of HMG-CoA shown in the tinted box is released as acetyl coenzyme A (acetyl CoA), and the remainder of the molecule forms acetoacetate. Acetoacetate is reduced to β -hydroxybutyrate or decarboxylated to acetone. Note that the dehydrogenase that interconverts acetoacetate and β -hydroxybutyrate is specific for the D-isomer. Thus, it differs from the dehydrogenases of β -oxidation, which act on 3-hydroxy acyl CoA derivatives and are specific for the L-isomer. CoA, coenzyme A; NAD, nicotinamide adenine dinucleotide.

Acetoacetate can enter the blood directly or it can be reduced by β -hydroxybutyrate dehydrogenase to β -hydroxybutyrate, which enters the blood (see Fig. 30.17). This dehydrogenase reaction is readily reversible and interconverts these two ketone bodies, which exist in an equilibrium ratio determined by the NADH/NAD⁺ ratio of the mitochondrial matrix. Under normal conditions, the ratio of β -hydroxybutyrate to acetoacetate in the blood is approximately 3:1.

An alternative fate of acetoacetate is spontaneous decarboxylation, a nonenzymatic reaction that cleaves acetoacetate into CO₂ and acetone (see Fig. 30.17). Because acetone is volatile, it is expired by the lungs. A small amount of acetone may be further metabolized in the body.

B. Oxidation of Ketone Bodies as Fuels

Acetoacetate and β -hydroxybutyrate can be oxidized as fuels in most tissues, including skeletal muscle, brain, certain cells of the kidney, and cells of the intestinal mucosa. Cells transport both acetoacetate and β -hydroxybutyrate from the circulating blood into the cytosol and into the mitochondrial matrix. Here β -hydroxybutyrate is oxidized back to acetoacetate by β -hydroxybutyrate dehydrogenase. This reaction produces NADH. Subsequent steps convert acetoacetate to acetyl CoA (Fig. 30.18).

D-β-Hydroxybutyrate

Acetoacetate

Acetoacetyl CoA

2 Acetyl CoA

FIGURE 30.18 Oxidation of ketone bodies. β -Hydroxybutyrate is oxidized to acetoacetate, which is activated by accepting a CoA group from succinyl CoA. Acetoacetyl CoA is cleaved to two acetyl CoA, which enter the TCA cycle and are oxidized. CoA, coenzyme A; NAD, nicotinamide adenine dinucleotide.

In mitochondria, acetoacetate is activated to acetoacetyl CoA by succinyl CoA acetoacetate CoA transferase. As the name suggests, CoA is transferred from succinyl CoA, a TCA cycle intermediate, to acetoacetate. Although the liver produces ketone bodies, it does not use them because this thioesterase enzyme is not present in sufficient quantity.

One molecule of acetoacetyl CoA is cleaved to two molecules of acetyl CoA by acetoacetyl CoA thiolase, the same enzyme as is involved in β -oxidation. The principal fate of this acetyl CoA is oxidation in the TCA cycle.

The energy yield from oxidation of acetoacetate is equivalent to the yield for oxidation of two molecules of acetyl CoA in the TCA cycle (20 ATP) minus the energy for activation of acetoacetate (1 ATP). The energy of activation is calculated at one high-energy phosphate bond, because succinyl CoA is normally converted to succinate in the TCA cycle, with generation of one molecule of GTP (the energy equivalent of ATP). However, when the high-energy thioester bond of succinyl CoA is transferred to acetoacetate, succinate is produced without the generation of this GTP. Oxidation of β -hydroxybutyrate generates one additional NADH. Therefore, the net energy yield from 1 mol of β -hydroxybutyrate is approximately 21.5 mol of ATP.

Ketogenic diets, which are high-fat diets with a 3:1 ratio of lipid to carbohydrate, are being used to reduce the frequency of epileptic seizures in children with refractory seizures. The reason for its effectiveness in the treatment of epilepsy is not known. Ketogenic diets are also used to treat children with pyruvate dehydrogenase deficiency. Ketone bodies can be used as a fuel by the brain in the absence of pyruvate dehydrogenase. They also can provide a source of cytosolic acetyl CoA for acetylcholine synthesis. They often contain medium-chain triglycerides, which induce ketosis more effectively than long-chain triglycerides.

C. Alternative Pathways of Ketone Body Metabolism

Although fatty acid oxidation is usually the major source of ketone bodies, they also can be generated from the catabolism of certain amino acids: leucine, isoleucine, lysine, tryptophan, phenylalanine, and tyrosine. These amino acids are called ketogenic amino acids because their carbon skeleton is catabolized to acetyl CoA or acetoacetyl CoA, which may enter the pathway of ketone body synthesis in liver. Leucine and isoleucine also form acetyl CoA and acetoacetyl CoA in other tissues as well as the liver.

Acetoacetate can be activated to acetoacetyl CoA in the cytosol by an enzyme similar to the acyl CoA synthetases. This acetoacetyl CoA can be used directly in cholesterol synthesis. It also can be cleaved to two molecules of acetyl CoA by a cytosolic thiolase. Cytosolic acetyl CoA is required for processes such as acetylcholine synthesis in neuronal cells.

Children are more prone to ketosis than adults because their bodies enter the fasting state more rapidly. Their bodies use more energy per unit mass (because their muscle to adipose tissue ratio is higher), and liver glycogen stores are depleted faster (the ratio of their brain mass to liver mass is higher). In children, blood ketone body levels reach 2 mM in 24 hours; in adults, it takes more than 3 days to reach this level. Mild pediatric infections that cause anorexia and vomiting are the most common causes of ketosis in children. Mild ketosis is observed in children after prolonged exercise, perhaps attributable to an abrupt decrease in muscular use of fatty acids liberated during exercise. The liver then oxidizes these fatty acids and produces ketone bodies.

IV. The Role of Fatty Acids and Ketone Bodies in Fuel Homeostasis

Fatty acids are used as fuels whenever fatty acid levels are elevated in the blood, that is, during fasting and starvation; because of a high-fat, low-carbohydrate diet; or during long-term low- to mild-intensity exercise. Under these conditions, a decrease in insulin and increased levels of glucagon, epinephrine, or other hormones stimulate adipose tissue lipolysis. Fatty acids begin to increase in the blood approximately 3 to 4 hours after a meal and progressively increase with time of fasting up to approximately 2 to 3 days (Fig. 30.19). In the liver, the rate of ketone body synthesis increases as the supply of fatty acids increases. However, the blood level of ketone bodies continues to increase, presumably because their utilization by skeletal muscles decreases.

FIGURE 30.19 Levels of ketone bodies in the blood at various times during fasting. Glucose levels remain relatively constant, as do levels of fatty acids. Ketone body levels, however, increase markedly, rising to levels at which they can be used by the brain and other nervous tissues. (From Cahill GF Jr, Aoki TT. How metabolism affects clinical problems. *Med Times*. 1970;98:106.)

After 2 to 3 days of starvation, ketone bodies rise to a level in the blood that enables them to enter brain cells, where they are oxidized, thereby reducing the amount of glucose required by the brain. During prolonged fasting, they may supply as much as two-thirds of the energy requirements of the brain. The reduction in glucose requirements spares skeletal muscle protein, which is a major source of amino acid precursors for hepatic glucose synthesis from gluconeogenesis.

A. Preferential Utilization of Fatty Acids

As fatty acid levels increase in the blood, they are used by skeletal muscles and certain other tissues in preference to glucose. Fatty acid oxidation generates NADH and FAD(2H) through both β -oxidation and the TCA cycle, resulting in relatively high NADH/NAD⁺ ratios, acetyl CoA concentrations, and ATP/ADP or ATP/AMP levels. In skeletal muscles, AMP-PK (see Section I.E) adjusts the concentration of malonyl CoA so that CPTI and β -oxidation operate at a rate that is able to sustain ATP homeostasis. With adequate levels of ATP obtained from fatty acid (or ketone body) oxidation, the rate of glycolysis is decreased. The activities of the regulatory enzymes in glycolysis and the TCA cycle (pyruvate dehydrogenase and PFK-1) are decreased by the changes in concentration of their allosteric regulators (concentrations of ADP, an activator of PDH, decrease; NADH, and acetyl CoA, inhibitors of PDH, increase under these conditions; and ATP and citrate, inhibitors of PFK-1, increase). As a consequence, glucose 6-phosphate (glucose 6-P) accumulates. Glucose 6-P inhibits hexokinase, thereby decreasing the uptake of glucose from the blood and its entry into glycolysis. In skeletal muscles, this pattern of fuel metabolism is facilitated by the decrease in insulin concentration (see Chapter 35). Preferential utilization of fatty acids does not, however, restrict the ability of glycolysis to respond to an increase in AMP or ADP levels, such as might occur during exercise or oxygen limitation.

B. Tissues That Use Ketone Bodies

Skeletal muscles, the heart, the liver, and many other tissues use fatty acids as their major fuel during fasting and under other conditions that increase fatty acids in the blood. However, a number of other tissues (or cell types), such as the brain, use ketone bodies to a greater extent. For example, cells of the intestinal mucosa, which transport fatty acids from the intestine to the blood, use ketone bodies and amino acids, rather than fatty acids, during starvation. Adipocytes, which store fatty acids in triacylglycerols, do not use fatty acids as a fuel during fasting but can use ketone bodies. Ketone bodies cross the placenta and can be used by the fetus. Almost all tissues and cell types, with the exception of liver and red blood cells, are able to use ketone bodies as fuel.

The level of total ketone bodies in **Dianne A.**'s blood greatly exceeds normal fasting levels and mild ketosis as produced during exercise. In a person on a normal mealtime schedule, total blood ketone bodies rarely exceed 0.2 mM. During prolonged fasting, they may rise to 4 to 5 mM. Levels >7 mM are considered evidence of ketoacidosis, because the acid produced must reach this level to exceed the bicarbonate buffer system in the blood and compensatory respiration (Kussmaul respiration) (see Chapter 4).

C. Regulation of Ketone Body Synthesis

Several events, in addition to the increased supply of fatty acids from adipose triacylglycerols, promote hepatic ketone body synthesis during fasting. The decreased insulin/glucagon ratio results in inhibition of acetyl CoA carboxylase and decreased malonyl CoA levels, which activates CPTI, thereby allowing fatty acyl CoA to enter the pathway of β -oxidation (Fig. 30.20). When oxidation of fatty acyl CoA to acetyl CoA generates enough NADH and FAD(2H) to supply the ATP needs of the liver, acetyl CoA is diverted from the TCA cycle into ketogenesis and oxaloacetate in the TCA cycle is diverted toward malate and into glucose synthesis (gluconeogenesis). This pattern is regulated by the NADH/NAD⁺ ratio, which is relatively high during β -oxidation. As the length of time of fasting continues, increased transcription of the gene for mitochondrial HMG-CoA synthase facilitates high rates of ketone body production. Although the liver has been described as “altruistic” because it provides ketone bodies for other tissues, it is simply getting rid of fuel that it does not need.

FIGURE 30.20 Regulation of ketone body synthesis. (1) The supply of fatty acids (FA) is increased. (2) The malonyl coenzyme A (malonyl CoA) inhibition of carnitine palmitoyltransferase I (CPTI) is lifted by inactivation of acetyl coenzyme A (acetyl CoA) carboxylase. (3) β -Oxidation supplies reduced nicotinamide adenine dinucleotide (NADH) and reduced flavin adenine dinucleotide (FAD[2H]), which are used by the electron transport chain for oxidative phosphorylation. As adenosine triphosphate (ATP) levels increase, less NADH is oxidized, and the NADH/NAD⁺ ratio is increased. (4) Oxaloacetate is converted into malate because of the high NADH levels, and the malate enters the cytoplasm for gluconeogenesis. (5) Acetyl CoA is diverted from the tricarboxylic acid (TCA) cycle into ketogenesis, in part because of low oxaloacetate levels, which reduces the rate of the citrate synthase reaction.

Why can't red blood cells use ketone bodies for energy?

CLINICAL COMMENTS

As **Otto S.** runs, he increases the rate at which his muscles oxidize all fuels. The increased rate of ATP utilization stimulates the electron transport chain, which oxidizes NADH and FAD(2H) much faster, thereby increasing the rate at which fatty acids are oxidized. During exercise, he also uses muscle glycogen stores,

which contribute glucose to glycolysis. In some of the fibers, the glucose is used anaerobically, thereby producing lactate. Some of the lactate will be used by his heart, and some will be taken up by the liver to be converted to glucose. As he trains, he increases his mitochondrial capacity, as well as his oxygen delivery, resulting in an increased ability to oxidize fatty acids and ketone bodies. As he runs, he increases fatty acid release from adipose tissue triacylglycerols. In the liver, fatty acids are being converted to ketone bodies, providing his muscles with another fuel. As a consequence, he experiences mild ketosis after his 12-mile run.

Lola B. Medium-chain acyl CoA dehydrogenase (MCAD) deficiency, the cause of **Lola B.**'s problems, has emerged as one of the most common of the inborn errors of metabolism, with an overall frequency of about 1 in 17,000 in the United States, with increased prevalence in some populations including people of northern European descent. More than 25 enzymes and specific transport proteins participate in mitochondrial fatty acid metabolism. At least 15 of these have been implicated in inherited diseases in the human.

MCAD deficiency is an autosomal recessive disorder caused by the substitution of a T for an A at position 985 of the *MCAD* gene. This mutation causes a lysine to replace a glutamate residue in the protein, resulting in the production of an unstable dehydrogenase.

The most frequent manifestation of MCAD deficiency is intermittent hypoketotic hypoglycemia during fasting (low levels of ketone bodies and low levels of glucose in the blood). Fatty acids normally would be oxidized to CO_2 and H_2O under these conditions. In MCAD deficiency, however, fatty acids are oxidized only until they reach medium-chain length. As a result, the body must rely to a greater extent on oxidation of blood glucose to meet its energy needs.

Mitochondrial trifunctional protein (TFP) is located in the inner mitochondrial membrane and catalyzes the final three steps of long-chain fatty acid oxidation (the hydratase step, the L-3-hydroxyacyl CoA dehydrogenase step, and the β -ketothiolase step). Deficiencies in TFP are very rare and the symptoms are quite diverse depending upon the nature of the mutation, and the enzyme activity affected by the mutation. Overall, defects in TFP are often associated with significant mortality and morbidity. Since long-chain fatty acid oxidation is impaired, treatment of the disorder often utilizes dietary supplementation with medium-chain triacylglycerol, as no pharmacological agents are currently available to treat this disorder.

However, hepatic gluconeogenesis appears to be impaired in MCAD. Inhibition of gluconeogenesis may be caused by the lack of hepatic fatty acid oxidation to supply the energy required for gluconeogenesis, or by the accumulation of unoxidized fatty acid metabolites that inhibit gluconeogenic enzymes. As a consequence, liver glycogen stores are depleted more rapidly, and hypoglycemia results. The decrease in hepatic fatty acid oxidation results in less acetyl CoA for ketone body synthesis, and consequently a hypoketotic hypoglycemia develops.

Some of the symptoms once ascribed to hypoglycemia are now believed to be caused by the accumulation of toxic fatty acid intermediates, especially in patients with only mild reductions in blood glucose levels. **Lola B.**'s mild elevation in the blood of liver transaminases may reflect an infiltration of her liver cells with unoxidized medium-chain fatty acids.

The management of MCAD-deficient patients includes the intake of a relatively high-carbohydrate diet and the avoidance of prolonged fasting.

Dianne A., a 26-year-old woman with type 1 diabetes mellitus, was admitted to the hospital in diabetic ketoacidosis. In this complication of diabetes mellitus, an acute deficiency of insulin, coupled with a relative excess of glucagon, results in a rapid mobilization of fuel stores from muscle (amino acids) and adipose tissue (fatty acids). Some of the amino acids are converted to glucose, and fatty acids are converted to ketones (acetoacetate, β -hydroxybutyrate, and acetone). The high glucagon:insulin ratio promotes the hepatic production of ketones. In response to the metabolic "stress," the levels of insulin-antagonistic hormones, such as catecholamines, glucocorticoids, and growth hormone, are increased in the blood. The insulin deficiency further reduces the peripheral utilization of glucose and ketones. As a result of this interrelated dysmetabolism, plasma glucose levels can reach 500 mg/dL (27.8 mmol/L) or more (normal fasting levels are 70 to 100 mg/dL, or 3.9 to 5.5 mmol/L), and plasma ketones rise to levels of 8 to 15 mmol/L or more (normal is in the range of 0.2 to 2 mmol/L, depending on the fed state of the individual).

The increased glucose presented to the renal glomeruli induces an osmotic diuresis, which further depletes intravascular volume, further reducing the renal excretion of hydrogen ions and glucose. As a result, the metabolic acidosis worsens, and the hyperosmolarity of the blood increases, at times exceeding 330 mOsm/kg

(normal is in the range of 285 to 295 mOsm/kg). The severity of the hyperosmolar state correlates closely with the degree of central nervous system dysfunction and may end in coma and even death if left untreated.

Red blood cells lack mitochondria, which is the site of ketone body utilization.

BIOCHEMICAL COMMENTS

Acetylation and regulation of fatty acid oxidation. Previously, in Chapter 15, acetylation of histones was described as a mechanism of regulating gene expression. Histone acetyltransferases (HATs) would catalyze histone acetylation on lysine sidechains, leading to histone dissociation from the DNA. This freed the DNA to bind factors important for transcription to occur. Recent work has indicated that acetylation of very-long-chain acyl CoA dehydrogenase (VLCAD) regulates the activity of the enzyme and offers more complexity to the regulation of fatty acid oxidation. Acetylation of VLCAD reduces enzymatic activity, while deacetylation will restore activity.

A family of proteins known as the sirtuins are NAD^+ -dependent protein deacetylases. There are seven forms in humans, designated SIRT1 through SIRT7, all of which impact certain areas of metabolism. The sirtuins catalyze the reaction shown in Figure 30.21, in which NAD^+ is split into nicotinamide and 2-O-acetyl ADP-ribose, and the protein target is deacetylated (the acetate group is transferred from the target to the 2'-hydroxyl group of the ribose attached to the nicotinamide in NAD^+).

FIGURE 30.21 Generalized sirtuin reaction.

Sirtuin 3 is localized to the mitochondrial matrix, and recent evidence indicates that it is a key regulator for fatty acid oxidation within the mitochondria. Using mice as a model system (which utilize long-chain acyl CoA dehydrogenase [LCAD], an enzyme present only at very low levels in human tissues), it was demonstrated that SIRT3 expression is upregulated during fasting in the liver. A primary target of SIRT3 deacetylation activity is LCAD, which is hyperacetylated on lysine-42. When hyperacetylated, LCAD activity is reduced. As LCAD will initiate fatty acid oxidation, regulating LCAD activity will regulate overall use of long-chain fatty acids by liver mitochondria. Fasting will upregulate the sirtuins leading to activation of LCAD, and increased fatty acid oxidation by the liver. Mice lacking SIRT3 activity were deficient in fatty acid oxidation during fasting conditions, accumulating long-chain intermediates and triglyceride in the liver. Human VLCAD (the predominant form in humans, as opposed to LCAD in mice) was also demonstrated to be acetylated, and SIRT3 would deacetylate the enzyme in a test tube.

The recent finding of acetylation as a regulatory tool for fatty acid oxidation provides another avenue for complex regulation between various aspects of metabolism and provides fertile ground for further research in this area.

KEY CONCEPTS

- ◆ Fatty acids are a major fuel for humans.
- ◆ During overnight fasting, fatty acids become the major fuel for cardiac muscle, skeletal muscle, and liver.
- ◆ The nervous system has a limited ability to use fatty acids directly as fuel. The liver converts fatty acids to ketone bodies, which can be used by the nervous system as a fuel during prolonged periods of fasting.
- ◆ Fatty acids are released from adipose tissue triacylglycerols under appropriate hormonal stimulation.
- ◆ In cells, fatty acids are activated to fatty acyl CoA derivatives by acyl CoA synthetases.
- ◆ Acyl CoAs are transported into the mitochondria for oxidation via carnitine.
- ◆ ATP is generated from fatty acids by the pathway of β -oxidation.
- ◆ In β -oxidation, the fatty acyl group is sequentially oxidized to yield FAD(2H), NADH, and acetyl CoA. Although the reactions are similar, enzyme specificity is determined by the acyl chain length of the substrate.
- ◆ Unsaturated and odd-chain-length fatty acids require additional reactions for their metabolism.
- ◆ β -Oxidation is regulated by the levels of FAD(2H), NADH, and acetyl CoA.
- ◆ The entry of fatty acids into mitochondria is regulated by malonyl CoA levels.
- ◆ Alternative pathways for very-long-chain and branched-chain fatty acid oxidation occur within peroxisomes.
- ◆ If β -oxidation is impaired, other pathways of oxidation will be utilized, such as α - and ω -oxidation.
- ◆ Table 30.2 summarizes the diseases discussed in this chapter.

TABLE 30.2 Diseases Discussed in Chapter 30

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Obesity	Both	The contribution of fatty acids to overall energy metabolism and energy storage.
MCAD deficiency	Genetic	Lack of medium-chain acyl CoA dehydrogenase activity, leading to hypoglycemia and reduced ketone body formation under fasting conditions.
Type 1 diabetes	Both	Ketoacidosis; overproduction of ketone bodies due to lack of insulin and metabolic dysregulation in the liver.
Carnitine deficiency	Both	A primary carnitine deficiency is the lack of a membrane transporter for carnitine; a secondary carnitine deficiency is due to other metabolic disorders.
Zellweger syndrome	Genetic	A defect in peroxisome biogenesis, leading to a lack of peroxisomes, inability to synthesize plasmalogens, or oxidize very-long-chain fatty acids.
TFP deficiency	Genetic	A lack of mitochondrial trifunctional protein, leading to hypoglycemia, lethargy, hypoketonemia, and liver problems.
Acute ackee fruit intoxication (Jamaican vomiting disorder)	Environmental	Inhibition of an acyl CoA dehydrogenase activity by hypoglycin can lead to death due to severe hypoglycemia.

REVIEW QUESTIONS—CHAPTER 30

1. A lack of the enzyme ETF:CoQ oxidoreductase may lead to death. This is due to which one of the following reasons?
 - A. The energy yield from glucose utilization is dramatically reduced.
 - B. The energy yield from alcohol utilization is dramatically reduced.
 - C. The energy yield from ketone body utilization is dramatically reduced.
 - D. The energy yield from fatty acid utilization is dramatically reduced.
 - E. The energy yield from glycogen utilization is dramatically reduced.
2. The ATP yield from the complete oxidation of 1 mol of a $C_{18:0}$ fatty acid to carbon dioxide and water would be closest to which one of the following?

- A. 105
 - B. 115
 - C. 120
 - D. 125
 - E. 130
3. Which one of the following sets of reactions best describes the oxidation of fatty acids?
- A. Oxidation, hydration, oxidation, carbon-carbon bond breaking
 - B. Oxidation, dehydration, oxidation, carbon-carbon bond breaking
 - C. Oxidation, hydration, reduction, carbon-carbon bond breaking
 - D. Oxidation, dehydration, reduction, oxidation, carbon-carbon bond breaking
 - E. Reduction, hydration, oxidation, carbon-carbon bond breaking
4. Elevated levels of ketone bodies can be found in the blood of untreated type I diabetics and individuals on severe diets. A major difference in the laboratory findings of metabolites in the blood of each type of individual (type I diabetic versus the dieter) would be which of the following?
- A. Glucose levels
 - B. Free fatty acid levels
 - C. Lactate levels
 - D. Six- and eight-carbon dicarboxylic acid levels
 - E. Carnitine levels
5. In which one of the following time spans will fatty acids be the major source of fuel for the tissues of the body?
- A. Immediately after breakfast
 - B. Minutes after a snack
 - C. Immediately after dinner
 - D. While running the first mile of a marathon
 - E. While running the last mile of a marathon
6. If your patient has classic carnitine palmitoyltransferase II deficiency, which one of the following laboratory test results would you expect to observe?
- A. Elevated blood acylcarnitine levels
 - B. Elevated ketone bodies in the blood
 - C. Elevated blood glucose levels
 - D. Low creatine phosphokinase blood levels
 - E. Reduced blood fatty acid levels
7. A 6-month-old infant is brought to your office due to frequent crying episodes, lethargy, and poor eating. These symptoms were especially noticeable after the child had an ear infection, at which time he did not eat well. The parents stated that this situation has happened before, but they found if they fed the child frequently, the lethargic episodes could be reduced in number. The results of blood work indicated that the child was hypoglycemic and hypoketotic. Six- to eight-carbon-chain dicarboxylic acids and acylcarnitine derivatives were found in the urine of the child as well. Based on your understanding of fatty acid metabolism, which enzyme would you expect to be defective in this child?
- A. CPTI
 - B. CPTII
 - C. LCAD
 - D. MCAD
 - E. Carnitine acylcarnitine translocase
8. Vitamin B₁₂ is a requirement in the complete oxidation of which of one the following fatty acids?
- A. Short chain
 - B. Medium chain
 - C. Long chain
 - D. Very long chain
 - E. Odd chain length
9. A diabetic patient in ketoacidosis has a specific odor to their breath. Which one of the following compounds is responsible for this odor?
- A. Acetoacetate
 - B. β-Hydroxybutyrate
 - C. Acetone

- D. Acetyl CoA
 - E. CO₂
0. A newborn child has been determined to be unable to oxidize phytanic acid and is placed on a diet containing very low levels of this unusual fatty acid. The organelle most likely to contain the defective enzyme, or be altered in this disorder, is which one of the following?
- A. Endoplasmic reticulum
 - B. Golgi apparatus
 - C. Lysosome
 - D. Mitochondria
 - E. Peroxisome
1. A marathon runner was taking supplements to help improve their ability to generate energy via fatty acid oxidation during their training sessions. Which of the following supplements are involved in the process of generating ATP from palmitic or stearic acid? Choose the one best answer.

	Pantothenic Acid	Coenzyme Q	Carnitine	Niacin	Thiamin
A	Yes	Yes	Yes	Yes	Yes
B	Yes	No	Yes	No	No
C	Yes	Yes	Yes	Yes	No
D	No	No	No	No	No
E	No	Yes	No	Yes	Yes
F	No	No	No	No	Yes

Questions 12 and 13 are based on the following case: A 2-year-old child, after a short illness, developed encephalopathy, cardiomyopathy, muscle weakness, and fasting hypoglycemia. Biopsies of muscle and liver tissue indicated an accumulation of free fatty acids.

2. Dietary treatment with which of the following could help to alleviate the symptoms?
- A. Carnitine
 - B. Niacin
 - C. Palmitic acid
 - D. Pantothenic acid
 - E. Riboflavin
3. Which one of the following would still be an effective energy source in the child despite their enzyme deficiency?
- A. Linolenic acid
 - B. Octanoic acid
 - C. Palmitic acid
 - D. Phytanic acid
 - E. Stearic acid
4. Hypoketotic hypoglycemia can result from a deficiency in which of the following enzymes or cofactors? Choose the one best answer.

	Carnitine	MCAD	Trifunctional Protein	PFK-I
A	Yes	No	Yes	No
B	No	No	No	No
C	Yes	Yes	Yes	No
D	No	No	No	Yes
E	Yes	Yes	Yes	Yes
F	No	Yes	No	Yes

5. The oxidation of phytanic acid (a C16 fatty acid with methyl branches at carbons 3, 7, 11, and 15) requires an α -oxidation step before β -oxidation can take place. In the absence of the α -oxidation step, β -oxidation would be blocked at which one of the following enzymatic steps?
- Acyl CoA oxidase
 - Acyl CoA synthetase
 - Hydratase
 - Hydroxyacyl CoA dehydrogenase
 - Ketothiolase

ANSWERS TO REVIEW QUESTIONS

- The answer is D.** The ETF:CoQ oxidoreductase is required to transfer the electrons from the FAD(2H) of the acyl CoA dehydrogenase to coenzyme Q. When the oxidoreductase is missing, the electrons cannot be transferred, and the acyl CoA dehydrogenase cannot continue to oxidize fatty acids because it contains a reduced cofactor instead of an oxidized cofactor. During times of fasting, when fatty acids are the primary energy source, no energy will be forthcoming, gluconeogenesis is shut down, and death may result. The lack of this enzyme does not affect the other pathways listed as potential answers.
- The answer is C.** An 18-carbon saturated fatty acid would require eight spirals of fatty acid oxidation, which yields 8 NADH, 8 FAD(2H), and 9 acetyl CoA. As each NADH gives rise to 2.5 ATP, and each FAD(2H) gives rise to 1.5 ATP, the reduced cofactors will give rise to 32 ATP. Each acetyl CoA gives rise to 10 ATP, for a total of 90 ATP. This then yields 122 ATP, but we must subtract 2 ATP for the activation step, at which two high-energy bonds are expended. Thus, the net yield is 120 ATPs for each molecule of fatty acid oxidized.
- The answer is A.** Fatty acid oxidation is initiated by the acyl CoA dehydrogenase (an oxidation step), followed by hydration of the double bond formed in the first step, followed by the hydroxyacyl CoA dehydrogenase step (another oxidation), and then attack of the β -carbonyl by CoA, breaking a carbon-carbon bond (the thiolase step).
- The answer is A.** Type I diabetics exhibit high blood glucose levels due to the lack of insulin and the inability of peripheral tissues to effectively transport glucose from the blood into the tissue. Individuals on diets would have low blood glucose levels, as the majority of energy is being derived from fat and ketone body production. The level of free fatty acids in the blood would be elevated under both conditions due to the high glucagon-to-insulin ratio. Lactate levels are low under both conditions, as glycolysis does not need to act rapidly to provide energy. Six- and eight-carbon dicarboxylic acids in the serum are indicative of a problem in oxidizing fatty acids (MCAD deficiency), which does not apply under these conditions. Carnitine levels in the blood would be expected to be low in both individuals, as the tissues require the carnitine for fatty acid oxidation, which is a primary energy source for each type of individual.

5. **The answer is E.** Fatty acids are the major fuel for the body during prolonged exercise and fasting. Answers A, B, and C are incorrect because glucose would be the major fuel after eating. Answer D is incorrect because, at the start of exercise, muscle glycogen and gluconeogenesis are being used as the major source of fuel.
6. **The answer is A.** A defect in CPTII activity would lead to fatty acids being added to carnitine (via CPTI), but not being able to have the carnitine removed. This would lead to a buildup of acylcarnitine levels in the blood. This would also lead to an inability to oxidize fatty acids or synthesize ketone bodies. Because of the lack of energy for gluconeogenesis (due to reduced fatty acid oxidation), blood glucose levels would be low. The buildup of acylcarnitine in muscle will damage the muscle and release creatine phosphokinase into circulation, leading to increased levels of creatine phosphokinase. The lack of carnitine to accept fatty acids would lead to an accumulation of free fatty acids in the blood.
7. **The answer is D.** The lack of energy from fatty acid oxidation resulted in an inability to synthesize sufficient glucose for the circulation, resulting in the lethargy. Eating frequently maintained blood glucose levels such that the brain could function, and the symptoms were alleviated. As medium-chain fatty acids could not be further metabolized by β -oxidation, ω -oxidation is used, and dicarboxylic acids accumulate. As short-chain dicarboxylic fatty acids are found in the urine, some fatty acid metabolism is occurring, but it cannot go to completion. Even if CPTI, CPTII, or carnitine acylcarnitine translocase were partially defective, once a fatty acid was transported into the mitochondria, it would be able to be oxidized to completion, and the short-chain dicarboxylic acids would not be observed. Since the observed dicarboxylic acids are short chain, LCAD activity is normal.
8. **The answer is E.** Fatty acids that contain an odd number of carbons produce propionyl CoA, a three-carbon fatty acyl CoA in the final spiral of β -oxidation. This is ultimately converted to succinyl CoA in a vitamin B₁₂-dependent reaction. Propionyl CoA also arises from the oxidation of branched-chain amino acids. Vitamin B₁₂ is not needed for the complete oxidation of fatty acids with an even number of carbons (saturated or unsaturated).
9. **The answer is C.** Acetoacetate and β -hydroxybutyrate are the ketone bodies produced by the liver. Acetoacetate can be converted to acetone and CO₂. Since acetone is volatile, it is expired by the lungs. In ketoacidosis, increased production of acetone gives the classic odor to the breath.
10. **The answer is E.** The child most likely has a peroxisomal biogenesis disorder such that functional peroxisomes are not produced. The first step of phytanic acid oxidation occurs in the peroxisomes, and lacking either the peroxisomes, or phytanic acid oxidase activity, can lead to an accumulation of phytanic acid in the blood.
11. **The answer is A.** Pantothenic acid is the precursor to coenzyme A, which is required to activate a fatty acid before it can be oxidized. Coenzyme Q is required for the electron transfer chain to function, and to accept electrons from the electron transfer flavoprotein, which accepts electrons from the acyl CoA dehydrogenases involved in fatty acid oxidation. Coenzyme Q is also required for transferring electrons from complexes I and II in the electron transfer chain to complex III. Carnitine is required to transfer the fatty acyl CoA across the inner mitochondrial membrane and into the matrix of the mitochondria. Niacin is required to synthesize NAD⁺, which accepts electrons during the oxidation of the fatty acids (the L-3-hydroxyacyl CoA dehydrogenase step). Thiamin is required such that α -ketoglutarate dehydrogenase can convert α -ketoglutarate to succinyl CoA. In the absence of thiamin, the TCA cycle would stop, leading to an accumulation of NADH, which would block fatty acid oxidation from occurring.
12. **The answer is A.** The child is exhibiting the symptoms of primary carnitine deficiency due to a mutation in the *SLC22A5* gene, which encodes a carnitine transporter (OCTN2). The protein OCTN2 transports carnitine from the blood into cells. In the absence of carnitine, fatty acid oxidation is reduced, leading to reduced energy production in the cells, which contributes to muscle weakness and fasting hypoglycemia. Fatty acids can also accumulate in the cells, which leads to the observed cardiomyopathy and encephalopathy. By increasing blood carnitine levels, the mutated OCTN2 protein may be able to transport some carnitine into the cells (particularly if the mutated protein had an increased K_m for carnitine), and thereby alleviate the symptoms. Riboflavin (precursor for FAD), Niacin (precursor for NAD⁺), and pantothenic acid (precursor for coenzyme A) would not be able to enhance carnitine transport into cells. Palmitic acid is a fatty acid and providing that to the patient would exacerbate the symptoms.
13. **The answer is B.** The child is exhibiting the symptoms of primary carnitine deficiency, and cells cannot transport carnitine from the blood into the cells. This results in a reduced ability to metabolize fatty acids, which require carnitine in their degradative pathway. Octanoic acid (C8, no double bond) does not require

carnitine to be transferred into the mitochondria and, once in the mitochondria, is activated to octanoyl CoA and oxidized. This is true for almost all short- and medium-chain fatty acids. All other answers listed are longer-chain fatty acids (palmitic acid is 16 carbons, linolenic acid is 18 carbons, as is stearic acid) or a longer branched-chain fatty acid (phytanic acid), which is initially oxidized in the peroxisomes, but is then transferred to carnitine to be routed to the mitochondria to complete its oxidation. In the absence of carnitine, phytanic acid would not be fully oxidized.

14. **The answer is C.** Hypoketotic hypoglycemia will result from mutations in enzymes involved in fatty acid oxidation, such that under conditions in which glucagon is released (falling blood glucose levels), fatty acid oxidation is impaired, leading to a reduction in ketone body synthesis, and a reduction in gluconeogenesis (due to reduced energy production). Thus, mutations in MCAD, or the trifunctional protein, would impair fatty acid oxidation and lead to hypoketotic hypoglycemia. A carnitine deficiency (either primary or secondary) would also lead to reduced fatty acid oxidation, and hypoketotic hypoglycemia. A mutated PFK-1, however, would affect glycolysis, but not fatty acid oxidation or gluconeogenesis, and would not lead to hypoketotic hypoglycemia.
15. **The answer is D.** Alpha-oxidation leads to the removal of carbon 1 as carbon dioxide, which then places the methyl groups on carbons 2, 6, and 10. Beta-oxidation can then proceed normally. If carbon 1 were not removed from the fatty acid prior to β -oxidation, the methyl group on carbon 3 would block the hydroxyacyl CoA dehydrogenase step. The acyl CoA oxidase would create a double bond between carbons 2 and 3, and the hydratase would add water across the double bond, with the hydroxyl group adding to carbon 3, and the proton to carbon 2. If carbon 3 has both a methyl group and a hydroxyl group attached to it, the energy required to oxidize the hydroxyl group to a carbonyl is too high to allow the reaction to proceed (usually a proton is attached to carbon 3, and leaves as a hydride ion, to be accepted by NAD^+ ; if a methyl group is attached to carbon 3 instead of a proton, a CH_3^- group would have to leave, which cannot occur with this enzyme system). By “moving” the methyl groups to even carbon numbers, this problem is avoided.

Synthesis of Fatty Acids, Triacylglycerols, and the Major Membrane Lipids

Fatty acids are synthesized mainly in the liver in humans, with dietary glucose serving as the major source of carbon. Glucose is converted through glycolysis to pyruvate, which enters the mitochondrion and forms both acetyl coenzyme A (acetyl CoA) and oxaloacetate (Fig. 31.1). These two compounds condense, forming citrate. Citrate is transported to the **cytosol**, where it is cleaved to form acetyl CoA, the source of carbon for the reactions that occur on the **fatty acid synthase complex**. The key regulatory enzyme for the process, **acetyl CoA carboxylase**, produces **malonyl CoA** from acetyl CoA.

FIGURE 31.1 Lipogenesis, the synthesis of triacylglycerols from glucose. In humans, the synthesis of fatty acids from glucose occurs mainly in the liver. Fatty acids (FA) are converted to triacylglycerols (TG), packaged in very-low-density lipoprotein (VLDL), and secreted into the blood. CoA, coenzyme A; DHAP, dihydroxyacetone phosphate; FACoA, fatty acyl coenzyme A; Glycerol 3-P, glycerol 3-phosphate; NADP, nicotinamide adenine dinucleotide phosphate; OAA, oxaloacetate.

The growing fatty acid chain, attached to the fatty acid synthase complex in the cytosol, is

elongated by the sequential addition of two-carbon units provided by malonyl CoA. **NADPH**, produced by the **pentose phosphate pathway** and the **malic enzyme**, provides **reducing equivalents**. When the growing fatty acid chain is 16 carbons in length, it is released as **palmitate**. After activation to a CoA derivative, palmitate can be elongated and desaturated to produce a series of fatty acids.

Eicosanoids are derived from polyunsaturated fatty acids containing 20 carbon atoms, which are found in cell membranes esterified to membrane phospholipids. Arachidonic acid, derived from the diet or synthesized from linoleate, is the compound from which most eicosanoids are produced in the body. Compounds that serve as signals for eicosanoid production bind to cell membrane receptors and activate phospholipases that cleave the polyunsaturated fatty acids from cell membrane phospholipids.

Fatty acids, produced in cells or obtained from the diet, are used by various tissues for the synthesis of **triacylglycerols** (the major storage form of fuel) and the **glycerophospholipids** and **sphingolipids** (the major components of cell membranes).

In the liver, triacylglycerols are produced from fatty acyl CoA and glycerol 3-phosphate. **Phosphatidic acid** serves as an intermediate in this pathway. The triacylglycerols are not stored in the liver but rather packaged with apolipoproteins and other lipids in **very-low-density lipoprotein (VLDL)** and secreted into the blood (see Fig. 31.1).

In the capillaries of various tissues (particularly adipose tissue, muscle, and the lactating mammary gland), **lipoprotein lipase (LPL)** digests the triacylglycerols of VLDL, forming **fatty acids** and **glycerol** (Fig. 31.2). The glycerol travels to the liver where it is used. Some of the fatty acids are oxidized by muscle and other tissues. After a meal, however, most of the fatty acids are converted to triacylglycerols in **adipose cells**, where they are **stored**. These fatty acids are released during fasting and serve as the predominant fuel for the body.

FIGURE 31.2 Fate of very-low-density lipoprotein (VLDL) triacylglycerol (TG). The TG of VLDL, produced in the liver, is digested by lipoprotein lipase (LPL) present on the endothelial cells lining the capillaries in adipose and skeletal muscle tissue. Fatty acids are released and either oxidized in the muscle or stored in adipose tissue as TG. Glycerol is used by the liver because hepatocytes exclusively contain glycerol kinase. FA, fatty acid (or fatty acyl group); FACoA, fatty acyl coenzyme A.

Glycerophospholipids are also synthesized from fatty acyl CoA, which forms esters with glycerol 3-phosphate, producing phosphatidic acid. Various head groups are added to carbon 3 of the glycerol 3-phosphate moiety of phosphatidic acid, generating amphipathic compounds such as **phosphatidylcholine**, **phosphatidylinositol**, and **cardiolipin** (Fig. 31.3A). In the formation of **plasmalogens** and **platelet-activating factor (PAF)**, a long-chain fatty alcohol forms an **ether** with carbon 1, replacing the fatty acyl ester (see Fig. 31.3B). Cleavage of phospholipids is catalyzed by **phospholipases** found in cell membranes, lysosomes, and pancreatic juice.

Sphingomyelin

Glycolipid

FIGURE 31.3 A. General structure of a glycerophospholipid. The fatty acids are joined by ester bonds to the glycerol moiety. Various combinations of fatty acids may be present. The fatty acid at carbon 2 of the glycerol is usually unsaturated. The head group is the group attached to the phosphate on position 3 of the glycerol moiety. The most common head group is choline, but ethanolamine, serine, inositol, or phosphatidylglycerol also may be present. The phosphate group is negatively charged, and the head group may carry a positive charge (choline and ethanolamine), or both a positive and a negative charge (serine). The inositol may be phosphorylated and thus negatively charged. **B.** General structure of a plasmalogen. Carbon 1 of glycerol is joined to a long-chain fatty alcohol by an ether linkage. The fatty alcohol group has a double bond between carbons 1 and 2. The head group is usually ethanolamine or choline. **C.** General structures of the sphingolipids. The “backbone” is sphingosine rather than glycerol. Ceramide is sphingosine with a fatty acid joined to its amino group by an amide linkage. Sphingomyelin contains phosphocholine, whereas glycolipids (**D**) contain carbohydrate groups.

Sphingolipids, which are prevalent in membranes and the myelin sheath of the central nervous system, are built on **serine** rather than glycerol. In the synthesis of sphingolipids, serine and palmitoyl CoA condense, forming a compound that is related to **sphingosine**. Reduction of this compound, followed by the addition of a second fatty acid in amide linkage, produces **ceramide**. Carbohydrate groups attach to ceramide, forming **glycolipids** such as the **cerebrosides**, **globosides**, and **gangliosides** (see Fig. 31.3D). The addition of **phosphocholine** to ceramide produces **sphingomyelin** (see Fig. 31.3C). These sphingolipids are degraded by lysosomal enzymes.

THE WAITING ROOM

Emma W. has done well with regard to her respiratory function since her earlier hospitalization for an acute asthma exacerbation (see Chapter 28). She has been maintained on two puffs of triamcinolone acetonide, a potent inhaled corticosteroid, two times per day, and has not required systemic steroids for months. The glucose intolerance precipitated by high intravenous and oral doses of the synthetic glucocorticoid prednisone during her earlier hospitalization resolved after this drug was discontinued. She has come to her doctor now because she is concerned that the low-grade fever and cough she has developed over the last 36 hours may trigger another asthma exacerbation.

The dietitian did a careful analysis of **Percy V.**'s diet, which was indeed low in fat, adequate in protein, but excessive in carbohydrates, especially refined sugars. His total caloric intake averaged about 430 kilocalories (kcal) a day in excess of his isocaloric requirements. This excess carbohydrate was being converted to fats, accounting for his weight gain. A new diet with a total caloric content that would prevent further gain in weight was prescribed.

Percy V.'s mental depression slowly responded to antidepressant medication, to the therapy sessions with his psychiatrist, and to frequent visits from an old high school sweetheart whose husband had died several years earlier. While he was hospitalized for malnutrition, **Percy V.**'s appetite returned. By the time of discharge, he had gained back 8 of the 22 lb he had lost and weighed 131 lb.

During the next few months, **Percy V.** developed a craving for “sweet foods” such as the candy he bought and shared with his new friend. After 6 months of this high-carbohydrate courtship, **Percy V.** had gained another 22 lb and now weighed 155 lb, which was 8 lb more than he weighed when his depression began. He became concerned about the possibility that he would soon be overweight and consulted his dietitian, explaining that he had faithfully followed his low-fat diet but had “gone overboard” with carbohydrates. He asked whether it was possible to become fat without eating fat.

Cholesterol determinations in serum utilize a sequence of enzyme-coupled reactions. Cholesteryl esterase is used to release the fatty acids esterified to circulating cholesterol, producing free cholesterol. The second enzyme in the sequence, cholesterol oxidase, oxidizes cholesterol and reduces oxygen to form hydrogen peroxide. Horseradish peroxidase is then utilized to catalyze the conversion of a colorless dye to a colored dye, via an oxidation–reduction reaction using the electrons from hydrogen peroxide. The intensity of the color obtained is directly proportional to the level of cholesterol in the sample.

Cora N.'s hypertension and systolic heart failure have been well controlled on medication, and she has lost 10 lb since she had her recent heart attack. Her fasting serum lipid profile before discharge from the hospital indicated a significantly elevated serum low-density lipoprotein (LDL) cholesterol

level of 175 mg/dL, a serum triacylglycerol level of 280 mg/dL (reference range, 60 to 150 mg/dL), and a serum high-density lipoprotein (HDL) cholesterol level of 34 mg/dL (reference range >50 mg/dL for healthy women). While she was still in the hospital, she was asked to obtain the most recent serum lipid profiles of her older brother and her younger sister, both of whom were experiencing chest pain. Her brother's profile showed normal triacylglycerols, moderately elevated LDL cholesterol, and significantly suppressed HDL cholesterol levels. Her sister's profile showed only hypertriglyceridemia (high blood triacylglycerols).

Christy L. was born 9 weeks prematurely. She appeared normal until about 30 minutes after delivery when her respirations became rapid at 64 breaths per minute with audible respiratory grunting. The spaces between her ribs (intercostal spaces) retracted inward with each inspiration, and her lips and fingers became cyanotic from a lack of oxygen in her arterial blood. An arterial blood sample indicated a low partial pressure of oxygen (PO_2) and a slightly elevated partial pressure of carbon dioxide (PCO_2). The arterial pH was somewhat suppressed, in part from an accumulation of lactic acid secondary to the hypoxemia (a low level of oxygen in her blood). A chest radiograph showed a fine reticular granularity of the lung tissue, especially in the left lower lobe area. From these clinical data, a diagnosis of respiratory distress syndrome (RDS) (formally known as hyaline membrane disease) was made.

Christy L. was immediately transferred to the neonatal intensive care unit, where, with intensive therapy, she improved.

I. Fatty Acid Synthesis

Fatty acids are synthesized whenever an excess of calories is ingested. The major source of carbon for the synthesis of fatty acids is dietary carbohydrate. An excess of dietary protein also can result in an increase in fatty acid synthesis. In this case, the carbon source is amino acids that can be converted to acetyl CoA or tricarboxylic acid (TCA) cycle intermediates (see Chapter 38). Fatty acid synthesis occurs primarily in the liver in humans, although it can also occur, to a lesser extent, in adipose tissue.

When an excess of dietary carbohydrate is consumed, glucose is converted to acetyl CoA, which provides the two-carbon units that condense in a series of reactions on the fatty acid synthase complex, producing **palmitate** (see Fig. 31.1). Palmitate is then converted to other fatty acids. The fatty acid synthase complex is located in the cytosol and, therefore, it uses **cytosolic acetyl CoA**.

A. Conversion of Glucose to Cytosolic Acetyl Coenzyme A

The pathway for the synthesis of cytosolic acetyl CoA from glucose begins with glycolysis, which converts glucose to pyruvate in the cytosol (Fig. 31.4). Pyruvate enters mitochondria, where it is converted to acetyl CoA by pyruvate dehydrogenase and to oxaloacetate by pyruvate carboxylase. The pathway pyruvate follows is dictated by the acetyl CoA levels in the mitochondria. When acetyl CoA levels are high, pyruvate dehydrogenase is inhibited and pyruvate carboxylase activity is stimulated. As oxaloacetate levels increase because of the activity of pyruvate carboxylase, oxaloacetate condenses with acetyl CoA to form citrate. This condensation reduces the acetyl CoA levels, which leads to the activation of pyruvate dehydrogenase and inhibition of pyruvate carboxylase. Through such reciprocal regulation, citrate can be continuously synthesized and transported across the inner mitochondrial membrane. In the cytosol, citrate is cleaved by citrate lyase to re-form acetyl CoA and oxaloacetate. This circuitous route is required because pyruvate dehydrogenase, the enzyme that converts pyruvate to acetyl CoA, is found only in mitochondria and because acetyl CoA cannot directly cross the mitochondrial membrane.

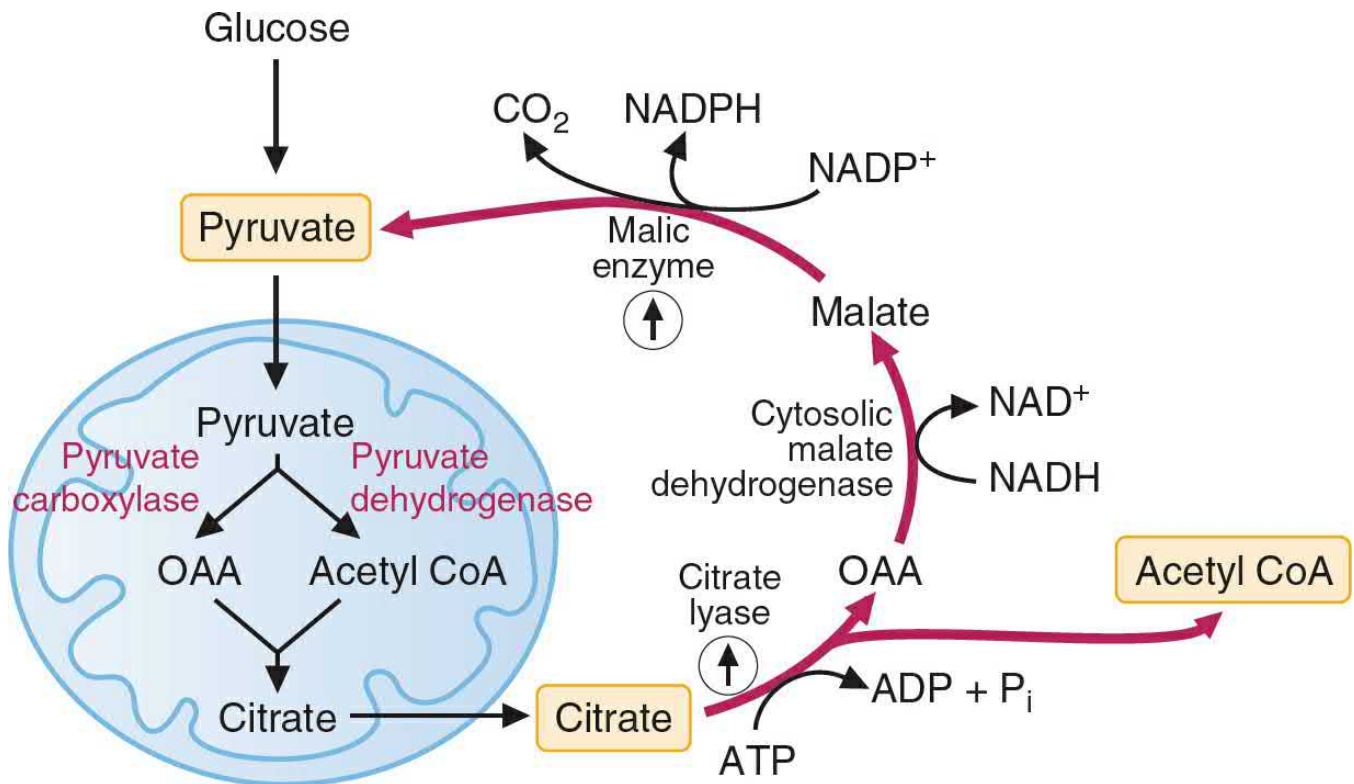

FIGURE 31.4 Conversion of glucose to cytosolic acetyl coenzyme A (acetyl CoA) and the fate of citrate in the cytosol. Citrate lyase is also called citrate cleavage enzyme. ADP, adenosine diphosphate; ATP, adenosine triphosphate; NAD, nicotinamide adenine dinucleotide; OAA, oxaloacetate; P_i , inorganic phosphate; \uparrow , inducible enzyme.

Reduced nicotinic adenine dinucleotide phosphate (NADPH) is required for fatty acid synthesis and is generated by the pentose phosphate pathway (see Chapter 27) and from recycling of the oxaloacetate produced by citrate lyase (see Fig. 31.4). Oxaloacetate is converted back to pyruvate in two steps: the reduction of oxaloacetate to malate by the NAD^+ -dependent malate dehydrogenase and the oxidation and decarboxylation of malate to pyruvate by an $NADP^+$ -dependent malate dehydrogenase (malic enzyme) (Fig. 31.5). The pyruvate formed by malic enzyme is reconverted to citrate. The NADPH that is generated by malic enzyme, along with the NADPH generated by glucose 6-phosphate dehydrogenase and gluconate 6-phosphate dehydrogenase in the pentose phosphate pathway, is used for the reduction reactions that occur on the fatty acid synthase complex.

FIGURE 31.5 Reaction catalyzed by malic enzyme. This enzyme is also called the decarboxylating or nicotinamide adenine dinucleotide phosphate (NADP)-dependent malate dehydrogenase.

The generation of cytosolic acetyl CoA from pyruvate is stimulated by elevation of the insulin/glucagon ratio after a carbohydrate meal. Insulin activates pyruvate dehydrogenase by stimulating the phosphatase that dephosphorylates the enzyme to an active form (see Chapter 23). The synthesis of malic enzyme, glucose 6-phosphate dehydrogenase, and citrate lyase is induced by the high insulin/glucagon ratio. The ability of citrate to accumulate and to leave the mitochondrial matrix for the synthesis of fatty acids is attributable to the allosteric inhibition of isocitrate dehydrogenase by high energy levels within the matrix under these conditions. The concerted regulation of glycolysis and fatty acid synthesis is described in Chapter 34.

Why might certain enzymes utilize AMP as an allosteric regulator signifying low energy levels as opposed to ADP?

B. Conversion of Acetyl CoA to Malonyl CoA

Cytosolic acetyl CoA is converted to **malonyl CoA**, which serves as the immediate donor of the two-carbon units that are added to the growing fatty acid chain on the fatty acid synthase complex. To synthesize malonyl CoA, **acetyl CoA carboxylase** adds a carboxyl group to acetyl CoA in a reaction that requires biotin and adenosine triphosphate (ATP) (Fig. 31.6).

FIGURE 31.6 Reaction catalyzed by acetyl coenzyme A (acetyl CoA) carboxylase. Initially, CO_2 is covalently attached to biotin, which is linked by an amide bond to the ϵ -amino group of a lysine residue of the enzyme. Hydrolysis of adenosine triphosphate (ATP) is required for the attachment of CO_2 to biotin. Subsequently, the CO_2 is transferred to acetyl CoA to form malonyl CoA. CoA, coenzyme A; P_i , inorganic phosphate.

Acetyl CoA carboxylase is the rate-limiting enzyme of fatty acid synthesis. Its activity is regulated by phosphorylation, allosteric modification, and induction/repression of its synthesis (Fig. 31.7). Citrate allosterically activates acetyl CoA carboxylase by causing the individual enzyme molecules (each composed of four subunits) to polymerize. Palmitoyl CoA, produced from palmitate (the end product of fatty acid synthase activity), inhibits acetyl CoA carboxylase. Phosphorylation by the AMP-activated protein kinase inhibits the enzyme in the fasting state when energy levels are low. Acetyl CoA carboxylase is activated by dephosphorylation in the fed state when energy and insulin levels are high. A high insulin/glucagon ratio also

results in induction of the synthesis of both acetyl CoA carboxylase and the next enzyme in the pathway, fatty acid synthase.

FIGURE 31.7 Regulation of acetyl coenzyme A (acetyl CoA) carboxylase. This enzyme is regulated allosterically, both positively and negatively, by phosphorylation (P) and dephosphorylation, and by diet-induced induction (↑). It is active in the dephosphorylated state when citrate causes it to polymerize. Dephosphorylation is catalyzed by an insulin-stimulated phosphatase. Low energy levels, via activation of the adenosine monophosphate (AMP)-activated protein kinase, cause the enzyme to be phosphorylated and inactivated. The ultimate product of fatty acid synthesis, palmitate, is converted to its coenzyme A (CoA) derivative, palmitoyl coenzyme A (palmitoyl CoA), which inhibits the enzyme. A high-calorie diet increases the rate of transcription of the gene for acetyl CoA carboxylase, whereas a low-calorie diet reduces transcription of this gene. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i, inorganic phosphate.

A The highly active adenylate kinase reaction, $2 \text{ADP} \rightleftharpoons \text{AMP} + \text{ATP}$ allows AMP to be a more sensitive indicator of low energy levels than ADP. Thus, as ADP levels increase, so do AMP levels. The ratio of $[\text{AMP}]/[\text{ATP}]$ is proportional to the square of the $[\text{ADP}]/[\text{ATP}]$ ratio. Thus, if the ratio of $[\text{ADP}]/[\text{ATP}]$ increases 5-fold, the $[\text{AMP}]/[\text{ATP}]$ may increase 25-fold. The alterations in the concentration of AMP, therefore, are a more sensitive indicator of low energy levels in the cell than alterations

in the concentration of ADP.

C. Fatty Acid Synthase Complex

As an overview, **fatty acid synthase** sequentially adds two-carbon units from malonyl CoA to the growing fatty acyl chain to form palmitate. After the addition of each two-carbon unit, the growing chain undergoes two reduction reactions that require NADPH.

Fatty acid synthase is a large enzyme composed of two identical subunits, which each have seven catalytic activities and an **acyl carrier protein (ACP)** segment in a continuous polypeptide chain. The ACP segment contains a phosphopantetheine residue that is derived from the cleavage of coenzyme A. The key feature of the ACP is that it contains a free sulfhydryl group (from the phosphopantetheine residue). The two dimers associate in a head-to-tail arrangement so that the phosphopantetheinyl sulfhydryl group on one subunit and a cysteinyl sulfhydryl group on another subunit are closely aligned.

In the **initial step** of fatty acid synthesis, an acetyl moiety is transferred from acetyl CoA to the ACP phosphopantetheinyl sulfhydryl group of one subunit and then to the cysteinyl sulfhydryl group of the other subunit. The malonyl moiety from malonyl CoA then attaches to the ACP phosphopantetheinyl sulfhydryl group of the first subunit. The acetyl and malonyl moieties condense, with the release of the malonyl carboxyl group as CO_2 . A four-carbon β -keto acyl chain is now attached to the ACP phosphopantetheinyl sulfhydryl group (Fig. 31.8).

FIGURE 31.8 Addition of a two-carbon unit to an acetyl group on fatty acid synthase (FAS). The malonyl group attaches to the phosphopantetheinyl residue (P) of the acyl carrier protein (ACP) of the fatty acid synthase. The acetyl group, which is attached to a cysteinyl sulfhydryl group, condenses with the malonyl group. CO₂ is released, and a 3-ketoacyl group is formed. The carbon that eventually forms the ω-methyl group of palmitate is labeled ω (and originates from acetyl CoA). CoA, coenzyme A; Malonyl CoA, malonyl coenzyme A.

A series of three reactions reduce the four-carbon keto group to an alcohol, then removes water to form a double bond, and finally reduces the double bond (Fig. 31.9). NADPH provides the reducing equivalents for these reactions. The net result is that the original acetyl group is elongated by two carbons.

FIGURE 31.9 Reduction of a β -ketoacyl group on the fatty acid synthase complex. Reduced nicotinamide adenine dinucleotide phosphate (NADPH) is the reducing agent.

The four-carbon fatty acyl chain is then transferred to the cysteinyl sulfhydryl group and subsequently condenses with a malonyl group. This sequence of reactions is repeated until the chain is 16 carbons in length. At this point, hydrolysis occurs, and palmitate is released (Fig. 31.10).

FIGURE 31.10 Synthesis of palmitate on the fatty acid synthase complex. Initially, acetyl coenzyme A (acetyl CoA) adds to the synthase. It provides the ω -methyl group of palmitate. Malonyl coenzyme A (Malonyl CoA) provides the two-carbon units that are added to the growing fatty acyl chain. The addition and reduction steps are repeated until palmitate is produced. (1) Transfer of the malonyl group to the phosphopantetheinyl residue. (2) Condensation of the malonyl and fatty acyl groups. (3) Reduction of the β -ketoacyl group. (4) Dehydration. (5) Reduction of the double bond. ADP, adenosine diphosphate; ATP, adenosine triphosphate; Cys-SH, a cysteinyl residue on a different subunit of the fatty acid synthase; NADP, nicotinamide adenine dinucleotide phosphate; P, a phosphopantetheinyl group attached to the fatty acid synthase complex; P_i, inorganic phosphate.

Palmitate is elongated and desaturated to produce a series of fatty acids. In the liver, palmitate and other newly synthesized fatty acids are converted to triacylglycerols that are packaged into VLDL for secretion.

In the liver, the oxidation of newly synthesized fatty acids back to acetyl CoA via the mitochondrial β -oxidation pathway is prevented by malonyl CoA. **Carnitine palmitoyltransferase I**, the enzyme involved in the transport of long-chain fatty acids into mitochondria (see Chapter 30), is inhibited by malonyl CoA (Fig. 31.11). Malonyl CoA levels are elevated when acetyl CoA carboxylase is activated, and thus fatty acid oxidation is inhibited while fatty acid synthesis is proceeding. This inhibition prevents the occurrence of a futile cycle.

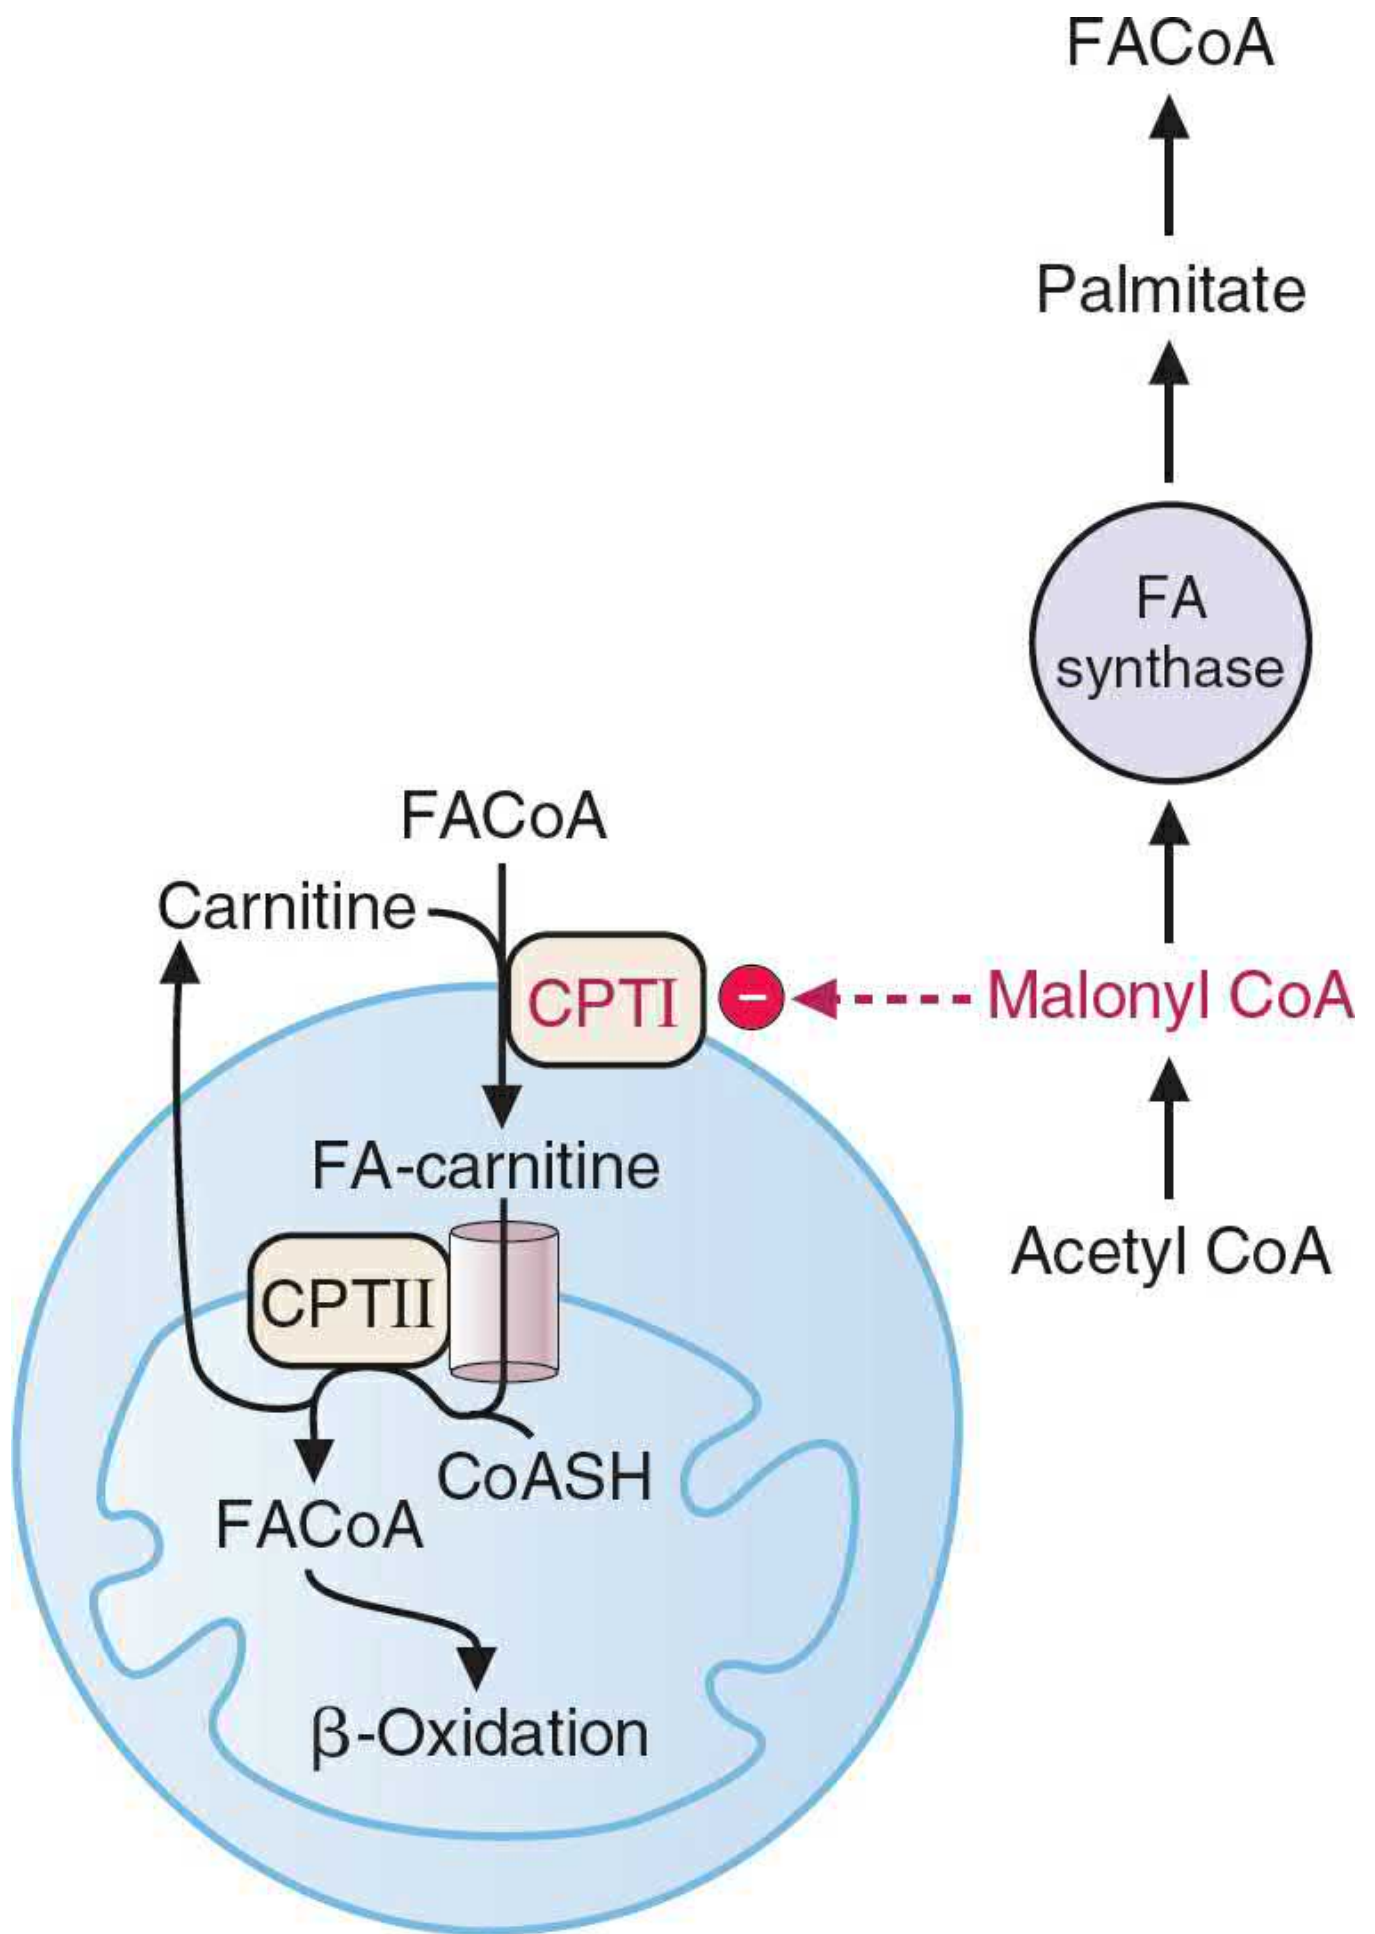

FIGURE 31.11 Inhibition of carnitine palmitoyltransferase I (CPTI, also called carnitine acyltransferase I) by malonyl coenzyme A (malonyl CoA). During fatty acid (FA) synthesis, malonyl CoA levels are high. This compound inhibits CPTI, which is involved in the transport of long-chain fatty acids into mitochondria for β -oxidation. This mechanism prevents newly synthesized fatty acids from undergoing immediate oxidation. Acetyl CoA, acetyl coenzyme A; CPTII, carnitine palmitoyltransferase II.

D. Elongation of Fatty Acids

After synthesis on the fatty acid synthase complex, palmitate is activated, forming palmitoyl CoA. Palmitoyl CoA and other activated long-chain fatty acids can be elongated, two carbons at a time, by a series of reactions that occur in the endoplasmic reticulum (Fig. 31.12). Malonyl CoA serves as the donor of the two-carbon units, and NADPH provides the reducing equivalents. The series of elongation reactions resemble those of fatty acid synthesis except that the fatty acyl chain is attached to coenzyme A rather than to the phosphopantetheinyl residue of an ACP. The major elongation reaction that occurs in the body involves the conversion of palmitoyl CoA (C16) to stearyl CoA (C18). Very-long-chain fatty acids (C22 to C24) are also produced, particularly in the brain.

FIGURE 31.12 Elongation of long-chain fatty acids in the endoplasmic reticulum. The example shown is palmitoyl CoA being extended to stearoyl CoA. CoA, coenzyme A; Malonyl CoA, malonyl coenzyme A; NADP, nicotinamide adenine dinucleotide phosphate.

Where does the methyl group of the first acetyl CoA that binds to fatty acid synthase appear in palmitate, the final product?

The methyl group of acetyl CoA becomes the ω -carbon (the terminal methyl group) of palmitate. Each new two-carbon unit is added to the carboxyl end of the growing fatty acyl chain (see Fig. 31.8).

E. Desaturation of Fatty Acids

Desaturation of fatty acids involves a process that requires molecular oxygen (O_2), NADH, and cytochrome b_5 . The reaction, which occurs in the endoplasmic reticulum, results in the oxidation of both the fatty acid and NADH (Fig. 31.13). The most common desaturation reactions involve the placement of a double bond between carbons 9 and 10 in the conversion of palmitic acid to palmitoleic acid (16:1, Δ^9) and the conversion of stearic acid to oleic acid (18:1, Δ^9). Other positions that can be desaturated in humans include carbons 5 and 6.

FIGURE 31.13 Desaturation of fatty acids. The process occurs in the endoplasmic reticulum and uses molecular oxygen. Both the fatty acid and reduced nicotinamide adenine dinucleotide (NADH) are oxidized. Human desaturases cannot introduce double bonds between carbon 9 and the methyl end and are limited to positions 5, 6, and 9. Therefore, m is ≤ 7 . CoA, coenzyme A; cyt, cytochrome; FAD, flavin adenine dinucleotide; Fatty acyl CoA, fatty acyl coenzyme A.

Polyunsaturated fatty acids with double bonds three carbons from the methyl end ($\omega 3$ fatty acids) and six carbons from the methyl end ($\omega 6$ fatty acids) are required for the synthesis of eicosanoids (see Section II of this chapter). Because humans cannot synthesize these fatty acids *de novo* (i.e., from glucose via palmitate), they must be present in the diet or the diet must contain other fatty acids that can be converted to these fatty acids. We obtain $\omega 6$ and $\omega 3$ polyunsaturated fatty acids mainly from dietary plant oils that contain the $\omega 6$ fatty acid linoleic acid (18:2, $\Delta^{9,12}$) and the $\omega 3$ fatty acid α -linolenic acid (18:3, $\Delta^{9,12,15}$). Linoleic and linolenic acids are thus considered essential fatty acids for the human diet. In the body, linoleic acid can be converted by elongation and desaturation reactions to arachidonic acid (20:4, $\Delta^{5,8,11,14}$), which is used for the synthesis of the major class of human prostaglandins and other eicosanoids (Fig. 31.14). Elongation and desaturation of α -linolenic acid produce eicosapentaenoic acid (EPA; 20:5, $\Delta^{5,8,11,14,17}$), which is the precursor of a different class of eicosanoids (see Section II).

Linoleoyl CoA ($\Delta^{9,12}$ -octadecadienoyl CoA)

γ -Linolenoyl CoA ($\Delta^{6,9,12}$ -octadecatrienoyl CoA)

Dihomo- γ -linolenoyl CoA ($\Delta^{8,11,14}$ -eicosatrienoyl CoA)

Arachidonyl CoA ($\Delta^{5,8,11,14}$ -eicosatetraenoyl CoA)

FIGURE 31.14 Conversion of linoleic acid to arachidonic acid. Dietary linoleic acid (as linoleoyl CoA) is desaturated at carbon

6, elongated by two carbons, and then desaturated at carbon 5 to produce arachidonyl CoA. CoA, coenzyme A; NAD, nicotinamide adenine dinucleotide.

Plants are able to introduce double bonds into fatty acids in the region between C10 and the ω -end and, therefore, can synthesize ω 3 and ω 6 polyunsaturated fatty acids. Fish oils also contain ω 3 and ω 6 fatty acids, particularly eicosapentaenoic acid (EPA; ω 3, 20:5, $\Delta^{5,8,11,14,17}$) and docosahexaenoic acid (DHA; ω 3, 22:6, $\Delta^{4,7,10,13,16,19}$). The fish obtain these fatty acids by eating phytoplankton (plants that float in water).

Arachidonic acid is listed in some textbooks as an essential fatty acid. Although it is an ω 6 fatty acid, it is not essential in the diet if linoleic acid is present because arachidonic acid can be synthesized from dietary linoleic acid (see Fig. 31.14).

The essential fatty acid linoleic acid is required in the diet for at least three reasons. (1) It serves as a precursor of arachidonic acid from which eicosanoids are produced. (2) It covalently binds another fatty acid attached to cerebrosides in the skin, forming an unusual lipid (acylglucosylceramide) that helps to make the skin impermeable to water. This function of linoleic acid may help to explain the red, scaly dermatitis and other skin problems associated with a dietary deficiency of essential fatty acids. (3) It is the precursor of important neuronal fatty acids.

II. Synthesis of the Eicosanoids

Eicosanoids (“eicosa” is the Greek word for the number 20) are biologically active lipids, derived from 20 carbon fatty acids. They consist primarily of the prostaglandins, thromboxanes, and leukotrienes. These lipids are the most potent regulators of cellular function in nature and are produced by almost every cell in the body. They act mainly as “local” hormones, affecting the cells that produce them or neighboring cells of a different type.

Eicosanoids participate in many processes in the body, particularly the **inflammatory response** that occurs after **infection** or **injury**. The inflammatory response is the sum of the body’s efforts to destroy invading organisms and to repair damage. It includes control of bleeding through the formation of blood clots. In the process of protecting the body from a variety of insults, the inflammatory response can produce **symptoms** such as **pain**, **swelling**, and **fever**. An exaggerated or inappropriate expression of the normal inflammatory response may occur in individuals who have **allergic** or **hypersensitivity** reactions.

In addition to participating in the inflammatory response, eicosanoids also regulate **smooth muscle contraction** (particularly in the intestine and uterus). They increase **water** and **sodium excretion** by the kidney and are involved in **regulating blood pressure**. They frequently serve as modulators; some eicosanoids stimulate and others inhibit the same process. For example, some serve as constrictors and others as dilators of blood vessels. They are also involved in regulating **bronchoconstriction** and **bronchodilation**.

A. Source of the Eicosanoids

The most abundant, and therefore the most common precursor of the eicosanoids is arachidonic acid (C20:4, Δ 5, 8, 11, 14), a polyunsaturated fatty acid with 20 carbons and four double bonds. Because arachidonic acid cannot be synthesized in the body (it is an ω -6 fatty acid), the diet must contain arachidonic acid or other fatty acids from which arachidonic acid can be produced (such as linoleic acid, found in plant oils). An overview of eicosanoid biosynthesis is shown in Figure 31.15.

FIGURE 31.15 Overview of eicosanoid metabolism. Eicosanoids are produced from fatty acids released from membrane phospholipids. In humans, arachidonic acid is the major precursor of the eicosanoids, which include the prostaglandins (PG), leukotrienes (LT), and thromboxanes (TX). ⊖ “inhibits”; cyt, cytochrome; NSAID, nonsteroidal anti-inflammatory drug.

The arachidonic acid present in membrane phospholipids is released from the lipid bilayer as a consequence of the activation of membrane-bound phospholipase A₂ or C (see Fig. 31.15). This activation occurs when a

variety of stimuli (agonists), such as histamine or the cytokines interact with a specific plasma membrane receptor on the target cell surface. Phospholipase A₂ is specific for the sn-2 position of phosphoacylglycerols, the site of attachment of arachidonic acid to the glycerol moiety. Phospholipase C, conversely, hydrolyzes phosphorylated inositol from the inositol glycerophospholipids, generating a diacylglycerol containing arachidonic acid. This arachidonic acid is subsequently released by the action of other lipases.

B. Pathways for Eicosanoid Synthesis

After arachidonic acid is released into the cytosol, it is converted to eicosanoids by a variety of enzymes with activities that vary among tissues. This variation explains why some cells, such as those in the vascular endothelium, synthesize prostaglandins E₂ and I₂ (PGE₂ and PGI₂), whereas cells such as platelets synthesize primarily thromboxane A₂ (TXA₂) and 12-hydroxyeicosatetraenoic acid (12-HETE).

Three major pathways for the metabolism of arachidonic acid occur in various tissues (Fig. 31.16). The first of these, the cyclooxygenase pathway, leads to the synthesis of prostaglandins and thromboxanes. The second, the lipoxygenase pathway, yields the leukotrienes, HETEs, and lipoxins. The third pathway, catalyzed by the cytochrome P450 system, is responsible for the synthesis of the epoxides, HETEs, and diHETEs. Only the **cyclooxygenase pathway** will be discussed further in this text. Information about the other pathways can be found in the Chapter 31 online supplement to the text. 

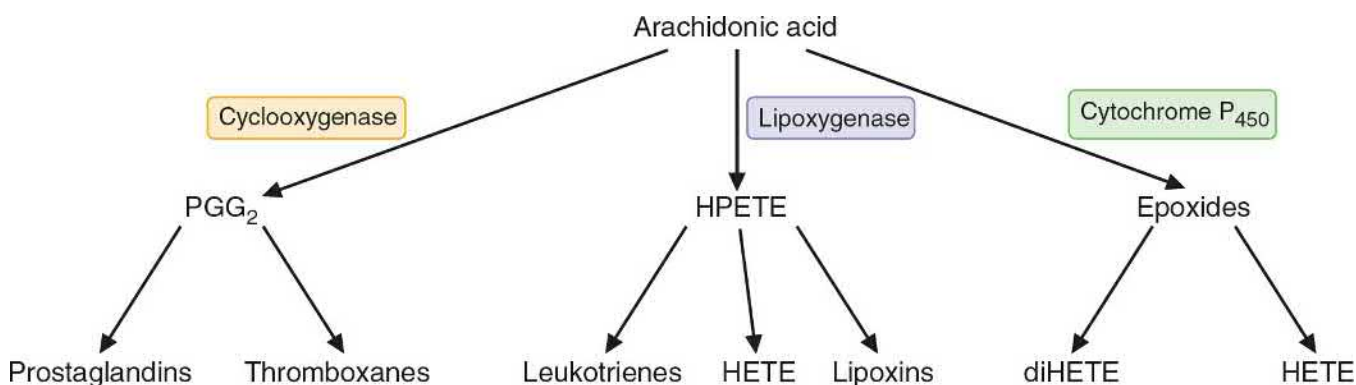

FIGURE 31.16 Pathways for the metabolism of arachidonic acid. diHETE, dihydroxyeicosatetraenoic acid; HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid; PG, prostaglandin.

C. Cyclooxygenase Pathway: Synthesis of the Prostaglandins and Thromboxanes

1. Structures of the Prostaglandins

Prostaglandins are fatty acids containing 20 carbon atoms, including an internal 5-carbon ring. In addition to this ring, each of the biologically active prostaglandins has a hydroxyl group at carbon 15, a double bond between carbons 13 and 14, and various substituents on the ring.

The nomenclature for the prostaglandins (PGs) involves the assignment of a capital letter (PGE), an Arabic numeral subscript (PGE₁), and, for the PGF family, a Greek letter subscript (e.g., PGF_{2α}). The capital letter, in this case, “F,” refers to the ring substituents shown in Figure 31.17.

PGA

PGD

PGE

PGF_α

PGG or PGH

PGI

FIGURE 31.17 Ring substituents of the prostaglandins (PG). The letter after PG denotes the configuration of the ring and its substituents. R₄, R₇, and R₈ represent the nonring portions of the molecule. R₄ contains four carbons (including the carboxyl group). R₇ and R₈ contain seven and eight carbons, respectively. Note that the prostacyclins (PGI) contain two rings.

The subscript that follows the capital letter (PGF₁) refers to the PG series 1, 2, or 3, determined by the number of unsaturated bonds present in the linear portion of the hydrocarbon chain. It does not include double bonds in the internal ring. Prostaglandins of the 1-series have one double bond (between carbons 13 and 14). The 2-series has two double bonds (between carbons 13 and 14, and 5 and 6), and the 3-series has three double bonds (between carbons 13 and 14, 5 and 6, and 17 and 18). The double bonds between carbons 13 and 14 are *trans*; the others are *cis*. The precursor for the 1-series of prostaglandins is *cis* Δ^{8,11,14} eicosatrienoic acid; for the 2-series, it is arachidonic acid; for the 3-series, it is *cis* Δ^{5,8,11,14,17} eicosapentaenoic acid.

M The measurement of prostaglandin levels, in plasma or urine, is best done by radioimmunoassay (see “Biochemical Comments,” Chapter 43). Antibodies specific for each prostaglandin, or thromboxane form, are commercially available, and through competition with a standard amount of antigen, one can determine the concentration of the metabolite in the biological fluid. Recently, a more sensitive technique has been developed, which can assay prostaglandin levels as low as 40 pg/mL. This technique is called fluorescent polarization immunoassay (FPIA). The method is based on the properties of small, fluorescent molecules. Molecules that fluoresce absorb light at a particular wavelength, and will emit light of a lower wavelength (the fluorescence). If one excites a small fluorophore with polarized light, the fluorescence will be polarized if the molecule rotates slowly; if the molecule rotates rapidly the emitted light will not be polarized. If, then, the fluorophore is bound to a much larger molecule, such as an antibody, its rotation would be greatly diminished, and the fluorescent signal emitted will be highly polarized. One can, therefore, measure the polarization of the emitted light as a function of how much fluorescent standard is bound to the antibody. For these assays, a known amount of a fluorescent prostaglandin is incubated with the samples; if the sample contains non-fluorescent prostaglandin it will compete for binding with the fluorescent prostaglandin, relegating some fluorescent prostaglandin to being non-bound. When the excitation light hits the sample, the amount of polarization will decrease in proportion to the amount of fluorescent prostaglandin displaced from the antibody. Through the use of a standard curve, one can then calculate the level of prostaglandin in the sample to very low levels.

The Greek letter subscript, found only in the F series, refers to the position of the hydroxyl group at carbon 9. This hydroxyl group primarily exists in the α position, where it lies below the plane of the ring, as does the hydroxyl group at carbon 11.

2. Structure of the Thromboxanes

The **thromboxanes**, derived from arachidonic acid via the cyclooxygenase pathway, closely resemble the prostaglandins in structure except that they contain a six-membered ring that includes an oxygen atom (see Fig. 31.15). The most common thromboxane, TXA₂, contains an additional oxygen atom attached both to carbon 9 and carbon 11 of the ring. The thromboxanes were named for their action in producing blood clots (thrombi).

3. Biosynthesis of the Prostaglandins and Thromboxanes

Only the biosynthesis of those prostaglandins derived from arachidonic acid (e.g., the 2-series, such as PGE₂, PGI₂, TXA₂) are described because those derived from eicosatrienoic acid (the 1-series) or from eicosapentaenoic acid (the 3-series) are present in very small amounts in humans on a normal diet.

The biochemical reactions that lead to the synthesis of prostaglandins and thromboxanes are illustrated in Figure 31.18. The initial step, which is catalyzed by a cyclooxygenase, forms the five-membered ring and adds four atoms of oxygen (two between carbons 9 and 11, and two at carbon 15) to form the unstable endoperoxide, PGG₂. The hydroperoxy group at carbon 15 is quickly reduced to a hydroxyl group by a peroxidase to form another endoperoxide, PGH₂.

FIGURE 31.18 Formation of prostaglandins (including the prostacyclin PGI₂) and thromboxane TXA₂ from arachidonic acid. The conversion of arachidonic acid to PGH₂ is catalyzed by a membrane-bound enzyme, prostaglandin-endoperoxide synthase, which has cyclooxygenase and peroxidase activities. The reducing agent is glutathione (GSH), which is oxidized to form a disulfide between the two glutathione molecules (GSSG).

The predominant eicosanoid in platelets is TXA₂, a potent vasoconstrictor and a stimulator of platelet aggregation. The latter action initiates thrombus formation at sites of vascular injury as well as in the vicinity of a ruptured atherosclerotic plaque in the lumen of vessels such as the coronary arteries. Such thrombi may cause sudden total occlusion of the vascular lumen, causing acute ischemic damage to tissues distal to the block (i.e., acute myocardial infarction).

Aspirin, by covalently acetylating the active site of cyclooxygenase, blocks the production of TXA₂ from its major precursor, arachidonic acid. By causing this mild hemostatic defect, low-dose aspirin has been shown to be effective in prevention of acute myocardial infarction. For **Ivan A.** (who has symptoms of coronary heart disease), aspirin is used to prevent a first heart attack (primary prevention). For **Anne J.** and **Cora N.** (who already have had heart attacks), aspirin is used in hopes of preventing a second heart attack (secondary prevention).

The next step is tissue-specific (see Fig. 31.18). Depending on the type of cell involved, PGH₂ may be reduced to PGE₂ or PGD₂ by specific enzymes (PGE synthase and PGD synthase). PGE₂ may be further reduced by PGE 9-ketoreductase to form PGF_{2α}. PGF_{2α} also may be formed directly from PGH₂ by the action of an endoperoxide reductase. Some of the major functions of the prostaglandins are listed in Table 31.1.

TABLE 31.1 Some Functions of the Prostaglandins

PGI ₂ , PGE ₂ , PGD ₂	PGF ₂ α
Increases	Increases
Vasodilation	Vasoconstriction
cAMP	Bronchoconstriction
Decreases	Smooth muscle contraction

T-cell proliferation	
Lymphocyte migration	

cAMP, cyclic adenosine monophosphate; PG, prostaglandin.

^aIL, interleukin, a cytokine that augments the activity of many cells in the immune system.

PGH₂ may be converted to the thromboxane TXA₂, a reaction catalyzed by TXA synthase (see Fig. 31.18). This enzyme is present in high concentration in platelets. In the vascular endothelium, however, PGH₂ is converted to the prostaglandin PGI₂ (prostacyclin) by PGI synthase (see Fig. 31.18). TXA₂ and PGI₂ have important antagonistic biological effects on vasomotor and smooth muscle tone and on platelet aggregation. Some of the known functions of the thromboxanes are listed in Table 31.2.

Bronchoconstriction

In the 1990s, the cyclooxygenase enzyme was found to exist as two distinct isoforms, designated COX-1 and COX-2. COX-1 is regarded as a constitutive form of the enzyme, is widely expressed in almost all tissues, is the only form expressed in mature platelets, and is involved in the production of prostaglandins and thromboxanes for “normal” physiological functions. COX-2 is an inducible form of the enzyme regulated by a variety of cytokines and growth factors. COX-2 mRNA and protein levels are usually low in most healthy tissue but are expressed at high levels in inflamed tissue.

Diets that include cold-water fish (e.g., salmon, mackerel, brook trout, herring), with a high content of polyunsaturated fatty acids, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA), result in a high content of these fatty acids in membrane phospholipids. It has been suggested that such diets are effective in preventing heart disease, in part because they lead to the formation of more TXA₃ relative to TXA₂. TXA₃ is less effective in stimulating platelet aggregation than its counterpart in the 2-series, TXA₂.

Because of the importance of prostaglandins in mediating the inflammatory response, drugs that block prostaglandin production should provide relief from pain. The cyclooxygenase enzyme is inhibited by all nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin (acetylsalicylic acid). Aspirin transfers an acetyl group to the enzyme, irreversibly inactivating it (Fig. 31.19). Other NSAIDs (e.g., ibuprofen, naproxen) act as reversible inhibitors of cyclooxygenase. Ibuprofen is the major ingredient in popular over-the-counter NSAIDs such as Motrin, Nuprin, and Advil (see Fig. 31.19). Although they have some relative selectivity for inhibiting either COX-1 or COX-2, NSAIDs block the activity of both isoforms. These findings provided the impetus for the development of selective COX-2 inhibitors, which act as potent anti-inflammatory agents by inhibiting COX-2 activity, but with less gastrointestinal and antiplatelet side effects than commonly associated with NSAID use. These adverse effects of NSAIDs are thought to be caused by COX-1 inhibition. However, the selective COX-2 inhibitors were found to have an increase in adverse cardiovascular events and several COX-2 inhibitors were withdrawn from the market. Celecoxib (Celebrex), an example of a selective COX-2 inhibitor, remains on the market with a boxed warning. Some properties of COX-1 and COX-2 are indicated in

Table 31.3.

TABLE 31.3 Properties of COX-1 and COX-2		
	COX-1	COX-2
Primary function	Platelet aggregation, stomach cytoprotection	Inflammation, hyperalgesia
Response to:		
NSAIDs	Decreased activity	Decreased activity
Steroids	No effect	Decreased synthesis and activity
COX-2 inhibitor	No effect	Decreased activity

Data adapted from Patrono and Baigent (see References ) indicate that low-dose aspirin (50 to 100 mg/day) reduces platelet TXA₂ levels by 97%, with no effect on whole-body PGI₂, thereby leading to cardioprotection. High-dose aspirin (650 to 1,300 mg/day), in addition to reducing TXA₂ levels, also reduced PGI₂ levels by 60% to 80%. Cox-II specific inhibitors, at high levels, had no effect on TXA₂ levels but reduced whole-body PGI₂ levels by 60% to 80%, leading to an increased risk of myocardial infarction.

FIGURE 31.19 Action of aspirin and other nonsteroidal anti-inflammatory drugs.

Although the COX-2 inhibitors did relieve the development of gastrointestinal ulcers in patients taking NSAIDs, further studies indicated that specific COX-2 inhibitors may have a negative effect on cardiovascular function. Vioxx was withdrawn from the market by its manufacturer because of these negative patient studies. It has been postulated that long-term use of COX-2 inhibitors alter the balance of prostacyclin (antithrombotic, PGI₂) and thromboxane (prothrombotic) because platelets, the major source of the thromboxanes, do not express COX-2 and thromboxane synthesis is not reduced with COX-2 inhibitors (see Fig. 31.18 and Table 31.3). This will tilt the balance of the eicosanoids synthesized toward a thrombotic pathway. The COX-2 inhibitors that remain on the market must be used with caution, as they are contraindicated in patients with ischemic heart disease or stroke.

4. Inactivation of the Prostaglandins and Thromboxanes

Prostaglandins and thromboxanes are rapidly inactivated. Their half-lives ($t_{1/2}$) range from seconds to minutes. The prostaglandins are inactivated by oxidation of the 15-hydroxy group, critical for their activity, to a ketone. The double bond at carbon 13 is reduced. Subsequently, both β - and ω -oxidation of the nonring portions occur, producing dicarboxylic acids that are excreted in the urine. Active TXA₂ is rapidly metabolized to TXB₂ by

cleavage of the oxygen bridge between carbons 9 and 11 to form two hydroxyl groups. TXB₂ has no biological activity.

D. Mechanism of Action of the Eicosanoids

The eicosanoids have a wide variety of physiological effects, which are generally initiated through the interaction of the eicosanoid with a specific receptor on the plasma membrane of a target cell (Table 31.4). This eicosanoid-receptor binding either activates the adenylate cyclase-cAMP-protein kinase A system (PGE, PGD, and PGI series) or causes an increase in the level of calcium in the cytosol of target cells (PGF₂α, TXA₂, the endoperoxides, and the leukotrienes).

RECEPTOR	TYPE OF LIGAND	G-PROTEIN COUPLED	cAMP RESPONSE	CALCIUM RESPONSE
DP	PGD series	Yes	Increase	Increase
CRTH2	PGD series	Yes	Decrease	Increase
EPI	PGE series	Yes	None	Increase
EP2	PGE series	Yes	Increase	None
EP3	PGE series	Yes	Decrease	None
EP4	PGE series	Yes	Increase	None
FP	PGF series	Yes	None	Increase
IP	PGI series	Yes	Increase or decrease ^a	None
TP	Thromboxane A	Yes	Increase or decrease ^b	Increase

cAMP, cyclic adenosine monophosphate; PG, prostaglandin.

^aDepends on a modification of the C-terminal of the receptor.

^bDepends on cell type responding to the ligand.

In some systems, the eicosanoids appear to modulate the degree of activation of adenylate cyclase in response to other stimuli. In these instances, the eicosanoid may bind to a regulatory subunit of the guanosine triphosphate (GTP)-binding proteins (G-proteins) within the plasma membrane of the target cell (see Chapter 10). If the eicosanoid binds to the stimulatory subunit, the effect of the stimulus is amplified. Conversely, if the eicosanoid binds to the inhibitory subunit, the cellular response to the stimulus is reduced. Through these influences on the activation of adenylate cyclase, eicosanoids contribute to the regulation of cell function.

Although our knowledge of the spectrum of biological actions of the endogenous eicosanoids is incomplete, several actions are well enough established to allow their application in a variety of clinical situations or diseases. For example, drugs that are analogs of PGE₁ and PGE₂ suppress gastric ulceration, in part by inhibiting the secretion of hydrochloric acid in the mucosal cells of the stomach. Analogs of PGE₁ are used in the treatment of sexual impotence. Men with certain forms of sexual impotence can self-inject this agent into the corpus cavernosum of the penis to induce immediate but temporary penile tumescence. The erection lasts for 1 to 3 hours. The stimulatory action of PGE₂ and PGF₂α on uterine muscle contraction has led to the use of these prostaglandins to induce labor and to control postpartum bleeding. PGE₁ is also used as palliative therapy in neonates with congenital heart defects to maintain patency of the ductus arteriosus until surgery can be performed. Analogs of PGI₂ have been shown to be effective in the treatment of primary pulmonary hypertension.

Some of the biological effects of certain eicosanoids occur as a result of a paracrine or autocrine action. One paracrine action is the contraction of vascular smooth muscle cells caused by TXA₂ released from circulating platelets (vasoconstriction). An autocrine action of eicosanoids is exemplified by platelet aggregation induced by TXA₂ produced by the platelets themselves.

The eicosanoids influence the cellular function of almost every tissue of the body. Certain organ systems

are affected to a greater degree than others.

III. Synthesis of Triacylglycerols and VLDL Particles

In liver and adipose tissue, **triacylglycerols** are produced by a pathway that contains a phosphatidic acid intermediate (Fig. 31.20). Phosphatidic acid is also the precursor of the glycerolipids found in cell membranes and the blood lipoproteins.

FIGURE 31.20 Synthesis of triacylglycerol in liver and adipose tissue. Glycerol 3-phosphate is produced from glucose in both tissues. It is also produced from glycerol in liver, but not in adipose tissue, which lacks glycerol kinase. The steps from glycerol 3-phosphate are the same in the two tissues. ADP, adenosine diphosphate; ATP, adenosine triphosphate; CoA, coenzyme A; DHAP, dihydroxyacetone phosphate; FA, fatty acyl group; NAD, nicotinamide adenine dinucleotide; VLDL, very-low-density lipoprotein.

The sources of glycerol 3-phosphate, which provides the glycerol moiety for triacylglycerol synthesis, differ in liver and adipose tissue. In liver, glycerol 3-phosphate is produced from the phosphorylation of glycerol by glycerol kinase or from the reduction of dihydroxyacetone phosphate derived from glycolysis. White adipose tissue lacks glycerol kinase and can produce glycerol 3-phosphate only from glucose via dihydroxyacetone phosphate. Thus, adipose tissue can store fatty acids only when glycolysis is activated, that is, in the fed state.

In both adipose tissue and liver, triacylglycerols are produced by a pathway in which glycerol 3-phosphate reacts with fatty acyl CoA to form phosphatidic acid. Dephosphorylation of phosphatidic acid produces diacylglycerol. Another fatty acyl CoA reacts with the diacylglycerol to form a triacylglycerol (see Fig. 31.20).

The gene for glycerol kinase is located on the X-chromosome, close to the DMD gene (which codes for dystrophin) and the NROB1 gene, which codes for a protein designated as DAX1. DAX1 is critical for the development of the adrenal glands, pituitary, hypothalamus, and gonads. Complex glycerol kinase deficiency results from a contiguous deletion of the X-chromosome, which deletes all or part of the glycerol kinase gene along with the NROB1 gene and/or the DMD gene. The patient exhibits adrenal insufficiency, hyperglycerolemia, and, if the DMD gene is deleted, Duchenne muscular dystrophy.

The triacylglycerol, which is produced in the smooth endoplasmic reticulum of the liver, is packaged with cholesterol, phospholipids, and proteins (synthesized in the rough endoplasmic reticulum) to form VLDL (Fig. 31.21, see Fig. 29.7). The microsomal triglyceride transfer protein (MTP), which is required for chylomicron assembly, is also required for VLDL assembly. The major protein of VLDL is apolipoprotein B-100 (apoB-100). There is one long apoB-100 molecule wound through the surface of each VLDL particle. ApoB-100 is encoded by the same gene as the apoB-48 of chylomicrons, but it is a longer protein. In intestinal cells, RNA editing produces a stop codon in the mRNA produced by the gene and a protein which is 48% the size of apoB-100 (apoB-48, see Fig. 15.19).

FIGURE 31.21 Composition of a typical very-low-density lipoprotein (VLDL) particle. The major component is triacylglycerol (TG). C, cholesterol; CE, cholesterol ester; PL, phospholipid.

Abetalipoproteinemia, which is due to a lack of MTP (microsomal triglyceride transfer protein; see Chapter 29) activity, results in an inability to assemble both chylomicrons in the intestine and VLDL particles in the liver.

Why do some people with alcohol use disorder have high VLDL levels?

VLDL is processed in the Golgi complex and secreted into the blood by the liver (Figs. 31.22 and 31.23). The fatty acid residues of the triacylglycerols ultimately are stored in the triacylglycerols of adipose cells. Note that, in comparison to chylomicrons (see Chapter 29), VLDL particles are more dense, as they contain a lower percentage of triglyceride (and hence more protein) than do the chylomicrons. Similar to chylomicrons, VLDL particles are first synthesized in a nascent form, and on entering the circulation they acquire apolipoproteins CII and E from HDL particles to become mature VLDL particles.

FIGURE 31.22 Synthesis of very-low-density lipoprotein (VLDL) from glucose in the liver. DHAP, dihydroxyacetone phosphate; F-1,6-BP, fructose 1,6-bisphosphate; F-6-P, fructose 6-phosphate; FA, fatty acyl group; G-6-P, glucose 6-phosphate; NADP, nicotinamide adenine dinucleotide phosphate; OAA, oxaloacetate; TG, triacylglycerol.

FIGURE 31.23 Synthesis, processing, and secretion of very-low-density lipoprotein (VLDL). Proteins synthesized on the rough endoplasmic reticulum (RER) (circle 1) are packaged with triacylglycerols in the ER and Golgi complex to form VLDL (circle 2). VLDL are transported to the cell membrane in secretory vesicles (circle 3) and secreted by exocytosis. *Red circles* represent VLDL particles. An enlarged VLDL particle is depicted at the bottom of the figure.

IV. Fate of the VLDL Triglyceride

Lipoprotein lipase (LPL), which is attached to the basement membrane proteoglycans of capillary endothelial cells, cleaves the triacylglycerols in both VLDL and chylomicrons, forming fatty acids and glycerol. Apolipoprotein CII, which these lipoproteins obtain from HDL, activates LPL. The low K_m of the muscle LPL isozyme permits muscle to use the fatty acids of chylomicrons and VLDL as a source of fuel even when the blood concentration of these lipoproteins is very low. The LPL isozyme in adipose tissue has a high K_m and is most active after a meal, when blood levels of chylomicrons and VLDL are elevated. The fate of the VLDL particle after triglyceride has been removed by LPL is the generation of an IDL particle (intermediate-density lipoprotein), which can further lose triglyceride to become an LDL particle (low-density lipoprotein). The fate of the IDL and LDL particles is discussed in Chapter 32.

The fact that a number of different abnormal lipoprotein profiles were found in **Cora N.** and her siblings, and that each had evidence of coronary artery disease, suggests that **Cora N.** has familial combined hyperlipidemia (FCH). This diagnostic impression is further supported by the finding that **Cora N.**'s profile of lipid abnormalities appeared to change somewhat from one determination to the next, a characteristic of FCH. This hereditary disorder of lipid metabolism is believed to be quite common, with an estimated prevalence of about 1 per 100 population.

The mechanisms for FCH are incompletely understood but may involve, in part, a genetically determined increase in the production of apolipoprotein B-100. As a result, packaging of VLDL is increased, and blood VLDL levels may be elevated. Depending on the efficiency of lipolysis of VLDL by LPL, VLDL levels may be normal and LDL levels may be elevated, or both VLDL and LDL levels may be high. In addition, the phenotypic expression of FCH in any given family member may be determined by the degree of associated obesity, the diet, the use of specific drugs, or other factors that change over time. Additionally, FCH may be a multigenic trait, and even though the disease appears as an autosomal dominant trait in pedigree analysis, no genes have yet been definitively linked to this condition.

V. Storage of Triacylglycerols in Adipose Tissue

After a meal, the triacylglycerol stores of adipose tissue increase (Fig. 31.24). Adipose cells synthesize LPL and secrete it into the capillaries of adipose tissue when the insulin/glucagon ratio is elevated. This enzyme digests the triacylglycerols of both chylomicrons and VLDL. The fatty acids enter adipose cells and are activated, forming fatty acyl CoA, which reacts with glycerol 3-phosphate to form triacylglycerol by the same pathway used in the liver (see Fig. 31.20). Because adipose tissue lacks glycerol kinase and cannot use the glycerol produced by LPL, the glycerol travels through the blood to the liver, which uses it for the synthesis of triacylglycerol. In adipose cells, under fed conditions, glycerol 3-phosphate is derived from glucose.

FIGURE 31.24 Conversion of the fatty acid (FA) from the triacylglycerols (TG) of chylomicrons and very-low-density lipoprotein (VLDL) to the TG stored in adipose cells. Note that insulin stimulates both the transport of glucose into adipose cells and the synthesis and secretion of lipoprotein lipase (LPL) from the cells. Glucose provides the glycerol 3-phosphate for TG synthesis. Apolipoprotein CII activates LPL. DHAP, dihydroxyacetone phosphate; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein.

A In people with alcohol use disorder, NADH levels in the liver are elevated (see Chapter 28). High levels of NADH inhibit the oxidation of fatty acids. Therefore, fatty acids, mobilized from adipose tissue, are re-esterified to glycerol 3-phosphate in the liver, forming triacylglycerols, which are packaged into VLDL and secreted into the blood. Elevated VLDL is frequently associated with chronic alcoholism. As alcohol-induced liver disease progresses, the ability to secrete the triacylglycerols is diminished, resulting in a fatty liver.

In addition to stimulating the synthesis and release of LPL, insulin stimulates glucose metabolism in adipose cells. Insulin leads to the activation of the glycolytic enzyme phosphofructokinase-1 by activation of the kinase activity of phosphofructokinase-2, which increases fructose 2,6-bisphosphate levels. Insulin also stimulates the dephosphorylation of pyruvate dehydrogenase, so that the pyruvate produced by glycolysis can be oxidized in the TCA cycle. Furthermore, insulin stimulates the conversion of glucose to fatty acids in adipose cells, although the liver is the major site of fatty acid synthesis in humans.

VI. Release of Fatty Acids from Adipose Triacylglycerols

During fasting, the decrease of insulin and the increase of glucagon cause cAMP levels to rise in adipose cells, stimulating lipolysis (Fig. 31.25). Protein kinase A phosphorylates hormone-sensitive lipase (HSL) to produce a more active form of the enzyme. Adipose triglyceride lipase (ATGL) is the rate-limiting enzyme of triglyceride degradation, and it catalyzes the conversion of triglyceride to diglyceride plus a free fatty acid. Activated HSL

converts diglyceride to monoacylglycerol plus a free fatty acid, and monoglyceride lipase converts monoacylglycerol to free glycerol and a free fatty acid.

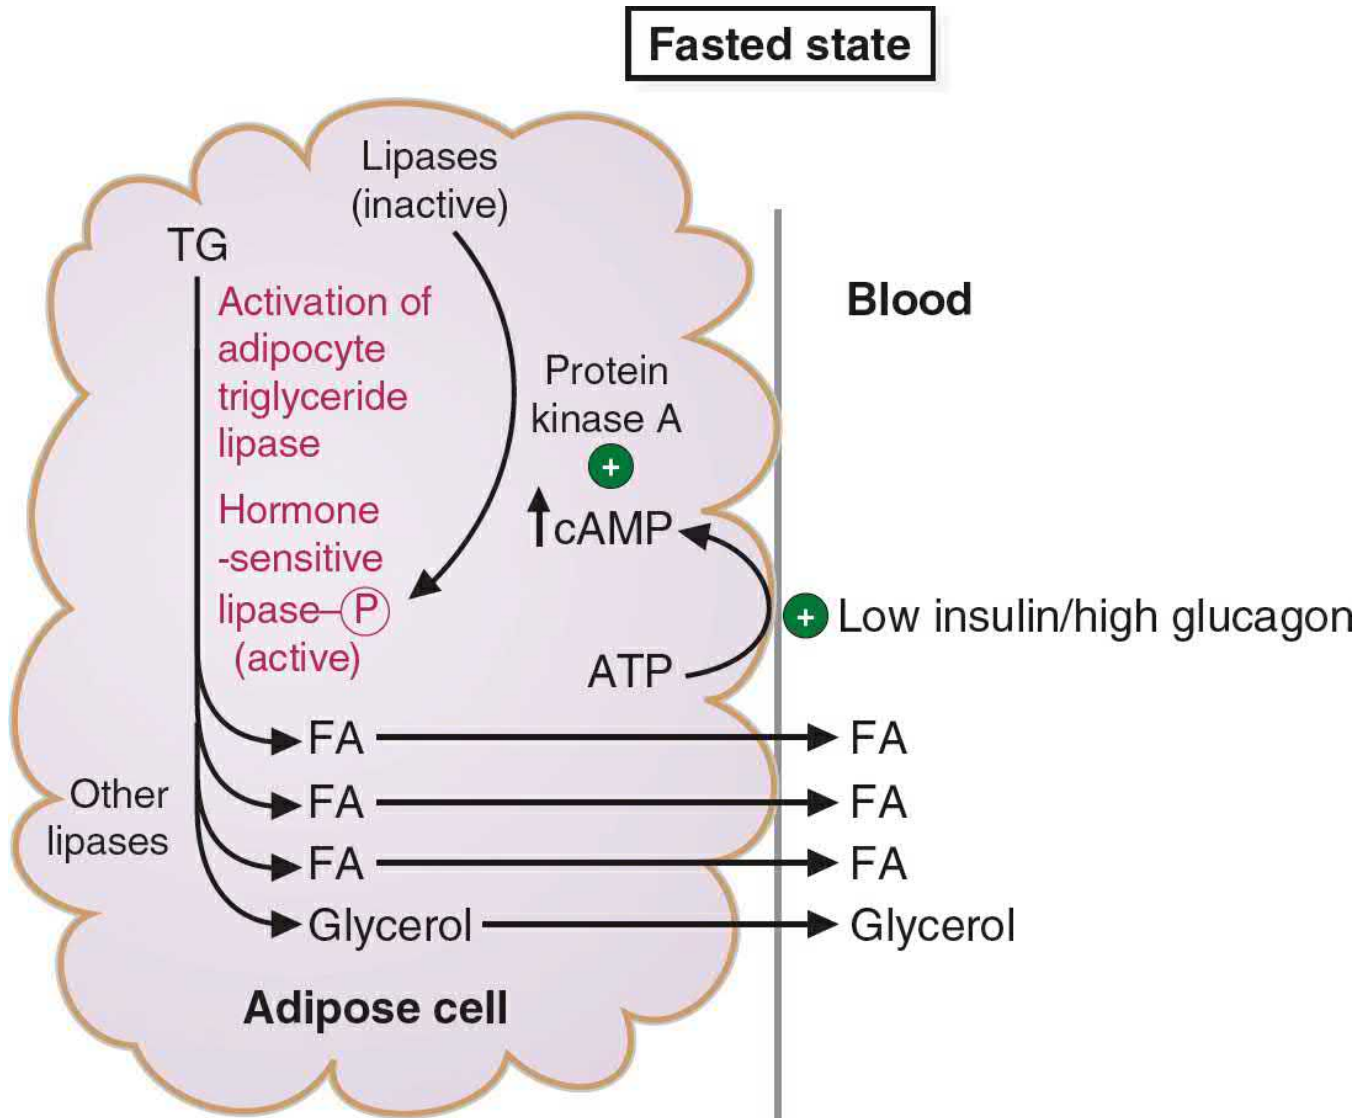

FIGURE 31.25 Mobilization of adipose triacylglycerol (TG). In the fasted state, when insulin levels are low and glucagon is elevated, intracellular cyclic adenosine monophosphate (cAMP) increases and activates protein kinase A, which phosphorylates both perilipin 1 and hormone-sensitive lipase (HSL). Phosphorylated perilipin-1 dissociates from CGI-58, which then binds to adipocyte triglyceride lipase (ATGL), activating the lipase. Phosphorylated HSL is active and participates in the breakdown of adipose TG. Reesterification of fatty acids does occur, along with the synthesis of glycerol 3-phosphate, in the fasted state, to regulate the release of fatty acids from the adipocyte. ATP, adenosine triphosphate; FA, fatty acid.

 Fatty acids for VLDL synthesis in the liver may be obtained from the blood or they may be synthesized from glucose. In a healthy individual, the major source of the fatty acids of VLDL triacylglycerol is excess dietary glucose. In individuals with diabetes mellitus, fatty acids mobilized from adipose triacylglycerols in excess of the oxidative capacity of tissues are a major source of the fatty acids re-esterified in liver to VLDL triacylglycerol. These individuals frequently have elevated levels of blood triacylglycerols.

ATGL is regulated, in part, by a protein designated as CGI-58 (comparative gene identification-58). In the basal state, CGI-58 is complexed with perilipin 1 (PLIN1), and ATGL activity is low. When PKA is activated, PLIN1 is phosphorylated, releasing bound CGI-58, which binds to ATGL to activate it. Perilipins are proteins that bind to triacylglycerol droplets and regulate their ability to be degraded. The end result, after PKA activation, is that fatty acids and glycerol are released into the blood. Simultaneously, to regulate the amount of fatty acids released into circulation, triglyceride synthesis occurs along with glyceroneogenesis (see a further explanation of glyceroneogenesis in the online supplement).  Glyceroneogenesis refers to the adipocyte

resynthesizing triglyceride from newly synthesized glycerol 3-phosphate (derived from amino acids or lactate) and free fatty acids, as a mechanism to reduce fatty acid export from the adipocyte.

Because the fatty acids of adipose triacylglycerols come both from chylomicrons and VLDL, we produce our major fat stores both from dietary fat (which produces chylomicrons) and dietary sugar (which produces VLDL). An excess of dietary protein also can be used to produce the fatty acids for VLDL synthesis. The dietician carefully explained to **Percy V.** that we can become fat from eating excess fat, excess sugar, or excess protein.

The fatty acids, which travel in the blood complexed with albumin, enter cells of muscle and other tissues, where they are oxidized to CO₂ and water to produce energy. During prolonged fasting, acetyl CoA produced by β-oxidation of fatty acids in the liver is converted to ketone bodies, which are released into the blood. The glycerol derived from lipolysis in adipose cells is used by the liver during fasting as a source of carbon for gluconeogenesis.

VII. Metabolism of Glycerophospholipids and Sphingolipids

Fatty acids, obtained from the diet or synthesized from glucose, are the precursors of **glycerophospholipids** and of **sphingolipids** (Fig. 31.26). These lipids are major components of cellular membranes. Glycerophospholipids are also components of blood lipoproteins, bile, and lung surfactant. They are the source of the polyunsaturated fatty acids, particularly arachidonic acid, that serve as precursors of the eicosanoids. **Ether glycerophospholipids** differ from other glycerophospholipids in that the alkyl or alkenyl chain (an alkyl chain with a double bond) is joined to carbon 1 of the glycerol moiety by an ether rather than an ester bond. Examples of ether lipids are the plasmalogens and PAF. Sphingolipids are particularly important in forming the myelin sheath surrounding nerves in the central nervous system, and in signal transduction.

FIGURE 31.26 Types of glycerolipids and sphingolipids. Glycerolipids contain glycerol, and sphingolipids contain sphingosine. The category of phospholipids overlaps both glycerolipids and sphingolipids. The head groups include choline, ethanolamine, serine, inositol, glycerol, and phosphatidylglycerol. The carbohydrates are monosaccharides (which may be sulfated), oligosaccharides, and oligosaccharides with branches of *N*-acetylneuraminic acid. P, phosphate.

In some cases of hyperlipidemia, LPL is defective. If a blood lipid profile is performed on patients with an LPL deficiency, which lipids will be elevated?

In glycerolipids and ether glycerolipids, glycerol serves as the backbone to which fatty acids and other substituents are attached. Sphingosine, derived from serine, provides the backbone for sphingolipids.

A. Synthesis of Phospholipids Containing Glycerol

1. Glycerophospholipids

The initial steps in the synthesis of glycerophospholipids are similar to those of triacylglycerol synthesis. Glycerol 3-phosphate reacts with two activated fatty acids to form phosphatidic acid. Two different mechanisms are then used to add a head group to the molecule (Fig. 31.27). A head group is a chemical group, such as choline or serine, attached to the phosphate on carbon 3 of a glycerol moiety that contains hydrophobic groups, usually fatty acids, at positions 1 and 2. Head groups are hydrophilic, either charged or polar. The head groups all contain a free hydroxyl group, which is used to link to the phosphate on carbon 3 of the glycerol backbone.

FIGURE 31.27 Strategies for addition of the head group to form glycerophospholipids. In both cases, cytidine triphosphate (CTP) is used to drive the reaction. CDP, cytidine diphosphate; CMP, cytidine monophosphate. Pi, inorganic phosphate; PPi, pyrophosphate.

A Individuals with a defective LPL have high blood triacylglycerol levels. Their levels of chylomicrons and VLDL (which contain large amounts of triacylglycerols) are elevated because they are not digested at the normal rate by LPL.

In the first mechanism, phosphatidic acid is cleaved by a phosphatase to form diacylglycerol (DAG). DAG then reacts with an activated head group. In the synthesis of phosphatidylcholine, the head group choline is activated by combining with CTP to form CDP-choline (Fig. 31.28). Phosphocholine is then transferred to carbon 3 of DAG, and CMP is released. Phosphatidylethanolamine is produced by a similar reaction involving CDP-ethanolamine.

FIGURE 31.28 Synthesis of phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine. The multiple pathways reflect the importance of phospholipids in membrane structure. For example, phosphatidylcholine (PC) can be synthesized from dietary choline when it is available. If choline is not available, PC can be made from dietary carbohydrate, although the amount synthesized is inadequate to prevent choline deficiency. SAM is S-adenosylmethionine, a methyl group donor for many biochemical reactions (see Chapter 38). CDP, cytidine diphosphate; CMP, cytidine monophosphate.

 Phosphatidylcholine (lecithin) is not required in the diet because it can be synthesized in the body. The components of phosphatidylcholine (including choline) all can be produced, as shown in Figure 31.28. A pathway for de novo choline synthesis from glucose exists, but the rate of synthesis is inadequate to provide for the necessary amounts of choline. Thus, choline has been classified as an essential nutrient, with an AI (adequate intake) of 425 mg/day in women and 550 mg/day in men.

Because choline is widely distributed in the food supply, primarily in phosphatidylcholine (lecithin), deficiencies have not been observed in humans on a normal diet. Deficiencies may occur, however, in patients on total parenteral nutrition (TPN), that is, supported solely by intravenous feeding. The fatty livers that have been observed in these patients probably result from a decreased ability to synthesize phospholipids for VLDL formation.

Various types of interconversions occur among these phospholipids (see Fig. 31.28). Phosphatidylserine is produced by a reaction in which the ethanolamine moiety of phosphatidylethanolamine is exchanged for serine. Phosphatidylserine can be converted back to phosphatidylethanolamine by a decarboxylation reaction. Phosphatidylethanolamine can be methylated to form phosphatidylcholine (see Chapter 38).

In the second mechanism for the synthesis of glycerolipids, phosphatidic acid reacts with CTP to form CDP-diacylglycerol (Fig. 31.29). This compound can react with phosphatidylglycerol (which itself is formed from the condensation of CDP-diacylglycerol and glycerol 3-phosphate) to produce cardiolipin or with inositol to produce phosphatidylinositol. Cardiolipin is a component of the inner mitochondrial membrane. Phosphatidylinositol can be phosphorylated to form phosphatidylinositol 4,5-bisphosphate (PIP₂), which is a component of cell membranes. In response to signals such as the binding of hormones to membrane receptors, PIP₂ can be cleaved to form the second messengers diacylglycerol and inositol triphosphate (see Chapter 10).

FIGURE 31.29 Synthesis of cardiolipin and phosphatidylinositol. CDP, cytidine diphosphate; CMP, cytidine monophosphate; CTP, cytidine triphosphate.

2. Ether Glycerolipids

The ether glycerolipids are synthesized from the glycolytic intermediate dihydroxyacetone phosphate (DHAP). A fatty acyl CoA reacts with carbon 1 of DHAP, forming an ester (Fig. 31.30). This fatty acyl group is exchanged for a fatty alcohol, produced by the reduction of a fatty acid. Thus, the ether linkage is formed. Then the keto group on carbon 2 of the DHAP moiety is reduced and esterified to a fatty acid. Addition of the head group proceeds by a series of reactions analogous to those for the synthesis of phosphatidylcholine. Formation of a double bond between carbons 1 and 2 of the alkyl group produces a plasmalogen. Ethanolamine plasmalogen is found in myelin and choline plasmalogen in heart muscle. Platelet-activating factor (PAF) is similar to choline plasmalogen except that an acetyl group replaces the fatty acyl group at carbon 2 of the glycerol moiety, and the alkyl group on carbon 1 is saturated. PAF is released from phagocytic blood cells in response to various stimuli. It causes platelet aggregation, edema, and hypotension, and it is involved in the allergic response. Plasmalogen synthesis occurs within peroxisomes, and, in individuals with Zellweger syndrome spectrum (a defect in peroxisome biogenesis), plasmalogen synthesis is compromised. The most severe form of these syndromes, Zellweger syndrome, usually leads to death at an early age.

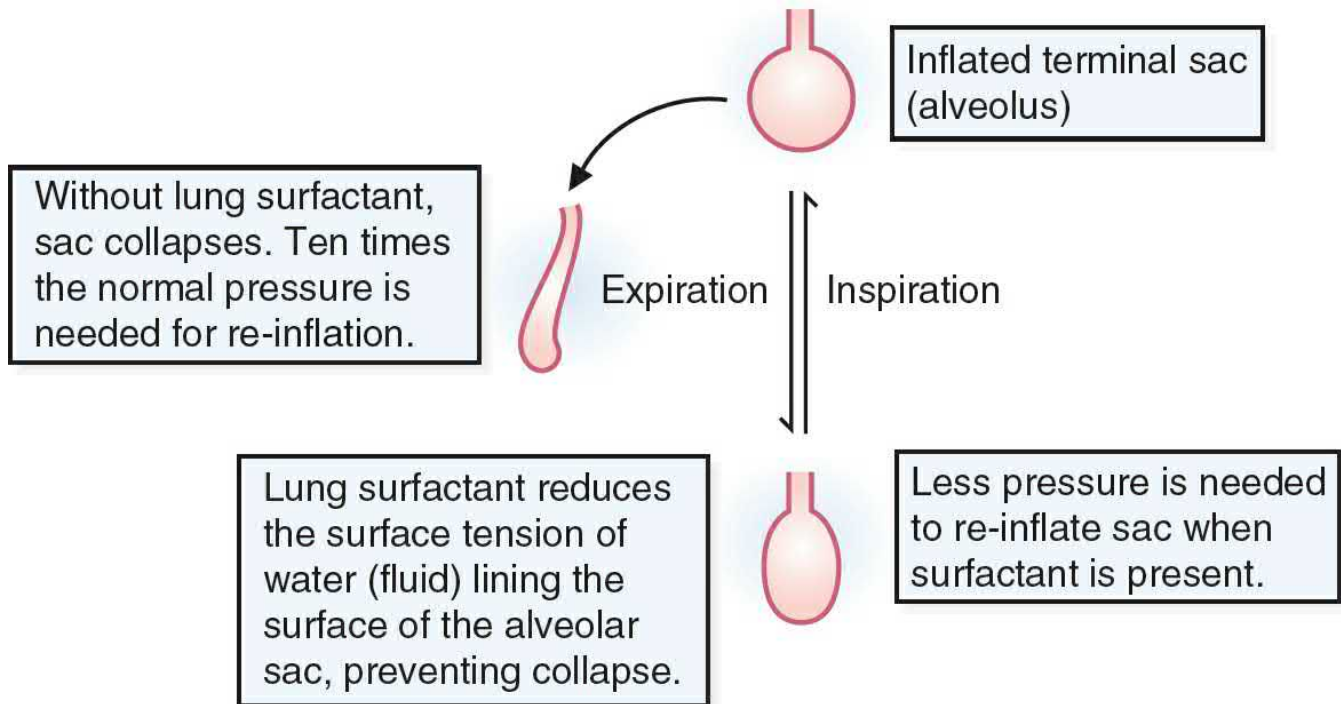

FIGURE 31.30 Synthesis of a plasmalogen. CDP, cytidine diphosphate; CoA, coenzyme A; DHAP, dihydroxyacetone phosphate; NADPH, reduced nicotinamide adenine dinucleotide phosphate.

The respiratory distress syndrome (RDS) of a premature infant such as **Christy L.** is, in part, related to a deficiency in the synthesis of a substance known as lung surfactant. The major constituents of surfactant are dipalmitoylphosphatidylcholine, phosphatidylglycerol, apolipoproteins (surfactant proteins: Sp-A,B,C), and cholesterol.

**Dipalmitoylphosphatidylcholine,
the major component of lung surfactant**

These components of lung surfactant normally contribute to a reduction in the surface tension within the air spaces (alveoli) of the lung, preventing their collapse. The premature infant has not yet begun to produce adequate amounts of lung surfactant.

The effect of lung surfactant

B. Degradation of Glycerophospholipids

Phospholipases located in cell membranes or in lysosomes degrade glycerophospholipids. Phospholipase A1 removes the fatty acyl group on carbon 1 of the glycerol moiety, and phospholipase A2 removes the fatty acid on carbon 2 (Fig. 31.31). The C2 fatty acid in cell membrane phospholipids is usually an unsaturated fatty acid,

which is frequently arachidonic acid. It is removed in response to signals for the synthesis of eicosanoids. The bond joining carbon 3 of the glycerol moiety to phosphate is cleaved by phospholipase C. Hormonal stimuli activate phospholipase C, which hydrolyzes PIP_2 to produce the second messengers DAG and inositol triphosphate (IP_3). The bond between the phosphate and the head group is cleaved by phospholipase D, producing phosphatidic acid and the free alcohol of the head group.

FIGURE 31.31 Bonds cleaved by phospholipases.

Phospholipase A₂ provides the major repair mechanism for membrane lipids damaged by oxidative free-radical reactions. Arachidonic acid, which is a polyunsaturated fatty acid, can be peroxidatively cleaved in free-radical reactions to malondialdehyde and other products. Phospholipase A₂ recognizes the distortion of membrane structure caused by the partially degraded fatty acid and removes it. Acyltransferases then add back a new arachidonic acid molecule.

C. Sphingolipids

Sphingolipids serve in intercellular communication and as the antigenic determinants of the ABO blood groups. Some are used as receptors by viruses and bacterial toxins, although it is unlikely that this was the purpose for which they originally evolved. Before the functions of the sphingolipids were elucidated, these compounds appeared to be inscrutable riddles. They were, therefore, named for the Sphinx of Thebes, who killed passersby that could not solve her riddle.

The synthesis of sphingolipids begins with the formation of ceramide (Fig. 31.32). Serine and palmitoyl CoA condense to form a product that is reduced. A very-long-chain fatty acid (usually containing 22 carbons) forms an amide with the amino group, a double bond is generated, and ceramide is formed.

FIGURE 31.32 Synthesis of ceramide. The changes that occur in each reaction are highlighted. CoA, coenzyme A; FA, fatty acid; FAD, flavin adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate; PLP, pyridoxal phosphate.

Ceramide reacts with phosphatidylcholine to form sphingomyelin, a component of the myelin sheath (Fig. 31.33) and the only sphingosine-based phospholipid. Ceramide also reacts with UDP-sugars to form cerebrosides (which contain a single monosaccharide, usually galactose or glucose). Galactocerebroside may react with 3'-phosphoadenosine 5'-phosphosulfate (PAPS, an active sulfate donor; Fig. 31.34) to form sulfatides, the major sulfolipids of the brain.

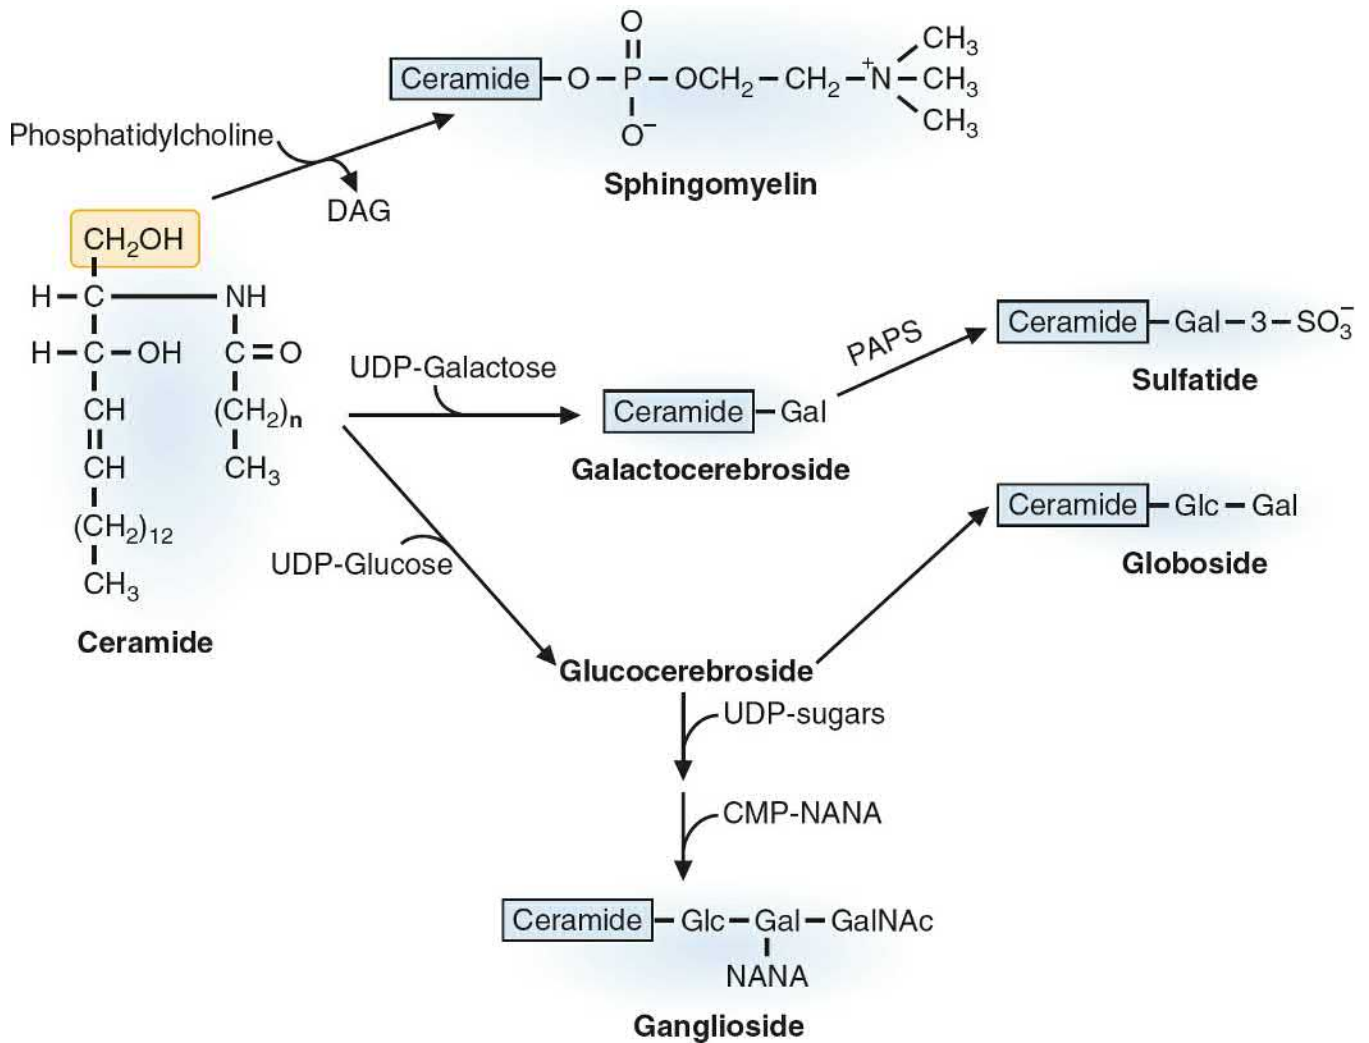

FIGURE 31.33 Synthesis of sphingolipids from ceramide. Phosphocholine or sugars add to the hydroxymethyl group of ceramide (in yellow box) to form sphingomyelins, cerebrosides, sulfatides, globosides, and gangliosides. The ganglioside shown in the figure is GM2. CMP, cytidine monophosphate; DAG, diacylglycerol; Gal, galactose; Glc, glucose; GalNAc, *N*-acetylgalactosamine; NANA, *N*-acetylneuraminic acid; PAPS, 3-phosphoadenosine 5-phosphosulfate; UDP, uridine diphosphate.

**3'-Phosphoadenosine 5'-phosphosulfate
(PAPS-“active sulfate”)**

FIGURE 31.34 The synthesis of 3'-phosphoadenosine 5'-phosphosulfate (PAPS), an active sulfate donor. PAPS donates sulfate groups to cerebrosides to form sulfatides and is also involved in glycosaminoglycan biosynthesis (see Chapter 47). Ad, adenine; ADP, adenosine diphosphate; ATP, adenosine triphosphate.

Additional sugars may be added to ceramide to form globosides, and gangliosides are produced by the addition of *N*-acetylneuraminic acid (NANA) as branches from the oligosaccharide chains (see Fig. 31.33 and Chapter 27).

Sphingolipids are degraded by lysosomal enzymes (see Table 27.5). Deficiencies of these enzymes result in a group of lysosomal storage diseases known as the sphingolipidoses.

VIII. The Adipocyte as an Endocrine Organ

It has become increasingly apparent in recent years that adipose tissue does more than just store triglyceride; it is also an active endocrine organ that secretes a variety of factors to regulate both glucose and fat metabolism. Two of the best-characterized factors are leptin and adiponectin.

A. Leptin

Leptin was initially discovered in an obese mouse model as a circulating factor that, when added to a genetically obese mouse (*ob/ob*), resulted in a loss of weight. Leptin binds to a receptor that is linked to JAK (see Chapter 10), so leptin's signal is transmitted by variations in the activity of the STAT transcription factors. Leptin is released from adipocytes as their triglyceride levels increase and binds to receptors in the hypothalamus, which leads to the release of neuropeptides that signal a cessation of eating (anorexigenic factors). Giving leptin to leptin-deficient patients will result in a weight loss, but administering leptin to obese patients does not have the same effect. It is believed that the lack of a leptin effect is due to the development of leptin resistance in many obese patients. Leptin resistance could result from the constant stimulation of the leptin receptors in obese individuals, leading to receptor desensitization. Another possibility is leptin-induced synthesis of factors that block leptin-induced signal transduction. As an example, leptin induces the synthesis of SOCS3 (suppressor of cytokine signaling-3), a factor that antagonizes STAT activation. Long-term leptin stimulation may lead to constant expression of SOCS3, which would result in a diminished cellular response to leptin.

B. Adiponectin

Adiponectin is the most abundantly secreted hormone from the adipocyte. Unlike leptin, adiponectin secretion is reduced as the adipocyte gets larger. The reduced secretion of adiponectin may be linked to the development of insulin resistance in obesity (reduced cellular responses to insulin; see the Biochemical Comments for a further discussion of insulin resistance). Adiponectin will bind to either of two receptors (AdipoR1 and AdipoR2), which initiate a signal transduction cascade resulting in the activation of the AMP-activated protein kinase (AMPK) and activation of the nuclear transcription factor PPAR α (peroxisome proliferator-activated receptor α).

Within the muscle, activation of AMPK leads to enhanced fatty acid oxidation and glucose uptake. Within the liver, activation of AMPK also leads to enhanced fatty acid oxidation as opposed to synthesis. AMPK activation in liver and muscle then lead to a reduction of blood glucose levels and free fatty acids. Recall that as the adipocytes increase in size, less adiponectin is released; so, as obesity occurs, it is more difficult for circulating fatty acids and glucose to be used by the tissues. This contributes, in part, to the elevated glucose and fat levels seen in the circulation of obese patients (the insulin-resistance syndrome).

Activation of PPAR α (see Chapter 44 for more details) leads to enhanced fatty acid oxidation by the liver and muscle. PPAR α is the target of the fibrate group of lipid-lowering drugs. PPAR α activation leads to increased transcription of genes involved in fatty acid transport, energy uncoupling, and fatty acid oxidation (for further information on the action of fibrates, see the "Biochemical Comments" in Chapter 33).

The thiazolidinedione group of antidiabetic drugs can be used to control type 2 diabetes. Because of some adverse side effects (weight gain and fluid retention), this class of drugs is usually prescribed as a second- or third-line agent. Pioglitazone is the main drug still in use. These drugs bind to and activate PPAR γ in adipose tissues, and lead, in part, to increased adiponectin synthesis and release, which aids in reducing circulating fat and glucose levels.

CLINICAL COMMENTS

Emma W. Corticosteroids reduce inflammation, in part, through their inhibitory effect on phospholipase A2. In addition, suppression of COX-2 induction is now thought to be a primary anti-inflammatory mechanism of action for glucocorticoids. Despite the unquestionable value of glucocorticoid therapy in a variety of diseases

associated with acute inflammation of tissues, it has many potential adverse effects. The sudden appearance of temporary glucose intolerance when **Emma W.** was treated with large doses of prednisone, a gluconeogenic steroid (glucocorticoid), is just one of the many potential adverse effects of this class of drugs when they are given systemically in pharmacological doses over an extended period. The inhaled steroids, conversely, have far fewer systemic side effects because their absorption across the bronchial mucosa into the circulation is very limited. This property allows them to be used over prolonged periods in the treatment of asthma. The fact that inhalation allows direct delivery of the agent to the primary site of inflammation adds to their effectiveness in the treatment of these patients.

If **Percy V.** had continued to eat a hypercaloric diet rich in carbohydrates, he would have become obese. In an effort to define obesity, it has been agreed internationally that the ratio of the patient's body weight in kilograms to his or her height in meters squared (W/H^2) is the most useful and reproducible measure. This ratio is referred to as the body mass index (BMI). A BMI of 18.5 to 25 represents a normal weight. His current value is 21.6 and rising.

It is estimated that >40% of adults in the United States have a BMI >30, with >70% exhibiting a BMI > 25. For individuals with a BMI >27, which is quite close to a weight 20% above the "ideal" or desirable weight, an attempt at weight loss should be strongly advised. The idea that obesity is a benign condition unless it is accompanied by other risk factors for cardiovascular disease is disputed by several long-term, properly controlled prospective studies. These studies show that obesity is an independent risk factor not only for heart attacks and strokes, but for the development of insulin resistance, type 2 diabetes mellitus, hypertension, and gallbladder disease.

Percy V. did not want to become overweight and decided to follow his new diet faithfully.

Because **Cora N.**'s lipid profile indicated an elevation in both serum triacylglycerols and LDL cholesterol, she was classified as having a combined hyperlipidemia. The dissimilarities in the lipid profiles of **Cora N.** and her two siblings, both of whom were experiencing anginal chest pain, are characteristic of the multigenic syndrome referred to as familial combined hyperlipidemia (FCH).

Approximately 1% of the North American population has FCH, and it is the most common genetic hyperlipidemia in people with coronary artery disease. In contrast to patients with familial hypercholesterolemia (FH), patients with FCH less commonly have fatty deposits within the skin or tendons (xanthomas) (see Chapter 32). In FCH, coronary artery disease usually appears by the fifth decade of life.

Treatment of FCH includes restriction of dietary fat and statin therapy to decrease cardiovascular risk and mortality. Additional medications can be added if patients who do not respond adequately to this therapy.

Because **Cora N.** has known coronary artery disease, she was prescribed a high-dose statin (atorvastatin). Treatment of hypercholesterolemia is based on overall risk of cardiovascular disease. Nicotinic acid (niacin) has been used to treat patients with hyperlipidemia, because these agents have the potential to lower serum triacylglycerol levels and cause a reciprocal rise in serum HDL cholesterol levels, as well as lowering serum total and LDL cholesterol levels. The mechanisms suggested for niacin's triacylglycerol-lowering action include enhancement of the action of LPL, inhibition of lipolysis in adipose tissue, and a decrease in esterification of triacylglycerols in the liver (see Chapter 32, Table 32.6). The mechanism by which niacin lowers the serum total and LDL cholesterol levels is related to the decrease in hepatic production of VLDL. When the level of VLDL in the circulation decreases, the production of its daughter particles, IDL and LDL, also decreases. Niacin's side effects of flushing and itching are often found to be intolerable. In addition, they have not been shown to decrease cardiovascular events or mortality in clinical trials.

Statins, such as atorvastatin, inhibit cholesterol synthesis by inhibiting the activity of hydroxymethylglutaryl CoA (HMG-CoA) reductase, the rate-limiting enzyme in the pathway (see Chapter 32). After 3 months of therapy, atorvastatin decreased **Cora N.**'s LDL cholesterol from a pretreatment level of 175 mg/dL to 122 mg/dL. Her fasting serum triacylglycerol concentration was decreased from a pretreatment level of 280 mg/dL to 178 mg/dL.

Cora N. was also told to take 81 mg of aspirin every day. In the presence of aspirin, cyclooxygenase is irreversibly inactivated by acetylation. New cyclooxygenase molecules are not produced in platelets, because platelets have no nuclei and, therefore, cannot synthesize new mRNA. Thus, the inhibition of cyclooxygenase by aspirin persists for the lifespan of the platelet (7 to 10 days). When aspirin is taken daily at doses between 81 and 325 mg, new platelets are affected as they are generated. Higher doses do not improve efficacy but do increase side effects, such as gastrointestinal bleeding and easy bruisability.

Patients with established or suspected atherosclerotic coronary disease, such as **Anne J.**, **Cora N.**, and **Ivan**

A., benefit from the action of low-dose aspirin (~81 mg/day), which produces a mild defect in hemostasis. This action of aspirin helps to prevent thrombus formation in the area of an atherosclerotic plaque at critical sites in the vascular tree.

Christy L. suffered from respiratory distress syndrome (RDS), which is a major cause of death in the newborn. RDS is preventable if prematurity can be avoided by appropriate management of high-risk pregnancy and labor. Before delivery, the obstetrician must attempt to predict and possibly treat pulmonary prematurity in utero. For example, estimation of fetal head circumference by ultrasonography, monitoring for fetal arterial oxygen saturation, and determination of the ratio of the concentrations of phosphatidylcholine (lecithin) and that of sphingomyelin in the amniotic fluid may help to identify premature infants who are predisposed to RDS (Fig. 31.35).

FIGURE 31.35 Comparison of phosphatidylcholine and sphingomyelin in amniotic fluid. Phosphatidylcholine is the major lipid in lung surfactant. The concentration of phosphatidylcholine relative to sphingomyelin rises at 35 weeks of gestation, indicating pulmonary maturity.

The administration of synthetic corticosteroids to women at risk of preterm birth can reduce the incidence or mortality of RDS by stimulating fetal synthesis of lung surfactants. They are given to women who are between 24 and 34 weeks pregnant and at risk of delivering within 7 days.

The administration of one dose of surfactant into the trachea of the premature infant immediately after birth, for babies with very poor respiratory function, can improve morbidity and mortality. In **Christy L.**'s case, intensive therapy allowed her to survive this acute respiratory complication of prematurity.

BIOCHEMICAL COMMENTS

Metabolic Syndrome. Obesity is a relatively modern problem brought about by an excess of nutrients and reduced physical activity. As individuals become obese, adipocyte function, in terms of its biochemical and endocrine roles, is altered. Adiponectin levels fall, and with it, reduced fatty acid oxidation occurs in tissues. The release of free fatty acids is also increased in large adipocytes, presumably because of the high concentration of substrate (triglyceride), even if HSL is not activated. This is coupled with a deficiency of perilipins in obese individuals. Perilipins are adipocyte phosphoproteins that bind to triacylglycerol droplets and regulate the accessibility of the triglyceride to the lipases. A decrease in perilipin synthesis leads to an enhanced basal rate of lipolysis.

Fat cells begin to proliferate early in life, starting in the third trimester of gestation. Proliferation essentially ceases before puberty, and thereafter fat cells change mainly in size. However, some increase in the number of fat cells can occur in adulthood if preadipocytes are induced to proliferate by growth factors and changes in the nutritional state. Weight reduction results in a decrease in the size of fat cells rather than a decrease in number. After weight loss, the amount of LPL, an enzyme involved in the transfer of fatty acids from blood triacylglycerols to the triacylglycerol stores of adipocytes, increases. In addition, the amount of mRNA for LPL also increases. All of these factors suggest that individuals who become obese, particularly those who do so early in life, will have difficulty losing weight and maintaining a lower body adipose mass.

Signals that initiate or inhibit feeding are extremely complex and include psychological and hormonal factors as well as neurotransmitter activity. These signals are integrated and relayed through the hypothalamus. Destruction of specific regions of the hypothalamus can lead to overeating and obesity or to anorexia and weight loss. Overeating and obesity are associated with damage to the ventromedial or the paraventricular nucleus, whereas weight loss and anorexia are related to damage to more lateral hypothalamic regions. Compounds that act as satiety signals have been identified in brain tissue and include leptin and glucagon-like peptide-1 (GLP-1). Appetite suppressors developed from compounds such as these may be used in the future for the treatment of obesity.

Increased circulating levels of nonesterified (or free) fatty acids (NEFA) are observed in obesity and are associated with insulin resistance. Insulin resistance is also a hallmark of type 2 diabetes. There are a number of theories as to why increased NEFA promote insulin resistance. One will be presented here, along with the effects of NEFA on insulin release from the pancreas. As NEFA levels in the circulation rise, muscle begins to use predominantly NEFA as an energy source. This reduces muscle glucose metabolism, as a result of the buildup of acetyl CoA in the mitochondria, export of citrate to the cytoplasm, and inhibition of PFK-1. Because glucose is not being metabolized, its uptake by muscle is reduced. As muscle is the predominant tissue that takes up glucose in response to insulin, impaired glucose uptake (resulting from fat oxidation) is manifest as a sign of insulin resistance. NEFA are also postulated to interfere with pancreatic β -cell secretion of insulin, further contributing to insulin resistance (see below for more on this topic).

Obesity, insulin resistance, and altered blood lipid levels have been described as a syndrome known as the metabolic syndrome. The metabolic syndrome is diagnosed most commonly based on criteria from the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III). For a diagnosis of metabolic syndrome, at least three of the following components should be evident:

- Abdominal Obesity, defined as a waist circumference >40 in men and >35 in women
- Elevated triglycerides (≥ 150 mg/dL)
- Reduced HDL (<40 mg/dL for men, <50 mg/dL for women)
- Elevated blood pressure ($\geq 130/85$ mm Hg)
- Elevated fasting glucose (≥ 100 mg/dL)

Individuals with metabolic syndrome are at increased risk for type 2 diabetes and cardiovascular disease. Treatment is based on the individual components, which also all carry their own individual risk of cardiovascular disease. This reason among others leads some experts to feel this should not be considered a syndrome.

One of the characteristics of the metabolic syndrome in most definitions is insulin resistance. Part of this resistance is due to altered insulin release from the β -cells of the pancreas under hyperlipidemic conditions. To understand how this occurs, it is necessary to revisit normal glucose-stimulated insulin secretion (see Fig. 19.11).

Glucose is metabolized in the pancreatic β -cell to generate ATP, which closes ATP-sensitive K^+ channels,

which leads to a membrane depolarization, which activates voltage-gated Ca^{2+} channels in the membrane. The corresponding increase in intracellular calcium levels leads to stimulation of the exocytosis of insulin-containing vesicles. However, the process is more complicated than this and is coupled to pyruvate cycling within the β -cell and the generation of NADPH. The exact role of NADPH in stimulating insulin release has not yet been elucidated.

Islet cells express pyruvate carboxylase but very low levels of PEPCK. As can be seen in Figure 31.36, NADPH is generated in the cytosol of the islets cells by malic enzyme and the cytosolic isozyme of isocitrate dehydrogenase, which utilizes NADP^+ instead of NAD^+ , as the mitochondrial enzyme does.

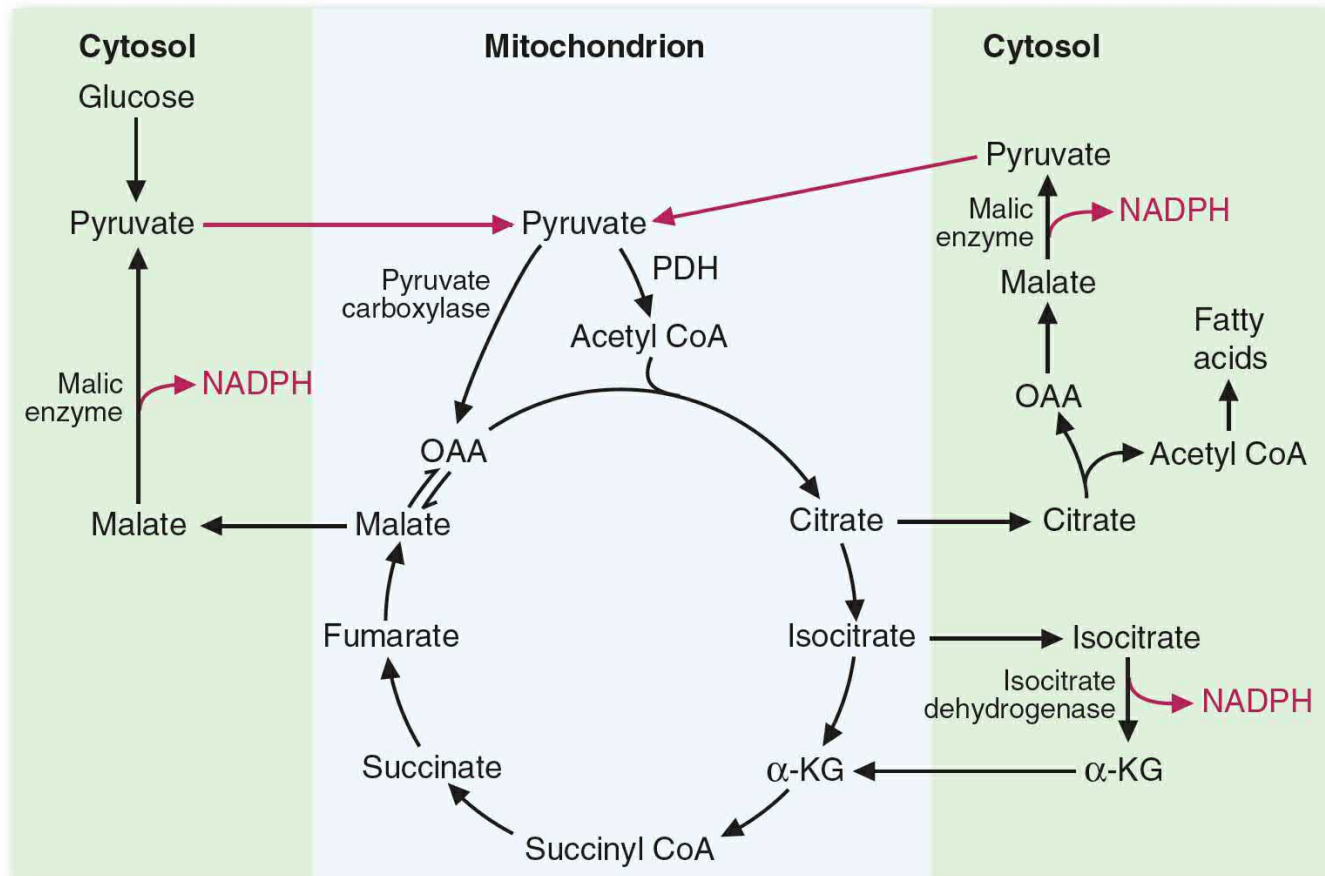

FIGURE 31.36 Generation of NADPH via pyruvate cycling in islet cells in response to glucose. Details are provided in the text. α -KG, α -ketoglutarate; Acetyl CoA, acetyl coenzyme A; DHAP, dihydroxyacetone phosphate; OAA, oxaloacetate. (Adapted with permission of Annual Reviews, Inc. from Muoio DM, Newgard CB. Obesity-related derangements in metabolic regulation. *Annu Rev Biochem.* 2006;75:367–401; permission conveyed through Copyright Clearance Center, Inc.)

Thus, under normal conditions, glucose is metabolized to pyruvate, and the pyruvate enters the mitochondria. Some of the pyruvate is converted to acetyl CoA to generate energy; some of the pyruvate is converted to oxaloacetate. The oxaloacetate generated can be converted to malate and exported to the cytoplasm, where it is recycled to pyruvate by malic enzyme, generating NADPH. Alternatively, the oxaloacetate and acetyl CoA generated within the mitochondria can condense and form citrate, isocitrate, and α -ketoglutarate, all of which can leave the mitochondria and enter the cytosol. Cytosolic isocitrate is oxidized to α -ketoglutarate, generating NADPH. Cytosolic citrate is split by citrate lyase to acetyl CoA and oxaloacetate, and the oxaloacetate is reduced to malate and cycled to pyruvate, generating more NADPH. The cytosolic acetyl CoA is utilized for limited fatty acid production in the islet cell. The elevated cytosolic NADPH then aids, in an unknown manner, in the release of insulin from the β -cell.

So what goes wrong when β -cells are chronically exposed to high levels of NEFA in the circulation? The β -cell begins to oxidize the fatty acids, which dramatically raises the acetyl CoA levels in the β -cell mitochondria. This leads to the activation of pyruvate carboxylase and enhanced pyruvate cycling, with significant increases in resting NADPH levels. This, then, leads to blunted increases in NADPH levels when glucose levels increase, as pyruvate cycling is already maximal because of the activation of pyruvate carboxylase. Thus, the β -cell

releases less insulin in response to the increase in blood glucose levels, thereby contributing further to hyperglycemia that was initiated by the resistance to insulin's action in peripheral tissues.

It has also been hypothesized that the β -cells on the pancreas, due to the constant stimulation by elevated blood glucose levels, develop an expanded and overworked endoplasmic reticulum (ER), leading to ER stress and the presence of improperly or unfolded proteins within the ER. The presence of such proteins leads to activating the adaptive unfolded protein response, which allows the ER to continue to function despite the presence of the mis- or unfolded proteins. However, the continued need to synthesize insulin, and the expansion of the ER within the β -cell, and the accumulation of unfolded proteins eventually overwhelms the capacity of the ER to continue synthesizing proteins, leading to β -cell apoptosis. Another potential fate for such β -cells is dedifferentiation (so the cell no longer secretes insulin). This eventually leads to type 2 diabetes and a reduced synthesis of insulin from the β -cells.

KEY CONCEPTS

- ◆ Fatty acids are synthesized mainly in the liver, primarily from glucose.
- ◆ Glucose is converted to pyruvate via glycolysis, which enters the mitochondrion and forms both acetyl CoA and oxaloacetate, which then forms citrate.
- ◆ The newly synthesized citrate is transported to the cytosol, where it is cleaved to form acetyl CoA, which is the source of carbons for fatty acid biosynthesis.
- ◆ Two enzymes, acetyl CoA carboxylase (the key regulatory step) and fatty acid synthase, produce palmitic acid (16 carbons, no double bonds) from acetyl CoA. After activation to palmitoyl CoA, the fatty acid can be elongated or desaturated (adding double bonds) by enzymes in the ER.
 - ◆ The eicosanoids (prostaglandins, thromboxanes, and leukotrienes) are potent regulators of cellular function (such as the inflammatory response, smooth muscle contraction, blood pressure regulation, and bronchoconstriction and bronchodilation) and are derived from polyunsaturated fatty acids containing 20 carbon atoms.
 - ◆ The prostaglandins and thromboxanes require cyclooxygenase activity to be synthesized, whereas the leukotrienes require lipoxygenase activity.
 - ◆ Cyclooxygenase is the target of nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, which covalently acetylates and inactivates the enzyme in platelets.
- ◆ Fatty acids are used to produce triacylglycerols (for energy storage) and glycerophospholipids and sphingolipids (for structural components of cell membranes).
- ◆ Liver-derived triacylglycerol is packaged with various apolipoproteins and secreted into the circulation as very-low-density lipoprotein (VLDL).
- ◆ As with dietary chylomicrons, LPL in the capillaries of adipose tissue, muscle, and the lactating mammary gland digests the triacylglycerol of VLDL, forming fatty acids, and glycerol.
- ◆ Glycerophospholipids, synthesized from fatty acyl CoA and glycerol 3-phosphate, are all derived from phosphatidic acid. Various head groups are added to phosphatidic acid to form the mature glycerophospholipids.
- ◆ Phospholipid degradation is catalyzed by phospholipases.
- ◆ Sphingolipids are synthesized from sphingosine, which is derived from palmitoyl CoA and serine. Glycolipids, such as cerebrosides, globosides, and gangliosides, are sphingolipids.
- ◆ The sole sphingosine-based phospholipid is sphingomyelin.
- ◆ The adipocyte is an active endocrine organ, producing adipokines that help to regulate appetite and adipocyte size.
- ◆ Metabolic syndrome refers to a clustering of a variety of metabolic abnormalities that together dramatically increase the risk of type 2 diabetes and cardiovascular disease.
- ◆ Diseases discussed in the chapter are summarized in Table 31.5.

TABLE 31.5 Diseases Discussed in Chapter 31

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Obesity	Both	Weight gain will occur because of excessive calorie consumption: fat can be derived from carbohydrates, protein, and triglyceride in the diet.

Heart disease (FCH), familial combined hyperlipidemia	Both	Familial combined hyperlipidemia, leading to elevated cholesterol and triglyceride levels in the serum. Levels of lipid in the blood, and symptoms displayed by patients, will vary from patient to patient.
Respiratory distress syndrome of the newborn	Both	Inability of lungs to properly expand and contract due to lack of surfactant, a complex mixture of lipids and apolipoproteins.
Abetalipoproteinemia	Genetic	Lack of microsomal triglyceride transport protein, leading to reduced production of VLDL and chylomicrons within the liver, and intestine, respectively.
Cardiovascular disease (protection against future myocardial infarctions)	Environmental	NSAIDs, such as aspirin, are used to block prostaglandin production via inhibition of cyclooxygenase. Low-dose aspirin provides potential protective effects for those with cardiovascular disease.
Asthma	Environmental	The use of inhalants containing corticosteroids, can control and reduce inflammation by inhibiting the recruitment of leukocytes and monocytes into affected areas. They also lead to a decrease in the synthesis of prostaglandins and leukotrienes.
Metabolic syndrome	Both	A combination of obesity, insulin resistance, and altered blood lipids leads to metabolic syndrome with an increased risk for type 2 diabetes and cardiovascular disease.

NSAIDs, nonsteroidal anti-inflammatory drugs; VLDL, very low-density lipoprotein.

REVIEW QUESTIONS—CHAPTER 31

- Which one of the following is involved in the synthesis of triacylglycerols in adipose tissue?
 - Fatty acids obtained from chylomicrons and VLDL
 - Glycerol 3-phosphate derived from blood glycerol
 - 2-Monoacylglycerol as an obligatory intermediate
 - LPL to catalyze the formation of ester bonds
 - Acetoacetyl CoA as an obligatory intermediate
- A molecule of palmitic acid, attached to carbon 1 of the glycerol moiety of a triacylglycerol, is ingested and digested. The fatty acid is stored in a fat cell and ultimately is oxidized to carbon dioxide and water in a muscle cell. Choose the molecular complex in which the palmitate residue is carried from the lumen of the gut to the surface of the gut epithelial cell.
 - VLDL
 - Chylomicron
 - Fatty acid–albumin complex
 - Bile salt micelle
 - LDL
- A patient with hyperlipoproteinemia would be most likely to benefit from a low-carbohydrate diet if the lipoproteins that are elevated in blood are which of the following?
 - Chylomicrons
 - VLDL
 - HDL
 - LDL
 - IDL
- Patients with MCAD deficiency exhibit fasting hypoglycemia due to a number of reasons. In such patients, under fasting conditions, which one of the following enzymes may not be fully activated, thus leading to an inability to carry out gluconeogenesis?
 - Glucose 6-phosphatase
 - Pyruvate carboxylase
 - Fructose 1,6 bisphosphatase
 - PEP carboxykinase
 - Glyceraldehyde 3-phosphate dehydrogenase
- Newly synthesized fatty acids are not immediately degraded because of which one of the following?
 - Tissues that synthesize fatty acids do not contain the enzymes that degrade fatty acids.

- B. High NADPH levels inhibit β -oxidation.
 - C. In the presence of insulin, the key fatty acid degrading enzyme is not induced.
 - D. Newly synthesized fatty acids cannot be converted to their CoA derivatives.
 - E. Transport of fatty acids into mitochondria is inhibited under conditions in which fatty acids are being synthesized.
6. In humans, prostaglandins are derived primarily from which one of the following?
 - A. Glucose
 - B. Acetyl CoA
 - C. Arachidonic acid
 - D. Oleic acid
 - E. Leukotrienes
 7. Individuals with a defect in glucose 6-phosphate dehydrogenase produce NADPH for the synthesis of fatty acids due to the presence of which one of the following enzymes?
 - A. Malic enzyme
 - B. Fatty acid synthase
 - C. Acetyl CoA carboxylase
 - D. C9-desaturase
 - E. Citrate lyase
 8. Which one of the following drugs leads to the covalent modification, and inactivation, of both the COX-1 and COX-2 enzymes?
 - A. Aspirin
 - B. Tylenol
 - C. Celebrex
 - D. Vioxx
 - E. Advil
 9. Dietary fatty acids are precursors for sphingolipids. Of the following, which one is formed from sphingolipids?
 - A. Lung surfactant
 - B. Myelin sheath
 - C. Bile
 - D. Arachidonic acid
 - E. Blood lipoproteins
 10. Low-dose aspirin is used as prevention for platelet aggregation and heart attacks, whereas high-dose aspirin is used as an anti-inflammatory drug. Low-dose aspirin is used to block the formation of which eicosanoid involved in platelet aggregation?
 - A. Prostaglandins
 - B. Thromboxanes
 - C. Leukotrienes
 - D. Lysoxins
 - E. Epoxides
 1. A rat is being treated with bempedoic acid, which is a liver-specific inhibitor of citrate lyase. The almost complete inhibition of liver citrate lyase would lead to which one of the following?
 - A. Increased fatty acid synthesis
 - B. Decreased VLDL formation
 - C. Increased LDL formation
 - D. Reduced chylomicron secretion
 - E. Increased chylomicron secretion
 2. A scientist isolated a liver cell line that at 32°C grew normally, but at 40°C (the nonpermissive temperature) grew very slowly. Analysis of the cell line indicated that the phospholipid composition of the membrane was altered at 40°C and that the synthesis of CDP-diacylglycerol was greatly impaired. This cell line would have difficulty synthesizing which phospholipids at the nonpermissive temperature?
 - B. High NADPH levels inhibit β -oxidation.
 - C. In the presence of insulin, the key fatty acid degrading enzyme is not induced.
 - D. Newly synthesized fatty acids cannot be converted to their CoA derivatives.
 - E. Transport of fatty acids into mitochondria is inhibited under conditions in which fatty acids are being synthesized.

	Phosphatidyl-Choline	Phosphatidyl-Ethanolamine	Cardiolipin	Phosphatidyl-Inositol
A	Yes	Yes	No	No
B	Yes	No	Yes	Yes
C	Yes	Yes	No	No
D	No	No	Yes	No
E	No	Yes	No	Yes
F	No	No	Yes	Yes

3. A premature newborn infant had trouble breathing shortly after birth, with audible respiratory grunting. An arterial blood sample indicated a low partial pressure of oxygen, and a slightly elevated partial pressure of carbon dioxide. The infant was given a lipid:protein mixture that greatly eased their breathing. The major lipid in this drug requires which of the following for its synthesis?
- CDP-DAG
 - Inositol
 - Serine
 - CDP-choline
 - Stearoyl CoA
4. A 51-year-old male was seen for his annual physical. His waist circumference was 44 in, his blood pressure was 145/90 (normal is 130/80 or lower). Blood work indicated elevated triglycerides (225 mg/dL; ≤ 150 mg/dL is desirable), and an HDL of 30 mg/dL (this is below the desirable range of >40 mg/dL for males). The patient's body mass index is 35.0 (desirable is between 25.0 and 29.9). Fasting blood glucose levels were 125 mg/dL (normal is <100 mg/dL). Circulating insulin levels were also found to be below normal, which could occur due to which of the following? Choose the one best answer.

	Elevated NADPH in the Cell	B-cell Apoptosis	B-cell Hyperplasia	B-cell Dedifferentiation
A	Yes	Yes	No	Yes
B	No	Yes	Yes	No
C	Yes	Yes	No	No
D	No	No	Yes	Yes
E	Yes	No	No	No
F	No	No	Yes	Yes

5. A liver cell line was isolated that exhibited normal acyl CoA synthetase activity at 32°C but greatly reduced activity at 40°C. This cell grows very slowly at 40°C due to a reduced ability to accomplish which of the following?

	Oxidize Fatty Acids	Synthesize Triacylglycerol	Synthesize Sphingolipids	Synthesize 18-Carbon Fatty Acids
A	Yes	Yes	Yes	Yes
B	No	Yes	No	No
C	Yes	Yes	Yes	No
D	No	No	No	Yes
E	Yes	No	Yes	No
F	No	No	No	Yes

ANSWERS TO REVIEW QUESTIONS

- The answer is A.** Fatty acids, cleaved from the triacylglycerols of blood lipoproteins by the action of LPL, are taken up by adipose cells and react with coenzyme A to form fatty acyl CoA. Glucose is converted via dihydroxyacetone phosphate to glycerol 3-phosphate, which reacts with fatty acyl CoA to form phosphatidic acid (adipose tissue lacks glycerol kinase, so it cannot use glycerol directly). After inorganic phosphate is released from phosphatidic acid, the resulting diacylglycerol reacts with another fatty acyl CoA to form a triacylglycerol, which is stored in adipose cells (2-monoacylglycerol is an intermediate of triglyceride synthesis only in the intestine, not in adipose tissue).
- The answer is D.** The triacylglycerol is degraded by pancreatic lipase, which releases the fatty acids at positions 1 and 3. The fatty acids released are then transported to the cell surface in a bile salt micelle. The only exception is short-chain fatty acids (shorter than palmitic acid), which can diffuse to the cell surface and enter the intestinal cell in the absence of micelle formation.
- The answer is B.** Dietary carbohydrate is converted to lipid in the liver and exported via VLDL. Thus, a low-carbohydrate diet will reduce VLDL formation and reduce the hyperlipoproteinemia.
- The answer is B.** Pyruvate carboxylase is activated, within the mitochondria, by acetyl CoA. High acetyl CoA will also inhibit pyruvate dehydrogenase, thereby allowing the pyruvate produced to be used for gluconeogenesis, and not energy production. In MCAD, fatty acids are not fully oxidized (thereby reducing the amount of energy available for gluconeogenesis), and acetyl CoA levels do not reach a point at which pyruvate carboxylase can be fully activated, thereby reducing precursor levels available for gluconeogenesis. Glucose 6-phosphatase activity is not affected by acetyl CoA levels, nor is PEP carboxykinase activity (which is regulated at a transcriptional level) or fructose 1,6 biphosphatase activity (which is inhibited by fructose 2,6 biphosphate). Glyceraldehyde 3-phosphate is not a regulated enzyme of glycolysis or gluconeogenesis.
- The answer is E.** When fatty acids are being synthesized, malonyl CoA accumulates, which inhibits carnitine:palmitoyl transferase I. This blocks fatty acid entry into the mitochondrion for oxidation. Many tissues both synthesize and degrade fatty acids (such as liver and muscle; thus, A is incorrect). NADPH blocks the glucose 6-phosphate dehydrogenase reaction but not fatty acid oxidation (thus, B is incorrect). Insulin has no effect on the synthesis of the enzymes involved in fatty acid degradation (unlike the effect of insulin on the induction of enzymes involved in fatty acid synthesis; thus, C is incorrect). Finally,

newly synthesized fatty acids are converted to their CoA derivatives for elongation and desaturation (thus, E is incorrect).

6. **The answer is C.** Most prostaglandins are synthesized from arachidonic acid (*cis*- Δ 5,8,11,14 $C_{20:4}$), which is derived from the essential fatty acid linoleic acid (*cis*- Δ 9,12 $C_{18:2}$). Glucose, oleic acid, or acetyl CoA cannot give rise to linoleic or arachidonic acid, as mammals cannot introduce double bonds six carbons from the ω -end of a fatty acid. Leukotrienes are also derived from arachidonic acid, but they are not precursors of prostaglandins; they follow a different pathway.
7. **The answer is A.** Fatty acid synthesis requires NADPH, which can be generated by the hexose monophosphate shunt pathway or by malic enzyme activity. In the absence of glucose 6-phosphate dehydrogenase activity, malic enzyme, along with a mitochondrial transhydrogenase, would provide the NADPH for fatty acid biosynthesis. Cytosolic isocitrate dehydrogenase can also produce NADPH under these conditions. Neither the fatty acid synthase, citrate lyase, C9-desaturase, nor acetyl CoA carboxylase generates NADPH.
8. **The answer is A.** Aspirin leads to the acetylation of COX-1 and COX-2, which inhibits the enzymes. Tylenol contains acetaminophen, which is a competitive inhibitor of both COX-1 and COX-2, but acetaminophen does not attach covalently to the enzymes. Advil contains ibuprofen, which is another competitive inhibitor of the COX enzymes. Vioxx and Celebrex contain inhibitors that are specific for COX-2, which is the form of cyclooxygenase that is induced during inflammation. Vioxx and Celebrex do not inhibit COX-1 activity.
9. **The answer is B.** Sphingolipids are important in signal transduction and the formation of myelin sheaths of the central nervous system. Glycerophospholipids are components of blood lipoproteins, bile, and lung surfactant. Arachidonic acid is a polyunsaturated fatty acid required for signal transduction, but it is not formed from a sphingolipid.
10. **The answer is B.** Aspirin irreversibly inhibits cyclooxygenase, which produces prostaglandins and thromboxanes. Thromboxanes are in platelets and inhibition of their aggregation reduces clotting, which can prevent a heart attack. Prostaglandins are involved in inflammation. Leukotrienes and lipoxins are produced by lipoxygenase and epoxides by a chromosome P450 system.
11. **The answer is B.** The inhibition of citrate lyase in the liver will lead to a reduction of both cholesterol and fatty acid synthesis as cytoplasmic acetyl CoA, which is required for their syntheses, cannot be produced from cytoplasmic citrate. The reduced levels of fatty acids and cholesterol will reduce VLDL formation in the liver, with a concomitant reduction in VLDL secretion by the liver. The reduction of VLDL levels in the blood leads to reduced levels of LDL, which is derived from VLDL. Chylomicrons are synthesized in the intestinal epithelial cells, and bempedoic acid does not block fatty acid, triglyceride, or cholesterol synthesis in those cells, such that chylomicron secretion, composed primarily of dietary lipids, would be normal.
12. **The answer is F.** There are two pathways for de novo phospholipid synthesis: the CDP-diacylglycerol pathway and the activated head group pathway (reacting with diacylglycerol). In these cells, since CDP-DAG synthesis is impaired, phospholipids which require that pathway for synthesis will not be able to be produced. The CDP-DAG pathway produces cardiolipin, phosphatidylglycerol, and phosphatidylinositol. The activated head group pathway produces phosphatidylethanolamine and phosphatidylcholine, along with phosphatidylserine.
13. **The answer is D.** The drug being given is pulmonary surfactant, which is composed primarily of surfactant proteins and dipalmitoylphosphatidylcholine (DPPC). The synthesis of phosphatidylcholine occurs through the head group activation pathway; dipalmitoyl phosphatidic acid is first produced, which is converted to dipalmitoyl diglyceride. The diglyceride reacts with the activated head group, CDP-choline, to form DPPC, which is required for surfactant synthesis. CDP-DAG is not required for phosphatidylcholine synthesis, and inositol and serine are also not required for DPPC production. DPPC does not contain stearic acid.
14. **The answer is A.** The patient has the signs of metabolic syndrome and is developing resistance to circulating insulin. He has even reached the point where the pancreas, due to constant stress in the ER, is producing reduced levels of insulin, insufficient for the amount of glucose in the blood. The insulin levels could be reduced due to increased NADPH in the pancreatic β -cell (leading to a blunted insulin response to glucose), loss of β -cells through apoptosis, or β -cell dedifferentiation such that they no longer produce insulin. Beta-cell hyperplasia is not a result of metabolic syndrome and would lead to increased levels of insulin being secreted until the cells lost the ability to do so, due to the reasons outlined above.
15. **The answer is A.** Acyl CoA synthetases catalyze the activation of free fatty acids to an acyl CoA. Acyl

CoA's are required for fatty acid oxidation (acyl CoA is the substrate for the acyl CoA dehydrogenase), for triglyceride synthesis (glycerol 3-phosphate plus an acyl CoA can add the fatty acid to the glycerol backbone), for sphingolipid biosynthesis (sphingosine is synthesized from palmitoyl CoA and serine), and for the synthesis of stearic acid (the fatty acid synthase releases palmitic acid, which must be activated to palmitoyl CoA before being extended by two carbons by fatty acid elongation systems).

Cholesterol Absorption, Synthesis, Metabolism, and Fate

Cholesterol is one of the most well-recognized molecules in human biology, in part because of the direct relationship between its concentrations in blood and tissues and the development of **atherosclerotic vascular disease**. Cholesterol, which is transported in the blood in **lipoprotein complexes** because of its absolute insolubility in water, serves as a **stabilizing component of cell membranes** and is a synthetic precursor of the **bile salts** and **steroid hormones**, which participate in cellular signaling. Precursors of cholesterol are converted to **ubiquinone**, **dolichol**, and, in the skin, to **cholecalciferol**, the **active form of vitamin D**. As a **major component of blood lipoproteins**, cholesterol can appear in its free, unesterified form in the outer shell of these macromolecules and as cholesterol esters in the lipoprotein core.

Cholesterol is obtained from the diet or synthesized by a pathway that occurs in the cytoplasm of most cells of the body, but to a greater extent in cells of the liver, intestine, and the adrenal cortex and gonads, where cholesterol is used as a precursor for steroid hormone synthesis. The precursor for cholesterol synthesis is **acetyl coenzyme A (acetyl CoA)**, which can be produced from glucose, fatty acids, or amino acids. Two molecules of acetyl CoA form **acetoacetyl CoA**, which condenses with another molecule of acetyl CoA to form **hydroxymethylglutaryl CoA (HMG-CoA)**. Reduction of HMG-CoA produces **mevalonate**. This reaction, catalyzed by **HMG-CoA reductase**, is the major rate-limiting step of cholesterol synthesis. Mevalonate is used to produce isoprene units that condense, eventually forming **squalene**. Cyclization of squalene produces the steroid ring system, and a number of subsequent reactions generate cholesterol.

Cholesterol is packaged in **chylomicrons** in the intestine and in **very-low-density lipoprotein (VLDL)** in the liver. Along with triacylglycerol, cholesterol is transported in the blood in these lipoprotein particles, which also transport triacylglycerols. As the triacylglycerols of the blood lipoproteins are digested by lipoprotein lipase, chylomicrons are converted to **chylomicron remnants**, and VLDL is converted to **intermediate-density lipoprotein (IDL)** and subsequently to **low-density lipoprotein (LDL)**. These products return to the liver, where they bind to receptors in cell membranes and are taken up by endocytosis and digested by lysosomal enzymes. LDL is also endocytosed by nonhepatic (peripheral) tissues. Cholesterol and other products of lysosomal digestion are released into the cellular pools. The liver uses this recycled cholesterol, and the cholesterol that is synthesized from acetyl CoA, to produce VLDL and to synthesize bile salts.

Intracellular cholesterol obtained from blood lipoproteins decreases the synthesis of cholesterol within cells, stimulates the storage of cholesterol as cholesterol esters, and decreases the synthesis of **LDL receptors**. LDL receptors are found on the surface of the cells and bind various classes of lipoproteins before endocytosis.

Although **high-density lipoprotein (HDL)** contains triacylglycerols and cholesterol, its function is very different from that of the chylomicrons and VLDL, which transport triacylglycerols. HDL exchanges proteins and lipids with the other lipoproteins in the blood. HDL transfers **apolipoprotein E (apoE)** and **apolipoprotein CII (apoCII)** to chylomicrons and VLDL. After digestion of the VLDL triacylglycerols in chylomicrons and VLDL, apoE and apoCII are transferred back to HDL. In addition, HDL obtains cholesterol from other lipoproteins and from cell membranes and converts it to **cholesterol esters** by the **lecithin:cholesterol acyltransferase (LCAT)** reaction. Then, HDL either directly transports cholesterol and cholesterol esters to the liver or transfers cholesterol esters to other lipoproteins via the **cholesterol ester transfer protein (CETP)**. Ultimately, lipoprotein particles carry the cholesterol and cholesterol esters to the liver, where endocytosis and lysosomal digestion occur. Thus, **reverse cholesterol transport** (i.e., the return of cholesterol to the liver) is a major function of HDL.

Elevated levels of cholesterol in the blood are associated with the formation of **atherosclerotic plaques** that can occlude blood vessels, causing heart attacks and strokes. Although high levels of LDL cholesterol are especially atherogenic, high levels of HDL cholesterol are protective because HDL particles are involved in the process of removing cholesterol from tissues, such as the cells lining the blood vessels, and returning it to the liver.

Bile salts, which are produced in the liver from cholesterol obtained from the blood lipoproteins or synthesized from acetyl CoA, are secreted into the bile. They are stored in the gallbladder and released into the intestine during a meal. The bile salts emulsify dietary triacylglycerols, thus aiding in digestion. The digestive products are absorbed by intestinal epithelial cells from bile salt micelles, tiny microdroplets that contain bile salts at their water interface. After the contents of the micelles are absorbed, most of the bile salts travel to the ileum, where they are resorbed and recycled by the liver. Less than 5% of the bile salts that enter the lumen of the small intestine are eventually excreted in the feces.

Although the fecal excretion of bile salts is relatively low, it is a major means by which the body disposes of the steroid nucleus of cholesterol. Because the ring structure of cholesterol cannot be degraded in the body, it is excreted mainly in the bile as free cholesterol and bile salts.

The **steroid hormones**, derived from cholesterol, include the adrenal cortical hormones (e.g., cortisol, aldosterone, and the adrenal sex steroids dehydroepiandrosterone [DHEA] and androstenedione) and the gonadal hormones (e.g., the ovarian and testicular sex steroids, such as testosterone and estrogen).

 Until recently, the concentration of LDL cholesterol could only be directly determined by sophisticated laboratory techniques not available for routine clinical use. As a consequence, the LDL cholesterol concentration in the blood was derived indirectly by using the Friedewald formula: the sum of the HDL cholesterol level and the triacylglycerol (TG) level divided by 5 (which gives an estimate of the VLDL cholesterol level) subtracted from the total cholesterol level:

$$\text{LDL cholesterol} = \text{total cholesterol} \\ - [\text{HDL cholesterol} \\ + (\text{TG}/5)]$$

This equation yields inaccurate LDL cholesterol levels 15% to 20% of the time and fails completely when serum triacylglycerol levels exceed 400 mg/dL.

A recently developed test called LDL direct isolates LDL cholesterol by using a special immunoseparation reagent. Not only is this direct assay for LDL cholesterol more accurate than the indirect Friedewald calculation, but it is also not affected by mildly to moderately elevated serum triacylglycerol levels and can be used for a patient who has not fasted. It does not require the expense of determining serum total cholesterol, HDL cholesterol, and triacylglycerol levels.

THE WAITING ROOM

At his next office visit, **Ivan A.**'s case was reviewed by his physician. **Ivan A.** has several of the major risk factors for coronary heart disease (CHD). These include a sedentary lifestyle, marked obesity, hypertension, hyperlipidemia, and early type 2 diabetes. Unfortunately, he has not been able to follow his doctor's advice with regard to a diabetic diet designed to effect a significant loss of weight, nor has he followed an aerobic exercise program. As a consequence, his weight has increased from 270 to 291 lb. After a 14-hour fast, his serum glucose is now 214 mg/dL (normal, <100 mg/dL), and his serum total cholesterol level is 314 mg/dL (according to recent guidelines, the LDL cholesterol value has an upper limit, but not total cholesterol). His serum triacylglycerol level is 295 mg/dL (desired level is 150 mg/dL or less), and his serum HDL cholesterol is 24 mg/dL (desired level is ≥ 40 mg/dL for a man). His calculated serum LDL cholesterol level is 231 mg/dL (when LDL cholesterol is >190 mg/dL treatment is strongly recommended to help prevent cardiovascular disease).

Anne J. was carefully followed by her physician after she survived her heart attack. Before she was discharged from the hospital, she had blood drawn for a fasting lipid panel. After a 14-hour fast, her serum triacylglycerol level was 158 mg/dL (slightly above the upper range of normal), and her HDL cholesterol level was low at 32

mg/dL (normal for women is ≥ 50 mg/dL). Her serum total cholesterol level was elevated at 420 mg/dL. From these values, her LDL cholesterol level was calculated to be 356 mg/dL (Table 32.1).

TABLE 32.1 Patient Treatment Algorithms

PATIENT STATUS (LINKING AGE WITH LDL CHOLESTEROL LEVELS AND STATUS OF CARDIOVASCULAR DISEASE) AND TREATMENT OPTIONS	TREATMENT RECOMMENDATIONS
Patient age <75 years with clinical ASCVD ^a (atherosclerotic cardiovascular disease)	<ul style="list-style-type: none">A. High-intensity^b statin therapy should be initiated or continued with the aim of achieving a 50% or greater reduction in LDL Cholesterol (LDL-C) levels.B. For patients with clinical ASCVD in whom high-intensity statin therapy is contraindicated or who experience statin-associated side-effects, moderate-intensity^c statin therapy should be initiated or continued with the goal of achieving a 30%–40% reduction in LDL-C levels.C. For patients with clinical ASCVD, who are judged to be very high risk and considered for PCSK9 therapy, maximally tolerated LDL-C lowering therapy should include maximally tolerated statin therapy and ezetimibe.^dD. For patients with clinical ASCVD, who are judged to be very high risk and who are on maximally tolerated LDL-C lowering therapy with LDL-C 70 mg/dL or higher or a non-HDL-C level of 100 mg/dL or higher, it is reasonable to add a PCSK9 inhibitor^d following a clinician–patient discussion about the net benefit, safety and cost.E. For patients with clinical ASCVD, who are on maximally tolerated statin therapy and are judged to be at a very high risk and have an LDL-C level of 70 mg/dL or higher, it is reasonable to add ezetimibe therapy.
Patient age >75 years of age with clinical ASCVD	<ul style="list-style-type: none">A. Initiate moderate- or high-intensity statin therapy after evaluation of the potential for ASCVD risk reduction, adverse effects, all drug–drug interactions, as well as patient frailty and patient preferences.B. If the patient is tolerant to high-intensity statin therapy, it is reasonable to continue high-intensity statin therapy after evaluation of the potential for ASCVD risk reduction, adverse effects, and drug–drug interactions, as well as patient frailty and patient preferences.C. For patients with clinical ASCVD, who are receiving maximally tolerable statin therapy and where LDL-C levels remain 70 mg/dL or higher, it may be reasonable to add ezetimibe.D. For patients with heart failure with reduced ejection fraction attributable to ischemic heart disease, who have a reasonable life expectancy (3–5 years) and are not already on a statin because of ASCVD, clinicians may consider initiation of moderate-intensity statin therapy to reduce the occurrence of ASCVD events.
Patient age 20–75 years LDL-C level of 190 mg/dL	<ul style="list-style-type: none">A. Maximally tolerated statin therapy is recommended.B. If <50% reduction in LDL-C occurs while receiving maximally tolerated statin therapy, or if the LDL-C level is 100 mg/dL or higher, ezetimibe therapy is reasonable.C. If <50% reduction in LDL-C occurs while receiving maximally tolerated statin therapy and ezetimibe and have fasting triglycerides of 300 mg/dL or lower, the addition of a bile acid sequestrant may be considered.
Patient age 30–75 years of age with heterozygous FH and with an LDL-C level of 100 mg/dL or higher	If maximally tolerated statin therapy and ezetimibe are used, the addition of a PCSK9 inhibitor may be considered.

Patient age 40–75 years of age with a baseline LDL-C level of 220 mg/dL or higher and who achieve an on-treatment LDL-C level of 130 mg/dL or higher with maximally tolerated statin and ezetimibe treatment	The addition of a PCSK9 inhibitor may be considered.
Adults 40–75 years of age with diabetes mellitus, regardless of estimated 10-year ASCVD risk	Moderate-intensity statin therapy is indicated.
Adults 40–75 years of age with LDL levels 70–189 mg/dL	In intermediate-risk patients, LDL-C levels should be reduced by 30% or more, and for optimal ASCVD risk reduction, especially in high-risk patients, by 50% or more.

^aClinical disease refers to acute coronary syndrome, or a history of heart attacks, stable or unstable angina, coronary or other arterial revascularization, stroke, transient ischemic attacks (TIA), or peripheral arterial disease

^bA high-intensity statin is a daily dose of statin that lowers LDL cholesterol by approximately $\geq 50\%$.

^cA moderate-intensity statin is a daily dose of statin that lowers LDL cholesterol by approximately 30% to 50%.

^dThe effects of PCSK9 inhibitors and ezetimibe will be described later in the chapter. They are both used for cholesterol-lowering purposes, and work through different mechanisms, and are different from the statin-induced reduction of cholesterol levels.

AHA/ACC/AACVPR/AAPA/ABC/ACPM/ADA/AGS/APhA/ASPC/NLA/PCNA Guideline on the management of blood cholesterol: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines. *Circulation*. 2019;139:e1082–e1143.

Both of **Anne J.**'s younger brothers had “very high” serum cholesterol levels, and both had suffered heart attacks in their mid-forties. With this information, a tentative diagnosis of familial hypercholesterolemia, type IIA, was made, and the patient was started on a diet and medication as recommended by the American College of Cardiology and the American Heart Association Task Force (see book’s online references). This task force recommends that decisions with regard to when dietary and drug therapy should be initiated is based on the risk of cardiovascular disease (Table 32.2).

NUTRIENT ^a	TARGET
Saturated Fat	5%–6% total calories
Trans fat	Avoid
Calories	To achieve and maintain desirable body weight

^aAll values are percentage of total calories eaten.

Data from Stone NJ, Robinson JG, Lichtenstein AH, et al. 2013 ACC/AHA Guideline on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol*. 2014;63:2889–2934.

Anne J. was started on a high-intensity statin, atorvastatin, as she had already experienced a myocardial infarction.

Vera L. is a 32-year-old woman in whom pubertal changes began at age 12, leading to the development of age-appropriate secondary sexual characteristics and the onset of menses at age 13. Her menstrual periods occurred on a monthly basis over the next 7 years, but the flow was scant. At age 20, she noted a gradual increase in her intermenstrual interval from her normal of 28 days to 32 to 38 days. The volume of her menstrual flow also gradually diminished. After 7 months, her menstrual periods ceased. She complained of increasing oiliness of her skin, the appearance of acne-like lesions on her face and upper back, and the appearance of short dark terminal hairs on the mustache and sideburn areas of her face. The amount of extremity hair also increased, and she noticed a disturbing loss of hair from her scalp.

I. Intestinal Absorption of Cholesterol

Cholesterol absorption by intestinal cells is a key regulatory point in human sterol metabolism because it ultimately determines what percentage of the 1,000 mg of biliary cholesterol produced by the liver each day and what percentage of the 300 mg of dietary cholesterol entering the gut per day is eventually absorbed into the blood. In normal subjects, approximately 55% of this intestinal pool enters the blood through the enterocyte

each day. The details of cholesterol absorption from dietary sources were outlined in Chapter 29.

Although the absorption of cholesterol from the intestinal lumen is a diffusion-controlled process, there is also a mechanism to remove unwanted or excessive cholesterol and plant sterols from the enterocyte. The transport of sterols out of the enterocyte and into the gut lumen is related to the products of genes that code for the adenosine triphosphate (ATP)-binding cassette (ABC) transporter protein family, specifically ABCG5 and ABCG8. These proteins form a complex called sterolin that couples ATP hydrolysis to the transport of unwanted or excessive cholesterol and plant sterols (phytosterols) from the enterocyte back into the gut lumen. Another member of the ABC family, ABCA1, is required for reverse cholesterol transport and the biogenesis of HDL. Cholesterol cannot be metabolized to CO_2 and water and is, therefore, eliminated from the body principally in the feces as unreabsorbed sterols and bile acids. ABC transporter protein expression increases the amount of sterols present in the gut lumen, with the potential to increase the elimination of the sterols into the feces. Patients with a condition known as **sitosterolemia** (a rare autosomal recessive disease, also known as **phytosterolemia**) have a defect in the function of either ABCG5 or ABCG8 in the enterocytes, which leads to the accumulation of cholesterol and phytosterols within these cells. These eventually reach the bloodstream, markedly elevating the level of cholesterol and phytosterol in the blood. This accounts for the increased cardiovascular morbidity in individuals with this disorder. From these genetic anomalies, it is clear that agents that either amplify the expression of the ABC transporter proteins within enterocytes or that block cholesterol absorption from the lumen have therapeutic potential in the treatment of patients with hypercholesterolemia. Ezetimibe is a compound that, although structurally distinct from the sterols, lowers serum cholesterol levels by blocking cholesterol absorption by the enterocyte. The target of ezetimibe is the Niemann–Pick C1-like 1 protein (NPC1L1), which is believed to transport cholesterol into cells via an absorptive endocytotic mechanism, involving the protein clathrin coat protein. The reduction of cholesterol absorption from the intestinal lumen has been shown to reduce blood levels of LDL cholesterol, particularly when used with a drug which also blocks endogenous cholesterol synthesis.

Phytosterols interfere with the intestinal absorption of dietary cholesterol by displacing cholesterol from the mixed micelles. Phytosterols also facilitate the excretion of biliary cholesterol in the feces. Phytosterols, once they enter the enterocyte, are poorly incorporated into chylomicrons, and are released into the circulation as free sterols, from which they are taken up by the liver. The ABCG5/G8 transporters then send the phytosterols into the bile for eventual excretion.

What effect would be predicted for ezetimibe on endogenous cholesterol synthesis?

II. Cholesterol Synthesis

Cholesterol is an alicyclic compound whose basic structure contains four fused rings (Fig. 32.1). In its “free” form, the cholesterol molecule contains a number of modifications to the basic ring structure (see Fig. 32.1B). Of note is the hydroxyl group at C3 of the A ring. Approximately one-third of plasma cholesterol exists in the free (or unesterified) form. The remaining two-thirds exist as **cholesterol esters** in which a long-chain fatty acid (usually **linoleic acid**) is attached by ester linkage to the hydroxyl group at C3 of the A ring. Esterified cholesterol is more hydrophobic than free cholesterol due to this modification. The proportions of free and esterified cholesterol in the blood can be measured using methods such as high-performance liquid chromatography (HPLC).

A**B**

FIGURE 32.1 The steroid ring nucleus and cholesterol. **A.** The basic ring structure of sterols; the perhydrocyclopentanophenanthrene nucleus. Each ring is labeled A, B, C, or D. **B.** The structure of cholesterol.

If less cholesterol is obtained from the diet, then cellular cholesterol synthesis would be upregulated. Thus, ezetimibe has a better chance of reducing whole-body cholesterol levels when endogenous cholesterol synthesis is also inhibited, than in the absence of such inhibition.

The synthesis of cholesterol, like that of fatty acids, occurs in the cytoplasm and requires significant reducing power, which is supplied in the form of NADPH. The NADPH is produced by the HMP shunt pathway. All 27 carbons are derived from one precursor, acetyl CoA. Acetyl CoA can be obtained from several sources, including the β -oxidation of fatty acids, the oxidation of ketogenic amino acids, such as leucine and lysine, and the pyruvate dehydrogenase reaction. Energy is also required, which is provided by the hydrolysis of high-energy thioester bonds of acetyl CoA and phosphoanhydride bonds of ATP. Cholesterol synthesis occurs in four stages.

A. Stage 1: Synthesis of Mevalonate from Acetyl CoA

The first stage of cholesterol synthesis leads to the production of the intermediate mevalonate (Fig. 32.2). The synthesis of mevalonate is the committed, rate-limiting step in cholesterol formation. In this cytoplasmic pathway, two molecules of acetyl CoA condense, forming acetoacetyl CoA, which then condenses with a third molecule of acetyl CoA to yield the 6-carbon compound 3-hydroxy-methylglutaryl-CoA (HMG-CoA). The HMG-CoA synthase in this reaction is present in the cytosol and is distinct from the mitochondrial HMG-CoA synthase that catalyzes HMG-CoA synthesis involved in the production of ketone bodies. The committed step and major point of regulation of cholesterol synthesis in stage 1 involves reduction of HMG-CoA to mevalonate, a reaction that is catalyzed by HMG-CoA reductase, an enzyme embedded in the membrane of the endoplasmic reticulum. HMG-CoA reductase contains eight membrane-spanning domains, and the carboxy-terminal domain, which faces the cytoplasm, possesses the enzymatic activity. The reducing equivalents for this reaction are donated by two molecules of NADPH. The regulation of the activity of HMG-CoA reductase is controlled in multiple ways and is described in Section II.E.

FIGURE 32.2 The conversion of three molecules of acetyl coenzyme A (acetyl CoA) to mevalonic acid. acetoacetyl CoA, acetoacetyl coenzyme A; CoA, coenzyme A; HMG-CoA, 3-hydroxymethylglutaryl coenzyme A; NADP, nicotinamide adenine dinucleotide phosphate.

Anne J.'s serum total and LDL cholesterol levels improved only modestly after 3 months on her revised diet and the statin. Three additional months on a more calorie-restricted heart-healthy diet, limited in saturated and trans fat, brought only a small weight loss, with little further improvement in her lab values.

B. Stage 2: Conversion of Mevalonate to Two Activated Isoprenes

In the second stage of cholesterol synthesis, three phosphate groups are transferred from three molecules of ATP to mevalonate (Fig. 32.3). The purpose of these phosphate transfers is to activate both carbon 5 and the hydroxyl group on carbon 3 for further reactions in which these groups will participate. The phosphate group attached to the C3 hydroxyl group of mevalonate in the 3-phospho-5-pyrophosphomevalonate intermediate is removed along with the carboxyl group on C1. This produces a double bond in the 5-carbon product, Δ^3 -isopentenyl pyrophosphate, the first of two activated isoprenes that are necessary for the synthesis of cholesterol. The second activated isoprene is formed when Δ^3 -isopentenyl pyrophosphate is isomerized to dimethylallyl pyrophosphate (see Fig. 32.3). Isoprenes, in addition to being used for cholesterol biosynthesis, are also utilized in the synthesis of coenzyme Q and dolichol.

C. Stage 3: Condensation of Six Activated 5-Carbon Isoprenes to Squalene

The next stage in the biosynthesis of cholesterol involves the head-to-tail condensation of isopentenyl pyrophosphate and dimethylallyl pyrophosphate. The “head” in this case refers to the end of the molecule to which pyrophosphate is linked. In this reaction, the pyrophosphate group of dimethylallyl pyrophosphate is displaced, and a 10-carbon chain, known as geranyl pyrophosphate, is generated (Fig. 32.4). Geranyl pyrophosphate then undergoes another head-to-tail condensation with isopentenyl pyrophosphate, resulting in the formation of the 15-carbon intermediate, farnesyl pyrophosphate. After this, two molecules of farnesyl pyrophosphate undergo a head-to-head fusion, and both pyrophosphate groups are removed to form squalene, a compound that was first isolated from the liver of sharks (genus *Squalus*). Squalene contains 30 carbons (24 in the main chain and 6 in the methyl group branches; see Fig. 32.4).

Geranyl pyrophosphate and farnesyl pyrophosphate are key components in cholesterol biosynthesis, and both farnesyl and geranylgeranyl groups can form covalent bonds with proteins, particularly the G-proteins and certain proto-oncogene products involved in signal transduction. These hydrophobic groups anchor the proteins in the cell membrane.

D. Stage 4: Conversion of Squalene to the Steroid Nucleus

The enzyme squalene monooxygenase adds a single oxygen atom from O_2 to the end of the squalene molecule, forming an epoxide. NADPH then reduces the other oxygen atom of O_2 to H_2O . The unsaturated carbons of the squalene 2,3-epoxide are aligned in a way that allows conversion of the linear squalene epoxide into a cyclic structure. The cyclization leads to the formation of lanosterol, a sterol with the four-ring structure characteristic of the steroid nucleus. A series of complex reactions, containing many steps and elucidated in the late 1950s, leads to the formation of cholesterol (Fig. 32.5).

E. Regulation of HMG-CoA Reductase

HMG-CoA reductase is the rate-limiting step of cholesterol biosynthesis and, as such, is highly regulated. It is also the target of the statins, which are cholesterol-lowering drugs. The regulation of HMG-CoA reductase activity is controlled in multiple ways, including transcriptional regulation, regulation of the amount of enzyme by proteolysis, and covalent modification.

1. Transcriptional Regulation

The rate of synthesis of HMG-CoA reductase messenger RNA (mRNA) is controlled by one of the family of sterol-regulatory element-binding proteins (SREBPs) (Fig. 32.6A). These transcription factors belong to the helix-loop-helix-leucine zipper (bHLH-Zip) family of transcription factors that directly activate the expression of >30 genes dedicated to the synthesis and uptake of cholesterol, fatty acids, triacylglycerols, and phospholipids as well as the production of the NADPH cofactors required to synthesize these molecules. A simplified view of the process is described in the following paragraph.

FIGURE 32.6 Regulation of 3-hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase activity. See text for details and abbreviations. **A.** Transcriptional control. **B.** Regulation by proteolysis. **C.** Regulation by phosphorylation. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; ER, endoplasmic reticulum; P_i , inorganic phosphate; SCAP, SREBP cleavage-activating protein; SRE, sterol-regulatory element; SREBP, sterol-regulatory element-binding proteins; S1P, site 1 protease; S2P, site 2 protease.

SREBPs specifically enhance transcription of the HMG-CoA reductase gene by binding to the sterol-regulatory element (SRE) upstream of the gene. When bound, the rate of transcription is increased. SREBPs are integral proteins of the endoplasmic reticulum (ER). The SREBP is bound to SCAP (SREBP cleavage-activating protein) in the ER membrane when cholesterol levels are high. When cholesterol levels drop, the sterol leaves its SCAP-binding site, and the SREBP:SCAP complex is transported to the Golgi apparatus in coat protein complex II (COPII) containing vesicles. Within the Golgi, two proteolytic cleavages occur (via the

site 1 [S1P] and site 2 [S2P] proteases), which release the *N*-terminal transcription factor domain from the Golgi membrane. Once released, the active amino-terminal component travels to the nucleus to bind to SREs. The soluble SREBPs are rapidly turned over and need to be continuously produced to stimulate reductase mRNA transcription effectively. When cytoplasmic sterol levels rise, the sterols bind to SCAP and prevent translocation of the complex to the Golgi, leading to a decrease in transcription of the reductase gene and thus less reductase protein being produced.

2. Proteolytic Degradation of HMG-CoA reductase

Rising levels of cholesterol and bile salts in cells that synthesize these molecules also may cause a change in the oligomerization state of the membrane domain of HMG-CoA reductase, rendering the enzyme more susceptible to ubiquitination and proteolysis by the proteasome (see Fig. 32.6B). This, in turn, decreases its activity. The membrane domains of HMG-CoA reductase contain sterol-sensing regions, which are similar to those in SCAP.

3. Regulation by Covalent Modification

In addition to the inductive and repressive pathways previously mentioned, the activity of the reductase is also regulated by phosphorylation and dephosphorylation (see Fig. 32.6C). Elevated glucagon levels increase phosphorylation of the enzyme, thereby inactivating it, whereas hyperinsulinemia increases the activity of the reductase by activating phosphatases, which dephosphorylate the reductase. Increased levels of intracellular sterols may also increase phosphorylation of HMG-CoA reductase, thereby reducing its activity as well (feedback inhibition). Thyroid hormone also increases enzyme activity, whereas glucocorticoids decrease its activity. The enzyme that phosphorylates HMG-CoA reductase is the adenosine monophosphate (AMP)-activated protein kinase, which itself is regulated by phosphorylation by one of several AMP-activated protein kinases (one of which is LKB1, see later). Thus, cholesterol synthesis decreases when ATP levels are low and increases when ATP levels are high, similar to what occurs with fatty acid synthesis (recall that acetyl CoA carboxylase is also phosphorylated and inhibited by the AMP-activated protein kinase). As has been seen during the discussion of cholesterol biosynthesis, large amounts of ATP are required to synthesize cholesterol, so low energy levels will lead to inhibition of the pathway.

III. Several Fates of Cholesterol

Almost all mammalian cells are capable of producing cholesterol. Most of the biosynthesis of cholesterol occurs within liver cells, although the gut, the adrenal cortex, and the gonads (as well as the placenta in pregnant women) also produce significant quantities of the sterol. A fraction of hepatic cholesterol is used for the synthesis of hepatic membranes, but the bulk of synthesized cholesterol is secreted from the hepatocyte as one of three moieties: cholesterol esters, biliary cholesterol (cholesterol found in the bile), or bile acids. Cholesterol ester production in the liver is catalyzed by acyl CoA-cholesterol acyl transferase (ACAT). ACAT catalyzes the transfer of a fatty acid from coenzyme A to the hydroxyl group on carbon 3 of cholesterol (Fig. 32.7). The liver packages some of the very hydrophobic esterified cholesterol into the hollow core of lipoproteins, primarily VLDL. VLDL is secreted from the hepatocyte into the blood and transports the cholesterol esters (and triacylglycerols, phospholipids, apolipoproteins, etc.) to the tissues that require greater amounts of cholesterol than they can synthesize *de novo*. These tissues then use the cholesterol for the synthesis of membranes, for the formation of steroid hormones, and for the biosynthesis of vitamin D. The residual cholesterol esters not used in these ways are stored in the liver for later use.

FIGURE 32.7 The acyl coenzyme A cholesterol acyltransferase (ACAT) reaction, producing cholesterol esters. CoA, coenzyme A.

The hepatic cholesterol pool also serves as a source of cholesterol for the synthesis of the relatively hydrophilic bile acids and their salts (see Chapter 29). These derivatives of cholesterol are very effective detergents because they contain both polar and nonpolar regions. They are introduced into the biliary ducts of the liver. They are stored and concentrated in the gallbladder and later discharged into the gut in response to the ingestion of food. They aid in the digestion of intraluminal lipids by forming micelles with them, which

increases the surface area of lipids exposed to the digestive action of intraluminal lipases. Free cholesterol also enters the gut lumen via the biliary tract (approximately 1,000 mg daily, which mixes with 300 mg of dietary cholesterol to form an intestinal pool, roughly 55% of which is resorbed by the enterocytes and enters the bloodstream daily). On a low-cholesterol diet, the liver synthesizes approximately 800 mg of cholesterol per day to replace bile salts and cholesterol lost from the enterohepatic circulation into the feces. Conversely, a greater intake of dietary cholesterol suppresses the rate of hepatic cholesterol synthesis (feedback inhibition).

IV. Synthesis of Bile Salts

A. Conversion of Cholesterol to Cholic Acid and Chenodeoxycholic Acid

Bile salts are synthesized in the liver from cholesterol by reactions that hydroxylate the steroid nucleus and cleave the side chain. In the first and rate-limiting reaction, an α -hydroxyl group is added to carbon 7 (on the α side of the B-ring). The activity of the 7α -hydroxylase that catalyzes this step is decreased by an increase in bile salt concentration (Fig. 32.8).

FIGURE 32.8 The reaction catalyzed by 7α -hydroxylase. An α -hydroxyl group is formed at position 7 of cholesterol. This reaction, which is inhibited by bile salts, is the rate-limiting step in bile salt synthesis. NADP, nicotinamide adenine dinucleotide phosphate.

In subsequent steps, the double bond in the B-ring is reduced, and an additional hydroxylation may occur.

Two different sets of compounds are produced. One set has α -hydroxyl groups at positions 3, 7, and 12 and produces the cholic acid series of bile salts. The other set has α -hydroxyl groups at positions 3 and 7 and produces the chenodeoxycholic acid series (also known as the chenocholic acid series, Fig. 32.9). Three carbons are removed from the side chain by an oxidation reaction. The remaining five-carbon fragment attached to the ring structure contains a carboxyl group (see Fig. 32.9).

FIGURE 32.9 Synthesis of bile salts. Two sets of bile salts are generated; one with α -hydroxyl groups at positions 3 and 7 (the chenodeoxycholate series) and the other with α -hydroxyls at positions 3, 7, and 12 (the cholate series). Note how bile salt accumulation will inhibit the initial step of the pathway, catalyzed by 7 α -hydroxylase.

The pK_a of the bile acids is approximately 6. Therefore, in the contents of the intestinal lumen, which normally have a pH of 6, approximately 50% of the molecules are present in the protonated form and 50% are ionized, which form bile salts. (The terms **bile acids** and **bile salts** are often used interchangeably, but **bile salts** actually refer to the ionized form of the molecules.)

B. Conjugation of Bile Salts

The carboxyl group at the end of the side chain of the bile salts is activated by a reaction that requires ATP and coenzyme A. The CoA derivatives can react with either glycine or taurine (which is derived from cysteine), forming amides that are known as conjugated bile salts (Fig. 32.10). In glycocholic acid and

glycochenodeoxycholic acid, the bile acids are conjugated with glycine. These compounds have a pK_a of approximately 4, so compared to their unconjugated forms, a higher percentage of the molecules is present in the ionized form at the pH of the intestine. The taurine conjugates, taurocholic and taurochenodeoxycholic acid, have a pK_a of approximately 2. Therefore, compared with the glycoconjugates, an even greater percentage of the molecules of these conjugates is ionized in the lumen of the gut.

FIGURE 32.10 Conjugation of bile salts. Conjugation lowers the pK_a of the bile salts, making them better detergents; that is, they are more ionized in the contents of the intestinal lumen ($pH \approx 6$) than are the unconjugated bile salts ($pK_a \approx 6$). The reactions are the same for the chenodeoxycholic acid series of bile salts. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; CoA, coenzyme A; PP_i , pyrophosphate.

C. Fate of the Bile Salts

Bile salts are produced in the liver and secreted into the bile (Fig. 32.11). They are stored in the gallbladder and released into the intestine during a meal, where they serve as detergents that aid in the digestion of dietary lipids (see Chapter 29).

FIGURE 32.11 Overview of bile salt metabolism.

Intestinal bacteria deconjugate and dehydroxylate the bile salts, removing the glycine and taurine residues and the hydroxyl group at position 7. The bile salts that lack a hydroxyl group at position 7 are called **secondary bile salts**. The deconjugated and dehydroxylated bile salts are less soluble and, therefore, are less readily resorbed from the intestinal lumen than the bile salts that have not been subjected to bacterial action (Fig. 32.12). Lithocholic acid, a secondary bile salt that has a hydroxyl group only at position 3, is the least soluble bile salt. Its major fate is excretion.

Primary bile salts

Cholic acid

Chenodeoxycholic acid

Secondary bile salts

Deoxycholic acid

Lithocholic acid

FIGURE 32.12 Structures of the primary and secondary bile salts. Primary bile salts form conjugates with taurine or glycine in the liver. After secretion into the intestine, they may be deconjugated and dehydroxylated by the bacterial flora, forming secondary bile salts. Note that dehydroxylation occurs at position 7, forming the deoxy family of bile salts. Dehydroxylation at position 12 also leads to the excretion of the bile salt.

Greater than 95% of the bile salts are resorbed in the ileum and return to the liver via the enterohepatic circulation (via the portal vein; see Fig. 32.11). The secondary bile salts may be reconjugated in the liver, but they are not rehydroxylated. The bile salts are recycled by the liver, which secretes them into the bile. This enterohepatic recirculation of bile salts is extremely efficient. Less than 5% of the bile salts entering the gut are excreted in the feces each day. Because the steroid nucleus cannot be degraded in the body, the excretion of bile salts serves as a major route for removal of the steroid nucleus and thus of cholesterol from the body.

V. Transport of Cholesterol by the Blood Lipoproteins

Because they are hydrophobic and essentially insoluble in the water of the blood, cholesterol and cholesterol esters, like triacylglycerols and phospholipids, must be transported through the bloodstream packaged as **lipoproteins**. These macromolecules are water soluble. Each lipoprotein particle is composed of a core of hydrophobic lipids such as cholesterol esters and triacylglycerols surrounded by a shell of polar lipids (the phospholipids), and a variety of apolipoproteins, which allows a hydration shell to form around the lipoprotein (see Fig. 29.7). This occurs when the positive charge of the nitrogen atom of the phospholipid (phosphatidylcholine, phosphatidylethanolamine, or phosphatidylserine) forms an ionic bond with the negatively charged hydroxyl ion of the environment. The surface-bound apolipoproteins also increase the water solubility of the lipoprotein particle. Free cholesterol molecules are dispersed throughout the lipoprotein shell to stabilize it in a way that allows it to maintain its spherical shape. The major carriers of lipids are **chylomicrons** (see Chapter 29), **VLDL**, and **HDL**. Metabolism of VLDL leads to **IDL** and **LDL**. Metabolism of chylomicrons leads to the formation of chylomicron remnants.

Through this carrier mechanism, lipids leave their tissue of origin, enter the bloodstream, and are transported to the tissues, where their components are either used in synthetic or oxidative process or stored for later use. The apolipoproteins (“apo” describes the protein within the shell of the particle in its lipid-free form) not only add to the hydrophilicity and structural stability of the particle, they have other functions as well: (1) They activate certain enzymes required for normal lipoprotein metabolism and (2) they act as ligands on the surface of the lipoprotein that target-specific receptors on peripheral tissues that require lipoprotein delivery for their innate cellular functions.

Ten principal apolipoproteins have been characterized. Their tissue sources, molecular mass, distribution within lipoproteins, and metabolic functions are shown in Table 32.3.

TABLE 32.3 Characteristics of the Major Apolipoproteins

APOLIPOPROTEIN	PRIMARY TISSUE SOURCE	MOLECULAR MASS (DALTONS)	LIPOPROTEIN DISTRIBUTION	METABOLIC FUNCTION
ApoA-I	Intestine, liver	28,016	HDL (chylomicrons)	Activates LCAT; structural component of HDL
ApoA-II	Liver	17,414	HDL (chylomicrons)	Structural proteins for HDL; activates hepatic lipase
ApoA-IV	Intestine	46,465	HDL (chylomicrons)	Uncertain; may be involved in assembly of HDL and chylomicrons
ApoA-V	Liver	39,000	VLDL, chylomicrons, HDL	Promotes LPL mediated triglyceride hydrolysis
ApoB-48	Intestine	241,000	Chylomicrons	Assembly and secretion of chylomicrons from small bowel
ApoB-100	Liver	512,000	VLDL, IDL, LDL, Lp(a)	VLDL assembly and secretion; structural protein of VLDL, IDL, and LDL; ligand for LDL receptor
ApoC-I	Liver	6,630	Chylomicrons, VLDL, HDL	Activates LCAT
ApoC-II	Liver	8,800	Chylomicrons, VLDL, HDL	Cofactor activator of lipoprotein lipase (LPL)
ApoC-III	Liver	8,800	Chylomicrons, VLDL, HDL	Inhibitor of LPL; inhibits hepatic uptake of chylomicrons and VLDL remnants
ApoE	Liver	34,145	Chylomicron remnants, IDL, HDL	Ligand for binding of several lipoproteins to the LDL receptor, to the LDL receptor-related protein (LRP) and possibly to a separate apoE receptor
Apo(a)	Liver	250,000–800,000	Lipoprotein "little" a [Lp(a)]	Consists of apoB100 linked by a disulfide bond to apolipoprotein (a); inhibits plasminogen activation and fibrinolysis

HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

Adapted from Feingold KR. Introduction to lipids and lipoproteins. *Endotext* [Internet]. <https://www.ncbi.nlm.nih.gov/books/NBK305896/>

The lipoproteins themselves have been assigned to eight major classes. Some of their characteristics are shown in Table 32.4. Each class of lipoprotein has a specific function determined by its apolipoprotein content, its tissue of origin, and the proportion of the macromolecule made up of triacylglycerols, cholesterol esters, free cholesterol, and phospholipids (see Tables 32.3 and 32.4).

LIPOPROTEIN	DENSITY RANGE (g/mL)	PARTICLE DIAMETER (nm) RANGE	ELECTROPHORETIC MOBILITY	TG	LIPID (%) ^a CHOL	PL	FUNCTION
Chylomicrons	< 0.930	75–1,200	Origin	80–95	2–7	3–9	Deliver dietary lipids (contains the apoproteins B48, C, E, A-1, A-2, A-IV)
Chylomicron remnants	0.930–1.006	30–80	Slow pre-β				Return excess dietary lipids to the liver (contains the apoproteins B48, E)
VLDL	0.930–1.006	30–80	Pre-β	55–80	5–15	10–20	Deliver endogenous lipids (contains the apoproteins B100, E, C)
IDL	1.006–1.019	25–35	Slow pre-β	20–50	20–40	15–25	Return endogenous lipids to the liver; precursor of LDL (contains the apoproteins B100, E, C)
LDL	1.019–1.063	18–25	β	5–15	40–50	20–25	Deliver cholesterol to cells (contains the apoprotein B100)
HDL ₂	1.063–1.125	9–12	α	5–10	15–25	20–30	Reverse cholesterol transport (contains the apoproteins A-1, A-2, C, E)
HDL ₃	1.125–1.210	5–9	α				Reverse cholesterol transport (contains the apoproteins A-1, A-2, C, E)
Lip(a)	1.050–1.120	25	Pre-β				Contains the apoproteins B100, Apo(a)

Chol, the sum of free and esterified cholesterol; IDL, intermediate-density lipoprotein; HDL, high-density lipoprotein; LDL, low-density lipoprotein; PL, phospholipid; TG, triacylglycerols; VLDL, very-low-density lipoprotein.

^aThe remaining percent composition is composed of apolipoproteins.

A. Chylomicrons

Chylomicrons are the largest of the lipoproteins and the least dense because of their rich triacylglycerol content.

They are assembled from dietary lipids (the exogenous lipoprotein pathway) within the epithelial cells of the small intestine and then secreted into the lymphatic vessels draining the gut (see Fig. 29.10). They enter the bloodstream via the left subclavian vein. The major apolipoproteins of chylomicrons are apolipoprotein B-48 (apoB-48), apoCII, and apoE (see Table 32.3). The apoCII activates lipoprotein lipase (LPL), an enzyme that projects into the lumen of capillaries in adipose tissue, cardiac muscle, skeletal muscle, and the acinar cells of mammary tissue. This activation allows LPL to hydrolyze the triacylglycerol of the chylomicrons, leading to the release of free fatty acids. The muscle cells then oxidize the fatty acids as fuel, while the adipocytes and mammary cells store them as triacylglycerols (fat) or, in the case of the lactating breast, use them for milk formation. The partially hydrolyzed chylomicrons remaining in the bloodstream (the chylomicron remnants), now partly depleted of their core triacylglycerols, have lost their apoCII but still retain their apoE and apoB-48 proteins. Receptors in the plasma membranes of the liver cells bind to apoE on the surface of these remnants, allowing them to be taken up by the liver through a process of receptor-mediated endocytosis (see later).

B. Very-Low-Density Lipoprotein

If dietary intake of carbohydrates exceeds the immediate fuel requirements of the liver, the excess carbohydrates are converted to triacylglycerols, which, along with free and esterified cholesterol, phospholipids, and the major apolipoprotein apoB-100 (see Table 32.3), are packaged to form nascent VLDL. These particles are then secreted from the liver (the “endogenous” pathway of lipoprotein metabolism) into the bloodstream (Fig. 32.13), where they accept apoCII and apoE from circulating HDL particles. This then forms the mature VLDL particle. These particles are then transported from the hepatic veins to capillaries in skeletal and cardiac muscle and adipose tissue, as well as lactating mammary tissues, where lipoprotein lipase is activated by apoCII in the VLDL particles. The activated enzyme facilitates the hydrolysis of the triacylglycerol in VLDL, causing the release of fatty acids and glycerol from a portion of core triacylglycerols. These fatty acids are oxidized as fuel by muscle cells, used in the resynthesis of triacylglycerols in fat cells, and used for milk production in the lactating breast. As the VLDL particles are depleted of triacylglycerol, VLDL remnants are formed. Approximately 50% of these remnants are taken up from the blood by liver cells through the binding of VLDL apoE to the hepatocyte plasma membrane apoE receptor, followed by endocytic internalization of the VLDL remnant (similar to the fate of the chylomicron remnant).

FIGURE 32.13 Fate of very-low-density lipoprotein (VLDL). VLDL triacylglycerol (TG) is degraded by lipoprotein lipase (LPL), forming intermediate-density lipoprotein (IDL). IDL can either be endocytosed by the liver through a receptor-mediated process or further digested, mainly by hepatic triacylglycerol lipase (HTGL), to form low-density lipoprotein (LDL). LDL may be endocytosed by receptor-mediated processes in the liver or in peripheral cells. LDL also may be oxidized and taken up by “scavenger” receptors on macrophages. The scavenger pathway plays a role in atherosclerosis. FA, fatty acids; P_i, inorganic phosphate.

 Patients have been identified who lack functional lipoprotein lipase activity (familial lipoprotein lipase deficiency). This is an autosomal recessive disorder with a frequency of 1 per million people worldwide. The hallmark of the disorder is hyperchylomicronemia (extremely high levels of triglyceride in the blood, due to an inability to digest the triglyceride from chylomicrons and VLDL). Patients present with abdominal pain, pancreatitis, hepatosplenomegaly, and eruptive xanthomas on the skin (blisters containing high levels of fats). Treatment consists of a low-fat diet (no more than 15% of total calories) and the addition of medium-chain fatty acids to the diet. Patients can present with this disorder at an early age. A similar disorder is apolipoprotein CII deficiency, in which the activator of lipoprotein lipase is altered. This disorder is usually not as severe as familial LPL deficiency and presents later in life than does LPL deficiency.

C. Intermediate-Density Lipoprotein and Low-Density Lipoprotein

Approximately half of the VLDL remnants are not taken up by the liver but, instead, have additional core triacylglycerols removed to form IDL, a specialized class of VLDL remnants. With the removal of additional triacylglycerols from IDL through the action of hepatic triglyceride lipase within hepatic sinusoids, LDL is generated from IDL. As can be seen in Table 32.4, the LDL particles are rich in cholesterol and cholesterol esters. Approximately 60% of the LDL is transported back to the liver, where its apoB-100 binds to specific apoB-100 receptors in the liver cell plasma membranes, allowing particles to be endocytosed into the hepatocyte. The remaining 40% of LDL particles is carried to extrahepatic tissues such as adrenocortical and gonadal cells that also contain apoB-100 receptors, allowing them to internalize the LDL particles and use their cholesterol for the synthesis of steroid hormones. Some of the cholesterol of the internalized LDL is used for membrane synthesis and vitamin D synthesis as well. If an excess of LDL particles is present in the blood, this specific receptor-mediated uptake of LDL by hepatic and nonhepatic tissue becomes saturated. The “excess” LDL particles are now more readily available for nonspecific uptake of LDL by macrophages (scavenger cells)

present near the endothelial cells of arteries. This exposure of vascular endothelial cells to high levels of LDL is believed to induce an inflammatory response by these cells, a process that has been suggested to initiate the complex cascade of atherosclerosis discussed later.

D. High-Density Lipoprotein

The fourth class of lipoproteins is HDL, which plays several roles in whole-body lipid metabolism.

1. Synthesis of HDL

HDL particles can be created by a number of mechanisms. The first is synthesis of nascent HDL by the liver and intestine as a relatively small complex whose shell, like that of other lipoproteins, contains phospholipids, free cholesterol, and a variety of apolipoproteins, predominant among which are apoA1, apoAII, apoCI, and apoCII (see Table 32.3). Very low levels of triacylglycerols or cholesterol esters are found in the hollow core of this early, or nascent, version of HDL.

A second method for HDL generation is the budding of apolipoproteins from chylomicrons and VLDL particles as they are digested by lipoprotein lipase. The apolipoproteins (particularly apoAI) and shells can then accumulate more lipid, as described later.

A third method for HDL generation is building upon free apoAI, which may be shed from other circulating lipoproteins. The apoAI acquires cholesterol and phospholipids from other lipoproteins and cell membranes, forming a nascent HDL-like particle while in circulation.

2. Maturation of Nascent HDL

In the process of maturation, the nascent HDL particles accumulate phospholipids and cholesterol from cells in which the nascent particles come into contact, including cells lining the blood vessels. As the central hollow core of nascent HDL progressively fills with cholesterol esters, HDL takes on a more globular shape to eventually form the mature HDL particle. The transfer of lipids to nascent HDL does not require enzymatic activity.

3. Reverse Cholesterol Transport

A major benefit of HDL particles derives from their ability to remove cholesterol from cholesterol-laden cells and to return the cholesterol to the liver, a process known as reverse cholesterol transport. This is particularly beneficial in vascular tissue; by reducing cellular cholesterol levels in the subintimal space, the likelihood that foam cells (lipid-laden macrophages that engulf oxidized LDL cholesterol and represent an early stage in the development of atherosclerotic plaque) will form within the blood vessel wall is reduced.

Reverse cholesterol transport requires a directional movement of cholesterol from the cell to the lipoprotein particle. Cells contain the protein ABCA1 (ATP-binding cassette protein 1) that uses ATP hydrolysis to move cholesterol from the inner leaflet of the membrane to the outer leaflet (similar to the efflux of phytosterols by ABCG5 and ABCG8, see section I of this chapter). Once the cholesterol has reached the outer membrane leaflet, the HDL particle can accept it, but if the cholesterol is not modified within the HDL particle, the cholesterol can leave the particle by the same route that it entered. To trap the cholesterol within the HDL core, the HDL particle acquires the enzyme lecithin-cholesterol acyltransferase (LCAT) from the circulation (LCAT is synthesized and secreted by the liver). LCAT catalyzes the transfer of a fatty acid from the 2-position of lecithin (phosphatidylcholine) in the phospholipid shell of the particle to the 3-hydroxyl group of cholesterol, forming a cholesterol ester (Fig. 32.14). The cholesterol ester migrates to the core of the HDL particle and is no longer free to return to the cell.

Lecithin (PC)

Lysolecithin

FIGURE 32.14 The reaction catalyzed by lecithin-cholesterol acyltransferase (LCAT). R₁, saturated fatty acid; R₂, unsaturated fatty acid.

Two genetically determined disorders, familial HDL deficiency and Tangier disease, result from mutations in the ATP-binding cassette 1 (ABCA1) protein. Cholesterol-depleted HDL cannot transport free cholesterol from cells that lack the ability to express this protein. As a consequence, HDL is rapidly degraded. These disorders have established a role for the ABCA1 protein in the regulation of HDL levels in the blood. In both disorders, early-onset coronary artery disease occurs due to the low levels of HDL.

Elevated levels of lipoprotein-associated cholesterol in the blood, particularly that associated with LDL and also the more triacylglycerol-rich lipoproteins, are associated with the formation of cholesterol-rich atheromatous plaque in the vessel wall, leading eventually to diffuse **atherosclerotic vascular disease** that can result in acute cardiovascular events, such as myocardial infarction, stroke, or symptomatic peripheral vascular insufficiency. High levels of HDL in the blood, therefore, are believed to be vasculoprotective because these high levels increase the rate of reverse cholesterol transport “away” from the blood vessels and “toward” the liver (“out of harm’s way”).

Because **Anne J.** continued to experience intermittent chest pain in spite of good control of her hypertension and a 20-lb weight loss, her physician decided that in addition to seeing a cardiologist to further evaluate the chest pain, a second drug needed to be added to her regimen to further lower her blood LDL cholesterol level. Consequently, treatment with ezetimibe, a drug that blocks cholesterol absorption from the intestine, was added to complement the atorvastatin she was already taking.

4. Fate of HDL Cholesterol

Mature HDL particles can bind to specific receptors on hepatocytes (such as the apoE receptor), but the primary means of clearance of HDL from the blood is through its uptake by the scavenger receptor SR-B1. This receptor is present on many cell types. It does not carry out endocytosis per se, but once the HDL particle is bound to the receptor, its cholesterol and cholesterol esters are transferred into the cells. When depleted of cholesterol and its esters, the HDL particle dissociates from the SR-B1 receptor and re-enters the circulation. SR-B1 receptors can be upregulated in certain cell types that require cholesterol for biosynthetic purposes, such as the cells that produce the steroid hormones. The SR-B1 receptors are not downregulated when cholesterol levels are high.

5. HDL Interactions with Other Particles

In addition to its ability to pick up cholesterol from cell membranes, HDL also exchanges apolipoproteins and lipids with other lipoproteins in the blood. For example, HDL transfers apoE and apoCII to chylomicrons and to VLDL. The apoCII stimulates the degradation of the triacylglycerols of chylomicrons and VLDL by activating LPL (Fig. 32.15). After digestion of the chylomicrons and the VLDL triacylglycerols, apoE and apoCII are transferred back to HDL. When HDL obtains free cholesterol from cell membranes, the free cholesterol is esterified at the third carbon of the A ring via the LCAT reaction (see Fig. 32.13). From this point, HDL either transports the free cholesterol and cholesterol esters directly to the liver, as described previously, or by cholesterol ester transfer protein (CETP) to circulating triacylglycerol-rich lipoproteins, such as VLDL and VLDL remnants (see Fig. 32.15). In exchange, triacylglycerols from the latter lipoproteins are transferred to HDL (Fig. 32.16). The greater the concentration of triacylglycerol-rich lipoproteins in the blood, the greater will be the rate of these exchanges.

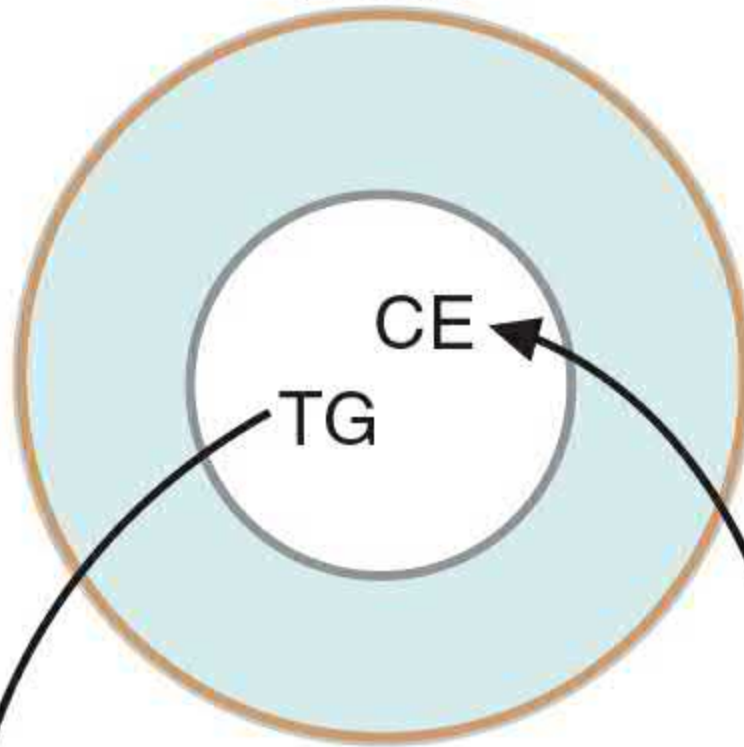

FIGURE 32.15 Functions and fate of high-density lipoprotein (HDL). Nascent HDL is synthesized in liver and intestinal cells. It exchanges proteins with chylomicrons and very-low-density lipoprotein (VLDL). HDL picks up cholesterol (C) from cell membranes. This cholesterol is converted to cholesterol ester (CE) by the lecithin-cholesterol acyltransferase (LCAT) reaction. HDL transfers CE to VLDL in exchange for triacylglycerol (TG). The cholesterol ester transfer protein (CETP) mediates this exchange. Apo, apolipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein.

CE

HDL

FIGURE 32.16 Function of cholesterol ester transfer protein (CETP). CETP transfers cholesterol esters (CE) from high-density lipoprotein (HDL) to very-low-density lipoprotein (VLDL) in exchange for triacylglycerol (TG).

The CETP reaction, under conditions of high levels of triglyceride-rich lipoproteins, generates elevated levels of HDL₃, which are less atheroprotective than HDL₂. CETP inhibitors are currently being evaluated as a means of increasing HDL₂ levels, with limited success. Initial clinical trials of a promising drug were terminated early due to an increased incidence of cardiovascular events when the drug was given in combination with an inhibitor of HMG-CoA reductase. Different CETP inhibitors, however, are currently being examined as potential HDL₂ elevating agents.

The CETP exchange pathway may explain the observation that whenever triacylglycerol-rich lipoproteins are present in the blood in high concentrations, the amount of cholesterol reaching the liver via cholesterol-enriched VLDL and VLDL remnants increases, coupled with a proportional reduction in the total amount of cholesterol and cholesterol esters that are transferred directly to the liver via HDL. Mature HDL particles are designated as HDL₃; after reverse cholesterol transport and the accumulation of cholesterol esters, they become the atherogenic protective form, HDL₂. The CETP reaction then leads to the loss of cholesterol and gain of triacylglycerol, such that the particles become larger and eventually regenerate HDL₃ particles (see Table 32.4). Hepatic lipase can then remove triacylglycerol from HDL₃ particles to regenerate HDL₂ particles.

VI. Receptor-Mediated Endocytosis of Lipoproteins

As stated earlier, each lipoprotein particle contains specific apolipoproteins on its surface that act as ligands for specific plasma membrane receptors on target tissues such as the liver, the adrenal cortex, the gonads, and other cells that require one or more of the components of the lipoproteins. With the exception of the scavenger receptor SR-B1, the interaction of ligand and receptor initiates the process of endocytosis shown for LDL in Figure 32.17. The receptors for LDL, for example, are found in specific areas of the plasma membrane of the target cell for circulating lipoproteins. These are known as coated pits, and they contain a unique protein called clathrin. The plasma membrane in the vicinity of the receptor-LDL complex invaginates and fuses to form an endocytic vesicle. These vesicles then fuse with lysosomes, acidic subcellular vesicles that contain several degradative enzymes. The cholesterol esters of LDL are hydrolyzed to form free cholesterol, which is rapidly re-esterified through the action of ACAT. This rapid reesterification is necessary to avoid the damaging effect of high levels of free cholesterol on cellular membranes. The newly esterified cholesterol contains primarily oleate or palmitoleate (monounsaturated fatty acids), unlike those of the cholesterol esters in LDL, which are rich in linoleate, a polyunsaturated fatty acid.

FIGURE 32.17 Cholesterol uptake by receptor-mediated endocytosis. LDL, low-density lipoprotein.

As is true for the synthesis and activity of HMG-CoA reductase, the synthesis of the LDL receptor itself is subject to feedback inhibition by increasing levels of cholesterol within the cell. As cholesterol levels increase within a cell, synthesis of the LDL receptor is inhibited. When the intracellular levels of cholesterol decrease, both synthesis of cholesterol from acetyl CoA and synthesis of the LDL receptor are stimulated. One probable mechanism for this feedback regulation involves one or more of the SREBPs described earlier. These proteins or the cofactors that are required for the full expression of genes that code for the LDL receptor are also capable of sensing the concentration of sterols within the cell. When sterol levels are high, the process that leads to the binding of the SREBP to the sterol-regulatory element of these genes is suppressed (see Fig. 32.6A). The rate of synthesis from mRNA for the LDL receptor is diminished under these circumstances. This, in turn, appropriately reduces the amount of cholesterol that can enter these cholesterol-rich cells by receptor-mediated endocytosis (downregulation of receptor synthesis). When the intracellular levels of cholesterol decrease, these processes are reversed, and cells act to increase their cholesterol levels. Both synthesis of cholesterol from acetyl CoA and synthesis of LDL receptors are stimulated. An increased number of receptors (upregulation of receptor synthesis) results in an increased uptake of LDL cholesterol from the blood, with a subsequent reduction of LDL cholesterol levels. At the same time, the cellular cholesterol pool is replenished. The upregulation of LDL receptors forms the basis of the mechanism of statin drugs lowering blood LDL levels.

VII. Lipoprotein Receptors

The best-characterized lipoprotein receptor, the LDL receptor, specifically recognizes apoB-100 and apo E. Therefore, this receptor binds VLDL, IDL, and chylomicron remnants in addition to LDL. The binding reaction is characterized by its saturability and occurs with high affinity and a narrow range of specificity. Other receptors, such as the LDL receptor-related proteins (LRP) and the macrophage scavenger receptor (notably types SR-A1 and SR-A2, which are located primarily near the endothelial surface of vascular endothelial cells) have broad specificity and bind many other ligands in addition to the blood lipoproteins.

A. The LDL Receptor

The **LDL receptor** has a mosaic structure encoded by a gene that was assembled by a process known as exon shuffling, in which certain exons are homologous to exons in other genes. The gene contains 18 exons and is >45 kilobases (kb) in length; it is located on the short arm of chromosome 19. The protein encoded by the gene is composed of six different regions (Fig. 32.18). The first region, at the amino terminus, contains the LDL-binding region, a cysteine-rich sequence of 40 residues. Acidic side chains in this region bind ionic calcium. When these side chains are protonated, calcium is released from its binding sites. This release leads to conformational changes that allow the LDL to dissociate from its receptor docking site. Disulfide bonds, formed between the cysteine residues, have a stabilizing influence on the structural integrity of this portion of the receptor.

FIGURE 32.18 Structure of the low-density lipoprotein (LDL) receptor. The protein has six major regions, which are described in the text.

The second region of the receptor contains two domains that are homologous with epidermal growth factor (EGF) as well as with a complex consisting of six repeats that resembles the blades of the transducin β -subunit, forming a propeller-like moiety. This region of the receptor is important for ligand release and recycling of the receptor.

The third region of the LDL receptor contains a chain of *N*-linked oligosaccharides, whereas the fourth region contains a domain that is rich in serine and threonine and contains *O*-linked sugars. This region may have a role in physically extending the receptor away from the membrane so that the LDL-binding region is accessible to the LDL molecule.

The fifth region contains 22 hydrophobic residues that constitute the membrane-spanning unit of the receptor, whereas the sixth region extends into the cytosol, where it regulates the interaction between the C-terminal domain of the LDL receptor and the clathrin-containing coated pit where the process of receptor-mediated endocytosis is initiated.

The number of LDL receptors, the binding of LDL to its receptors, and the postreceptor binding process can be diminished for a variety of reasons. Any interference with receptor binding or uptake can lead to an accumulation of LDL cholesterol in the blood and premature atherosclerosis. These abnormalities can result from mutations in one (heterozygous—seen in ~ 1 in 300 people) or both (homozygous—seen in about 1 in 1 million people) of the alleles for the LDL receptor (**familial hypercholesterolemia**). Heterozygotes produce approximately half of the normal complement of LDL receptors, whereas the homozygotes produce almost no LDL receptor protein (receptor-negative familial hypercholesterolemia). The latter have serum LDL cholesterol levels >500 mg/dL.

The mutations that cause familial hypercholesterolemia are mainly deletions, but insertions or duplications also occur, as well as missense and nonsense mutations. Four classes of mutations have been identified. The first class involves “null” alleles that either direct the synthesis of no protein at all or a protein that cannot be precipitated by antibodies to the LDL receptor. In the second class, the alleles encode proteins, but they cannot be transported to the cell surface. The third class of mutant alleles encodes proteins that reach the cell surface but cannot bind LDL normally. Finally, the fourth class encodes proteins that reach the surface and bind LDL but fail to cluster and internalize the LDL particles. The result of each of these mutations is that blood levels of LDL are elevated because cells cannot take up these particles at a normal rate.

Anne J.'s blood lipid levels (in mg/dL) were as follows:

Triacylglycerol	158
Total cholesterol	420
HDL cholesterol	32
LDL cholesterol	356

She was diagnosed as having familial hypercholesterolemia (FH), type IIA, which is caused by genetic defects in the gene that encodes the LDL receptor (see Fig. 32.18). As a result of the receptor defect, LDL cannot readily be taken up by cells, and its concentration in the blood is elevated.

LDL particles contain a high percentage, by weight, of cholesterol and cholesterol esters, more than other blood lipoproteins. However, LDL triacylglycerol levels are low because LDL is produced by digestion of the triacylglycerols of VLDL and IDL. Therefore, individuals with type IIA hyperlipoproteinemia have very high blood cholesterol levels, but their levels of triacylglycerols may be in or near the normal range (see Table 32.4).

B. LDL Receptor-Related Protein-1

The LRP-1 is structurally related to the LDL receptor but recognizes a broader spectrum of ligands. LRP-1 is a member of a family of at least 8 proteins, all of which bind multiple ligands and have distinct roles in the cell. In addition to lipoproteins, LRP-1 binds the blood proteins α_2 -macroglobulin (a protein that inhibits blood proteases) and tissue plasminogen activator (TPA) and its inhibitors. The LRP-1 receptor recognizes the apoE of lipoproteins and binds remnants produced by the digestion of the triacylglycerols of chylomicrons and VLDL by LPL. Thus, one of its functions is believed to be clearing these remnants from the blood. The LRP-1

receptor is abundant in the cell membranes of the liver, brain, and placenta. In contrast to the LDL receptor, synthesis of the LRP-1 receptor is not significantly affected by an increase in the intracellular concentration of cholesterol. However, insulin causes the number of these receptors on the cell surface to increase, consistent with the need to remove chylomicron remnants that otherwise would accumulate after eating a meal.

Ivan A.'s blood lipid levels were as follows:

Triacylglycerol	295
Total cholesterol	314
HDL cholesterol	24
LDL cholesterol	231

The elevated serum levels of LDL cholesterol found in patients such as **Ivan A.** who have type 2 diabetes mellitus is multifactorial. One of the mechanisms responsible for this increase involves the presence of chronically elevated levels of glucose in the blood of poorly controlled diabetics. This prolonged hyperglycemia increases the rate of nonenzymatic attachment of glucose to various proteins in the body, a process referred to as glycation or glycosylation of proteins.

Glycation may adversely affect the structure or the function of the protein involved. For example, glycation of the LDL receptor and of proteins in the LDL particle may interfere with the normal “fit” of LDL particles with their specific receptors. As a result, less circulating LDL is internalized into cells by receptor-mediated endocytosis, and the serum LDL cholesterol level rises. Additionally, because **Ivan A.** is obese, he exhibits higher than normal levels of circulating free fatty acids, which the liver uses to increase the synthesis of VLDL, leading to hypertriglyceridemia.

C. Macrophage Scavenger Receptor

Some cells, particularly the phagocytic macrophages, have nonspecific receptors known as scavenger receptors that bind various types of molecules, including oxidatively modified LDL particles. There are several different types of scavenger receptors. SR-B1 is used primarily for HDL binding, whereas the scavenger receptors expressed on macrophages are SR-A1 and SR-A2. SR-A1 and SR-A2 recognize a variety of ligands, such as β -amyloid, surface molecules of bacteria, and modified LDL, such as acetylated or oxidized LDL. Modification of LDL frequently involves oxidative damage, particularly of polyunsaturated fatty acyl groups (see Chapter 25). In contrast to the LDL receptors, the scavenger receptors are not subject to downregulation. The continued presence of scavenger receptors in the cell membrane allows the cells to take up oxidatively modified LDL long after intracellular cholesterol levels are elevated. When the macrophages become engorged with lipid, they are called **foam cells**. An accumulation of these foam cells in the subendothelial space of blood vessels forms the earliest gross evidence of a developing atherosclerotic plaque known as a fatty streak.

The processes that cause oxidation of LDL involve exposure to superoxide radicals, nitric oxide, hydrogen peroxide, and other oxidants (see Chapter 25). Antioxidants, such as vitamin E, ascorbic acid (vitamin C), and carotenoids, may be involved in protecting LDL from oxidation.

VIII. Anatomic and Biochemical Aspects of Atherosclerosis

The normal artery is composed of three distinct layers (Fig. 32.19). The layer closest to the lumen of the vessel, the **intima**, is lined by a monolayer of endothelial cells that are bathed by the circulating blood. Just beneath these specialized cells lies the **subintimal extracellular matrix**, in which some vascular smooth muscle cells are embedded (the subintimal space). The middle layer, known as the **tunica media**, is separated from the intima by the **internal elastic lamina**. The tunica media contains lamellae of smooth muscle cells surrounded by an elastin- and collagen-rich matrix. The external elastic lamina forms the border between the tunica media and the outermost layer, the **adventitia**. This layer contains nerve fibers and mast cells. It is the origin of the vasa vasorum, which supplies blood to the outer two-thirds of the tunica media.

FIGURE 32.19 The layers of the arterial wall.

 In addition to nutrition therapy, aimed at reducing her blood cholesterol levels, **Anne J.** was treated with atorvastatin, an HMG-CoA reductase inhibitor. The HMG-CoA reductase inhibitors decrease the rate of synthesis of cholesterol in cells. As cellular cholesterol levels decrease, the synthesis of LDL receptors increases. As the number of receptors increase on the cell surface, the uptake of LDL is accelerated. Consequently, the blood level of LDL cholesterol decreases. **Anne J.** was also treated with ezetimibe, which blocks cholesterol absorption from the intestinal lumen, but has not yet been shown to decrease cardiovascular risk.

The initial step in the development of an atherosclerotic lesion within the wall of an artery is the formation of a **fatty streak**. The fatty streak represents an accumulation of lipid-laden macrophages or foam cells in the subintimal space. These fatty streaks are visible as yellow-white linear streak that bulge slightly into the lumen of the vessel. These streaks are initiated when one or more known vascular risk factors for atherosclerosis, all of which have the potential to injure the vascular endothelial cells, reach a critical threshold at the site of future lesions. Examples of such risk factors include elevated intra-arterial pressure (arterial hypertension), elevated circulating levels of various lipids such as LDL, chylomicron remnants, and VLDL remnants; low levels of circulating HDL, cigarette smoking, chronic elevations in blood glucose levels, high circulating levels of the vasoconstricting octapeptide angiotensin II, and others. The resulting insult to endothelial cells may trigger these cells to secrete adhesion molecules that bind to circulating monocytes and markedly slow their rate of movement past the endothelium. When these monocytic cells are slowed enough, they accumulate and have access to the physical spaces that exist between endothelial cells. This accumulation of monocytic cells resembles the classical inflammatory response to injury. These changes have led to the suggestion that atherosclerosis is, in fact, an inflammatory disorder and, therefore, is one that might be prevented or attenuated through the use of anti-inflammatory agents. Two such agents, acetylsalicylic acid (aspirin) and HMG-CoA reductase inhibitors (statins), have been shown to suppress the inflammatory cascade.

 HDL is considered to be the “good cholesterol,” because it accepts free cholesterol from peripheral tissues, such as cells in the walls of blood vessels. This cholesterol is converted to cholesterol ester, part of which is transferred to VLDL by CETP, and returned to the liver by IDL and LDL. The remainder of the cholesterol is transferred directly as part of the HDL molecule to the liver. The liver reutilizes the cholesterol in the synthesis of VLDL, converts it to bile salts, or excretes it directly into the bile. HDL, therefore, tends to lower blood cholesterol levels. Lower blood cholesterol levels correlate with lower rates of death caused by atherosclerosis.

The monocytic cells are transformed into macrophages that migrate through the spaces between endothelial cells. They enter the subintimal space under the influence of chemoattractant cytokines (e.g., chemokine macrophage chemoattractant protein 1) secreted by vascular cells in response to exposure to oxidatively modified fatty acids within the lipoproteins.

These macrophages can replicate and exhibit augmented expression of receptors that recognize oxidatively modified lipoproteins. Unlike the classic LDL receptors on liver and many nonhepatic cells, these macrophage-bound receptors are high-capacity, low-specificity receptors (scavenger receptors). They bind to and internalize oxidatively modified fatty acids within LDLs eventually becoming subintimal foam cells as described previously. As these foam cells accumulate, they deform the overlying endothelium, causing microscopic separations between endothelial cells, exposing these foam cells and the underlying extracellular matrix to the blood. These exposed areas serve as sites for platelet adhesion and aggregation. Activated platelets secrete cytokines that perpetuate this process and increase the potential for thrombus (clot) formation locally. As the evolving plaque matures, a **fibrous cap** forms over its expanding “roof,” which now bulges into the vascular lumen, thereby partially occluding it. Vascular smooth muscle cells now migrate from the tunica media to the subintimal space and secrete additional plaque matrix material. The smooth muscle cells also secrete metalloproteinases that thin the fibrous cap near its “elbow” at the periphery of the plaque. This thinning progresses until the fibrous cap ruptures, allowing the plaque contents to physically contact the procoagulant elements present within the circulation. This leads to acute thrombus formation. If this thrombus completely occludes the remaining lumen of the vessel, an infarction of tissues distal to the occlusion (i.e., an acute myocardial infarction) may occur (Fig. 32.20). Most plaques that rupture also contain focal areas of calcification, which appear to result from the induction of the same cluster of genes as those that promote the formation of bone. The inducers for this process include oxidized sterols as well as transforming growth factor β (TGF- β) derived from certain vascular cells.

FIGURE 32.20 Evolution of an atherosclerotic plaque. Plaque capsule eroded near the “elbow” of plaque creating an early plaque fissure (A), which may heal as plaque increases in size (B) or may grow as thrombus expands, having an intraluminal portion and an inraintimal portion (C). If the fissure is not properly sealed, the thrombus may grow and completely occlude the vessel lumen (D), causing an acute infarction of tissues downstream of the vessel occlusion.

In patients such as **Anne J.** and **Ivan A.**, who have elevated levels of VLDL or LDL, HDL levels are often low. These patients are predisposed to atherosclerosis and suffer from a high incidence of heart attacks and strokes.

Physical activity and estrogen administration both increase HDL levels. This is one of the reasons physical activity is often recommended to aid in the prevention or treatment of heart disease. Before menopause, the incidence of heart attacks is relatively low in women, but it rises after menopause and increases to the level found in men by the age of 65 or 70 years. Moderate consumption of ethanol (alcohol) has also been correlated with increased HDL levels. Recent studies suggest that the beneficial amount of ethanol may be quite low, about two small glasses of wine a day, and that beneficial effects ascribed to ethanol may result from other components of wine and alcoholic beverages. In spite of the evidence that postmenopausal hormone replacement therapy (HRT) decreases circulating levels of LDL and increases HDL levels, data from controlled trials show that HRT may actually increase the rate of atherosclerotic vascular disease in these women. As a result, the accepted indications for estrogen administration are now limited to intolerable “hot flashes” or vaginal dryness.

Finally, high intraluminal shear forces develop in these thinning or eroded areas of the plaque's fibrous cap, inducing macrophages to secrete additional metalloproteinases that further degrade the arterial-fibrous cap matrix. This contributes further to plaque rupture and thrombus formation (Fig. 32.20). The consequence is a macrovascular ischemic event such as an acute myocardial infarction (AMI) or an acute cerebrovascular accident (CVA).

Studies on LDL receptor metabolism have identified a new potential drug target to increase LDL receptor expression on the cell surface. A protease with the cumbersome name of proprotein convertase subtilisin-like kexin type 9 (PCSK9) has been shown to regulate the levels of LDL receptor on the cell surface. PCSK9 does so by causing degradation of internalized receptors, thereby reducing receptor expression on the cell surface. Patients with FH have been identified with gain of function mutations in PCSK9; the protease is always active, reduces LDL receptor levels, and hypercholesterolemia results. Conversely, individuals have been identified with nonfunctional variants of PCSK9; their LDL levels are extremely low, and in population studies, this group is much less likely to experience atherosclerotic disease than those with functional PCSK9. Recall that statins work, in part, by leading to the activation of SREBP-2, which upregulates LDL receptor synthesis. SREBP-2 also upregulates PCSK9, which aids in regulating LDL receptor expression. Clinical trials using monoclonal antibodies directed against PCSK9, given in conjunction with a statin, showed a significant lowering of circulating LDL levels, and the FDA approved the use of two of these drugs (alirocumab and evolocumab) in the summer of 2015.

IX. Steroid Hormones

Cholesterol is the precursor of all five classes of **steroid hormones**: glucocorticoids, mineralocorticoids, androgens, estrogens, and progestogens. These hormones are synthesized in the adrenal cortex, ovaries, testes, and ovarian corpus luteum. Steroid hormones are transported through the blood from their sites of synthesis to their target organs, where, because of their hydrophobicity, they cross the cell membrane and bind to specific receptors in either the cytoplasm or the nucleus. The bound receptors then bind to DNA to regulate gene transcription (see Chapter 15, Section III.C.2, and Fig. 15.12). Because of their hydrophobicity, steroid hormones in the blood must be complexed with a serum protein. Serum albumin can act as a nonspecific carrier for the steroid hormones, but there are specific carriers as well. For example, sex hormone-binding globulin (SHBG) carries estradiol and testosterone, the corticosteroid-binding globulin (CBG) carries glucocorticoids, and thyroid-binding globulin (TBG) and transthyretin (TTR) both carry thyroid hormones. The use of specific carriers aids in allowing the hormones to interact with their appropriate targets on cells.

Lipoprotein(a) is essentially an LDL particle that is covalently bound to apolipoprotein(a). It is called "lipoprotein little a" to avoid confusion with the apolipoprotein A found in HDL. The structure of apolipoprotein(a) is very similar to that of plasminogen, a precursor of the protease plasmin that degrades fibrin, a major component of blood clots. Lipoprotein(a), however, cannot be converted to active plasmin. There are reports that high concentrations of lipoprotein(a) correlate with an increased risk of coronary artery disease, even in patients in whom the lipid profile is otherwise normal. The physiological function of lipoprotein(a) remains elusive, although it will block plasminogen activation and ultimately, fibrinolysis.

The cholesterol used for steroid hormone synthesis is either synthesized in the tissues from acetyl CoA, extracted from intracellular cholesterol ester pools, or taken up by the cell in the form of cholesterol-containing lipoproteins (either internalized by the LDL receptor or absorbed by the SR-B1 receptor). In general, glucocorticoids and progestogens contain 21 carbons, androgens contain 19 carbons, and estrogens contain 18 carbons. The specific complement of enzymes present in the cells of an organ determines which hormones the organ can synthesize.

A. Overview of Steroid Hormone Synthesis

The biosynthesis of glucocorticoids and mineralocorticoids (in the adrenal cortex), and that of sex steroids (in the adrenal cortex and gonads), requires a number of distinct cytochrome P450 (CYP) enzymes (see Chapter 25 and Table 32.5). These monooxygenases are involved in the transfer of electrons from NADPH through electron transfer protein intermediates to molecular oxygen, which then oxidizes a variety of the ring carbons of cholesterol.

TABLE 32.5 Overview of Steroid Hormones

STEROID GROUP	SITE OF SYNTHESIS	SYNTHESIS STIMULATED BY:	COMMENTS
Glucocorticoids	Adrenal Cortex	Adrenal corticotrophic hormone (ACTH)	Requires a series of oxidative reactions

(Example—cortisol)			
Mineralocorticoids (Example—aldosterone)	Adrenal Cortex	Angiotensin I Angiotensin II Increased potassium concentration in the blood Reduced sodium concentration in the blood	Angiotensins are released in response to a reduction in extracellular fluid volume. Aldosterone stimulates sodium resorption in tissues, resulting in an increase in extracellular fluid volume and blood pressure.
Androgens (Example—testosterone)	Leydig cells of testes Ovary	Luteinizing Hormone (LH)	In males, testosterone is converted to dihydrotestosterone, a higher potency form of the hormone, in specific tissues.
Estrogens (Example—17 β -estradiol)	Ovarian follicle Corpus luteum	Follicle-stimulating hormone (FSH)	Estradiol inhibits the synthesis and secretion of FSH.
Progestogens (Example—progesterone)	Corpus luteum	LH	In combination with estradiol, progesterone prepares the uterine endometrium for implantation of the fertilized ovum and acts as a differentiation factor in mammary gland development.

 **Vera L.** consulted her gynecologist, who confirmed that her problems were probably the result of an excess production of androgens (virilization) and ordered blood and urine studies to determine whether **Vera L.**'s adrenal cortices or her ovaries were causing her virilizing syndrome.

Cholesterol is converted to progesterone in the first two steps of the synthesis of all steroid hormones. Cytochrome P450_{SCC} (scc = side-chain cleavage) side-chain cleavage enzyme (previously referred to as cholesterol desmolase, and classified as CYP11A) is located in the mitochondrial inner membrane and removes six carbons from the side chain of cholesterol, forming pregnenolone, which has 21 carbons (Fig. 32.21). The next step, the conversion of pregnenolone to progesterone, is catalyzed by 3- β -hydroxysteroid dehydrogenase, an enzyme that is not a member of the cytochrome P450 family. Other steroid hormones are produced from progesterone by reactions that involve members of the P450 family. These include the mitochondrial enzyme cytochrome P450_{C11} (CYP11B1), which catalyzes β -hydroxylation at carbon 11, and two ER enzymes, P450_{C17} (17- α -hydroxylation, CYP17) and P450_{C21} (hydroxylation at carbon 21, CYP21). As the synthesis of the steroid hormones is discussed, notice how certain enzymes are used in more than one pathway. Defects in these enzymes lead to multiple abnormalities in steroid synthesis, which, in turn, results in a variety of abnormal phenotypes.

FIGURE 32.21 Synthesis of the steroid hormones. The rings of the precursor, cholesterol, are lettered. Dihydrotestosterone is produced from testosterone by reduction of the carbon–carbon double bond in ring A. The *dashed lines* indicate alternative pathways to the major pathways indicated. The starred enzymes are those that may be defective in congenital adrenal hyperplasia. CYP, a designation for a cytochrome P450 containing enzyme; DHEA, dehydroepiandrosterone.

B. Synthesis of Cortisol

The adrenocortical biosynthetic pathway that leads to **cortisol** synthesis occurs in the middle layer of the adrenal cortex, known as the zona fasciculata. Free cholesterol is transported by an intracellular carrier protein to the inner mitochondrial membrane of cells (Fig. 32.22), where the side chain is cleaved to form pregnenolone. Pregnenolone returns to the cytosol, where it forms progesterone. Pregnenolone returns to the cytosol, where it forms progesterone.

FIGURE 32.22 Cellular route for cortisol synthesis. Cholesterol is synthesized from acetyl CoA or derived from low-density lipoprotein (LDL), which is endocytosed and digested by lysosomal enzymes. Cholesterol is stored in cells of the adrenal cortex as cholesterol esters. Adrenocorticotropic hormone (ACTH) signals the cell to convert cholesterol to cortisol and transmits its signal through a G-protein-coupled receptor that results in the activation of adenylate cyclase, and, ultimately, PKA. (1) cholesterol desmolase (P450_{SCC}, involved in side-chain cleavage); (2) 3 β -hydroxysteroid dehydrogenase; (3) 17 α -hydroxylase (P450_{C17}); (4) 21-hydroxylase (P450_{C21}); (5) 11 β -hydroxylase (P450_{C11}). ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate.

In the membrane of the ER, the enzyme P450_{C17} (CYP17) catalyzes the hydroxylation of C17 of progesterone or pregnenolone and can also catalyze the cleavage of the two-carbon side chain of these compounds at C17 (a C17–C20 lyase activity), which forms androstenedione from 17- α -hydroxyprogesterone. These two separate functions of the same enzyme allow further steroid synthesis to proceed along two separate pathways: The 17-hydroxylated steroids that retain their side chains are precursors of cortisol (C21), whereas those from which the side chain was cleaved (C19 steroids) are precursors of androgens (male sex hormones) and estrogens (female sex hormones).

In the pathway of cortisol synthesis, the 17-hydroxylation of progesterone yields 17- α -hydroxyprogesterone, which, along with progesterone, is transported to the smooth ER. There, the membrane-bound P450_{C21} (CYP21, 21- α -hydroxylase) complex catalyzes the hydroxylation of C21 of 17- α -hydroxyprogesterone to form 11-deoxy cortisol and progesterone to form deoxycorticosterone (DOC), a precursor of the mineralocorticoid, aldosterone (see Fig. 32.21).

The final step in cortisol synthesis requires transport of 11-deoxycortisol back to the inner membrane of the mitochondria, where P450_{C11} (11- β -hydroxylase, CYP11B1) catalyzes the β -hydroxylation of the substrate at carbon 21, in a reaction that requires molecular oxygen and electrons derived from NADPH, to form cortisol. The rate of biosynthesis of cortisol and other adrenal steroids depends on stimulation of the adrenal cortical cells in the zona fasciculata, by adrenocorticotropic hormone (ACTH), as the cells in this area of the adrenal gland are responsive to ACTH via a G-protein linked receptor. ACTH is produced in the anterior of the pituitary gland and is often released in response to biological stress.

C. Synthesis of Aldosterone

The synthesis of the potent mineralocorticoid **aldosterone** in the zona glomerulosa of the adrenal cortex also begins with the conversion of cholesterol to progesterone (see Figs. 32.21 and 32.22). Progesterone is then hydroxylated at C21, a reaction catalyzed by P450_{C21} (CYP21), to yield 11-DOC. The P450_{C11} (CYP11B1) enzyme system then catalyzes the reactions that convert DOC to corticosterone. The terminal steps in aldosterone synthesis, catalyzed by the P450 aldosterone system (CYP11B2), involve the oxidation of corticosterone to 18-hydroxycorticosterone, which is oxidized to aldosterone.

Hyperplasia or tumors of the adrenal cortex that produce excess aldosterone result in a condition known as primary aldosteronism, which is characterized by enhanced sodium and water retention, resulting in hypertension.

Although aldosterone is the major mineralocorticoid in humans, excessive production of a weaker mineralocorticoid, DOC, which occurs in patients with a deficiency of the 11-hydroxylase (the P450_{C11} enzyme, CYP11B1), may lead to clinical signs and symptoms of mineralocorticoid excess even though aldosterone secretion is suppressed in these patients.

The primary stimulus for aldosterone production is the octapeptide angiotensin II, although hyperkalemia (greater than normal levels of potassium in the blood) or hyponatremia (less than normal levels of sodium in the blood) may stimulate aldosterone synthesis directly as well. ACTH has a permissive action in aldosterone production. It allows cells to respond optimally to their primary stimulus, angiotensin II. The cells in the zona glomerulosa contain angiotensin II receptors, which are G-protein linked receptors.

D. Synthesis of the Adrenal Androgens

Adrenal androgen biosynthesis proceeds from cleavage of the two-carbon side chain of 17-hydroxypregnenolone at C17 to form the 19-carbon adrenal androgen dehydroepiandrosterone (DHEA) and its sulfate derivative (DHEAS) in the zona reticularis of the adrenal cortex (see Fig. 32.21). These compounds, which are weak androgens, represent a significant percentage of the total steroid production by the normal adrenal cortex and are the major androgens synthesized in the adrenal gland.

Androstenedione, another weak adrenal androgen, is produced by oxidation of the β -hydroxy group to a carbonyl group by 3- β -hydroxysteroid dehydrogenase. This androgen is converted to testosterone primarily in extra-adrenal tissues. Although the adrenal cortex makes very little estrogen, the weak adrenal androgens may be converted to estrogens in the peripheral tissues, particularly in adipose tissue (Fig. 32.23).

Adrenal

Dehydroepiandrosterone

Androstenedione

FIGURE 32.23 Adrenal androgens. These weak androgens are converted to testosterone or estrogens in other tissues.

E. Synthesis of Testosterone

Luteinizing hormone (LH) from the anterior pituitary stimulates the synthesis of testosterone and other androgens by the Leydig cells of the human testicle. In many ways, the pathways leading to androgen synthesis in the testicle are similar to those described for the adrenal cortex. In the human testicle, the predominant pathway leading to testosterone synthesis is through pregnenolone to 17- α -hydroxypregnenolone to dehydroepiandrosterone (DHEA, the Δ^5 pathway), and then from DHEA to androstenedione, and from androstenedione to testosterone (see Fig. 32.21). As for all steroids, the rate-limiting step in testosterone production is the conversion of cholesterol to pregnenolone. LH controls the rate of side-chain cleavage from cholesterol at carbon 21 to form pregnenolone and thus regulates the rate of testosterone synthesis. In its target cells, the double bond in ring A of testosterone is reduced through the action of 5- α -reductase, forming the active hormone dihydrotestosterone (DHT).

Congenital adrenal hyperplasia (CAH) is a group of diseases caused by a genetically determined deficiency in a variety of enzymes required for cortisol synthesis. The most common deficiency is that of 21- α -hydroxylase (CYP21), the activity of which is necessary to convert progesterone to 11-deoxycorticosterone and 17- α -hydroxyprogesterone to 11-deoxycortisol. Thus, this deficiency reduces both aldosterone and cortisol production without affecting androgen production. If the enzyme deficiency is severe, the precursors for aldosterone and cortisol production are shunted to androgen synthesis, producing an overabundance of androgens, which leads to prenatal masculinization in females and postnatal virilization of males. Another enzyme deficiency in this group of diseases is that of 11- β -hydroxylase (CYP11B1), which results in the accumulation of 11-deoxycorticosterone. An excess of this mineralocorticoid leads to hypertension (through abnormal activation of the aldosterone receptor by excess 11-deoxycorticosterone). In this form of CAH, 11-deoxycortisol also accumulates, but its biological activity is minimal, and no specific clinical signs and symptoms result. The androgen pathway is

unaffected, and the increased ACTH levels may increase the levels of adrenal androgens in the blood. A third possible enzyme deficiency is that of 17- α -hydroxylase (CYP17). A defect in 17- α -hydroxylase leads to aldosterone excess and hypertension; however, because adrenal androgen synthesis requires this enzyme, no virilization occurs in these patients.

F. Synthesis of Estrogens and Progesterone

Ovarian production of **estrogens**, **progestogens** (compounds related to progesterone), and **androgens** requires the activity of the cytochrome P450 family of oxidative enzymes used for the synthesis of other steroid hormones. Ovarian estrogens are C18 steroids with a phenolic hydroxyl group at C3 and either a hydroxyl group (estradiol) or a ketone group (estrone) at C17. Although the major steroid-producing compartments of the ovary (the granulosa cell, the theca cell, the stromal cell, and the cells of the corpus luteum) have all of the enzyme systems required for the synthesis of multiple steroids, the granulosa cells secrete primarily estrogens, the thecal and stromal cells secrete primarily androgens, and the cells of the corpus luteum secrete primarily progesterone.

The ovarian granulosa cell, in response to stimulation by follicle-stimulating hormone (FSH) from the anterior pituitary gland and through the catalytic activity of P450 aromatase (CYP19), converts testosterone to estradiol, the predominant and most potent of the ovarian estrogens (see Fig. 32.21). Similarly, androstenedione is converted to estrone in the ovary, although the major site of estrone production from androstenedione occurs in extraovarian tissues, principally skeletal muscle and adipose tissue.

G. Vitamin D Synthesis

Vitamin D is unique in that it can be either obtained from the diet (as vitamin D₂ or D₃) or synthesized from a cholesterol precursor, a process that requires reactions in the skin, liver, and kidney. The calciferols, including several forms of vitamin D, are a family of steroids that affect calcium homeostasis (Fig. 32.24). Cholecalciferol (vitamin D₃) requires ultraviolet light for its production from 7-dehydrocholesterol, which is present in cutaneous tissues (skin) in animals and available from ergosterol in plants. UV irradiation cleaves the carbon-carbon bond at C9-C10, opening the B-ring to form cholecalciferol, an inactive precursor of 1,25-(OH)₂-cholecalciferol (calcitriol). Calcitriol is the most potent biologically active form of vitamin D (see Fig. 32.24).

(1,25-(OH)₂D₃)**

FIGURE 32.24 Synthesis of active vitamin D. $1,25\text{-(OH)}_2\text{D}_3$ is produced from 7-dehydrocholesterol, a precursor of cholesterol. In the skin, ultraviolet (UV) light produces cholecalciferol, which is hydroxylated at the 25-position in the liver and the 1-position in the kidney to form the active hormone. PTH, parathyroid hormone.

Biologically, the most potent circulating androgen is testosterone. Approximately 50% of the testosterone in the blood in a normal woman is produced equally in the ovaries and in the adrenal cortices. The remaining half is derived from ovarian and adrenal androstenedione, which, after secretion into the blood, is converted to testosterone in adipose tissue, muscle, liver, and skin. The adrenal cortex, however, is the major source of the relatively weak androgen dehydroepiandrosterone (DHEA). The serum concentration of its stable metabolite, DHEAS, is used as a measure of adrenal androgen production in hyperandrogenic patients with diffuse excessive growth of secondary sexual hair, for example, facial hair as well as that in the axillae, the suprapubic area, the chest, and the upper extremities.

Rickets is a disorder of young children caused by a deficiency of vitamin D. Low levels of calcium and phosphorus in the blood are associated with skeletal deformities in these children.

The formation of calcitriol from cholecalciferol begins in the liver and ends in the kidney, where the pathway is regulated. In this activation process, carbon 25 of vitamin D_2 or D_3 is hydroxylated in the microsomes of the liver to form 25-hydroxycholecalciferol (calcidiol). Calcidiol circulates to the kidney bound to vitamin D-binding globulin (transcalfiferin). In the proximal convoluted tubule of the kidney, a mixed-function oxidase, which requires molecular O_2 and NADPH as cofactors, hydroxylates carbon 1 on the A ring to form calcitriol. This step is tightly regulated and is the rate-limiting step in the production of the active hormone. The release of parathyroid hormone from the parathyroid gland results in activation of this last step of active vitamin D formation.

$1,25\text{-(OH)}_2\text{D}_3$ (calcitriol) is approximately 100 times more potent than 25-(OH)D_3 in its actions, yet 25-(OH)D_3 is present in the blood in a concentration that may be 100 times greater, which suggests that it may play some role in calcium and phosphorus homeostasis.

The biologically active forms of vitamin D are steroid hormones and, like other steroids, diffuse passively through the plasma membrane. In the intestine, bone, and kidney, the steroid then moves into the nucleus and binds to specific vitamin D_3 receptors. The resulting complex activates genes that encode proteins mediating the action of active vitamin D_3 . In the intestinal mucosal cell, for example, transcription of genes that encode calcium-transporting proteins are activated. These encoded proteins are capable of carrying Ca^{2+} (and phosphorus) absorbed from the gut lumen across the cell, making it available for eventual passage into the circulation.

CLINICAL COMMENTS

Anne J. is typical of patients with essentially normal serum triacylglycerol levels and elevated serum total cholesterol levels that are repeatedly in the upper 1% of the general population (e.g., 325 to 500 mg/dL). When similar lipid abnormalities are present in other family members in a pattern of autosomal dominant inheritance and no secondary causes for these lipid alterations (e.g., hypothyroidism) are present, the entity referred to as familial hypercholesterolemia (FH), type IIA, is the most likely cause of this hereditary dyslipidemia.

FH is a genetic disorder caused by an abnormality in one or more alleles responsible for the biosynthesis or the functional integrity of high-affinity LDL receptors on the plasma membrane of cells that normally initiate the internalization of circulating LDL and other blood lipoproteins. Heterozygotes for FH (1 in 500 of the population) have roughly one-half of the normal complement or functional capacity of such receptors, whereas homozygotes (1 in 1 million of the population) have essentially no functional LDL receptors. The rare patient with the homozygous form of FH has a more extreme elevation of serum total and LDL cholesterol than does the heterozygote and, as a result, has a more profound predisposition to premature coronary artery disease.

Chronic hypercholesterolemia not only may cause the deposition of lipid within vascular tissues leading to atherosclerosis but also may cause the deposition of lipid within the skin and eye. When this occurs in the medial aspect of the upper and lower eyelids, it is referred to as xanthelasma. Similar deposits known as xanthomas may occur in the iris of the eye (arcus lipidalis) as well as the tendons of the hands (“knuckle pads”) and Achilles tendons.

Although therapy aimed at inserting competent LDL receptor genes into the cells of patients with

homozygous FH is being designed for the future, the current approach in the treatment of heterozygotes is to attempt to increase the rate of synthesis of LDL receptors in cells pharmacologically.

 The results of the blood tests on **Vera L.** showed that her level of testosterone was normal but that her serum dehydroepiandrosterone sulfate (DHEAS) level was significantly elevated. Which tissue was the most likely source of the androgens that caused **Vera L.**'s hirsutism (a male pattern of secondary sexual hair growth)?

HMG-CoA reductase inhibitors, such as atorvastatin, which **Anne J.** is taking, stimulate the synthesis of additional LDL receptors by inhibiting HMG-CoA reductase, the rate-limiting enzyme for cholesterol synthesis. The subsequent decline in the intracellular free cholesterol pool stimulates the synthesis of additional LDL receptors. These additional receptors reduce circulating LDL cholesterol levels by increasing receptor-mediated endocytosis of LDL particles.

A combination of strict dietary and pharmacological therapy, aimed at decreasing the cholesterol levels of the body, is usually quite effective in correcting the lipid abnormality and, hopefully, the associated risk of atherosclerotic cardiovascular disease in patients with heterozygous FH.

 **Ivan A.** Low-density lipoprotein cholesterol is the primary target of cholesterol-lowering therapy because both epidemiological and experimental evidence strongly suggest a benefit of lowering serum LDL cholesterol in the prevention of atherosclerotic cardiovascular disease. Similar evidence for raising subnormal levels of serum HDL cholesterol is less conclusive but adequate to support such efforts, particularly in high-risk patients, such as **Ivan A.**, who have multiple cardiovascular risk factors.

 **Anne J.** was treated with a statin (atorvastatin) and ezetimibe. Ezetimibe reduces the percentage of absorption of free cholesterol present in the lumen of the gut and hence the amount of cholesterol available to the enterocyte to package into chylomicrons. This, in turn, reduces the amount of cholesterol returning to the liver in chylomicron remnants. The net result is a reduction in the cholesterol pool in hepatocytes. The latter induces the synthesis of an increased number of LDL receptors by the liver cells. As a consequence, the capacity of the liver to increase hepatic uptake of LDL from the circulation leads to a decrease in serum LDL levels. Despite this decrease in LDL levels, the drug has not been shown to decrease cardiovascular events in patients.

So far, **Ivan A.** has failed in his attempts to reach his diet and physical activity goals. His LDL cholesterol level is 231 mg/dL. Based on his cardiovascular risk, he is a candidate for drug treatment. He should be given a high-intensity HMG-CoA reductase inhibitor. It is important to gain early control of his cardiovascular risk factors before the effects can no longer be reversed. A variety of lipid-lowering agents are summarized in Table 32.6.

AGENT	MECHANISM OF ACTION	PERCENTAGE CHANGE IN SERUM LIPID LEVEL (MONOTHERAPY)			
		TOTAL CHOLESTEROL	LDL CHOLESTEROL	HDL CHOLESTEROL	TRIACYLGLYCEROLS
Statins	Inhibits HMG-CoA reductase activity	↓ 15–60	↓ 20–60	↑ 5–15	↓ 10–40
Bile acid resins	Increase fecal excretion of bile salts	↓ 15–20	↓ 10–25	↑ 3–5	Variable, depending on pretreatment level of triacylglycerols (may increase)
Niacin (high dose)	Activates LPL; reduces hepatic production of VLDL; reduces catabolism of HDL	↓ 22–25	↓ 10–25	↑ 15–35	↓ 20–50
Fibrates	Antagonizes the transcription factor PPAR- α , causing an increase in LPL activity, a decrease in apolipoprotein CIII production, and an increase in apolipoprotein AI production	↓ 12–15	Variable, depending on pretreatment levels of other lipids	↑ 5–15	↓ 20–50
Ezetimibe	Reduces intestinal absorption of free cholesterol from the gut lumen	↓ 10–15	↓ 15–20	↑ 1–3	↓ 5–8 if triacylglycerols are high pretreatment

HDL, high-density lipoprotein; HMG-CoA, 3-hydroxymethylglutaryl coenzyme A; LPL, lipoprotein lipase; LDL, low-density

lipoprotein; PPAR, peroxisome proliferator-activated receptor; triacylglycerols, triglycerides.

Adapted from Third report of the National Cholesterol Education Program (NCEP) expert panel on detection, evaluation, and treatment of high blood cholesterol in adults (Adult Treatment Panel III) final report. *Circulation*. 2002;106:3143–3257.

Vera L. was born with a female genotype and phenotype, she had normal female sexual development, spontaneous onset of puberty, and regular, although somewhat scanty, menses until the age of 20 years. At that point, she developed secondary amenorrhea (cessation of menses) and evidence of male hormone excess with early virilization (masculinization).

Recent recommendations from the 2019 ACC/AHA guideline on the prevention of cardiovascular disease have clarified when low-dose aspirin (81 mg/day) should be offered to patients. Aspirin is well established for secondary prevention in individuals who have experienced a cardiac event, but the literature suggests that there is no net benefit of low-dose aspirin preventing a primary cardiovascular event. The overall recommendation states that “low-dose aspirin might be considered for primary prevention of atherosclerotic cardiovascular disease (ASCVD) in select higher risk ASCVD adults aged 40 to 70 years who are not at increased bleeding risk.” In addition, the recommendation discourages aspirin use for primary prevention of ASCVD in adults >70 years of age, or for those of any age (primary prevention) who are at increased bleeding risk. See: Arnett DK, Blumenthal RS, Albert MA, et al. 2019 ACC/AHA guideline on the primary prevention of cardiovascular disease: A report of the American College of Cardiology/American Heart Association task force on clinical practice guidelines. *J Am Coll Cardiol*. 2019;140:e596–e646.

The differential diagnosis included an ovarian versus an adrenocortical source of the excess androgenic steroids. A screening test to determine whether the adrenal cortex or the ovary is the source of excess male hormone involves measuring the concentration of dehydroepiandrosterone sulfate (DHEAS) in the patient’s plasma because the adrenal cortex makes most of the DHEA and the ovary makes little or none. **Vera L.**’s plasma DHEAS level was moderately elevated, identifying her adrenal cortices as the likely source of her virilizing syndrome.

If the excess production of androgens is not the result of an adrenal tumor, but rather the result of a defect in the pathway for cortisol production, the simple treatment is to administer glucocorticoids by mouth. The rationale for such treatment can be better understood by reviewing Figure 32.21. If **Vera L.** has a genetically determined partial deficiency in the P450_{C11} enzyme system needed to convert 11-deoxycortisol to cortisol (nonclassic congenital adrenal hyperplasia), her blood cortisol levels would fall. By virtue of the normal positive feedback mechanism, a subnormal level of cortisol in the blood would induce the anterior pituitary to make more ACTH. The latter would not only stimulate the cortisol pathway to increase cortisol synthesis to normal but, in the process, would also induce increased production of adrenal androgens such as DHEA and DHEAS. The increased levels of the adrenal androgens (although relatively weak androgens) would cause varying degrees of virilization, depending on the severity of the enzyme deficiency. The administration of a glucocorticoid by mouth would suppress the high level of secretion of ACTH from the anterior pituitary gland that occurs in response to the reduced levels of cortisol secreted from the adrenal cortex. Treatment with prednisone (a synthetic glucocorticoid), therefore, will prevent the ACTH-induced overproduction of adrenal androgens. However, when ACTH secretion returns to normal, endogenous cortisol synthesis falls below normal. The administered prednisone brings the net glucocorticoid activity in the blood back to physiological levels. **Vera L.**’s adrenal androgen levels in the blood returned to normal after several weeks of therapy with prednisone. As a result, her menses eventually resumed, and her virilizing features slowly resolved.

Vera L.’s hirsutism was most likely the result of a problem in her adrenal cortex that caused excessive production of DHEA.

Because **Vera L.**’s symptoms began in adult life, her genetically determined adrenal hyperplasia is referred to as a “nonclassic” or “atypical” form of the disorder. A more severe enzyme deficiency leads to the “classic” disease, which is associated with excessive fetal adrenal androgen production in utero and manifests at birth, often with ambiguous external genitalia and virilizing features in the female neonate.

BIOCHEMICAL COMMENTS

Drugs used to treat certain aspects of the metabolic syndrome improve insulin sensitivity and regulate lipid levels through modulation of the pathways discussed in Chapters 29 through 32. These drugs work by modifying the regulatory pathways that have been discussed so far with regard to carbohydrate and lipid

metabolism.

 The LKB1 protein is a tumor suppressor; loss of LKB1 activity leads to Peutz–Jeghers syndrome (PJS). PJS exhibits the early development of hamartomatous polyps (benign polyps) in the gastrointestinal tract, and an increased incidence of carcinomas at a relatively young age. LKB1 regulates the activity of 14 kinases that include, and are similar to, the AMP-activated protein kinase. Loss of the normal regulation of these kinases, due to the absence of LKB1 activity, significantly contributes to tumor formation.

Metformin. Metformin has been used for >30 years as a treatment for type 2 diabetes. Metformin reduces blood glucose levels by inhibiting hepatic gluconeogenesis, which is active in these patients due to the liver's resistance to the effects of insulin. Metformin also reduces lipid synthesis in the liver, which aids in modulating blood lipid levels in these patients.

Metformin accomplishes its effects by activating the AMP-activated protein kinase (AMPK). It does so through activation of an upstream protein kinase, LKB1, via an unknown mechanism. As has been discussed previously, AMPK, when active, phosphorylates and reduces the activity of acetyl CoA carboxylase (required for fatty acid synthesis) and HMG-CoA reductase (reducing the biosynthesis of cholesterol). Activation of AMPK also activates glucose uptake by the muscle (see Chapter 45), which is significant for reducing circulating blood glucose levels.

The activation of AMPK also leads to a cascade of transcriptional regulation that reduces the liver's ability to undergo both gluconeogenesis and lipogenesis. Activated AMPK phosphorylates a coactivator of the cAMP response element-binding protein (CREB) transcription factor named **transducer of regulated CREB activity 2 (TORC2)** (Fig. 32.25). When TORC2 is phosphorylated, it is sequestered in the cytoplasm, and CREB becomes very inefficient at transcribing a gene that is required to upregulate genes that code for the enzymes involved in gluconeogenesis. This important transcriptional coactivator is named peroxisome proliferator-activated receptor- γ coactivator 1 α (PGC1 α). PGC1 α participates in the transcriptional activation of key gluconeogenic enzymes, such as glucose 6-phosphatase and phosphoenolpyruvate carboxykinase (PEPCK). Thus, in the presence of metformin, hepatic gluconeogenesis is reduced and muscle uptake of blood glucose is enhanced, leading to stabilization of blood glucose levels. The physiological regulators of LKB1 have yet to be identified.

FIGURE 32.25 Action of metformin on gluconeogenesis. Under normal conditions, increases of hepatic cyclic adenosine monophosphate (cAMP) levels (e.g., in response to glucagon) activate cAMP response element-binding protein (CREB), which, in combination with transducer of regulated CREB activity 2 (TORC2), leads to increased transcription of genes required for gluconeogenesis. Under conditions of insulin resistance, this pathway remains stimulated, even in the presence of insulin. Metformin stimulates the activation of AMPK, which phosphorylates TORC2 and sequesters it in the cytoplasm,

thereby decreasing synthesis of gluconeogenic enzymes and reducing hepatic output of glucose. The abbreviations used are defined in the text. PGC1 α , a peroxisome proliferator-activated receptor- γ coactivator 1 α .

Activation of AMPK also inhibits liver lipogenesis. In addition to phosphorylating and inhibiting acetyl CoA carboxylase activity (which reduces malonyl CoA levels, leading to reduced fatty acid synthesis and enhanced fatty acid oxidation), AMPK activity decreases the transcription of key lipogenic enzymes, including fatty acid synthase and acetyl CoA carboxylase. The reduced transcriptional activity is mediated via an AMPK inhibition of the transcription of SREBP-1, which in addition to regulating the transcription of HMG-CoA reductase, also regulates the transcription of other lipogenic enzymes. The AMPK is discussed in more detail in the “Biochemical Comments” section of Chapter 34.

Fibrates. The fibrates are a class of drugs used to decrease lipid levels (principally triglycerides) in patients. A major target of the fibrates is peroxisome proliferator-activated receptor- α (PPAR α). Fibrate binding to PPAR α activates this transcription factor, which then leads to the transcription of a multitude of genes whose products participate in lipid uptake and degradation. These targets include the genes for fatty acid transport proteins (so there is an enhanced rate of fatty acid transport into cells), fatty acid translocase (to increase mitochondrial uptake of the fatty acids), long-chain fatty acyl CoA synthetase (activation of the fatty acids in the cytoplasm), and carnitine:palmitoyltransferase I (which enhances the uptake of fatty acids into the mitochondria). In addition, PPAR α activation enhances lipoprotein lipase (LPL) expression, represses apoCIII expression (apoCIII inhibits the apoCII activation of LPL), and stimulates apoAI and apoAII synthesis, the major proteins in HDL. These transcriptional changes all lead to enhanced fat utilization and a reduction of circulating lipoprotein particles.

TZDs. A third class of drugs used for the treatment of insulin resistance and type 2 diabetes mellitus is the thiazolidinediones, which activate the PPAR γ class of transcription factors. PPAR γ is expressed primarily in adipose tissue. This transcription factor is responsible for activating the transcription of adiponectin (see Chapter 31, Section VIII.B), leading to increased circulating adiponectin levels. The increase in adiponectin reduces the fat content of the liver and enhances insulin sensitivity via an AMPK-dependent pathway. Thiazolidinediones also lead to a reduction in plasma-free fatty acid levels, which leads to enhanced insulin sensitivity (see the “Biochemical Comments” in Chapter 31).

Lomitapide and Mipomersen. Both lomitapide and mipomersen are utilized for patients with homozygous FH (lack of the LDL receptor). Statins are ineffective for such patients so alternative drug targets are used by these agents to reduce circulating cholesterol levels. Lomitapide inhibits the microsomal triglyceride transfer protein (MTP), thereby reducing circulating chylomicron and VLDL levels. Studies have indicated a 50% drop in circulating LDL levels with this agent. Patients taking lomitapide should stay on a low-fat diet (otherwise gastrointestinal discomfort and diarrhea can result from ineffective fat digestion) supplemented with the essential fatty acids and fat-soluble vitamins. Mipomersen is an antisense oligonucleotide which blocks apolipoprotein B-100 synthesis in liver cells, thereby reducing VLDL production, and since LDL is derived from VLDL, LDL production. Studies indicate a 25% drop in LDL levels in patients on mipomersen, but there is the potential for fatty liver disease and patients should be monitored closely for liver damage while on the drug.

KEY CONCEPTS

- ◆ Cholesterol regulates membrane fluidity and is a precursor of bile salts, steroid hormones (such as estrogen and testosterone), and vitamin D.
- ◆ Cholesterol, because of its hydrophobic nature, is transported in the blood as a component of lipoproteins.
- ◆ Within the lipoproteins, cholesterol can appear in its unesterified form in the outer shell of the particle or as cholesterol esters in the core of the particle.
- ◆ De novo cholesterol synthesis requires acetyl CoA as a precursor, which is initially converted to hydroxymethylglutaryl CoA (HMG-CoA). The cholesterol synthesized in this way is packaged, along with triglyceride, into VLDL in the liver and then released into circulation.
- ◆ The conversion of HMG-CoA to mevalonic acid, catalyzed by HMG-CoA reductase, is the regulated and rate-limiting step of cholesterol biosynthesis.
- ◆ In the circulation, the triglycerides in VLDL are digested by lipoprotein lipase, which converts the particle to IDL and then to LDL.
- ◆ IDL and LDL bind specifically to receptors on the liver cell, are internalized, and the particle components

are recycled.

- ◆ A third lipoprotein particle, HDL, functions to transfer apolipoprotein E and apolipoprotein CII to nascent chylomicrons and nascent VLDL.
- ◆ HDL also participates in reverse cholesterol transport, the movement of cholesterol from cell membranes to the HDL particle, which returns the cholesterol to the liver.
- ◆ Atherosclerotic plaques are associated with elevated levels of blood cholesterol levels. High levels of LDL are more strongly associated with the generation of atherosclerotic plaques, whereas high levels of HDL are protective, because of their participation in reverse cholesterol transport.
- ◆ Bile salts are required for fat emulsification and micelle formation in the small intestine.
- ◆ Bile salts are recycled via the enterohepatic circulation, forming the secondary bile acids in the process.
- ◆ The steroid hormones are derived from cholesterol, which is converted to pregnenolone, which is the precursor for the mineralocorticoids (such as aldosterone), the glucocorticoids (such as cortisol), and the sex steroids (such as testosterone and estrogen).
- ◆ Lipid-lowering drugs act on a variety of targets within liver, intestine, and adipocytes.
- ◆ Diseases discussed in this chapter are summarized in Table 32.7.

TABLE 32.7 Diseases Discussed in Chapter 32

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Hypercholesterolemia	Both	Defined by elevated levels of cholesterol in the blood, often leading to coronary artery disease.
Familial hypercholesterolemia, type II	Genetic	Defect in LDL receptor, leading to elevated cholesterol levels, and premature death due to coronary artery disease.
Tangier disease	Genetic	A mutation in the ABCA1 gene, leading to an inability to transport cholesterol from peripheral cells to HDL particles. This results in very low circulating HDL particles, and an increased risk of atherosclerotic disease in the patient.
Hyperchylomicronemia	Genetic	A mutation in either the lipoprotein lipase gene or apolipoprotein CII gene can lead to an inability to degrade the triglyceride in chylomicrons, leading to elevated triglycerides in the blood.
Virilization	Both	Excessive release of androgenic steroids, due to a variety of causes.
Congenital adrenal hyperplasia (CAH)	Genetic	CAH is a constellation of disorders due to mutations in enzymes required for cortisol synthesis. One potential consequence is excessive androgen synthesis, which may lead to prenatal masculinization of females. The different symptoms observed between patients are due to different enzyme deficiencies in the patients.
Rickets	Environmental	Due to a lack of vitamin D calcium metabolism is altered, leading to skeletal deformities.

HDL, low-density lipoprotein; LDL, low-density lipoprotein.

REVIEW QUESTIONS—CHAPTER 32

1. The statins are the major class of medications used to lower elevated serum cholesterol by initially inhibiting the major rate-limiting step of cholesterol synthesis. Which metabolite of the pathway would accumulate under conditions of taking a statin?
 - A. Acetoacetyl CoA
 - B. Hydroxymethylglutaryl CoA (HMG-CoA)
 - C. Mevalonate
 - D. Squalene
 - E. Steroid ring
2. Cholesterol, and its precursors and products, have a variety of functions within cells. Which one statement correctly describes a function of a cholesterol precursor, cholesterol itself, or a product derived from cholesterol?

- A. Cholesterol is hydrophilic
 - B. Steroid hormones are precursors of cholesterol
 - C. Precursors of cholesterol can be converted to vitamin D
 - D. Cholesterol can appear in its free unesterified form in the core of lipoprotein particles
 - E. Malonyl CoA is the major precursor of cholesterol synthesis
3. A new patient is being evaluated for cardiovascular disease. The values for his lipid panel are a total cholesterol of 400 mg/dL, an HDL reading of 35 mg/dL, and a triglyceride reading of 200 mg/dL. What would be his calculated LDL cholesterol reading?
 - A. 165
 - B. 193
 - C. 205
 - D. 325
 - E. 365
 4. Which one of the following apolipoproteins acts as a cofactor activator of the enzyme lipoprotein lipase (LPL)?
 - A. ApoC-III
 - B. ApoC-II
 - C. ApoB-100
 - D. ApoB-48s
 - E. ApoE
 5. Which one of the following sequences places the lipoproteins in the order of most dense to least dense?
 - A. HDL/VLDL/chylomicrons/LDL
 - B. HDL/LDL/VLDL/chylomicrons
 - C. LDL/chylomicrons/HDL/VLDL
 - D. VLDL/chylomicrons/LDL/HDL
 - E. LDL/chylomicrons/VLDL/HDL
 6. Which one of the following would you expect to observe in a patient lacking MTP (microsomal triglyceride transfer protein) after eating a normal diet, in which each meal consisted of 30% fat?
 - A. Constipation
 - B. Elevated chylomicrons
 - C. Steatorrhea
 - D. Elevated VLDL
 - E. Elevated IDL
 7. Patients with elevated serum LDL levels (>120 mg/dL) are first encouraged to reduce these levels through a combination of diet and exercise. If this fails, they are often prescribed statins. The key for statin treatment reducing circulating cholesterol levels is which of the following?
 - A. Reduced synthesis of chylomicrons
 - B. Increased activity of lipoprotein lipase
 - C. Reduced synthesis of HDL
 - D. Upregulation of LDL receptors
 - E. Increased activity of cholesterol ester transfer protein (CTEP)
 8. A consequence of abetalipoproteinemia is a fatty liver (hepatic steatosis). This occurs due to which one of the following?
 - A. Inability to produce VLDL
 - B. Inability to produce chylomicrons
 - C. Inability to produce HDL
 - D. Inability to produce triglyceride
 - E. Inability to produce lipoprotein lipase
 9. Hormones are typically synthesized in one type of tissue, often in response to the release of a stimulatory hormone. Which one of the following correctly matches a hormone with its stimulatory hormone, and its site of synthesis?
 - A. Cortisol, ACTH, adrenal cortex
 - B. Aldosterone, ACTH, adrenal cortex
 - C. Testosterone, FSH, Leydig cells
 - D. Estrogen, LH, ovarian follicle
 - E. Progesterone, LH, ovarian follicle

0. Because the steroid nucleus cannot be degraded by the human body, excretion of bile salts in stool serves as a major route of removal of steroids from the body. Which one of the following must occur to bile salts in order for bile salts to be excreted in the stool?
- Intestinal bacteria deconjugate bile salts
 - Intestinal bacteria conjugate bile salts
 - ATP and coenzyme Q conjugate bile salts
 - ATP and coenzyme A deconjugate bile salts
 - Enterohepatic circulation occurs at 100% efficiency
1. A 52-year-old male visited a cardiologist due to intermittent chest pain. A nuclear stress test revealed blockages in two arteries, indicative of atherosclerotic disease. Serum LDL levels in the patient were 155 mg/dL (for a patient with atherosclerotic disease a value of 100 mg/dL or lower is desirable). In addition to improving nutrition and increasing exercise, the patient was prescribed atorvastatin, which after 3 months had lowered the LDL levels to 120 mg/dL. Combined treatment with an anti-PCSK9 antibody resulted in lowering the LDL levels to 100 mg/dL. The mechanism of drug action in the patient is best represented by which one of the following?
- Both inhibit HMG-CoA reductase, leading to almost 100% inhibition of the enzyme
 - Both inhibit liver-specific MTP, leading to reduced VLDL levels, which leads to reduced LDL levels
 - Both block cholesterol absorption from the intestine, thereby reducing dietary cholesterol in the blood
 - Both lead to upregulation of the LDL receptor
 - Both upregulate lipoprotein lipase expression, thereby reducing the levels of LDL in the blood
2. Acute intermittent porphyria (AIP) is a disorder that interrupts the pathway of heme synthesis. Individuals who are experiencing an onset of symptoms have been demonstrated to express reduced cortisol levels. This could occur due to which one of the following?
- Reduced oxygen delivery to the zona glomerulosa of the adrenal gland
 - Reduced activity of enzymes in the zona fasciculata of the adrenal gland
 - Increased activity of enzymes in the zona fasciculata of the adrenal gland
 - Reduced expression of ACTH from the pituitary gland
 - Increased expression of ACTH from the pituitary gland
3. Under conditions of low energy within the liver cell, both fatty acid biosynthesis and cholesterol synthesis are inhibited. This bifunctional regulation occurs through the activation of which one of the following?
- A transport protein
 - A protease
 - A protein kinase
 - A lysosomal enzyme
 - A phosphatase
4. The regulation of HMG-CoA reductase is complex and involves transcriptional regulation. The transcription factor involved in this regulation is regulated via intracellular cholesterol levels, and a key regulatory event involving this transcription factor is best described as which one of the following?
- Activation of a kinase
 - Activation of a phosphatase
 - Activation of a protease
 - Activation of a chaperone
 - Activation by acylation
5. Targets of cholesterol-lowering drugs include which of the following? Choose the one best answer.

	HMG-CoA Reductase	Niemann-Pick CI-Like I	Apo-B 100	PCSK9
A	Yes	Yes	Yes	No
B	Yes	No	No	No
C	Yes	Yes	Yes	Yes
D	No	No	No	Yes
E	No	Yes	Yes	No
F	No	No	No	Yes

ANSWERS TO REVIEW QUESTIONS

- The answer is B.** The statins inhibit the enzyme HMG-CoA reductase, which reduces HMG-CoA to mevalonic acid. Therefore, HMG-CoA would be the metabolite that accumulates. The pathway is initiated with acetyl CoA, which then forms acetoacetyl CoA, and then HMG-CoA. The HMG-CoA is reduced to mevalonic acid, which is then converted to isoprene units, to farnesyl units, geranyl units, and finally to squalene, which is converted to cholesterol.
- The answer is C.** Cholesterol is absolutely insoluble in water (it is very hydrophobic). It is a precursor of both the bile acids and the steroid hormones. Precursors of cholesterol are converted to ubiquinone, dolichol, and cholecalciferol (the active form of vitamin D). Cholesterol can appear unesterified in the outer shell of lipoproteins, but as cholesterol esters in the core of such particles. Malonyl CoA is the precursor of fatty acids; acetyl CoA is the precursor for all the cholesterol carbons.
- The answer is D.** Total cholesterol is equal to the lipoproteins that carry it since cholesterol cannot freely float in blood serum. The total cholesterol would then be composed of the cholesterol content of HDL, VLDL, and LDL. Under fasting conditions, taking the triglyceride concentration and dividing it by 5 can estimate the cholesterol content of VLDL. Thus, for this patient, the HDL is 35, and the VLDL is 40 mg/dL. The total cholesterol is 400 mg/dL, indicating that the calculated LDL cholesterol is $400 - 75$, or 325 mg/dL.
- The answer is B.** Apo-CIII appears to inhibit the activation of LPL. ApoE acts as a ligand in binding several lipoproteins to the LDL receptor, the LDL receptor-related protein (LRP), and possibly to a separate apoE receptor. ApoB-48 is required for the normal assembly and secretion of chylomicrons from the small bowel, whereas apoB-100 is required in the liver for the assembly and secretion of VLDL. ApoCII is the activator of LPL.
- The answer is B.** Because chylomicrons contain the most triacylglycerol, they are the least dense of the blood lipoproteins. Because VLDL contains more protein, it is denser than chylomicrons. Because LDL is produced by the degradation of the triacylglycerol in VLDL, LDL is denser than VLDL. HDL is the densest of the blood lipoproteins. It has the most protein and the least triacylglycerol.
- The answer is C.** MTP is required for the synthesis of nascent chylomicrons and VLDL. In the intestine, the lack of MTP activity leads to an accumulation of lipid in the intestinal epithelial cells, such that further lipid is not transported in from the lumen. This leads to elevated lipid content in the stools, which is manifest as steatorrhea. As MTP is also needed for VLDL production, VLDL levels will drop, as will IDL and LDL levels, since they are derived from VLDL.
- The answer is D.** Statins directly inhibit HMG-CoA reductase, thereby reducing endogenous cholesterol synthesis in the tissues. As the cell becomes “starved” for cholesterol, the LDL receptors are upregulated (increased in number on the cell surface) such that more circulating cholesterol can be taken up by the

cells, thereby satisfying the cell's need for cholesterol while lowering serum cholesterol levels. In the absence of functional LDL receptors (homozygous FH IIA and IIB), statins are ineffective in significantly reducing circulating LDL cholesterol levels. Statins do not reduce the synthesis of chylomicrons or HDL, nor do they alter the activity of lipoprotein lipase or CTEP.

8. **The answer is A.** Abetalipoproteinemia is due to a mutation in MTP such that neither chylomicrons (in the intestine) nor VLDL (in the liver) are produced. Thus, as the liver produces triglyceride from dietary carbohydrate the triglyceride cannot be exported and accumulates within the liver. The triglyceride will eventually interfere with hepatic function and structure, leading to liver failure if nontreated. The inability to produce chylomicrons would not affect liver function (the intestinal cells would become lipid-laden, but that does not lead to hepatic steatosis). A defect in MTP does not affect lipoprotein lipase (LPL) production or secretion, nor does it affect triglyceride (TG) production. HDL synthesis is not affected by the loss of MTP as well.
9. **The answer is A.** Cortisol is produced by the middle layer of the adrenal cortex as a result of stimulation by ACTH. Aldosterone is produced by the outer layer of the adrenal cortex in response to stimulation by angiotensin II. Testosterone is produced by the Leydig cells of the testes and in the ovary in response to LH. Estrogen is produced by the ovarian follicle and corpus luteum in response to FSH. Progesterone is produced by the corpus luteum in response to LH.
10. **The answer is A.** Bile salts are conjugated in the liver by a reaction that requires ATP and glycine or taurine such that a form of the bile salt is created in which the pKa of the terminal carboxylate group is reduced as compared to the native bile salt. This allows for a higher percentage of the ionized form of the bile salt in the intestine (which is approximately at pH 6.0), which greatly aids in the emulsification and digestion of the dietary fats. As the bile salts travel through the intestine, bacteria deconjugate and dehydroxylate the steroids, making them less soluble and less readily reabsorbed into the enterohepatic circulation. Consequently, a percentage of the modified bile salts are lost in the stool. If the enterohepatic circulation is operated at 100% efficiency, no bile acids would be lost to the stool, and this route for elimination of the steroid nucleus would not exist. CoQ has no role in conjugating or deconjugating bile salts.
11. **The answer is D.** Atorvastatin is an inhibitor of HMG-CoA reductase, thereby reducing intracellular levels of cholesterol. The reduced intracellular cholesterol levels stimulate the upregulation of the LDL receptor such that an increased amount of LDL can be removed from circulation, thereby reducing circulating cholesterol levels. PCSK9 is a circulating protease that associates with the LDL receptor as it is internalized and degrades the receptor during internalization. Blocking PCSK9 action with anti-PCSK9 antibodies leads to increased LDL receptor expression on the cell surface and increased clearance of LDL from the circulation. Thus, both drugs work by increasing the levels of LDL receptor on the cell surface. Neither drug affects MTP (lomitapide will block MTP action), cholesterol absorption from the small intestine (ezetimibe will block absorption) or alter lipoprotein lipase action.
12. **The answer is B.** During an onset of the symptoms of AIP heme synthesis is impaired due to the inherited defect in the third step of heme synthesis. Cortisol synthesis requires the action of enzymes that contain cytochrome P450, which requires heme for activity. Thus, when heme synthesis is impaired cortisol synthesis will also be impaired. Cortisol is synthesized in the zona fasciculata of the adrenal gland (not the zona glomerulosa). The reduction of heme synthesis does not alter ACTH release from the pituitary gland. Corticotropin-releasing hormone, from the hypothalamus, is the agent that stimulates ACTH release from the anterior portion of the pituitary gland.
13. **The answer is C.** Under low-energy conditions, the levels of AMP increase in the cell, leading to the activation of the AMP-activated protein kinase. When active, the AMP-activated protein kinase phosphorylates both HMG-CoA reductase, reducing the activity of the enzyme, as well as acetyl CoA carboxylase, reducing the activity of the enzyme needed for fatty acid biosynthesis. While increasing levels of sterols will lead to the proteolytic degradation of HMG-CoA reductase (via the ER-associated degradation pathway), the same is not true for enzymes involved in fatty acid synthesis. Phosphatases, lysosomal enzymes, or transport proteins are not involved in the concomitant regulation of both cholesterol and fatty acid biosynthesis.
14. **The answer is C.** The transcription factor which regulates HMG-CoA transcription is sterol-regulatory element-binding protein 2 (SREBP-2), and in its inactive form is found as part of a transmembrane complex in the ER. As cholesterol levels inside the cell drop the complex moves to the Golgi complex, where the complex associates with the SCAP proteases. The proteases cleave a portion of SREBP-2, which then acts as a transcription factor, moving to the nucleus, to stimulate the transcription of HMG-

CoA reductase. Activation of a kinase, or phosphatase, or chaperone, or acylation does not play a role in the activation of transcription of HMG-CoA reductase.

15. **The answer is C.** Serum cholesterol levels can be lowered by targeting all of the proteins indicated in the answer. Statins inhibit HMG-CoA reductase, reducing intracellular cholesterol levels, thereby upregulating LDL receptor synthesis, and increasing the removal of LDL from circulation. Ezetimibe inhibits cholesterol absorption in the small intestine, which is mediated by the Niemann–Pick C1-like 1 protein. Less cholesterol absorbed from the diet leads to a reduction in circulating cholesterol levels. Mipomersen, an antisense RNA drug, inhibits apo-B100 synthesis in the liver, thereby reducing circulating VLDL levels, and since LDL is derived from VLDL, reducing LDL levels. PCSK9 is an extracellular protease that cleaves internalized LDL receptors, reducing LDL receptor expression and increasing circulating LDL levels. Anti-PCSK9 antibodies block PCSK9 action, thereby increasing LDL receptor levels on the cell surface, leading to a reduction in circulating LDL cholesterol.

Metabolism of Ethanol

Ethanol is a **dietary fuel** that is metabolized to acetate principally in the liver, with the generation of reduced nicotinamide adenine dinucleotide (NADH). The principal route for metabolism of ethanol is through hepatic **alcohol dehydrogenases**, which oxidize ethanol to **acetaldehyde** in the cytosol (Fig. 33.1). Acetaldehyde is further oxidized by **acetaldehyde dehydrogenases** to **acetate**, principally **in mitochondria**. Acetaldehyde, which is toxic, also may enter the blood. **NADH** produced by these reactions is used for adenosine triphosphate (ATP) generation through oxidative phosphorylation. Most of the acetate enters the blood and is taken up by skeletal muscles and other tissues, where it is activated to **acetyl coenzyme A (acetyl CoA)** and is oxidized in the tricarboxylic acid (TCA) cycle.

FIGURE 33.1 The major route for metabolism of ethanol and use of acetate by the muscle. Acetyl CoA, acetyl coenzyme A; ACS, acetyl CoA synthetase; ADH, alcohol dehydrogenase; ALDH, acetaldehyde dehydrogenase; FAD, flavin adenine dinucleotide; NAD, nicotinamide adenine dinucleotide; TCA, tricarboxylic acid.

Approximately 10% to 20% of ingested ethanol is oxidized through a microsomal ethanol-oxidizing system (**MEOS**), comprising **cytochrome P450** enzymes in the endoplasmic reticulum (especially **CYP2E1**). CYP2E1 has a high K_m for ethanol and is inducible by ethanol. Therefore, the proportion of ethanol metabolized through this route is greater at high ethanol concentrations and greater after chronic consumption of ethanol.

Acute effects of alcohol ingestion arise principally from the generation of NADH, which greatly increases the NADH/NAD^+ ratio of the liver. As a consequence, **fatty acid oxidation is inhibited**, and **ketogenesis** may occur. The elevated NADH/NAD^+ ratio may also cause **lactic acidosis** and inhibit **gluconeogenesis**.

Ethanol metabolism may result in **alcohol-induced liver disease**, including **hepatic steatosis** (fatty liver), **alcohol-induced hepatitis**, and **cirrhosis**. The principal toxic products of ethanol metabolism include **acetaldehyde** and **free radicals**. Acetaldehyde forms **adducts** with proteins and other compounds. The **hydroxyethyl radical** produced by the MEOS and other radicals produced

during inflammation cause irreversible damage to the liver. Many other tissues are adversely affected by ethanol, acetaldehyde, or by the consequences of **hepatic dysmetabolism** and injury. **Genetic polymorphisms** in the enzymes of ethanol metabolism may be responsible for individual variations in the development of alcohol use disorder or the development of liver cirrhosis.

THE WAITING ROOM

A dietary history for **Ivan A.** showed that he had continued his habit of drinking scotch and soda each evening while watching TV, but he did not add the ethanol calories to his dietary intake. He justifies this calculation on the basis of a comment he heard on a radio program that calories from alcohol ingestion “don’t count” because they are empty calories that do not cause weight gain.

The anion gap is calculated by subtracting the sum of the value for two anions, serum chloride, and serum HCO_3^- , from the serum sodium concentration. If the gap is greater than normal, it suggests that acids such as the ketone bodies acetoacetate and β -hydroxybutyrate are present in the blood in increased amounts.

Al M. was found lying semiconscious at the bottom of the stairs by his landlady when she returned from an overnight visit with friends. His face had multiple bruises and his right forearm was grotesquely angulated. Nonbloody dried vomitus stained his clothing. **Al M.** was rushed by ambulance to the emergency room at the nearest hospital. In addition to multiple bruises and the compound fracture of his right forearm, he had deep and rapid (Kussmaul) respirations and was moderately dehydrated.

Jaundice is a yellow discoloration involving the sclerae (the “whites” of the eyes) and skin. It is caused by the deposition of bilirubin, a yellow degradation product of heme. Bilirubin accumulates in the blood under conditions of liver injury, bile duct obstruction, and excessive degradation of heme.

Initial laboratory studies showed a relatively large anion gap of 34 mmol/L (reference range, 9 to 15 mmol/L). An arterial blood gas analysis (which measures pH in addition to the levels of dissolved O_2 and CO_2) confirmed the presence of a metabolic acidosis. **Al M.**'s blood alcohol level was only slightly elevated. His serum glucose was 68 mg/dL (low normal).

Jean T.'s admitted ethanol consumption exceeds the definition of risky alcohol use, which is the amount of alcohol that puts an individual at risk for health consequences. Per the National Institute on Alcohol Abuse and Alcoholism, the amount of alcohol that increases health risk is defined as more than 14 standard drinks per week or more than 4 drinks on any day for men, and more than 7 drinks per week or more than 3 drinks on any day for women. A drink is defined as 12 oz of regular beer, 5 oz of wine, or 1.5 oz distilled spirits (80-proof).

Jean T., a 46-year-old commercial artist, recently lost her job because of absenteeism. Her husband of 24 years had left her 10 months earlier. She complains of loss of appetite, fatigue, muscle weakness, and emotional depression. She has had occasional pain in the area of her liver, at times accompanied by nausea and vomiting.

On physical examination, the physician notes tenderness to light percussion over her liver and her abdomen is mildly distended. There is a suggestion of mild jaundice (yellow discoloration of her skin and mucus membranes). No obvious neurological or cognitive abnormalities are present.

After detecting a hint of alcohol on **Jean T.**'s breath, the physician questions **Jean T.** about her drinking. **Jean T.** admits that for the last 5 or 6 years, she has been drinking gin on a daily basis (~4 to 5 drinks, or 68 to 85 g ethanol) and eating infrequently. Laboratory tests showed that her serum ethanol level on the initial office visit was 245 mg/dL (0.245%); values above 200 mg/dL (0.1%) are indicative of significant intoxication.

I. Ethanol Metabolism

Ethanol is a small molecule that is both lipid and water soluble. It is therefore readily absorbed from the intestine by passive diffusion. A small percentage of ingested ethanol (0% to 5%) enters the gastric mucosal

cells of the upper gastrointestinal (GI) tract (tongue, mouth, esophagus, and stomach), where it is metabolized. The remainder enters the blood. Of this, 85% to 98% is metabolized in the liver, and only 2% to 10% is excreted through the lungs or kidneys.

The major route of ethanol metabolism in the liver is through liver **alcohol dehydrogenase**, a cytosolic enzyme that oxidizes ethanol to acetaldehyde with reduction of NAD^+ to NADH (Fig. 33.2). Alcohol dehydrogenase is a dimer of either identical or different subunits. If acetaldehyde is not removed by metabolism, it can exert toxic actions in the liver and can enter the blood and exert toxic effects in other tissues.

Ethanol

Acetaldehyde

Acetate

FIGURE 33.2 The pathway of ethanol metabolism. ADH, alcohol dehydrogenase; ALDH, acetaldehyde dehydrogenase; NAD, nicotinamide adenine dinucleotide.

Approximately 90% of the acetaldehyde that is generated is further metabolized to acetate in the liver. The major enzyme involved is a low- K_m mitochondrial acetaldehyde dehydrogenase (ALDH), which oxidizes acetaldehyde to acetate with generation of NADH (see Fig. 33.2). Acetate, which has no toxic effects, may be activated to acetyl CoA in the liver (where it can enter either the TCA cycle or the pathway for fatty acid synthesis). However, most of the acetate that is generated enters the blood and is activated to acetyl CoA in skeletal muscles and other tissues (see Fig. 33.1). Acetate is generally considered nontoxic and is a normal constituent of the diet.

The other principal route of ethanol oxidation in the liver is the **microsomal ethanol-oxidizing system (MEOS)**, which also oxidizes ethanol to acetaldehyde (Fig. 33.3). The principal microsomal enzyme involved is a cytochrome P450 mixed-function oxidase isozyme (CYP2E1), which uses NADPH as an additional electron donor and O_2 as an electron acceptor. This route accounts for only 10% to 20% of ethanol oxidation in a moderate drinker.

FIGURE 33.3 The reaction catalyzed by the microsomal ethanol-oxidizing system (MEOS) (which includes CYP2E1) in the endoplasmic reticulum (ER). NADP, nicotinamide adenine dinucleotide phosphate.

Each of the enzymes involved in ethanol metabolism (alcohol dehydrogenase, acetaldehyde dehydrogenase, and CYP2E1) exists as a family of isoenzymes. Individual variations in the quantity of these isoenzymes influence a number of factors, such as the rate of ethanol clearance from the blood, the degree of inebriation exhibited by an individual, and differences in individual susceptibility to the development of alcohol-induced liver disease.

A. Alcohol Dehydrogenase

Alcohol dehydrogenase (ADH) exists as a family of isoenzymes with varying specificity for chain length of the alcohol substrate (Table 33.1). Ethanol is a small molecule that does not exhibit much in the way of unique structural characteristics and, at high concentrations, is nonspecifically metabolized by many members of the ADH family. The alcohol dehydrogenases that exhibit the highest specificity for ethanol are members of the *ADH1* family. Humans have six genes for this family of alcohol dehydrogenases, each of which exists as allelic variants (polymorphisms).

GENE	SUBUNIT	TISSUE DISTRIBUTION	PROPERTIES
<i>ADH1A</i> ^a	α	Most abundant in liver and adrenal glands. Much lower levels in kidney, lung, colon, small intestine, eye, ovary, blood vessels. None in brain or heart.	K_m of 0.013–4 mM for ethanol. Active only with ethanol. High tissue capacity.
<i>ADH1B</i>	β		
<i>ADH1C</i>	γ		
<i>ADH4</i>	π	Primarily liver, stomach, lower levels in GI tract.	K_m of 11 mM for ethanol.
<i>ADH5</i>	χ	Ubiquitously expressed, but at higher levels in liver. The only isozyme present in germinal cells.	Relatively inactive toward ethanol ($K_m = 3,400$ mM). Active mainly toward long-chain alcohols, and ω-OH fatty acids.
<i>ADH7</i>	σ	Present in highest levels in upper GI tract, gingiva, and mouth, esophagus, down to the stomach. Not present in liver.	K_m of 58 mM. It is the most active of medium-chain alcohol dehydrogenases toward the substrate retinal.

GI, gastrointestinal.

^aThe *ADH1A*, *B*, and *C* genes are classified as Class I ADH. *ADH1B* can also be designated as *ADH2*, while *ADH1C* can be designated as *ADH3*.

A gene for *ADH6* has also been identified, and mRNA corresponding to *ADH6* has been detected in cells, but the *ADH6* protein has not been found in any ADH dimers.

The *ADH1* family members are present in high quantities in the liver, representing approximately 3% of all soluble protein. These alcohol dehydrogenases, commonly referred to collectively as liver alcohol dehydrogenase, have a low K_m for ethanol between 0.013 and 4 mM (high affinities). Thus, the liver is the major site of ethanol metabolism and the major site at which the toxic metabolite acetaldehyde is generated.

The human has at least seven, and possibly more, genes that code for specific isoenzymes of medium-chain-length alcohol dehydrogenases, the major enzyme responsible for the oxidation of ethanol to acetaldehyde in the human. These different alcohol dehydrogenases have an approximately 60% to 70% identity and are assumed to have arisen from a common ancestral gene similar to the *ADH3* isoenzyme many millions of years ago. The *ADH1* alcohol dehydrogenases (*ADH1A*, *ADH1B*, and *ADH1C*) are all present in high concentration in the liver, and they have relatively high affinity and capacity for ethanol at low concentrations. (These properties are quantitatively reflected by their low K_m , a parameter discussed in Chapter 9.) They have a 90% to 94% sequence identity and are able to form heterodimers among themselves. However, none of the *ADH1s* can form dimers with an ADH subunit from any of the other *ADH* genes, which function as homodimers. The three genes for class I alcohol dehydrogenases are arranged in tandem, head to tail, on chromosome 4. The genes for the other classes of alcohol dehydrogenase are also on chromosome 4 in nearby locations.

B. Acetaldehyde Dehydrogenases

Acetaldehyde is oxidized to acetate, with the generation of NADH, by acetaldehyde dehydrogenases (see Fig. 33.2). More than 80% of acetaldehyde oxidation in the human liver is normally catalyzed by mitochondrial acetaldehyde dehydrogenase (*ALDH2*), which has a high affinity for acetaldehyde (K_m of 0.2 μM) and is highly specific. However, individuals with a common allelic variant of *ALDH2* (designated as *ALDH2*2*) have a greatly decreased capacity for acetaldehyde metabolism, due to an increased K_m (46 μM) and a decreased V_{max} (0.017 units/mg vs. 0.60 units/mg).

Most of the remainder of acetaldehyde oxidation occurs through a cytosolic acetaldehyde dehydrogenase (*ALDH1*). Additional aldehyde dehydrogenases act on a variety of organic alcohols, toxins, and pollutants.

The accumulation of acetaldehyde causes nausea and vomiting, and, therefore, inactive acetaldehyde dehydrogenases are associated with a distaste for alcoholic beverages and protection against alcoholism. In one of the common allelic variants of *ALDH2* (*ALDH2*2*), a single substitution increases the K_m for acetaldehyde 230-fold (lowers the affinity) and decreases the V_{max} 35-fold, resulting in a very inactive enzyme. Homozygosity for the *ALDH2*2* allele affords absolute protection against alcoholism; no individual with this genotype has been found among individuals with alcohol use disorder. Patients with alcohol use disorder are sometimes treated with acetaldehyde dehydrogenase inhibitors (e.g., disulfiram) to help them abstain from alcohol intake. Unfortunately, patients who continue to drink while taking this drug are exposed to the toxic effects of elevated acetaldehyde levels, so it can only be used in patients who are not drinking.

C. Fate of Acetate

Metabolism of acetate requires activation to acetyl CoA by acetyl CoA synthetase in a reaction similar to that catalyzed by fatty acyl CoA synthetases (Fig. 33.4). In liver, the principal isoform of acetyl CoA synthetase (ACSI) is a cytosolic enzyme that generates acetyl CoA for the cytosolic pathways of cholesterol and fatty acid synthesis. Acetate entry into these pathways is under regulatory control by mechanisms involving cholesterol or insulin. Thus, most of the acetate generated enters the blood.

FIGURE 33.4 The activation of acetate to acetyl coenzyme A (acetyl CoA). AMP, adenosine monophosphate; ATP, adenosine triphosphate; CoA, coenzyme A; PPi, pyrophosphate.

Acetate is taken up and oxidized by other tissues, notably heart and skeletal muscle, which have a high concentration of the mitochondrial acetyl CoA synthetase isoform (ACSI). This enzyme is present in the mitochondrial matrix. It, therefore, generates acetyl CoA that can enter the TCA cycle directly and be oxidized

to CO₂.

D. The Microsomal Ethanol-Oxidizing System

Ethanol is also oxidized to acetaldehyde in the liver by the microsomal ethanol-oxidizing system, which comprises members of the cytochrome P450 superfamily of enzymes. Ethanol and NADPH both donate electrons in the reaction, which reduces O₂ to H₂O (Fig. 33.5). The cytochrome P450 enzymes all have two major catalytic protein components: an electron-donating reductase system that transfers electrons from NADPH (cytochrome P450 reductase) and a cytochrome P450. The cytochrome P450 protein contains the binding sites for O₂ and the substrate (e.g., ethanol) and carries out the reaction. The enzymes are present in the endoplasmic reticulum, which on isolation from disrupted cells forms a membrane fraction after centrifugation that was formerly called “microsomes” by biochemists.

FIGURE 33.5 General structure of cytochrome P450 enzymes. O₂ binds to the P450 Fe-heme in the active site and is activated to a reactive form by accepting electrons (e⁻). The electrons are donated by the cytochrome P450 reductase, which contains a flavin adenine dinucleotide (FAD) plus a flavin adenine mononucleotide (FMN) or Fe-S center to facilitate the transfer of single electrons from NADPH to O₂. The P450 enzymes involved in steroidogenesis have a somewhat different

structure. For CYP2E1, RH is ethanol ($\text{CH}_3\text{CH}_2\text{OH}$) and ROH is acetaldehyde (CH_3CHO). NADP, nicotinamide adenine dinucleotide phosphate.

1. CYP2E1

The MEOS is part of the superfamily of cytochrome P450 enzymes, all of which catalyze similar oxidative reactions. Within the superfamily, at least 10 distinct gene families are found in mammals. More than 100 different cytochrome P450 isozymes exist within these 10 gene families. Each isoenzyme has a distinct classification according to its structural relationship with other isoenzymes. The isoenzyme that has the highest activity toward ethanol is called CYP2E1. CYP represents cytochrome P450. In CYP2E1, the “2” refers to the gene family (isozymes with >40% amino acid sequence identity), the “E” to the subfamily (isozymes with >55% sequence identity), and the “1” refers to the individual enzymes within this subfamily. A great deal of overlapping specificity exists among the various P450 isoenzymes, and ethanol is also oxidized by several other P450 isoenzymes. “MEOS” refers to the combined ethanol-oxidizing activity of all the P450 enzymes.

CYP2E1 has a much higher K_m for ethanol than the *ADH1* family members (11 mM [51 mg/dL], compared with 0.013 to 4 mM [0.06 to 18 mg/dL]). Thus, a greater proportion of ingested ethanol is metabolized through CYP2E1 at high levels of ethanol consumption than at low levels.

2. Induction of P450 Enzymes

The P450 enzymes are inducible both by their most specific substrate and by substrates for some of the other cytochrome P450 enzymes. Chronic consumption of ethanol increases hepatic CYP2E1 levels approximately 5- to 10-fold. However, it also causes a 2- to 4-fold increase in some of the other P450s from the same subfamily, from different subfamilies, and even from different gene families. The endoplasmic reticulum undergoes proliferation, with a general increase in the content of microsomal enzymes, including those that are not involved directly in ethanol metabolism.

ADH1A and *ADH1C* are present as functional polymorphisms that differ in their properties. Genetic polymorphisms for ADH partially account for the observed differences in ethanol elimination rates among various individuals or populations. Although susceptibility to alcoholism is a complex function of genetics and socioeconomic factors, possession of the *ADH1B*2* allele, which encodes a relatively fast ADH (high V_{max}), is associated with a decreased susceptibility to alcoholism—presumably because of nausea and flushing caused by acetaldehyde accumulation (because the aldehyde dehydrogenase gene cannot keep up with the amount of acetaldehyde produced). This particular allele has a relatively high frequency in the East Asian population and a low frequency among white Europeans. In contrast, the *ADH1B*1/1B*1* genotype (homozygous for allele 1 of the *ADH1B* gene) is a risk factor for the development of Wernicke–Korsakoff syndrome, a neuropsychiatric syndrome that is commonly associated with alcohol use disorder.

The increase in CYP2E1 with ethanol consumption occurs through transcriptional, posttranscriptional, and posttranslational regulation. Increased levels of mRNA, resulting from induction of gene transcription or stabilization of message, are found in actively drinking patients. The protein is also stabilized against degradation. In general, the mechanism for induction of P450 enzymes by their substrates occurs through the binding of the substrate (or related compound) to an intracellular receptor protein, followed by binding of the activated receptor to a response element in the target gene. Ethanol induction of CYP2E1 appears to act via stabilization of the protein and protection against degradation (an increased half-life for the synthesized protein).

Although induction of CYP2E1 increases ethanol clearance from the blood, it has negative consequences. Acetaldehyde may be produced faster than it can be metabolized by acetaldehyde dehydrogenases, thereby increasing the risk of hepatic injury. An increased amount of acetaldehyde can enter the blood and can damage other tissues. In addition, cytochrome P450 enzymes are capable of generating free radicals, which also may lead to increased hepatic injury and cirrhosis (see Chapter 25).

As blood ethanol concentration rises above 18 mM (the legal intoxication limit is now defined as 0.08% in most states of the United States, which is ~18 mM), the brain and central nervous system are affected. Induction of CYP2E1 increases the rate of ethanol clearance from the blood, thereby contributing to increased alcohol tolerance. However, the apparent ability to drink without appearing inebriated is partly a learned behavior by people with alcohol use disorder.

Overlapping specificity in the catalytic activity of P450 enzymes and in their inducers is responsible for several types of drug interactions. For example, phenobarbital, one of the oldest medications used for the treatment of epilepsy, is converted to an inactive metabolite by cytochrome P450 monooxygenases CYP2B1

and CYP2B2. After treatment with phenobarbital, CYP2B2 is increased 50- to 100-fold. Individuals who take phenobarbital for prolonged periods develop a drug tolerance as CYP2B2 is induced, and the drug is metabolized to an inactive metabolite more rapidly. Consequently, these individuals use progressively higher doses of phenobarbital.

Ethanol is an inhibitor of the phenobarbital-oxidizing P450 system. When large amounts of ethanol are consumed, the inactivation of phenobarbital is directly or indirectly inhibited. Therefore, when high doses of phenobarbital and ethanol are consumed at the same time, toxic levels of the barbiturate can accumulate in the blood.

E. Variations in the Pattern of Ethanol Metabolism

The routes and rates of ethanol oxidation vary from individual to individual. Differences in ethanol metabolism may influence whether an individual develops alcohol use disorder, develops alcohol-induced liver disease, or develops other diseases associated with increased alcohol consumption (such as hepatocarcinogenesis, lung cancer, or breast cancer). Factors that determine the rate and route of ethanol oxidation in individuals include:

- **Genotype**—Polymorphic forms of alcohol dehydrogenases and acetaldehyde dehydrogenases can greatly affect the rate of ethanol oxidation and the accumulation of acetaldehyde. CYP2E1 activity may vary as much as 20-fold among individuals, partly because of differences in the inducibility of different allelic variants.
- **Drinking history**—The level of gastric alcohol dehydrogenase decreases and CYP2E1 increases with the progression from a naïve to a moderate and to a heavy and chronic consumer of alcohol.
- **Gender**—Blood levels of ethanol after consuming a drink are normally higher for women than for men, partly because of lower levels of gastric ADH activity in women. After chronic consumption of ethanol, gastric ADH decreases in both men and women, but the gender differences become even greater. Gender differences in blood alcohol levels also occur because women are normally smaller. Furthermore, in women, alcohol is distributed in a 12% smaller water space because a woman's body composition generally consists of more fat and less water than that of a man.
- **Quantity**—The amount of ethanol an individual consumes over a short period of time determines its metabolic route. Small amounts of ethanol are metabolized most efficiently through the low- K_m pathway of *ADH1* genes and *ALDH2* genes. Little accumulation of NADH occurs to inhibit ethanol metabolism via these dehydrogenases. However, when higher amounts of ethanol are consumed within a short period, a disproportionately greater amount is metabolized through the MEOS. The MEOS, which has a much higher K_m for ethanol, functions principally at high concentrations of ethanol. A higher activity of the MEOS may be expected to correlate with a tendency to develop alcohol-induced liver disease because both acetaldehyde and free radical levels will be increased.

F. The Energy Yield of Ethanol Oxidation

The ATP yield from ethanol oxidation to acetate varies with the route of ethanol metabolism. If ethanol is oxidized by the major route of cytosolic ADH and mitochondrial ALDH, one cytosolic and one mitochondrial NADH are generated, with a maximum yield of 5 ATP. Oxidation of acetyl CoA in the TCA cycle and the electron transport chain leads to the generation of 10 high-energy phosphate bonds. However, activation of acetate to acetyl CoA requires two high-energy phosphate bonds (one in the cleavage of ATP to AMP + pyrophosphate and one in the cleavage of pyrophosphate to phosphate), which must be subtracted. Thus, the maximum total energy yield is 13 mol of ATP per mole of ethanol.

At **Ivan A.**'s low level of ethanol consumption, ethanol is oxidized to acetate via ADH and ALDH in the liver and the acetate is activated to acetyl CoA and oxidized to CO₂ in skeletal muscle and other tissues. The overall energy yield of 13 ATP per ethanol molecule accounts for the caloric value of ethanol, approximately 7 kcal/g. However, chronic consumption of substantial amounts of alcohol does not have the effect on body weight expected from the caloric intake. This is partly attributable to induction of MEOS, resulting in a proportionately greater metabolism of ethanol through the MEOS with its lower energy yield (~8 ATP). In general, weight loss diets recommend no, or low, alcohol consumption because ethanol calories are "empty" in the sense that alcoholic beverages are generally low in vitamins, essential amino acids, and other required nutrients, but not empty of calories.

In contrast, oxidation of ethanol to acetaldehyde by CYP2E1 consumes energy in the form of NADPH,

which is equivalent to 2.5 ATP. Thus, for every mole of ethanol metabolized by this route, only a maximum of 8 mol of ATP can be generated (10 ATP from acetyl CoA oxidation through the TCA cycle, minus 2 for acetate activation; the NADH generated by aldehyde dehydrogenase is balanced by the loss of NADPH in the MEOS step).

II. Toxic Effects of Ethanol Metabolism

Alcohol-induced liver disease, a common and sometimes fatal consequence of chronic ethanol use, may manifest itself in three forms: fatty liver, alcohol-induced hepatitis, and cirrhosis. Each may occur alone, or they may be present in any combination in a given patient. In 2010, Alcohol-induced cirrhosis was estimated to be responsible for about 1% of all deaths in the United States.

Fetal alcohol syndrome disorder is the name given to behavioral anomalies and problems in neurodevelopment induced in human embryos exposed to alcohol during fetal development. A number of theories have been proposed to explain this, including an increase of ethanol-induced ROS in the fetus. Another theory is based on ethanol/acetaldehyde interference with retinoic acid synthesis. Retinoic acid is derived from vitamin A in two successive oxidation reactions, catalyzed by an ADH and an ALDH enzyme. Once formed retinoic acid can bind to and activate transcription complexes (composed of the retinoic acid receptor, RAR, and the retinoid X receptor, RXR) to stimulate new gene transcription, particularly during embryogenesis and differentiation. As acetaldehyde levels increase in the fetus (due to maternal ethanol consumption during pregnancy) there is competition for the ALDH gene product, and the fetus becomes retinoic acid deficient, leading to altered developmental patterns being expressed.

However, ethanol ingestion also has acute effects on liver metabolism, including inhibition of fatty acid oxidation and stimulation of triacylglycerol synthesis, leading to a fatty liver. It also can result in ketoacidosis or lactic acidosis and cause hypoglycemia or hyperglycemia, depending on the dietary state. These effects are considered reversible.

In contrast, acetaldehyde and free radicals generated from ethanol metabolism can result in alcohol-induced hepatitis, a condition in which the liver is inflamed and cells become necrotic and die. Diffuse damage to hepatocytes results in cirrhosis, characterized by fibrosis (scarring), disturbance of the normal architecture and blood flow, loss of liver function, and, ultimately, hepatic failure.

A. Acute Effects of Ethanol Arising from the Increased NADH/NAD⁺ Ratio

Many of the acute effects of ethanol ingestion arise from the increased NADH/NAD⁺ ratio in the liver (Fig. 33.6). At lower levels of ethanol intake, the rate of ethanol oxidation is regulated by the supply of ethanol (usually determined by how much ethanol we consume) and the rate at which NADH is reoxidized in the electron transport chain. NADH is not a very effective product inhibitor of ADH or ALDH, and there is no other feedback regulation by ATP, ADP, or AMP. As a consequence, NADH generated in the cytosol and mitochondria tends to accumulate, increasing the NADH/NAD⁺ ratio to high levels (see Fig. 33.6, circle 1). The increase is even greater as the mitochondria become damaged from acetaldehyde or free-radical injury.

FIGURE 33.6 Acute effects of ethanol metabolism on lipid metabolism in the liver. (1) Metabolism of ethanol generates a high NADH/NAD⁺ ratio. (2) The high NADH/NAD⁺ ratio inhibits fatty acid oxidation and the tricarboxylic acid (TCA) cycle, resulting in accumulation of fatty acids. (3) Fatty acids are re-esterified to glycerol 3-phosphate by acyltransferases in the endoplasmic reticulum (ER). Glycerol-3-phosphate levels are increased because a high NADH/NAD⁺ ratio favors its formation from dihydroxyacetone phosphate (an intermediate of glycolysis). Ethanol-stimulated increases of endoplasmic reticulum enzymes also favor triacylglycerol formation. (4) NADH generated from ethanol oxidation can meet the requirements of the cell for adenosine triphosphate (ATP) generation from oxidative phosphorylation. Thus, acetyl coenzyme A (acetyl CoA) oxidation in the TCA cycle is inhibited. (5) The high NADH/NAD⁺ ratio shifts oxaloacetate (OAA) toward malate, and acetyl CoA is directed into ketone body synthesis. Options (6) through (8) are discussed in the text. ADH, alcohol dehydrogenase; ALDH, acetaldehyde dehydrogenase; etc, electron transport chain; FAD, flavin adenine dinucleotide; MEOS, microsomal ethanol-oxidizing system; NAD, nicotinamide adenine dinucleotide; VLDL, very-low-density lipoprotein.

1. Changes in Fatty Acid Metabolism

The high NADH/NAD⁺ ratio generated from ethanol oxidation inhibits the oxidation of fatty acids, which accumulate in the liver (see Fig. 33.6, circles 2 and 3). These fatty acids are re-esterified into triacylglycerols by combining with glycerol 3-phosphate (glycerol 3-P). The increased NADH/NAD⁺ ratio increases the availability of glycerol-3-P by promoting its synthesis from intermediates of glycolysis. The triacylglycerols are incorporated into very-low-density lipoproteins (VLDLs), which accumulate in the liver and enter the blood, resulting in an ethanol-induced hyperlipidemia.

Although just a few drinks may result in hepatic fat accumulation, chronic consumption of alcohol greatly enhances the development of a fatty liver. Reesterification of fatty acids into triacylglycerols by fatty acyl CoA transferases in the endoplasmic reticulum is enhanced (see Fig. 33.6). Because the transferases are microsomal enzymes, they are induced by ethanol consumption just as the MEOS is induced. The result is a fatty liver (hepatic steatosis).

The source of the fatty acids can be dietary fat, fatty acids synthesized in the liver, or fatty acids released from adipose tissue stores. Adipose tissue lipolysis increases after ethanol consumption, possibly because of a release of epinephrine.

2. Alcohol-Induced Ketoacidosis

Fatty acids that are oxidized are converted to acetyl CoA and subsequently to ketone bodies (acetoacetate and β -hydroxybutyrate). Enough NADH is generated from oxidation of ethanol and fatty acids that there is no need to oxidize acetyl CoA in the TCA cycle. The very high NADH/NAD⁺ ratio shifts the oxaloacetate in the TCA cycle to malate, leaving the oxaloacetate levels too low for citrate synthase to synthesize citrate (see Fig. 33.6, circle 4). The acetyl CoA enters the pathway for ketone body synthesis instead of the TCA cycle.

AI M.'s admitting physician suspected an alcohol-induced ketoacidosis superimposed on a starvation ketoacidosis. Tests showed that his plasma β -hydroxybutyrate level was 40 times the upper limit of normal and if measured would show his plasma-free fatty acid level was elevated. The increased NADH/NAD⁺ ratio from ethanol consumption inhibited the TCA cycle and shifted acetyl CoA from fatty acid oxidation into the pathway of ketone body synthesis. The presence of the ketone bodies helped to explain the large anion gap measured when **AI M.** entered the hospital.

Although ketone bodies are being produced at a high rate, their metabolism in other tissues is restricted by the supply of acetate, which is the preferred fuel. Thus, the blood concentration of ketone bodies may be much higher than is found under normal fasting conditions.

3. Lactic Acidosis, Hyperuricemia, and Hypoglycemia

Another consequence of the very high NADH/NAD⁺ ratio is that the balance in the lactate dehydrogenase reaction is shifted toward lactate, resulting in a lactic acidosis (see Fig. 33.6, circle 6). The elevation of blood lactate may decrease the excretion of uric acid (see Fig. 33.6, circle 7) by the kidney. Consequently, patients with gout (which results from precipitated uric acid crystals in the joints) are advised not to drink excessive amounts of ethanol. Increased degradation of purines also may contribute to hyperuricemia.

The increased NADH/NAD⁺ ratio also can cause hypoglycemia in a fasting individual who has been drinking and is dependent on gluconeogenesis to maintain blood glucose levels (Fig. 33.6, circles 6 and 8). Alanine and lactate are major gluconeogenic precursors that enter gluconeogenesis as pyruvate. The high NADH/NAD⁺ ratio shifts the lactate dehydrogenase equilibrium to lactate, so that pyruvate formed from alanine is converted to lactate and cannot enter gluconeogenesis. The high NADH/NAD⁺ ratio also prevents other major gluconeogenic precursors, such as oxaloacetate and glycerol, from entering the gluconeogenic pathway.

In contrast, ethanol consumption with a meal may result in a transient hyperglycemia, possibly because the high NADH/NAD⁺ ratio inhibits glycolysis at the glyceraldehyde 3-phosphate dehydrogenase step.

B. Acetaldehyde Toxicity

Many of the toxic effects of chronic ethanol consumption result from the accumulation of acetaldehyde, which is produced from ethanol by both alcohol dehydrogenases and the MEOS. Acetaldehyde accumulates in the liver and is released into the blood after heavy doses of ethanol (Fig. 33.7). It is highly reactive and binds covalently to amino groups, sulfhydryl groups, nucleotides, and phospholipids to form “adducts.”

FIGURE 33.7 The development of alcohol-induced hepatitis. (1) Acetaldehyde-adduct formation decreases protein synthesis and impairs protein secretion. (2) Free-radical injury results partly from acetaldehyde-adduct formation with glutathione. (3) Induction of the microsomal ethanol-oxidizing system (MEOS) increases the formation of free radicals, which leads to lipid peroxidation and cell damage. (4) Mitochondrial damage inhibits the electron transport chain, which decreases acetaldehyde oxidation. (5) Microtubule damage increases very-low-density lipoprotein (VLDL) and protein accumulation. (6) Cell damage leads to the release of the hepatic enzymes alanine aminotransferase (ALT) and aspartate aminotransferase (AST). ADH, alcohol dehydrogenase; etc, electron transport chain; NAD, nicotinamide adenine dinucleotide; ROS, reactive oxygen species.

1. Acetaldehyde and Alcohol-Induced Hepatitis

One of the results of acetaldehyde-adduct formation with amino acids is a general decrease in hepatic protein synthesis (see Fig. 33.7, circle 1). Calmodulin, ribonuclease, and tubulin are some of the proteins affected. Proteins in the heart and other tissues also may be affected by acetaldehyde that appears in the blood.

As a consequence of forming acetaldehyde adducts of tubulin, there is a diminished secretion of serum proteins and VLDL from the liver. The liver synthesizes many blood proteins, including serum albumin, blood coagulation factors, and transport proteins for vitamins, steroids, and iron. These proteins accumulate in the liver, together with lipid. The accumulation of proteins results in an influx of water (see Fig. 33.7, circle 6) within the hepatocytes and a swelling of the liver that contributes to portal hypertension and a disruption of hepatic architecture.

2. Acetaldehyde and Free-Radical Damage

Acetaldehyde-adduct formation enhances free-radical damage. Acetaldehyde binds directly to glutathione and diminishes its ability to protect against H₂O₂ and prevent lipid peroxidation (see Fig. 33.7, circle 2). It also binds to free-radical defense enzymes.

Damage to mitochondria from acetaldehyde and free radicals perpetuates a cycle of toxicity (see Fig. 33.7, circles 3 and 4). With chronic consumption of ethanol, mitochondria become damaged, the rate of electron transport is inhibited, and oxidative phosphorylation tends to become uncoupled. Fatty acid oxidation is decreased even further, thereby enhancing lipid accumulation (see Fig. 33.7, circle 5). The mitochondrial changes further impair mitochondrial acetaldehyde oxidation, thereby initiating a cycle of progressively increasing acetaldehyde damage.

The noncaloric effect of heavy and chronic ethanol ingestion that led **Ivan A.** to believe ethanol has no calories may be attributable to uncoupling of oxidative phosphorylation. The hepatic mitochondria from tissues of people with chronic alcohol use disorder may be partially uncoupled and unable to maintain the transmembrane proton gradient necessary for normal rates of ATP synthesis. Consequently, a greater proportion of the energy in ethanol is converted to heat. Metabolic disturbances such as the loss of ketone bodies in urine, or futile cycling of glucose, also might contribute to a diminished energy value for ethanol.

C. Ethanol and Free-Radical Formation

Increased oxidative stress in the liver during chronic ethanol intoxication arises from increased production of free radicals, principally by CYP2E1. FAD and FMN in the reductase and heme in the cytochrome P450 system transfer single electrons, thus operating through a mechanism that can generate free radicals. The hydroxyethyl radical ($\text{CH}_3\text{CH}_2\text{O}\cdot$) is produced during ethanol metabolism and can be released as a free radical. Induction of CYP2E1, as well as other cytochrome P450 enzymes, can increase the generation of free radicals from drug metabolism and from the activation of toxins and carcinogens (see Fig. 33.7, circle 3). These effects are enhanced by acetaldehyde-adduct damage.

Phospholipids, the major lipid in cellular membranes, are a primary target of peroxidation caused by free-radical release. Peroxidation of lipids in the inner mitochondrial membrane may contribute to the inhibition of electron transport and uncoupling of mitochondria, leading to inflammation and cellular necrosis. Induction of CYP2E1 and other P450 cytochromes also increases the formation of other radicals and the activation of hepatocarcinogens.

Because of the possibility of mild alcoholic hepatitis and perhaps chronic alcohol-induced cirrhosis, the physician ordered liver function studies on **Jean T.** The tests indicated an alanine aminotransferase (ALT) level of 46 U/L (reference range, 5 to 30 U/L) and an aspartate aminotransferase (AST) level of 98 U/L (reference range, 10 to 30 U/L). The concentration of these enzymes is high in hepatocytes. When hepatocellular membranes are damaged in any way, these enzymes are released into the blood. **Jean T.**'s serum alkaline phosphatase level was 195 U/L (reference range, 56 to 155 U/L for an adult female). The serum total bilirubin level was 2.4 mg/dL (reference range, 0.2 to 1.0 mg/L). These tests show impaired capacity for normal liver function. Her blood hemoglobin and hematocrit levels were slightly below the normal range, consistent with a toxic effect of ethanol on red blood cell production by bone marrow. Serum folate and vitamin B₁₂ levels were also slightly suppressed. Folate is dependent on the liver for its activation and recovery from the enterohepatic circulation. Vitamin B₁₂ is dependent on the liver for synthesis of its blood carrier proteins. Thus, **Jean T.** shows many of the consequences of hepatic damage.

D. Hepatic Cirrhosis and Loss of Liver Function

Liver injury is irreversible at the stage that hepatic cirrhosis develops. Initially, the liver may be enlarged, full of fat, crossed with collagen fibers (fibrosis), and have nodules of regenerating hepatocytes ballooning between the fibers. As liver function is lost, the liver becomes shrunken (Laennec cirrhosis). During the development of cirrhosis, many of the normal metabolic functions of the liver are lost, including biosynthetic and detoxification pathways. Synthesis of blood proteins, including blood coagulation factors and serum albumin, is decreased. The capacity to incorporate amino groups into urea is decreased, resulting in the accumulation of toxic levels of ammonia in the blood. Conjugation and excretion of the yellow pigment bilirubin (a product of heme degradation) are diminished, and bilirubin accumulates in the blood. It is deposited in many tissues, including the skin and sclerae of the eyes, causing the patient to become visibly yellow. Such a patient is said to be jaundiced.

CLINICAL COMMENTS

When ethanol consumption is low (<15% of the calories in the diet), it is used efficiently to produce ATP, thereby contributing to **Ivan A.**'s weight gain. However, in individuals with chronic consumption of large amounts of ethanol, the caloric content of ethanol is not converted to ATP as effectively. Some of the factors that may contribute to this decreased efficiency include mitochondrial damage (inhibition of oxidative phosphorylation and uncoupling) resulting in the loss of calories as heat, increased recycling of metabolites such as ketone bodies, and inhibition of the normal pathways of fatty acid and glucose oxidation. In addition, people who drink increased alcohol chronically metabolize an increased amount of alcohol through the MEOS, which generates less ATP.

Al M. was suffering from acute effects of high ethanol ingestion in the absence of food intake. Both ethanol consumption and low caloric intake increase adipose tissue lipolysis and elevate blood fatty acids. As a consequence of his elevated hepatic NADH/NAD⁺ ratio, acetyl CoA produced from fatty acid oxidation was diverted from the TCA cycle into the pathway of ketone body synthesis. Because his skeletal muscles were using acetate as a fuel, ketone body utilization was diminished, resulting in ketoacidosis. Al's moderately low blood glucose level also suggests that his high hepatic NADH level prevented pyruvate and glycerol from entering the gluconeogenic pathway. Pyruvate is diverted to lactate, which may have contributed to his metabolic acidosis and anion gap, along with the ketone bodies.

Rehydration with intravenous fluids containing glucose, thiamin, and potassium was initiated. **Al M.**'s initial potassium level was low, possibly secondary to vomiting. Thiamin is given in case there is thiamin deficiency. An orthopedic surgeon was consulted regarding the compound fracture of his right forearm.

Jean T.'s signs and symptoms, as well as her laboratory profile, were consistent with the presence of mild reversible alcohol-induced hepatocellular inflammation (alcohol-induced hepatitis) superimposed on a degree of irreversible scarring of liver tissues known as chronic alcoholic (Laennec) cirrhosis of the liver. The chronic inflammatory process associated with long-term ethanol use in patients such as **Jean T.** is accompanied by increases in the levels of serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Her elevated bilirubin and alkaline phosphatase levels in the blood were consistent with hepatic damage. Her values for ALT and AST were significantly below those seen in acute viral hepatitis. In addition, the ratio of the absolute values for serum AST and ALT often differ in the two diseases, tending to be 2:1 in alcohol-induced liver disease. The reason for the difference in ratio of enzyme activities released is not fully understood, but a lower level of ALT in the serum may be attributable to an alcohol-induced deficiency of pyridoxal phosphate. In addition, serological tests for viral hepatitis were nonreactive. Her serum folate and vitamin B₁₂ were also slightly suppressed, indicating impaired nutritional status.

In liver fibrosis, disruption of the normal liver architecture, including sinusoids, impairs blood flow from the portal vein. Increased portal vein pressure (portal hypertension) causes capillaries to anastomose (to meet and unite or run into each other) and form thin-walled dilated esophageal venous conduits known as esophageal varices. When these burst, there is hemorrhaging into the gastrointestinal tract. The bleeding can be very profuse because of the high venous pressure within these varices in addition to the adverse effect of impaired hepatic function on the production of blood clotting proteins.

Jean T. was counseled to abstain from alcohol and to improve her nutritional status. She was referred to the hospital drug and alcohol rehabilitation unit for appropriate psychologic therapy and supportive social counseling. The physician also arranged for a follow-up office visit in 2 weeks.

BIOCHEMICAL COMMENTS

Fibrosis in Chronic Alcohol-Induced Liver Disease. Fibrosis is the excessive accumulation of connective tissue in parenchymal organs. In the liver, it is a frequent event following a repeated or chronic insult of sufficient intensity (such as chronic ethanol intoxication or infection by a hepatitis virus) to trigger a "wound healing-like" reaction. Regardless of the insult, the events are similar: An overproduction of extracellular matrix components occurs, with the tendency to progress to sclerosis, accompanied by a degenerative alteration in the composition of matrix components (Table 33.2). Some individuals (<20% of those who chronically consume alcohol) go on to develop cirrhosis.

TABLE 33.2 Hepatic Injury

STAGE OF INJURY	MAIN FEATURES
Fibrosis: increase of connective tissue	<ul style="list-style-type: none"> Accumulation of both fibrillar and basement membrane-like collagens Increase of laminin and fibronectin Thickening of connective tissue septae Capillary formation within the sinusoids
Sclerosis: aging of fibrotic tissue	Decrease of hyaluronic acid and heparan sulfate

	proteoglycans Increase of chondroitin sulfate proteoglycans Progressive fragmentation and disappearance of elastic fibers Distortion of sinusoidal architecture and parenchymal damage
Cirrhosis: end-stage process of liver fibrotic degeneration	Whole liver heavily distorted by thick bands of collagen surrounding nodules of hepatocytes with regenerative foci

Although the full spectrum of alcohol-induced liver disease may be present in a well-nourished individual, the presence of nutritional deficiencies enhances the progression of the disease. Ethanol creates nutritional deficiencies in a number of different ways. The ingestion of ethanol reduces the gastrointestinal absorption of foods that contain essential nutrients, including vitamins, essential fatty acids, and essential amino acids. For example, ethanol interferes with absorption of folate, thiamin, and other nutrients. Secondary malabsorption can occur through gastrointestinal complications, pancreatic insufficiency, and impaired hepatic metabolism or impaired hepatic storage of nutrients, such as vitamin A. Changes in the level of transport proteins produced by the liver also strongly affect nutrient status.

The development of hepatic fibrosis after ethanol consumption is related to stimulation of the mitogenic development of stellate (Ito) cells into myofibroblasts, and stimulation of the production of collagen type I and fibronectin by these cells. The stellate cells are perisinusoidal cells lodged in the space of Disse that produce extracellular matrix protein. Normally the space of Disse contains basement membrane-like collagen (collagen type IV) and laminin. As the stellate cells are activated, they change from a resting cell filled with lipids and vitamin A to one that proliferates, loses its vitamin A content, and secretes large quantities of extracellular matrix components.

One of the initial events in the activation and proliferation of stellate cells is the activation of Kupffer cells, which are macrophages that reside in the liver sinusoids (Fig. 33.8). The Kupffer cells are probably activated by a product of the damaged hepatocytes, such as necrotic debris, iron, reactive oxygen species (ROS), acetaldehyde, or aldehyde products of lipid peroxidation. Kupffer cells also may produce acetaldehyde from ethanol internally through their own MEOS pathway.

FIGURE 33.8 Proposed model for the development of hepatic fibrosis involving hepatocytes, Kupffer cells, and stellate (Ito) cells. NO, nitric oxide; ROS, reactive oxygen species; TGF- β_1 , transforming growth factor β_1 .

Activated Kupffer cells produce a number of products that contribute to activation of stellate cells. They generate additional ROS through NADPH oxidase during the oxidative burst and RNOS through inducible NO synthase (see Chapter 25). In addition, they secrete an impressive array of growth factors, such as cytokines, chemokines, prostaglandins, and other reactive molecules. The cytokine transforming growth factor β_1 (TGF- β_1), produced by both Kupffer cells and sinusoidal endothelial cells, is a major player in the activation of stellate cells. Once they are activated, the stellate cells produce collagen and proteases, leading to an enhanced fibrotic network within the liver. Stellate cells may also be partially activated by hepatocyte release of ROS and acetaldehyde directly, with the involvement of Kupffer cells.

Recent evidence also indicates that chronic alcohol use can disrupt gene regulation within the liver, through modification of the activity of sirutin1 (see “Biochemical Comments” in Chapter 30). Sirutin 1 (SIRT-1) is a histone deacetylase, which utilizes NAD⁺ as a substrate (see Fig. 30.21), producing nicotinamide and acetyl-ADP-ribose. Deacetylation of appropriate targets leads to alterations in gene expression. Ethanol will lead to a downregulation of SIRT-1 activity. Ethanol may lead to reduced SIRT-1 activity through an increase in the NADH/NAD⁺ ratio in the liver, thereby reducing the level of substrate (NAD⁺) required for SIRT-1 activity.

Interestingly, it also appears that a reduction in SIRT-1 activity leads to a reduction in AMP-activated protein kinase activity (AMPK). Under normal conditions SIRT-1 deacetylates LBK1, activating it, which phosphorylates and activates the AMPK. AMPK (see “Biochemical Comments” in Chapter 32) phosphorylates and inhibits acetyl CoA carboxylase, resulting in reduced production of malonyl CoA. Malonyl CoA is an inhibitor of carnitine palmitoyltransferase I (CPT1), so reduced levels of malonyl CoA lead to increased

activity of CPT1, and increased levels of fatty acid oxidation. Ethanol-induced inhibition of SIRT-1 will lead to inhibition of hepatic AMPK (due to LKB1 remaining inactive), thereby activating acetyl CoA carboxylase, producing malonyl CoA, and blocking fatty acid oxidation in the liver. This will result in the fatty acid and triglyceride synthesis in the liver, leading to the development of alcoholic fatty liver disease.

KEY CONCEPTS

- ◆ Ethanol metabolism occurs primarily in the liver, via a two-step oxidation sequence to acetate, plus NADH.
- ◆ Acetate is activated to acetyl CoA for energy generation by most tissues of the body.
- ◆ The alcohol dehydrogenase family of enzymes catalyzes the first step of alcohol oxidation. The aldehyde dehydrogenase family of enzymes catalyzes the second step of the pathway.
- ◆ When ethanol levels are high, the MEOS, consisting of CYP2E1, is induced.
- ◆ Acute effects of ethanol ingestion are due to the elevated NADH/NAD⁺ ratio, which leads to
 - ◆ Inhibition of fatty acid oxidation
 - ◆ Ketogenesis
 - ◆ Hyperlipidemia
 - ◆ Inhibition of gluconeogenesis
 - ◆ Lactic acidosis
 - ◆ Hyperuricemia
- ◆ Chronic effects of ethanol ingestion include:
 - ◆ Hepatic steatosis (fatty acid accumulation within the liver)
 - ◆ Hepatitis
 - ◆ Fibrosis (excessive collagen production within the liver)
 - ◆ Cirrhosis (eventual liver death)
- ◆ The chronic effects of ethanol are due to acetaldehyde and ROS production during ethanol metabolism.
- ◆ The diseases discussed in this chapter are summarized in Table 33.3.

TABLE 33.3 Diseases Discussed in Chapter 33

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Obesity	Both	Ethanol is a nutrient, and its caloric content can contribute to obesity.
Alcohol use disorder	Both	Alcohol use disorder may occur, leading to damage of internal organs by acetaldehyde production.
Jaundice	Environmental	Altered liver function leads to a reduced ability to conjugate and solubilize bilirubin, which leads to bilirubin deposition in the eyes and skin, giving them a yellow pallor (Jaundice). This is an indication of liver disease.
Liver Fibrosis	Environmental	Excessive damage to liver, often due to alcohol metabolism, particularly acetaldehyde accumulation, leading to extensive collagen secretion and loss of liver function.

REVIEW QUESTIONS—CHAPTER 33

1. The fate of acetate, the product of ethanol metabolism, is which one of the following?
 - A. It is taken up by other tissues and activated to acetyl CoA.
 - B. It is toxic to the tissues of the body and can lead to hepatic necrosis.
 - C. It is excreted in bile.
 - D. It enters the TCA cycle directly to be oxidized.

- E. It is converted into NADH by alcohol dehydrogenase.
- Which one of the following would be expected to occur after acute alcohol ingestion?
 - Activation of fatty acid oxidation
 - Lactic acidosis
 - Inhibition of ketogenesis
 - An increase in the NAD^+/NADH ratio
 - An increase in gluconeogenesis
 - An individual is in treatment for chronic alcohol abuse. The drug disulfiram is prescribed for the patient. This drug deters the consumption of alcohol by which one of the following mechanisms?
 - Inhibiting the absorption of ethanol so that an individual cannot become intoxicated, regardless of how much he or she drinks
 - Inhibiting the conversion of ethanol to acetaldehyde, which cause the excretion of unmetabolized ethanol
 - Blocking the conversion of acetaldehyde to acetate, which causes the accumulation of acetaldehyde
 - Activating the excessive metabolism of ethanol to acetate, which causes inebriation with consumption of a small amount of alcohol
 - Preventing the excretion of acetate, which causes nausea and vomiting
 - Induction of CYP2E1 would result in which of the following?
 - A decreased clearance of ethanol from the blood
 - A decrease in the rate of acetaldehyde production
 - A low possibility of the generation of free radicals
 - Protection from hepatic damage
 - An increase of one's alcohol tolerance level
 - Which one of the following consequences of chronic alcohol consumption is irreversible?
 - Inhibition of fatty acid oxidation
 - Activation of triacylglycerol synthesis
 - Ketoacidosis
 - Lactic acidosis
 - Liver cirrhosis
 - An abuser of alcohol use, on a binge, is severely hypoglycemic. Under these conditions, gluconeogenic precursors are trapped and cannot progress to form glucose. Which one of the following is such a trapped intermediate?
 - Glycerol
 - Dihydroxyacetone phosphate
 - Glyceraldehyde 3-phosphate
 - Glycerol 3-phosphate
 - Pyruvate
 - Your patient is a chronic abuser of alcohol use who is frequently malnourished and is exhibiting symptoms of a vitamin deficiency due to excessive alcohol consumption. This patient would most likely have trouble catalyzing which one of the following reactions due to the vitamin deficiency?
 - Sedoheptulose 7-phosphate + glyceraldehyde 3-phosphate \rightarrow Erythrose 4-phosphate + fructose 6-phosphate
 - Ribose 5-phosphate + Xylulose 5-phosphate \rightarrow Sedoheptulose 7-phosphate + Glyceraldehyde 3-phosphate
 - Glucose 6-phosphate + 2 NADP^+ \rightarrow CO_2 + Ribulose 5-phosphate + 2 NADPH
 - Isocitrate + NAD^+ \rightarrow CO_2 + α -ketoglutarate + NADH
 - Oxaloacetate + GTP \rightarrow Phosphoenolpyruvate + CO_2 + GDP
 - The enzymes that metabolize ethanol exist as a variety of isozymes in the general population. A slow activity isozyme of which enzyme is most likely responsible for an individual to exhibit a very low tolerance to alcohol, leading to the individual rarely drinking?
 - Acetyl CoA synthetase
 - MEOS
 - Acetyl CoA carboxylase
 - Alcohol dehydrogenase
 - Aldehyde dehydrogenase
 - What would be an outcome if a person had a defect in which the metabolites of ethanol could not enter the

mitochondria?

- A. Acetate would accumulate which is toxic
 - B. Acetaldehyde would accumulate which is toxic
 - C. Acetate would be activated by tissues to acetyl CoA
 - D. Acetaldehyde would be activated by tissues to acetyl CoA
 - E. The MEOS would not function
0. The possibility of ROS being generated during ethanol metabolism occurs via which one of the following enzyme systems?
- A. MEOS
 - B. Alcohol dehydrogenase
 - C. Aldehyde dehydrogenase
 - D. Acetyl CoA synthetase
 - E. Citrate synthase
1. A fatty liver will develop in individuals who have abused alcohol for a significant period of time. Potential mechanisms that allow this to occur include which of the following? Choose the one best answer.

	NADH Inhibition of Fatty Acid Oxidation	Microtubule- acetaldehyde Adducts	Ethanol Inhibition of MTP Activity	Acetaldehyde Inhibition of Lipoprotein Lipase
A	Yes	Yes	No	Yes
B	No	Yes	Yes	No
C	Yes	Yes	No	No
D	No	No	Yes	No
E	Yes	No	No	Yes
F	No	No	Yes	Yes

2. A 27-year-old woman gave birth to a child who had a small head, abnormal facial features, and below-average height and weight. The woman had sporadic doctor visits during her pregnancy, and when questioned after the birth admitted to binge drinking during her pregnancy. The phenotypic features of her child may have resulted from which one of the following?
- A. Fatty liver development in the fetus
 - B. Induction of MEOS in the fetal liver
 - C. Ethanol inhibition of fetal aldehyde reductase
 - D. Altered gene transcription in the fetus
 - E. Ethanol-induced reduction of gluconeogenesis in the fetus
3. The liver is the prime target for ethanol-induced damage due to which one of the following?
- A. Alcohol dehydrogenase is only expressed in the liver
 - B. Aldehyde dehydrogenase is only expressed in the liver
 - C. All of the high K_m forms for alcohol dehydrogenase are in the liver
 - D. All of the high K_m forms for aldehyde dehydrogenase are in the liver
 - E. 90% of ethanol metabolism occurs in the liver
4. The ATP yield from the complete oxidation of ethanol to carbon dioxide and water is less when metabolized

through MEOS rather than the pathway of alcohol and aldehyde dehydrogenase. This is due to which of the following?

- A. Using MEOS only cytoplasmic NADH is formed
 - B. Using MEOS the net yield of NADH is reduced
 - C. The formation of hydrogen peroxide in the mitochondria reduces ATP yield
 - D. Using MEOS the aldehyde dehydrogenase step is skipped
 - E. The use of MEOS partially uncouples oxidative phosphorylation
5. Patients with von Gierke disease often develop gout, as can patients who abuse alcohol. The commonality between these two disorders, leading to gout, is which of the following?
- A. The generation of a high NADH/NAD⁺ ratio
 - B. Fasting hypoglycemia
 - C. Ketoacidosis
 - D. Lactate production
 - E. Mitochondrial uncoupling

ANSWERS TO REVIEW QUESTIONS

1. **The answer is A.** Acetate is converted to acetyl CoA by other tissues so that it can enter the TCA cycle to generate ATP. Answer B is incorrect because acetaldehyde, not acetate, is toxic to cells. Answer C is incorrect because acetate is excreted by the lung and kidney, and not in the bile. Answer D is incorrect because acetate cannot enter the TCA cycle directly. It must be converted to acetyl CoA first. Answer E is incorrect because alcohol dehydrogenase converts ethanol into acetaldehyde. It does not convert acetate into NADH.
2. **The answer is B.** There is an increase in the NADH/NAD⁺ ratio because NADH is produced by the conversion of ethanol to acetate (thus, D is incorrect). The increased ratio of NADH/NAD⁺ favors the conversion of gluconeogenic precursors (such as pyruvate and oxaloacetate) to their reduced counterparts (lactate and malate, respectively), to generate NAD⁺ for ethanol metabolism. This reduces the concentration of gluconeogenic precursors, and slows down gluconeogenesis (thus, E is incorrect), and can lead to lactic acidosis. Answer A is incorrect because the increase of NADH inhibits fatty acid oxidation. Answer C is incorrect because ketogenesis increases as a result of the increase of NADH and acetyl CoA in the mitochondria. NADH inhibits key enzymes of the TCA cycle, thereby diverting acetyl CoA from the TCA cycle and toward ketone body synthesis.
3. **The answer is C.** Disulfiram blocks the conversion of acetaldehyde to acetate (the reaction catalyzed by aldehyde dehydrogenase). The accumulation of acetaldehyde is toxic and causes vomiting and nausea. Answers A and B are incorrect because disulfiram would not interfere with the absorption of ethanol or the first step of its metabolism. Answer D is incorrect because an acetaldehyde dehydrogenase inhibitor (such as disulfiram) would inhibit the conversion of ethanol to acetate, not increase the rate of the conversion. Answer E is incorrect because disulfiram does not interfere with the excretion of acetate, nor does acetate accumulation lead to nausea and vomiting.
4. **The answer is E.** An increase in the concentration of CYP2E1 (the MEOS system) would result in an increase of ethanol metabolism and clearance from the blood (thus, A is incorrect). An increased rate of acetaldehyde production would result (thus, B is incorrect). The increase in CYP2E1 would cause an increase in the probability of producing free radicals (thus, C is incorrect). Answer D is incorrect because hepatic damage would be more likely to occur because there is an increase of free-radical production. Answer E is correct because the increased clearance rate of ethanol from the blood results in a higher alcohol tolerance level.
5. **The answer is E.** Liver cirrhosis is irreversible. It is an end-stage process of liver fibrosis. Answers A, B, C, and D are all consequences of liver disease, but they are all reversible. Therefore, E is the only answer that is correct.
6. **The answer is D.** The gluconeogenic precursors are lactate, glycerol, and amino acids (primarily alanine) from muscle protein degradation. Under the conditions of high alcohol intake, for extended periods, the NADH/NAD⁺ ratio is very high, due to alcohol being converted to acetaldehyde, and then acetic acid. Gluconeogenesis is impaired due to the high levels of NADH present. Lactate cannot be converted to pyruvate (the reaction requires NAD⁺, which is present in very low levels). Alanine can be converted to

pyruvate, which is converted to oxaloacetate via pyruvate carboxylase, but the oxaloacetate is trapped, and cannot be converted to malate, due to the low NAD^+ levels as well. Glycerol metabolism requires first, phosphorylation to glycerol 3-phosphate, and then oxidation of carbon 2 to form dihydroxyacetone phosphate, an NAD^+ requiring reaction. Thus, when NAD^+ levels are low, glycerol 3-phosphate, lactate, and oxaloacetate will all be trapped and cannot efficiently progress through the gluconeogenic pathway.

7. **The answer is B.** The patient is likely to be thiamin deficient, which is a required factor for oxidative decarboxylation reactions (pyruvate dehydrogenase and α -ketoglutarate dehydrogenase) and transketolase. Ethanol interferes with the absorption of thiamin from the digestive tract. The reaction of ribose 5-phosphate with xylulose 5-phosphate to produce sedoheptulose 7-phosphate and glyceraldehyde 3-phosphate is catalyzed by transketolase. The conversion of sedoheptulose 7-phosphate and glyceraldehyde 3-phosphate to erythrose 4-phosphate and fructose 6-phosphate is a three-carbon transfer catalyzed by transaldolase, which does not require an exogenous vitamin for activity. The conversion of glucose 6-phosphate to ribulose 5-phosphate is catalyzed by glucose 6-phosphate dehydrogenase, which requires niacin as a cofactor, but not thiamin. Isocitrate dehydrogenase, which requires niacin (but not thiamin), catalyzes the conversion of isocitrate to α -ketoglutarate. PEP carboxykinase catalyzes the conversion of oxaloacetate to PEP and does not require a vitamin cofactor.
8. **The answer is E.** An isozyme of aldehyde dehydrogenase has a dramatically increased K_m (>200 -fold) and a 10-fold reduced V_{max} . In such individuals, acetaldehyde, the toxic component of alcohol ingestion, accumulates to a large extent, leading to the individual having a very low tolerance for alcohol. A slow-acting alcohol dehydrogenase would not lead to a low tolerance to alcohol, as acetaldehyde accumulation (the toxic intermediate of alcohol metabolism) would be slowed such that the acetaldehyde produced can be safely metabolized without any side effects. Acetate, once produced, is not toxic, so a slow-acting acetyl CoA synthetase (which uses acetate as a substrate) would not lead to the accumulation of a toxic intermediate. MEOS is utilized as an alternative ethanol-oxidizing system when ethanol levels are high. A slow-acting MEOS would reduce the production of acetaldehyde, which is the toxic intermediate of alcohol metabolism. This would not lead to a low level of tolerance to alcohol. Acetyl CoA carboxylase is not involved in ethanol metabolism (the acetyl CoA formed would be used for energy). Acetyl CoA carboxylase is needed for fatty acid synthesis, and if its activity were low, fatty acid production would be reduced, but it would have no effect on the tolerance to alcohol.
9. **The answer is B.** The main route for metabolism of ethanol is through alcohol dehydrogenase in the cytosol producing acetaldehyde, which is the toxic intermediate of alcohol metabolism. Acetaldehyde is further oxidized in mitochondria to acetate, which is then activated by tissues to acetyl CoA, which is oxidized in the TCA cycle. If entry of acetaldehyde into the mitochondria is blocked then acetaldehyde accumulates and acetate is not formed. The MEOS is in the endoplasmic reticulum (cytosolic) and would continue to produce acetaldehyde and NADP^+ .
10. **The answer is A.** The MEOS is induced by ethanol and utilizes a cytochrome P450 system to oxidize ethanol. The cytochrome P450 enzyme systems transfer a single electron at a time through an iron within a heme group in the cytochrome, and this is the step at which the electron may escape, and convert oxygen to superoxide, thereby generating ROS. Alcohol dehydrogenase and aldehyde dehydrogenase transfer hydride ions to NAD^+ , and there is a very low probability of electrons escaping from those oxidation-reduction reactions. Acetyl CoA synthetase does not catalyze an oxidation-reduction reaction (it catalyzes the conversion of acetate to acetyl CoA), nor does citrate synthase (the formation of citrate from acetyl CoA and oxaloacetate). The possibility of losing an electron during a reaction in which electrons are not being transferred is very low.
11. **The answer is C.** The accumulation of triglyceride in the liver results from a number of factors. Ethanol oxidation leads to an increased NADH/NAD^+ ratio in the liver and mitochondria, leading to an inhibition of fatty acid oxidation. The increased levels of fatty acids in the liver cytoplasm lead to triglyceride synthesis, increasing triglyceride levels in the liver. The accumulation of acetaldehyde (due to ethanol oxidation) in the liver increases microtubule-acetaldehyde adducts, blocking microtubule function and leading to an inability to export VLDL from the liver. The increased VLDL contributes to the increased triglyceride in the liver. Ethanol does not alter MTP activity (VLDL synthesis is not impaired), and acetaldehyde does not alter lipoprotein lipase activity on the surface of the capillary epithelial cells.
12. **The answer is D.** The child has the symptoms of fetal alcohol distress syndrome due to the mother drinking during her pregnancy. One theory of why these symptoms occur is due to reduced retinoic acid production, due to ethanol and acetaldehyde competition with retinoic acid precursors for alcohol and

aldehyde dehydrogenases. The reduced retinoic acid levels alter gene transcription during embryogenesis, leading to altered patterns of differentiation. The development of fetal alcohol distress syndrome is not thought to be due to an accumulation of fat in the fetal liver, or the induction of MEOS in the fetal liver. Ethanol does not inhibit aldehyde reductase, and the fetus obtains glucose from the mother's blood, so an inhibition of fetal gluconeogenesis would not deprive the fetus of glucose.

13. **The answer is E.** 90% of the ethanol oxidation occurs in the liver due to the low- K_m (high-affinity) alcohol dehydrogenase isozymes expressed in the liver. Both alcohol dehydrogenase and aldehyde dehydrogenase genes are expressed in many tissues, not just the liver. The high K_m forms of alcohol and aldehyde dehydrogenase are the low-affinity forms of the enzymes and are expressed in tissues outside of the liver.
14. **The answer is B.** When ethanol is oxidized through the alcohol and acetaldehyde dehydrogenase pathway 13 mol of ATP are generated per mole of ethanol (one NADH from the alcohol dehydrogenase pathway, one NADH from the aldehyde dehydrogenase pathway, 10 from acetyl CoA being oxidized via the TCA cycle, and -2 for the activation of acetate to acetyl CoA). Using the MEOS pathway there is no net NADH production (1 NADPH is utilized in the MEOS reaction, which is balanced by the NADH generated by the aldehyde dehydrogenase reaction, 10 from acetyl CoA, and -2 for the activation of acetate to acetyl CoA). While MEOS is found in the endoplasmic reticulum, aldehyde dehydrogenase is a mitochondrial enzyme. The oxidation of ethanol does not generate hydrogen peroxide in the mitochondria. In a chronic abuser of alcohol use, the continued use of MEOS can lead to liver damage through an uncoupling mechanism, altering oxidative phosphorylation, but in terms of ATP yield, occasional use of MEOS will not lead to uncoupling.
15. **The answer is D.** A lack of glucose 6-phosphatase activity leads to von Gierke disease, which is characterized by fasting hypoglycemia, gout, and lactic acidosis. Lactate production is elevated due to the inability to convert glucose 6-phosphate to glucose, such that the glucose 6-phosphate goes through glycolysis, producing lactate. The glucose 6-phosphate also stimulates the HMP shunt pathway, leading to increased ribose 5-phosphate production, and increased purine synthesis. The excess purines are degraded to uric acid, which is normally excreted by the kidney. However, the elevated lactate levels block the ability of the kidney to remove urate from the blood, leading to hyperuricemia, and gout. Excessive ethanol metabolism leads to an elevated NADH/NAD⁺ ratio, which will convert pyruvate to lactate. The elevated lactate in the blood will block urate uptake by the kidney, leading to gout.

Integration of Carbohydrate and Lipid Metabolism

This chapter summarizes and integrates the major pathways for the utilization of carbohydrates and fats as fuels. We concentrate on reviewing the regulatory mechanisms that determine the flux of metabolites in the fed and fasting states, integrating the pathways that were described separately under carbohydrate and lipid metabolism. The next section of the book covers the mechanisms by which the pathways of nitrogen metabolism are coordinated with fat and carbohydrate metabolism.

For the species to survive, it is necessary for us to store excess food when we eat and to use these stores when we are fasting. Regulatory mechanisms direct compounds through the pathways of metabolism involved in the storage and utilization of fuels. These mechanisms are controlled by **hormones**, by the **concentration of available fuels**, and by the **energy needs** of the body.

Changes in hormone levels, in the concentration of fuels, and in energy requirements affect the activity of key enzymes in the major pathways of metabolism. Intracellular **enzymes** are generally regulated by **activation** and **inhibition**, by **phosphorylation** and **dephosphorylation** (or other covalent modifications), by **induction** and **repression** of synthesis, and by **degradation**. Activation and inhibition of enzymes cause immediate changes in metabolism. Phosphorylation and dephosphorylation of enzymes affect metabolism slightly less rapidly. Induction and repression of enzyme synthesis are much slower processes, usually affecting metabolic flux over a period of hours. Degradation of enzymes decreases the amount available to catalyze reactions.

The pathways of metabolism have **multiple control points** and **multiple regulators** at each control point. The function of these complex mechanisms is to produce a graded response to a stimulus and to provide sensitivity to multiple stimuli so that an exact balance is maintained between flux through a given step (or series of steps) and the need or use for the product. Pyruvate dehydrogenase (PDH) is an example of an enzyme that has multiple regulatory mechanisms. Regardless of insulin levels, the enzyme cannot become fully activated in the presence of products and the absence of substrates.

The major hormones that regulate the pathways of fuel metabolism are **insulin** and **glucagon**. In liver, all effects of glucagon are reversed by insulin, and some of the pathways that insulin activates are inhibited by glucagon. Thus, the pathways of carbohydrate and lipid metabolism are generally regulated by changes in the **insulin/glucagon ratio**.

Although **glycogen** is a critical storage form of fuel because blood glucose levels must be carefully maintained, adipose **triacylglycerols** are quantitatively the major fuel store in the human. After a meal, both dietary glucose and fat are stored in adipose tissue as triacylglycerol. This fuel is released during fasting, when it provides the main source of energy for the tissues of the body. The length of time we can survive without food depends mainly on the size of our bodies' fat stores.

THE WAITING ROOM

Within 2 months of her surgery to remove a benign insulin-secreting β -cell tumor of the pancreas, **Connie C.** (see Chapter 19) was again jogging lightly. She had lost the 8 lb that she had gained in the 6 weeks before her surgery. Because her hypoglycemic episodes were no longer occurring, she had no need to eat frequent carbohydrate snacks to prevent the adrenergic and neuroglycopenic symptoms that she had experienced when her tumor was secreting excessive amounts of insulin.

A few months after her last hospitalization, **Dianne A.** was once again brought to the hospital emergency room in diabetic ketoacidosis (DKA). Blood samples for glucose and electrolytes were drawn repeatedly during the first 24 hours. The hospital laboratory reported that the serum in each of these specimens appeared opalescent rather than having its normal clear or transparent appearance. This opalescence results from light scattering caused by the presence of elevated levels of triacylglycerol-rich lipoproteins in the blood.

When **Deborah S.** initially presented (see Chapter 19) with type 2 diabetes mellitus at age 39, she was approximately 30 lb over her ideal weight. Her high serum glucose levels were accompanied by abnormalities in her 14-hour fasting lipid profile. Her serum total cholesterol, low-density lipoprotein (LDL) cholesterol, and triacylglycerol levels were elevated, and her serum high-density lipoprotein (HDL) cholesterol level was below the normal range.

I. Regulation of Carbohydrate and Lipid Metabolism in the Fed State

A. Mechanisms That Affect Glycogen and Triacylglycerol Synthesis in Liver

After a meal, the liver synthesizes glycogen and triacylglycerol. The level of glycogen stored in the liver can increase from approximately 80 g after an overnight fast to a limit of approximately 200 to 300 g. Although the liver synthesizes triacylglycerol, it does not store this fuel, but rather packages it in very-low-density lipoprotein (VLDL) and secretes it into the blood. The fatty acids of the VLDL triacylglycerols secreted from the liver are stored as adipose triacylglycerols. Adipose tissue has an almost infinite capacity to store fat, limited mainly by the ability of the heart to pump blood through the capillaries of the expanding adipose mass. Although we store fat throughout our bodies, it tends to accumulate in places where it does not interfere too much with our mobility: in the abdomen, hips, thighs, and buttocks.

Both the synthesis of liver glycogen and the conversion by the liver of dietary glucose to triacylglycerol (lipogenesis) are regulated by mechanisms involving key enzymes in these pathways.

1. Glucokinase

After a meal, glucose can be converted to glycogen or to triacylglycerol in the liver. For both processes, glucose is first converted to glucose 6-phosphate by glucokinase, a liver enzyme that has a high K_m for glucose (Fig. 34.1). Because of the enzyme's low affinity for glucose, this enzyme is most active in the fed state, when the concentration of glucose is particularly high because the hepatic portal vein carries digestive products directly from the intestine to the liver. Synthesis of glucokinase is also induced by insulin (which is elevated after a meal) and repressed by glucagon (which is elevated during fasting). In keeping with the liver's function in maintaining blood glucose levels, this system is set up such that the liver can metabolize glucose only when sugar levels are high and not when sugar levels are low.

FIGURE 34.1 Regulation of glucokinase, phosphofructokinase-1 (PFK-1), and pyruvate kinase in the liver. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; F-1,6-BP, fructose 1,6-bisphosphate; F-2,6-BP, fructose 2,6-bisphosphate.

2. Glycogen Synthase

In the conversion of glucose 6-phosphate to glycogen, the key regulatory enzyme is glycogen synthase. This enzyme is activated by dephosphorylation, which occurs when insulin is elevated and glucagon is decreased (Fig. 34.2) and by the increased level of glucose.

FIGURE 34.2 Regulation of glycogen synthase. This enzyme is phosphorylated by a series of kinases, which are initiated by the cyclic adenosine monophosphate (cAMP)-dependent protein kinase under fasting conditions. It is dephosphorylated and active after a meal, and glycogen is stored. (P), phosphate; ⊕, activated by; ADP, adenosine diphosphate; ATP, adenosine triphosphate; Glucose-1-P, glucose 1-phosphate; glucose-6-P, glucose 6-phosphate; P_i, inorganic phosphate; PP_i, pyrophosphate; UDP, uridine diphosphate; UTP, uridine triphosphate.

3. Phosphofructokinase-1 and Pyruvate Kinase

For lipogenesis, glucose 6-phosphate is converted through glycolysis to pyruvate. Key enzymes that regulate this pathway in the liver are phosphofructokinase-1 (PFK-1) and pyruvate kinase. PFK-1 is allosterically activated in the fed state by fructose 2,6-bisphosphate and adenosine monophosphate (AMP) (see Fig. 34.1). Phosphofructokinase-2 (PFK-2), the enzyme that produces the activator fructose 2,6-bisphosphate, is dephosphorylated and the kinase activity is active after a meal (see Chapter 22). Pyruvate kinase is also activated by dephosphorylation, which is stimulated by the increase of the insulin/glucagon ratio in the fed state (see Fig. 34.1).

4. Pyruvate Dehydrogenase and Pyruvate Carboxylase

The conversion of pyruvate to fatty acids requires a source of acetyl coenzyme A (acetyl CoA) in the cytosol. Pyruvate can only be converted to acetyl CoA in mitochondria, so it enters mitochondria and forms acetyl CoA through the PDH reaction. This enzyme is dephosphorylated and most active when its supply of substrates and adenosine diphosphate (ADP) is high, its products are used, and insulin is present (see Fig. 23.13).

Pyruvate is also converted to oxaloacetate. The enzyme that catalyzes this reaction, pyruvate carboxylase, is activated by acetyl CoA. Because acetyl CoA cannot cross the mitochondrial membrane directly to form fatty acids in the cytosol, it condenses with oxaloacetate, producing citrate. The citrate that is not required for tricarboxylic acid (TCA) cycle activity crosses the membrane and enters the cytosol.

As fatty acids are produced under conditions of high energy, the high NADH/NAD⁺ ratio in the mitochondria inhibits isocitrate dehydrogenase, which leads to citrate accumulation within the mitochondrial matrix. As the citrate accumulates, it is transported out into the cytosol to donate carbons for fatty acid synthesis.

5. Citrate Lyase, Malic Enzyme, and Glucose 6-Phosphate Dehydrogenase

In the cytosol, citrate is cleaved by citrate lyase, an inducible enzyme, to form oxaloacetate and acetyl CoA (Fig. 34.3). The acetyl CoA is used for fatty acid biosynthesis and for cholesterol synthesis, pathways that are activated by insulin. Oxaloacetate is recycled to pyruvate via cytosolic malate dehydrogenase and malic enzyme, which is inducible. Malic enzyme generates NADPH for the reactions of the fatty acid synthase complex. NADPH is also produced by the two enzymes of the pentose phosphate pathway (see Chapter 27): glucose 6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase. Glucose 6-phosphate dehydrogenase is also induced by insulin.

FIGURE 34.3 Regulation of citrate lyase, malic enzyme, glucose 6-phosphate dehydrogenase, and fatty acid synthase. Citrate lyase, which provides acetyl coenzyme A (acetyl CoA) for fatty acid biosynthesis, the enzymes that provide NADPH (malic enzyme, glucose 6-phosphate dehydrogenase), as well as fatty acid synthase, are inducible (↑). ADP, adenosine diphosphate; ATP, adenosine triphosphate; FA, fatty acid; malonyl CoA, malonyl coenzyme A; NAD, nicotinamide adenine dinucleotide; OAA, oxaloacetate; P_i, inorganic phosphate.

6. Acetyl CoA Carboxylase

Acetyl CoA is converted to malonyl CoA, which provides the two-carbon units for elongation of the growing fatty acyl chain on the fatty acid synthase complex. Acetyl CoA carboxylase, the enzyme that catalyzes the conversion of acetyl CoA to malonyl CoA, is controlled by three of the major mechanisms that regulate enzyme activity (Fig. 34.4). It is activated by citrate, which causes the enzyme to polymerize, and inhibited by long-chain fatty acyl CoA. A phosphatase stimulated by insulin activates the enzyme by dephosphorylation. The third means by which this enzyme is regulated is induction: the quantity of the enzyme increases in the fed state.

FIGURE 34.4 Regulation of acetyl CoA carboxylase (ACC). ACC is regulated by activation and inhibition, by phosphorylation (mediated by the adenosine monophosphate [AMP]-activated protein kinase) and dephosphorylation (via an insulin-stimulated phosphatase), and by induction (\uparrow) and repression. It is active in the fed state. ADP, adenosine diphosphate; ATP, adenosine triphosphate; malonyl CoA, malonyl coenzyme A; Palmitoyl CoA, palmitoyl coenzyme A; P_i, inorganic phosphate.

M The measurement of triglycerides in blood samples is performed using a coupled assay. The sample is incubated with a lipase that converts the triglyceride to glycerol and three FA. The glycerol is then converted to glycerol 3-phosphate by glycerol kinase and ATP, and the glycerol 3-phosphate is then oxidized by a bacterial glycerol 3-phosphate dehydrogenase to produce DHAP and hydrogen peroxide. The hydrogen peroxide, in the presence of peroxidase, will oxidize a colorless substrate, which turns color when oxidized. Measurement of the color change is directly proportional to the amount of glycerol generated in the sample. Comparing values before and after lipase addition will also allow the free glycerol content in the blood to be determined.

Malonyl CoA, the product of the acetyl CoA carboxylase reaction, provides the carbons for the synthesis of palmitate on the fatty acid synthase complex. Malonyl CoA also inhibits carnitine:palmitoyltransferase I (CPTI, also known as carnitine:acyltransferase I), the enzyme that prepares long-chain fatty acyl CoA for transport into

mitochondria (Fig. 34.5). In the fed state, when acetyl CoA carboxylase is active and malonyl CoA levels are elevated, newly synthesized fatty acids are converted to triacylglycerols for storage rather than being transported into mitochondria for oxidation and formation of ketone bodies.

FIGURE 34.5 Inhibition of transport of fatty acids (FA) into mitochondria by malonyl coenzyme A (malonyl CoA). In the fed state, malonyl CoA (the substrate for fatty acid synthesis produced by acetyl coenzyme A [acetyl CoA] carboxylase) is elevated. It inhibits carnitine palmitoyltransferase I (CPTI), preventing the transport of long-chain fatty acids into mitochondria. Therefore, substrate is not available for β -oxidation and ketone body synthesis. CoA, coenzyme A; CPTII, carnitine palmitoyltransferase II.

7. Fatty Acid Synthase Complex

In a well-fed individual, the quantity of the fatty acid synthase complex is increased (see Fig. 34.3). The genes that produce this enzyme complex are induced by increases in the insulin/glucagon ratio. The amount of the complex increases slowly after a few days of a high-carbohydrate diet.

Glucose 6-phosphate dehydrogenase, which generates NADPH in the pentose phosphate pathway, and malic enzyme, which produces NADPH, are also induced by the increase of insulin.

The palmitate produced by the synthase complex is converted to palmitoyl CoA and elongated and desaturated to form other fatty acyl CoA molecules, which are converted to triacylglycerols. These triacylglycerols are packaged and secreted into the blood as VLDL.

B. Mechanisms That Affect the Fate of Chylomicrons and VLDL

The lipoprotein triacylglycerols in chylomicrons and VLDL are hydrolyzed to fatty acids and glycerol by lipoprotein lipase (LPL), an enzyme attached to endothelial cells of capillaries in muscles and adipose tissues. The enzyme found in muscle, particularly heart muscle, has a low K_m for these blood lipoproteins. Therefore, it acts even when these lipoproteins are present at very low concentrations in the blood. The fatty acids enter muscle cells and are oxidized for energy. The enzyme found in adipose tissue has a higher K_m and is most active after a meal when blood lipoprotein levels are elevated.

Dianne A. has type 1 diabetes mellitus, a disease associated with a severe deficiency or absence of insulin caused by the destruction of the β -cells of the pancreas. One of the effects of insulin is to stimulate the production of LPL. Because of low insulin levels, **Dianne A.** tends to have low levels of this enzyme. Hydrolysis of the triacylglycerols in chylomicrons and in VLDL is decreased, and hypertriglyceridemia results.

C. Mechanisms That Affect Triacylglycerol Storage in Adipose Tissue

Insulin stimulates adipose cells to synthesize and secrete LPL, which hydrolyzes the chylomicron and VLDL triacylglycerols. Apolipoprotein CII, donated to chylomicrons and VLDL by HDL, activates LPL (Fig. 34.6).

FIGURE 34.6 Regulation of the storage of triacylglycerols (TG) in adipose tissue. Insulin stimulates the secretion of lipoprotein lipase (LPL) from adipose cells and the transport of glucose into these cells. ApoCII activates LPL. CII, apolipoprotein CII; CoA, coenzyme A; DHAP, dihydroxyacetone phosphate; FA, fatty acids; HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very-low-density lipoprotein.

Q Why does **Deborah S.** have hypertriglyceridemia?

A Twenty to thirty percent of patients with an insulinoma gain weight as part of their syndrome. **Connie C.** gained 8 lb in the 6 weeks before her surgery. Although she was primed by her high insulin levels both to store and to use fuel more efficiently, she would not have gained weight if she had not consumed more calories than she required for her daily energy expenditure during her illness (see Chapter 1). She consumed extra carbohydrate calories, mostly as hard candies and table sugar, to avoid the symptoms of hypoglycemia.

Fatty acids released from chylomicrons and VLDL by LPL are stored as triacylglycerols in adipose cells. The glycerol released by LPL is not used by adipose cells because they lack glycerol kinase. Glycerol can be used by liver cells, however, because these cells do contain glycerol kinase. In the fed state, liver cells convert glycerol to the glycerol moiety of the triacylglycerols of VLDL, which is secreted from the liver to distribute the newly synthesized triglycerides to the tissues.

Insulin causes the number of glucose transporters in adipose cell membranes to increase. Glucose enters these cells and is oxidized, producing energy and providing the glycerol 3-phosphate moiety for triacylglycerol synthesis (via the dihydroxyacetone phosphate intermediate of glycolysis).

II. Regulation of Carbohydrate and Lipid Metabolism during Fasting

A. Mechanisms in Liver That Serve to Maintain Blood Glucose Levels

During fasting, the insulin/glucagon ratio decreases. Liver glycogen is degraded to produce blood glucose because enzymes of glycogen degradation are activated by cAMP-directed phosphorylation (see Fig. 26.7). Glucagon stimulates adenylate cyclase to produce cAMP, which activates protein kinase A (PKA). PKA phosphorylates phosphorylase kinase, which then phosphorylates and activates glycogen phosphorylase. PKA also phosphorylates but, in this case, **in**activates glycogen synthase.

Dianne A. suffers from hyperglycemia because her insulin levels tend to be low and her glucagon levels tend to be high. Her muscle and adipose cells do not take up glucose at a normal rate, and she produces glucose by glycogenolysis and gluconeogenesis. As a result, her blood glucose levels are elevated. **Deborah S.** is in a similar metabolic state. However, in this case, she produces insulin, but her tissues are resistant to its actions.

Gluconeogenesis is stimulated because the synthesis of phosphoenolpyruvate carboxykinase, fructose 1,6-bisphosphatase, and glucose 6-phosphatase is induced and because there is an increased availability of precursors. Fructose 1,6-bisphosphatase is also activated because the levels of its inhibitor, fructose 2,6-bisphosphate, are low (Fig. 34.7). During fasting, the activities of the corresponding enzymes of glycolysis are decreased.

Glycolysis

Gluconeogenesis

FIGURE 34.7 Regulation of gluconeogenesis (red arrows) and glycolysis (black arrows) during fasting. The gluconeogenic

enzymes phosphoenolpyruvate carboxykinase, fructose 1,6-bisphosphatase, and glucose 6-phosphatase are induced (†). Fructose 1,6-bisphosphatase is also active because, during fasting, the level of its inhibitor, fructose 2,6-bisphosphate, is low. The corresponding enzymes of glycolysis are not very active during fasting. The rate of glucokinase is low because it has a high K_m for glucose and the glucose concentration is low. Phosphofructokinase-1 is not very active because the concentration of its activator fructose 2,6-bisphosphate is low. Pyruvate kinase is inactivated by cyclic adenosine monophosphate (cAMP)-mediated phosphorylation. Acetyl CoA, acetyl coenzyme A; F-2,6-BP, fructose 2,6-bisphosphate; P_i , inorganic phosphate.

Deborah S. has type 2 diabetes mellitus. She produces insulin, but her adipose tissue is partially resistant to its actions. Therefore, her adipose tissue does not produce as much LPL as a normal person, which is one of the reasons why VLDL and chylomicrons remain elevated in her blood.

Insulin normally inhibits lipolysis by decreasing the lipolytic activity of adipocyte triglyceride lipase and HSL in the adipocyte. Individuals such as **Dianne A.**, who have a deficiency of insulin, have increased lipolysis and a subsequent increase in the concentration of free FA in the blood. The liver, in turn, uses some of these FA to synthesize triacylglycerols, which then are used in the hepatic production of VLDL. VLDL is not stored in the liver but is secreted into the blood, raising its serum concentration. **Dianne A.** also has low levels of LPL because of decreased insulin levels. Her hypertriglyceridemia is the result, therefore, of both overproduction of VLDL by the liver and decreased breakdown of VLDL triacylglycerol for storage in adipose cells.

The serum begins to appear cloudy when the triacylglycerol level reaches 200 mg/dL. As the triacylglycerol level increases still further, the degree of serum opalescence increases proportionately.

Induction of enzyme synthesis requires activation of transcription factors. One of the factors that is activated is CREB, which stands for cAMP response element-binding protein. CREB is phosphorylated and activated by the cAMP-dependent protein kinase (PKA), which itself is activated upon glucagon or epinephrine stimulation. Other transcription factors are activated by cAMP, but the regulation of those factors by cAMP is not as well understood as it is for CREB.

B. Mechanisms That Affect Lipolysis in Adipose Tissue

During fasting, as blood insulin levels fall and glucagon and epinephrine levels rise, the level of cAMP rises in adipose cells. Consequently, PKA is activated, which leads to the activation of both adipocyte triglyceride lipase and hormone-sensitive lipase (HSL, see Fig. 31.25). These activated lipases cleave fatty acids from triacylglycerols. Other hormones (e.g., epinephrine, adrenocorticotrophic hormone [ACTH], growth hormone) also lead to the activation of these enzymes (see Chapter 41). The resynthesis of triglyceride (using regenerated glycerol 3-phosphate) by the adipocyte regulates the rate of release of fatty acids during fasting.

C. Mechanisms That Affect Ketone Body Production by the Liver

As fatty acids are released from adipose tissue during fasting, they travel in the blood complexed with albumin. These fatty acids are oxidized by various tissues, particularly muscle. In the liver, fatty acids are transported into mitochondria because acetyl CoA carboxylase is inactive, malonyl CoA levels are low, and CPTI (carnitine:acyltransferase I) is active (see Fig. 34.5). Acetyl CoA, produced by β -oxidation, is converted to ketone bodies. Ketone bodies are used as an energy source by many tissues (Table 34.1) to spare the use of glucose and the necessity of degrading muscle protein to provide the precursors for gluconeogenesis. The high levels of acetyl CoA in the liver (derived from fat oxidation) inhibit PDH (which prevents pyruvate from being converted to acetyl CoA) and activate pyruvate carboxylase, which produces oxaloacetate for gluconeogenesis. The oxaloacetate does not condense with acetyl CoA to form citrate for two reasons. The first is that under these conditions (a high rate of fat oxidation in the liver mitochondria), energy levels in the mitochondrial matrix are high; that is, there are high levels of NADH and ATP present. The high NADH level inhibits isocitrate dehydrogenase. As a result, citrate accumulates and inhibits citrate synthase from producing more citrate. The second reason that citrate synthesis is depressed is that the high NADH/NAD⁺ ratio also diverts oxaloacetate into malate, such that the malate can exit the mitochondria (via the malate/aspartate shuttle) for use in gluconeogenesis.

TABLE 34.1 Fuel Utilization by Various Tissues during Starvation (Fasting)

D. Regulation of the Use of Glucose and Fatty Acids by Muscle

During exercise, the fuel that is used initially by muscle cells is muscle glycogen. As exercise continues and the blood supply to the tissue increases, glucose is taken up from the blood and oxidized. Liver glycogenolysis and gluconeogenesis replenish the blood glucose supply. However, as insulin levels drop, the concentration of the GLUT4 transporters in the membrane is reduced, thereby reducing glucose entry from the circulation into the muscle. However, muscle GLUT4 transporters are also induced by high AMP levels, through the action of the AMP-activated protein kinase (AMPK). Thus, if energy levels are low and the concentration of AMP increases, glucose can still be transported from the circulation into the muscle to provide energy. This will most frequently be the case during periods of exercise.

Because **Dianne A.** produces very little insulin, she is prone to developing ketoacidosis. When insulin levels are low, adipocyte triglyceride lipase and HSL of adipose tissue are very active, resulting in increased lipolysis. The FA that are released travel to the liver, where they are converted to the triacylglycerols of VLDL. They also undergo β -oxidation and conversion to ketone bodies. If **Dianne A.** does not take exogenous insulin or if her insulin levels decrease abruptly for some physiologic reason, she may develop ketoacidosis (DKA). In fact, she has had repeated bouts of DKA.

For reasons that are not as well understood, individuals with type 2 diabetes mellitus, such as **Deborah S.**, do not tend to develop ketoacidosis. One possible explanation is that the insulin resistance is tissue-specific; the insulin sensitivity of adipocytes may be greater than that of muscle and the liver. It has been suggested that the level of insulin required to suppress lipolysis is only 10% that required to enhance glucose use by muscle and adipocyte. Such a tissue-specific sensitivity would lead to less FA being released from adipocytes in type 2 diabetes than in type 1 diabetes, although in both cases the release of FA would be greater than that of an individual without the disease. If, however, a type 2 diabetic has a precipitating event, such as the release of stress hormones (see Chapter 41), then ketoacidosis is more likely to be found as the stress hormones counteract the effects of insulin on the adipocyte.

Additionally, as fatty acids become available because of increased lipolysis of adipose triacylglycerols, the exercising muscle begins to oxidize fatty acids. β -Oxidation produces NADH and acetyl CoA, which slow the flow of carbon from glucose through the reaction catalyzed by PDH (see Fig. 23.13). Thus, the oxidation of fatty acids provides a major portion of the increased demand for ATP generation and spares blood glucose.

III. The Importance of AMP and Fructose 2,6-Bisphosphate

The switch between catabolic and anabolic pathways is often regulated by the levels of AMP and fructose 2,6-bisphosphate in cells, particularly the liver. It is logical for AMP to be a critical regulator. Because a cell uses ATP in energy-requiring pathways, the levels of AMP accumulate more rapidly than that of ADP because of the adenylate kinase reaction ($2 \text{ ADP} \rightarrow \text{ATP and AMP}$). The rise in AMP levels then signals that more energy is required (usually through allosteric binding sites on enzymes and the activation of the AMPK), and the cell will switch to the activation of catabolic pathways. As AMP levels drop, and ATP levels rise, the anabolic pathways are activated to store the excess energy.

The levels of fructose 2,6-bisphosphate are also critical in regulating glycolysis versus gluconeogenesis in the liver. Under conditions of high blood glucose, and insulin release, fructose 2,6-bisphosphate levels are high because the PFK-2 kinase is in its activated state. The fructose 2,6-bisphosphate activates PFK-1 and inhibits fructose 1,6-bisphosphatase, thereby allowing glycolysis to proceed. When blood glucose levels are low and glucagon is released, PFK-2 is phosphorylated by the cAMP-dependent protein kinase and the kinase activity is inhibited (and the phosphatase activity is activated), thereby lowering fructose 2,6-bisphosphate levels and inhibiting glycolysis, while favoring gluconeogenesis.

IV. General Summary

All of the material in this chapter was presented previously. However, because this information is so critical for understanding biochemistry in a way that will allow it to be used in interpreting clinical situations, it was summarized in this chapter. In addition, the information presented previously under carbohydrate metabolism has been integrated with lipid metabolism. We have, for the most part, left out the role of allosteric modifiers

and other regulatory mechanisms that finely coordinate these processes to an exquisite level. Because such details may be important for specific clinical situations, we hope this summary will serve as a framework to which the details can be fitted as students advance in their clinical studies.

Figure 34.8 is a comprehensive figure, and Tables 34.2 and 34.3 provide a list of the major regulatory enzymes of carbohydrate and lipid metabolism in the liver, an order to the events that occur, and the mechanisms by which they are controlled. This figure and tables should help students to integrate this mass of material.

TABLE 34.3 Regulation of Liver Enzymes Involved in Glycogen, Blood Glucose, and Triacylglycerol Synthesis and Degradation		
LIVER ENZYMES REGULATED BY ACTIVATION/INHIBITION		
ENZYME	ACTIVATED BY	STATE IN WHICH ACTIVE
Phosphofructokinase-1	Fructose 2,6-bisP, AMP	Fed
Pyruvate carboxylase	Acetyl CoA	Fed and fasting
Acetyl CoA carboxylase	Citrate	Fed
Carnitine:palmitoyltransferase I	Loss of inhibitor (malonyl CoA)	Fasting
LIVER ENZYMES REGULATED BY PHOSPHORYLATION/DEPHOSPHORYLATION		
ENZYME	ACTIVE FORM	STATE IN WHICH ACTIVE
Glycogen synthase	Dephosphorylated	Fed
Phosphorylase kinase	Phosphorylated	Fasting
Glycogen phosphorylase	Phosphorylated	Fasting
Phosphofructokinase-2/fructose 2,6-bisphosphatase (acts as a kinase, increasing fructose 2,6-bisP levels)	Dephosphorylated	Fed
Phosphofructokinase-2/fructose 2,6-bisphosphatase (acts as a phosphatase, decreasing fructose 2,6-bisP levels)	Phosphorylated	Fasting
Pyruvate kinase	Dephosphorylated	Fed
Pyruvate dehydrogenase	Dephosphorylated	Fed
Acetyl CoA carboxylase	Dephosphorylated	Fed
LIVER ENZYMES REGULATED BY INDUCTION/REPRESSION		
ENZYME	STATE IN WHICH INDUCED	PROCESS AFFECTED

Glucokinase	Fed	Glucose → TG
Citrate lyase	Fed	Glucose → TG
Acetyl CoA carboxylase	Fed	Glucose → TG
Fatty acid synthase	Fed	Glucose → TG
Malic enzyme	Fed	Production of NADPH
Glucose-6-P dehydrogenase	Fed	Production of NADPH
Glucose 6-phosphatase	Fasted	Production of blood glucose
Fructose 1,6-bisphosphatase	Fasted	Production of blood glucose
Phosphoenolpyruvate carboxykinase	Fasted	Production of blood glucose

AMP, adenosine monophosphate; fructose 2,6-bisP, fructose 2,6-bisphosphate; TG, triacylglycerol.

FIGURE 34.8 Regulation of carbohydrate and lipid metabolism in the liver. *Solid red arrows* indicate the flow of metabolites in the fed state. *Solid black arrows* indicate the flow during fasting. ACC, acetyl CoA carboxylase; α KG, α -ketoglutarate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; F1,6-BP, fructose 1,6-bisphosphate; F2,6-BP, fructose 2,6-bisphosphate; F-6-P, fructose 6-phosphate; FA, fatty acid or fatty acyl group; G-6-P, glucose 6-phosphate; GDP, guanosine diphosphate; GK, glucokinase; GS, glycogen synthase; GTP, guanosine triphosphate; HDL, high-density lipoprotein; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; NAD, nicotinamide adenine dinucleotide; OAA, oxaloacetate; circled P, phosphate group; PEP, phosphoenolpyruvate; PFK, phosphofructokinase-1; Phos, glycogen phosphorylase; PhK, phosphorylase kinase; PK, pyruvate kinase; TG, triacylglycerol; UDP, uridine diphosphate; UTP, uridine triphosphate; VLDL, very-low-density lipoprotein.

Now that many of the details of the pathways have been presented; it may be worthwhile to reread the first three chapters of this book. A student who understands biochemistry within the context of fuel metabolism is in a very good position to solve clinical problems that involve metabolic derangements.

CLINICAL COMMENTS

Connie C.'s younger sister was very concerned that **Connie C.**'s pancreatic tumor might be genetically determined or potentially malignant, so she accompanied **Connie C.** to her second postoperative visit to the endocrinologist. The doctor explained that insulinomas are very rarely familial, with around 6% of patients with insulinomas having a genetically determined syndrome known as multiple endocrine neoplasia, type I, or simply MEN I. This syndrome includes additional secretory neoplasms, which may occur in the anterior pituitary or the parathyroid glands. **Connie C.**'s tumor showed no evidence of malignancy, and the histologic slides, although not always definitive, showed a benign-appearing process. The doctor was careful to explain, however, that close observation for recurrent hypoglycemia and for the signs and symptoms suggestive of other facets of MEN I would be necessary for the remainder of **Connie C.**'s and her immediate family's life.

Dianne A. Diabetes mellitus is a well-accepted risk factor for the development of coronary artery disease; the risk is three to four times higher in the population with diabetes than in the population without diabetes. Although chronically elevated serum levels of chylomicrons and VLDL may contribute to this atherogenic predisposition, the premature vascular disease seen in **Dianne A.** and other patients with type 1 diabetes mellitus, as well as **Deborah S.** and other patients with type 2 diabetes mellitus, is also related to other abnormalities in lipid metabolism. Among these are the increase in glycation (nonenzymatic attachment of glucose molecules to proteins) of LDL apolipoproteins, which occurs when serum glucose levels are chronically elevated. These glycations interfere with the normal interaction or "fit" of the circulating LDL particles with their specific receptors on cell membranes. As a consequence, the rate of uptake of circulating LDL by the normal target cells is diminished. The LDL particles, therefore, remain in the circulation and eventually bind nonspecifically to "scavenger" receptors located on macrophages adjacent to the endothelial surfaces of blood vessels, one of the early steps in the process of atherogenesis.

BIOCHEMICAL COMMENTS

AMPK. The AMPK is a pivotal regulatory molecule in the metabolism of carbohydrates and fats. The biochemistry of AMPK is quite complex and is beyond the scope of this text. The following summarizes some important insights into AMP kinase action. The hepatic targets of AMPK include the following proteins:

- Acetyl CoA carboxylase (phosphorylation reduces activity, leading to reduced fatty acid synthesis)
- eEF2 kinase (this protein is activated when phosphorylated, and it will lead to a reduction in protein synthesis)
- Glycerol 3-phosphate acyltransferase (GPAT) (phosphorylation reduces activity, leading to reduced triglyceride synthesis)
- HMG-CoA reductase (phosphorylation reduces activity, leading to reduced cholesterol synthesis)
- Malonyl CoA decarboxylase (MCD, active when phosphorylated, reduces malonyl CoA levels, allowing fatty acid oxidation to occur)
- mTOR (mechanistic target of rapamycin; reduced activity when phosphorylated, leading to reduced protein synthesis)
- Tuberous sclerosis complex 2 (TSC2, increased activity when phosphorylated, leading to reduced protein synthesis)
- TORC2 (the protein is sequestered in the cytoplasm when phosphorylated, leading to decreased expression [at the transcriptional level] of gluconeogenic enzymes)

The overall effect of AMPK activation is reduced fatty acid and triglyceride synthesis (via effects on acetyl CoA carboxylase, GPAT, and MCD), reduced cholesterol synthesis (via inhibition of HMG-CoA reductase),

and reduced protein synthesis (via effects on mTOR and TSC2). There is a concomitant increase in fatty acid oxidation, to raise ATP levels. As the processes described above are all highly energy-dependent, it makes sense to turn them off when energy levels are low, as exemplified by increased AMP levels.

mTOR (rapamycin is a drug that is a potent immunosuppressant) is a protein kinase, which, when active, phosphorylates key proteins that regulate and initiate protein synthesis. AMPK phosphorylation of mTOR blocks the activation of mTOR. mTOR can be activated by TSC2 through a complex pathway involving the GTP-binding protein Rheb. The TSC complex (consisting of TSC1 and TSC2) acts as a GTPase-activating protein for Rheb. Rheb-GTP activates mTOR, whereas Rheb-GDP does not. Phosphorylation of TSC2 by the AMPK activates the GTPase-activating activity of TSC2, leading to Rheb-GDP formation, and reduced mTOR activity. The reduced mTOR activity leads to a reduction of protein synthesis.

mTOR also plays a critical role in transmitting the signal from the insulin receptor to an increase in protein synthesis within the cell. Insulin receptor activation leads to akt activation (see Fig. 10.20). The protein kinase akt (protein kinase B) will phosphorylate the TSC1/TSC2 complex and inactivate the GTPase-activating component of the complex. Under these conditions, then, Rheb-GTP will be long-lived, and mTOR will be active, leading to an enhancement of protein synthesis in the cell. The interaction of TSC1/TSC2, mTOR, and its regulatory kinases is depicted in Figure 34.9.

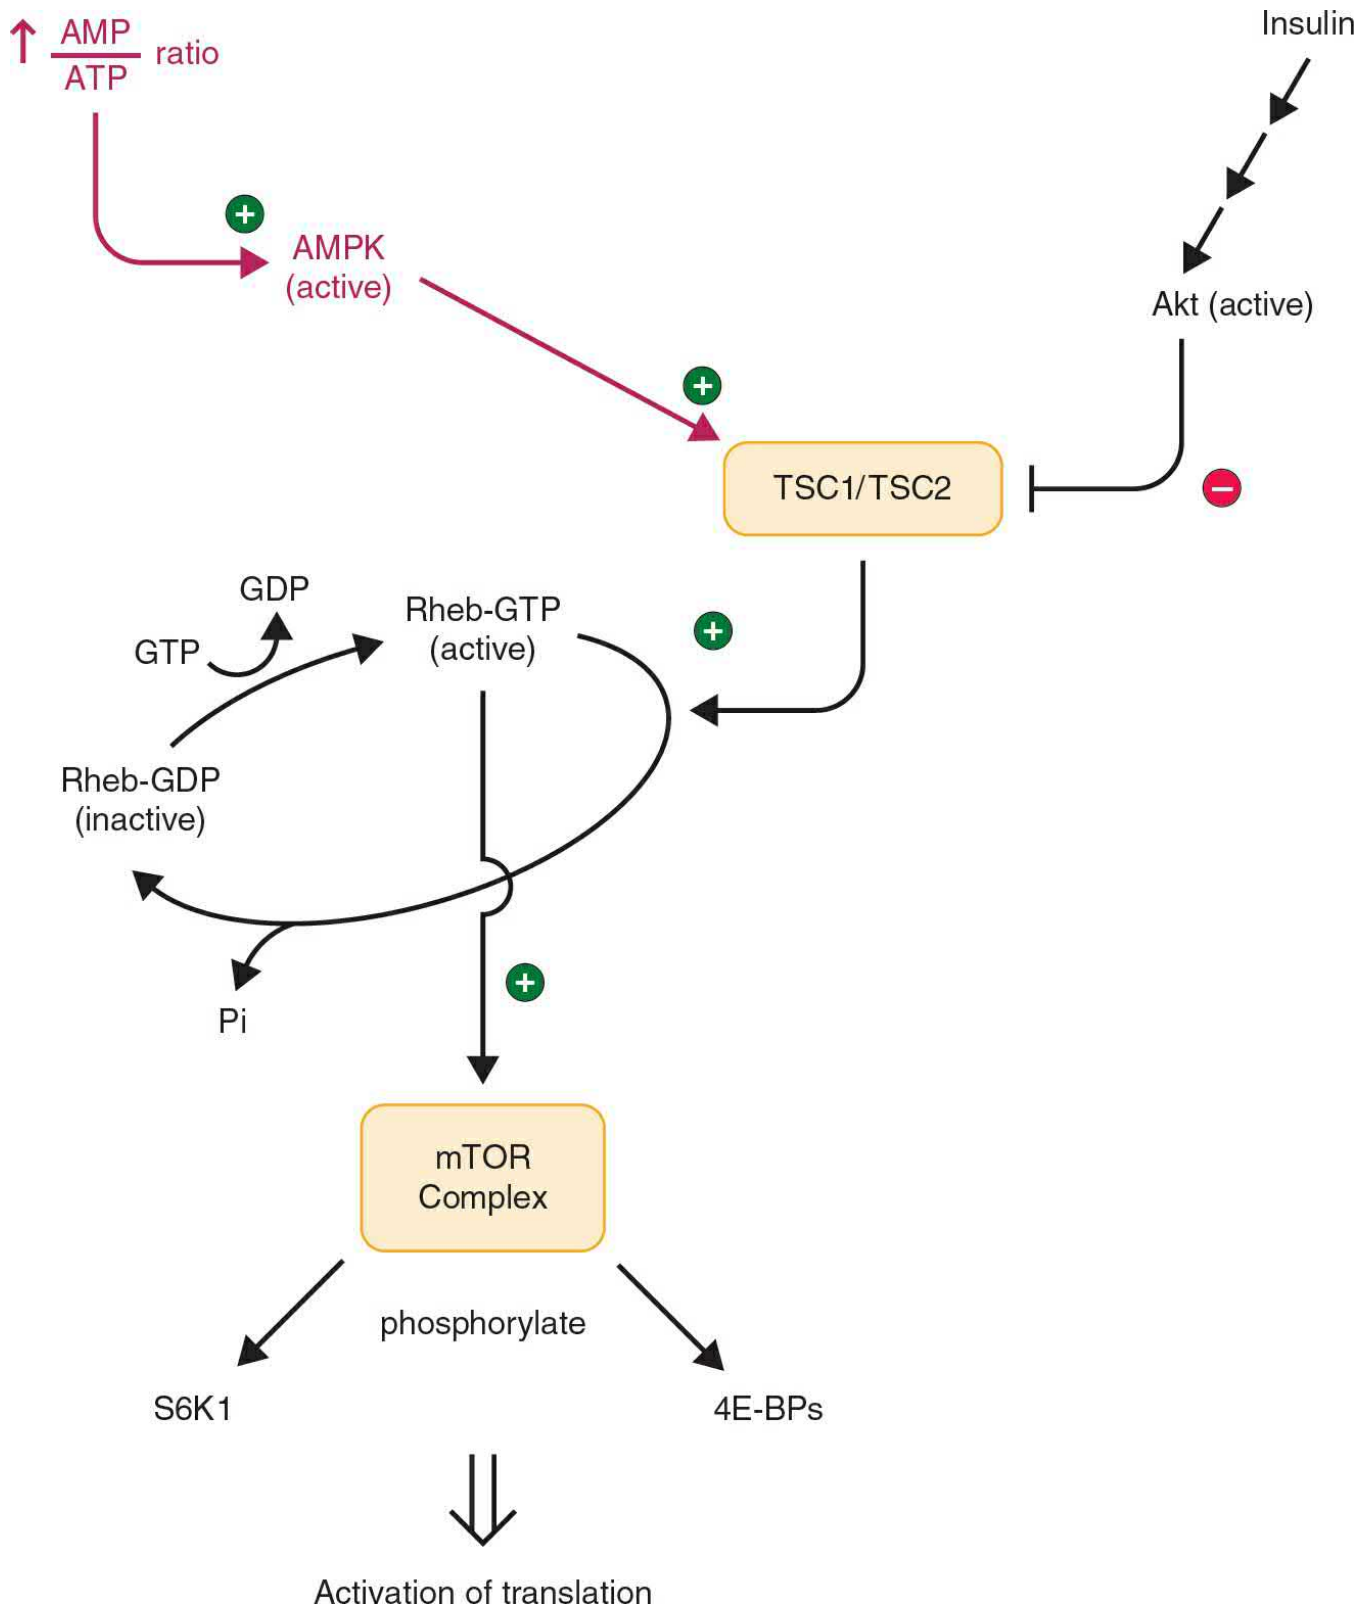

FIGURE 34.9 Central role of mTOR and the TSC1/TSC2 complex in regulating protein synthesis. The TSC1/TSC2 complex acts as a GTPase-activating protein for the G-protein Rheb. When active, Rheb-GTP activates the mTOR kinase, leading to phosphorylation events that promote protein synthesis (S6K1 and 4E-BPs are phosphorylated). AMP-activated protein kinase (AMPK) phosphorylation of the TSC1/TSC2 complex activates the complex such that the GTPase activity of Rheb is enhanced, leading to Rheb inactivation and loss of mTOR kinase activity. This will lead to a decrease in protein synthesis. Insulin binding to its receptor leads to the activation of the protein kinase akt (see Fig. 10.20). Akt will phosphorylate the TSC1/TSC2 complex at sites distinct from AMPK, which inhibits the GTPase-activating activity of the complex. This allows Rheb-GTP to be active for extended periods of time, activating mTOR, and increasing protein synthesis in the cell in response to insulin. AMP, adenosine monophosphate; ATP, adenosine triphosphate; GDP, guanosine diphosphate; GTP, guanosine triphosphate; P_i, inorganic phosphate.

The AMPK can be activated in a number of ways, all of which depend on increased AMP levels within the cell. As the concentration of AMP increases AMPK is activated by allosteric means, or by phosphorylation by LKB1 (see Chapter 33), or by phosphorylation by a calmodulin kinase kinase. AMPK is inactivated by dephosphorylation by protein phosphatases or a decrease in AMP levels. Small changes in intracellular AMP levels can have profound effects on AMPK activity because of these multiple regulatory pathways.

AMPK is a heterotrimeric complex that consists of a catalytic subunit (α) and two regulatory subunits (β and γ). The allosteric activation of AMPK occurs via AMP binding to the α -subunit; the phosphorylation activation of AMPK occurs via threonine phosphorylation on the α -subunit. Different tissues express different isoforms of the α -, β -, and γ -subunits, giving rise to 12 different, functional isozymes of AMPK in the different tissues.

The AMPK has also been implicated in mitochondrial health, including an increase in the number of mitochondria within a cell, or the destruction of mitochondria, through mitophagy.

To summarize, the actions of AMPK are to increase ATP generation and reduce ATP consumption. Catabolic processes are activated, and anabolic processes (including protein synthesis) are inhibited.

The mTOR protein is an extremely important component in overall metabolic regulation and cell growth regulation. mTOR acts as part of a complex (mTORC1 and mTORC2) which affects multiple pathways in cells. In general, mTOR promotes anabolic processes and suppresses catabolic processes (the opposite of the AMPK). The interactions between mTOR and AMPK are incredibly complex and the subject of intensive investigation. Drugs are being developed to block mTOR activity in cancer cells to reduce the growth potential of such cells. Some of these drugs are in clinical trials in combination with other known antitumor drugs.

KEY CONCEPTS

- ◆ Three key controlling elements determine whether fuel is metabolized or stored: hormones, concentration of available fuels, and energy needs of the body.
- ◆ Key intracellular enzymes are generally regulated by allosteric activation and inhibition, by covalent modification, by transcriptional control, and by degradation.
- ◆ Regulation is complex in order to allow sensitivity and feedback to multiple stimuli so that an exact balance can be maintained between the synthesis of a product and the need for the product.
- ◆ The insulin/glucagon ratio is primarily responsible for the hormonal regulation of carbohydrate and lipid metabolism.
- ◆ The key enzymes of glycolysis, fatty acid synthesis, fatty acid degradation, glycogen synthesis, glycogenolysis, and gluconeogenesis are all regulated in a coordinated manner, allowing the appropriate pathways to be activated and inhibited without the creation of futile cycles.
- ◆ This chapter summarizes, in one package, all of the major regulatory events discussed in the previous 15 chapters.
- ◆ Diseases discussed in this chapter are summarized in Table 34.4.

TABLE 34.4 Diseases Discussed in Chapter 34

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Insulinoma	Environmental (approximately 6% genetic)	A tumor of the pancreas leading to excessive, episodic insulin secretion, usually coupled with weight gain to avoid hypoglycemia.
Diabetic ketoacidosis (type 1 diabetes)	Environmental	Diabetic ketoacidosis (DKA) occurs due to an elevation of ketone body levels due to reduced levels of insulin in a type 1 diabetic. DKA is not normally seen in type 2 diabetics due to only a partial resistance of adipocytes to circulating insulin.
Type 2 diabetes	Both	Reduced ability of tissues to respond to insulin, even though insulin is being produced. Different tissues may display a differential sensitivity to insulin, particularly fat cells as compared to muscle cells.

REVIEW QUESTIONS—CHAPTER 34

1. A 20-year-old woman with diabetes mellitus was admitted to the hospital in a semiconscious state with fever, nausea, and vomiting. Her breath smelled of acetone. A urine sample was strongly positive for ketone bodies. Which one of the following statements about this woman is correct?
 - A. A blood glucose test will probably show that her blood glucose level is well below 80 mg/dL.
 - B. An injection of insulin will decrease her ketone body production.
 - C. She should be given a glucose infusion, so she will regain consciousness.
 - D. Glucagon should be administered to stimulate glycogenolysis and gluconeogenesis in the liver.
 - E. The acetone was produced by decarboxylation of the ketone body β -hydroxybutyrate.
2. A woman was told by her physician to go on a low-fat diet. She decided to continue to consume the same number of calories by increasing her carbohydrate intake while decreasing her fat intake. Which of the following blood lipoprotein levels would be decreased as a consequence of her diet?
 - A. VLDL
 - B. IDL
 - C. LDL
 - D. Chylomicrons
 - E. HDL
3. Assume that an individual has been eating excess calories daily such that he will gain weight. Under which one of the following conditions will the person gain weight most rapidly?
 - A. If all the excess calories are due to carbohydrate.
 - B. If all the excess calories are due to triacylglycerol.
 - C. If all the excess calories are split 50%/50% between carbohydrate and triacylglycerol.
 - D. If all the excess calories are split 25%/75% between carbohydrate and triacylglycerol.
 - E. It makes no difference what form the excess calories are in.
4. An individual with alcohol use disorder has been admitted to the hospital because of a severe hypoglycemic episode brought about by excessive alcohol consumption for the past 5 days. A blood lipid analysis indicates much higher than expected VLDL levels. The elevated VLDL is attributable to which one of the following underlying causes?
 - A. Alcohol-induced inhibition of LPL
 - B. Elevated NADH levels in the liver
 - C. Alcohol-induced transcription of the apoB-100 gene
 - D. NADH activation of phosphoenolpyruvate carboxykinase
 - E. Acetaldehyde induction of enzymes on the endoplasmic reticulum
5. Certain patients with abetalipoproteinemia frequently have difficulty maintaining blood volume; their blood has trouble clotting. This symptom is attributable to which of the following?
 - A. Inability to produce chylomicrons
 - B. Inability to produce VLDL
 - C. Inability to synthesize the mRNA for clotting factors
 - D. Inability to synthesize fatty acids
 - E. Inability to absorb short-chain fatty acids
6. Which one of the following schemes most accurately depicts the timeline of the metabolic processes of the liver and adipose tissue after a carbohydrate meal is ingested followed by 3 hours of fasting?
 - A. Glycolysis, glycogen synthesis, lipolysis, glycogenolysis, gluconeogenesis
 - B. Glycogen synthesis, lipolysis, glycogenolysis, gluconeogenesis
 - C. Glycolysis, lipolysis, glycogenolysis, gluconeogenesis, glycogen synthesis
 - D. Glycogen synthesis, lipolysis, gluconeogenesis, glycolysis
 - E. Glycogen synthesis, glycogenolysis, lipolysis, gluconeogenesis
7. A type 1 diabetic who has neglected to take insulin for 2 days, yet who ate normally, would exhibit elevated levels of circulating triglycerides due to which one of the following?
 - A. Reduced synthesis of apolipoprotein CII
 - B. Reduced release of LPL from muscle and fat cells
 - C. Increased synthesis of LDL
 - D. Reduced synthesis of chylomicrons
 - E. Reduced synthesis of VLDL
8. Under conditions of a low insulin/glucagon ratio, which one of the following allosteric modifiers in muscle can lead to stimulation of both glycolysis and fatty acid oxidation?
 - A. ATP

- B. ADP
 - C. AMP
 - D. Acetyl CoA
 - E. Citrate
9. Which one of the following is a major difference between patients with diabetes mellitus types 1 and 2?
- A. In type 1, insulin levels are very low and insulin resistance is high.
 - B. In type 2, insulin levels are very low and insulin resistance is high.
 - C. In both types, the patient is usually at or below ideal body weight.
 - D. In type 1, C-peptide levels are very low.
 - E. In type 1, the patient is usually overweight.
10. A person is training for a half marathon. After running 5 miles, which one of the following is providing most of the products for ATP generation in the muscles?
- A. Muscle glycogen
 - B. Liver glycogen
 - C. Blood glucose
 - D. Ketone bodies
 - E. Fatty acids

Questions 11 to 13 are based on the following case:

A physician is seeing a 45-year-old male, new to the practice, who complains of being out of shape and having trouble exercising due to running out of breath. The patient weighs 225 lb and is 5.5 ft tall. His waist circumference is 42 in. Laboratory analysis indicates a HbA1c level of 7% (normal is <6.4%), a fasting triglyceride level of 250 mg/dL (normal is <150 mg/dL), and a fasting LDL of 140 mg/dL (desired is <100). The patient is not on any medications, nor does he take any dietary supplements.

1. The most likely diagnosis for this patient is which one of the following?
- A. Type 1 diabetes
 - B. Type 2 diabetes
 - C. GLUT4 deficiency
 - D. LPL deficiency
 - E. MTP deficiency
2. The elevated triglyceride in the patient's blood is due, in part, to which one of the following?
- A. Elevated MTP activity
 - B. Decreased LPL activity
 - C. Apolipoprotein CII glycation
 - D. Enhanced GLUT4 activity
 - E. Increased triglyceride synthesis in the intestinal epithelial cells
3. The elevated LDL in the patient's blood is due, in part, to which one of the following?
- A. Increased VLDL synthesis
 - B. Decreased LDL-receptor expression
 - C. LDL glycation
 - D. Enhanced chylomicron formation
 - E. Elevated MTP activity
4. A pharmaceutical firm is developing a drug designed to inhibit muscle acetyl CoA carboxylase isozymes. If successful, this drug would be useful as which one of the following?
- A. A cholesterol-lowering drug
 - B. A muscle-building drug
 - C. A drug which reduces triglyceride synthesis
 - D. A drug used to lose weight
 - E. A drug used to gain weight
5. As cellular energy levels drop the AMPK is activated and will alter target enzyme activity, either directly or indirectly. For the enzymes indicated below which row of answers correctly indicates if an enzyme is activated, inhibited, or there is no effect upon activating the AMPK. Choose the one best answer.

	HMG-CoA Reductase	mTOR Kinase	Acetyl CoA Carboxylase	PFK-I
A	Activate	Activate	Activate	Inhibit
B	Inhibit	Activate	Inhibit	Activate
C	Activate	Activate	Activate	Inhibit
D	Inhibit	Inhibit	Inhibit	Activate
E	Activate	Inhibit	Activate	No effect
F	Inhibit	Inhibit	Inhibit	No effect

ANSWERS TO REVIEW QUESTIONS

- The answer is B.** The acetone on the woman's breath (which is produced by decarboxylation of acetoacetate; thus, E is incorrect) and the ketones in her urine indicate that she is in diabetic ketoacidosis. This is caused by low insulin levels, so her blood glucose levels are high because the glucose is not being taken up by the peripheral tissues (thus, A and C are incorrect). An insulin injection will reduce her blood glucose levels and decrease the release of fatty acids from adipose triglycerides. Consequently, ketone body production will decrease. Glucagon injections would just exacerbate the woman's current condition (thus, D is incorrect).
- The answer is D.** Chylomicrons are blood lipoproteins produced from dietary fat. VLDL is produced mainly from dietary carbohydrate. IDL and LDL are produced from VLDL. HDL does not transport triacylglycerol to the tissues.
- The answer is B.** Consider the energy required to convert dietary carbohydrates to triacylglycerol. Some ATP is generated from glycolysis and the pyruvate dehydrogenase reaction, but energy is also lost as the fatty acids are synthesized (the synthesis of each malonyl CoA requires ATP, and the reduction steps require two molecules of NADPH). Dietary fat, however, only requires activation and attachment to glycerol; the fatty acid chain does not need to be synthesized. Therefore, it requires less energy to package dietary fat into chylomicrons than it does to convert dietary carbohydrate into fatty acids for incorporation into VLDL. Thus, weight gain will be more rapid if all the excess calories are derived from fat as opposed to carbohydrates.
- The answer is B.** Metabolism of ethanol leads to the production of NADH in the liver, which will inhibit fatty acid oxidation in the liver. Because the patient has not eaten for 5 days, the insulin/glucagon ratio is low, adipocyte triglyceride lipase and hormone-sensitive lipase are activated, and fatty acids are being released by the adipocyte and taken up by the muscle and liver. However, because the liver NADH levels are high as a result of ethanol metabolism, the fatty acids received from the adipocyte are repackaged into triacylglycerol (the high NADH promotes the conversion of dihydroxyacetone phosphate to glycerol 3-phosphate as well) and secreted from the liver in the form of VLDL. None of the other answers is a correct statement.
- The answer is A.** The clotting problems are due to a lack of vitamin K, a lipid-soluble vitamin. Vitamin K is absorbed from the diet in mixed micelles and packaged with chylomicrons for delivery to the other tissues. Individuals with abetalipoproteinemia lack the microsomal triglyceride transfer protein and cannot produce chylomicrons effectively; vitamin K deficiency can result. Such patients also cannot produce VLDL, but lipid-soluble vitamin distribution does not depend on VLDL particles, only on chylomicrons.

The other answers are all incorrect statements.

6. **The answer is E.** After eating a high-carbohydrate meal, the excess carbohydrates in the liver are first stored as glycogen, then sent through glycolysis to generate pyruvate, then acetyl CoA, for eventual fatty acid production. After time, as the blood glucose is utilized by tissues, its levels will drop, and glucagon will be released from the pancreas, which will stimulate glycogenolysis in the liver such that glucose can be exported to raise blood glucose levels. The glucagon release also stimulates lipolysis, and energy from fatty acid oxidation is used to produce glucose via gluconeogenesis.
7. **The answer is B.** Insulin is required for muscle and fat cells to synthesize and release LPL to bind to the capillary walls of the capillaries supplying these tissues with blood. In the absence of insulin, LPL levels would be reduced and there would be a reduced rate of triglyceride removal from both chylomicrons and VLDL particles. Chylomicron synthesis would be normal on a normal diet. The problem is that the lipid is not leaving the chylomicron as rapidly as it normally would due to the reduced levels of LPL on the capillary walls. VLDL synthesis would actually increase, due to fatty acid synthesis by the liver (due to the high levels of glucose in the blood), and due to excess fatty acids reaching the liver due to increased lipolysis of triacylglycerol in the fat cell, as induced by the absence of insulin.
8. **The answer is C.** When blood glucose levels are low, and the muscle requires energy, ATP is used and ADP is produced. Adenylate kinase catalyzes the conversion of two ADP to ATP and AMP, and an increase in AMP leads to the activation of the AMPK. This kinase phosphorylates and inactivates acetyl CoA carboxylase. This leads to lower levels of malonyl CoA, and a release of the inhibition of carnitine:palmitoyltransferase I, such that fatty acid oxidation is enhanced since the fatty acids can enter the mitochondrial matrix to be oxidized. The increase in AMP levels also activates PFK-1, speeding up the glycolytic pathway. Citrate does not accumulate under conditions in which the insulin/glucagon ratio is low, and acetyl CoA is not an allosteric modifier of any glycolytic enzyme.
9. **The answer is D.** In type 1 diabetes mellitus, the patient is producing low or no insulin, which means that C-peptide levels are very low or nondetectable. The patients are usually thin since low insulin does not promote adipose tissue storage of triacylglycerol. There is no insulin resistance in type 1 because the patients are not producing insulin. Insulin resistance at the cellular level primarily causes type 2 diabetes mellitus. Because of the resistance, insulin levels are generally elevated to attempt to overcome this resistance. With elevated insulin levels, adipose tissue storage of triacylglycerol is high and the patient is almost always overweight. There are exceptions to this general statement, and those are patients who have inherited a mutation leading to type 2 diabetes, such as MODY.
10. **The answer is E.** Initially muscles utilize glucose from muscle glycogen and fatty acids provided by the adipocyte. As the run continues the levels of AMP increase in the muscle, which leads to activation of the AMPK. This kinase leads to a reduction of malonyl CoA levels in the muscle (by inhibiting, via phosphorylation, acetyl CoA carboxylase, and activating, via phosphorylation, MCD), which allows for fatty acid entrance into the mitochondria. The muscle does not contain sufficient glycogen to provide energy for the entire marathon, so a mixture of fatty acids and glucose (from glycogen) is utilized by the muscle for optimum performance. In an adult there is no ketone body production during the race. Blood glucose can be taken up by the muscle (the activation of the AMPK stimulates the fusion of GLUT4 containing vesicles with the plasma membrane), but the runner will race at a pace that allows the blood glucose to be used by the nervous system, which requires that the muscles use fatty acids to generate energy.
11. **The answer is B.** The patient is exhibiting the signs of metabolic syndrome and most likely has type 2 diabetes. In type 2 diabetes the pancreas is still producing insulin, but the peripheral tissues have developed a resistance to responding to insulin. The muscle and adipose tissue are not increasing the level of GLUT4 transporters in the membrane, leading to high blood glucose levels, as indicated by the elevated HbA1c levels. LPL is synthesized and released by muscle and fat cells in response to insulin, so less LPL is produced, leading to elevated circulating triglyceride levels. The high blood glucose levels lead to LDL glycation, which interferes with LDL binding to the LDL receptor, resulting in elevated serum LDL levels. In type 1 diabetes the patient does not synthesize insulin and does not present with the signs of metabolic syndrome. A GLUT4 deficiency would lead to elevated blood glucose levels, but not the other abnormal laboratory values seen in the patient. An LPL deficiency would lead to elevated chylomicrons and VLDL in circulation, but not necessarily LDL, and not elevated blood glucose levels. An MTP deficiency would show a decrease in triglyceride levels in the blood and both VLDL and chylomicrons could not be synthesized with a defective MTP.
12. **The answer is B.** As the patient has type 2 diabetes his muscle and adipose tissues are not responding to

insulin appropriately, and the synthesis and secretion of LPL from those tissues are reduced, leading to a reduced ability to degrade chylomicrons and VLDL. The triglyceride remains in those particles for an extended period of time, leading to the high triglyceride levels seen in the patient's blood. Insulin does not regulate MTP activity, so there is no reason to assume that increased levels of chylomicrons and VLDL will be synthesized and released into the circulation. Apolipoprotein CII does not appear to be glycosylated when blood glucose levels are high, so apoCII should still activate LPL normally. Glut4 activity is reduced in type 2 diabetes, as the cells have a reduced response to insulin and will not translocate GLUT4 from internal vesicles to the plasma membrane. Triglyceride synthesis in the intestinal epithelial cell is a function of the fat content of the diet and will not be affected by the reduced responsiveness to insulin in the peripheral tissues.

13. **The answer is C.** The high blood glucose nonenzymatically glycosylates membrane-associated (and circulating) proteins, and the proteins within LDL (such as apolipoprotein B-100) are examples of proteins which can be glycosylated. When glycosylated the LDL particle can no longer bind well to the LDL receptor, so it remains in circulation longer, leading to the elevated cholesterol seen in the patient. The longer the LDL remains in circulation the higher the probability that it becomes oxidized, at which point it is taken up by scavenger receptors on macrophages, leading to the development of a fatty streak in the blood vessel. The rate of VLDL synthesis is dependent upon the diet and the amount of carbohydrate entering the liver cell. The slowed degradation of VLDL (due to a reduction in LPL expression) leads to the elevated triglyceride levels seen in the patient. LDL-receptor expression is not decreased under these conditions, but the receptor does not bind the glycosylated LDL as well as non-glycosylated LDL. Chylomicron formation is a function of dietary fat, and enhanced chylomicron formation (which requires MTP activity) does not, by itself, lead to elevated triglyceride and cholesterol levels in the blood.
14. **The answer is D.** In muscle acetyl CoA carboxylase produces malonyl CoA, which inhibits fatty acid entry into the mitochondria by inhibiting carnitine acyltransferase I (CAT-1) activity. If acetyl CoA carboxylase activity is reduced, the muscle will oxidize an increased amount of fatty acids (derived from the triglyceride stores in the adipocyte), leading to a loss of stored triglyceride and weight loss. Acetyl CoA carboxylase is not required or involved in cholesterol synthesis or protein synthesis (which would be needed to increase muscle mass).
15. **The answer is F.** When the AMPK is active, it will directly phosphorylate HMG-CoA reductase and acetyl CoA carboxylase, leading to an inhibition of their activities (recall, when energy levels are low anabolic pathways are turned off, and catabolic pathways are activated). The AMPK also phosphorylates the tuberous sclerosis complex 1/2 (TSC1/TSC2), which activates the complex. The activated complex acts as a GTPase-activating protein (GAP) for the Rheb-GTP-binding protein, leading to the inactivation of Rheb. Active Rheb (when it has GTP bound to it) activates mTOR, which leads to a stimulation of protein synthesis. When Rheb is inactive mTOR activity is inhibited, leading to a cessation of protein synthesis (an anabolic pathway). AMPK does not affect PFK-1 activity in any tissue.

SECTION VI

Nitrogen Metabolism

Dietary proteins are the primary source of the nitrogen that is metabolized by the body (Fig. VI.1). Amino acids, produced by digestion of dietary proteins, are absorbed through intestinal epithelial cells and enter the blood. Various cells take up these amino acids, which enter the cellular pools. They are used for the synthesis of proteins and other nitrogen-containing compounds, or they are oxidized for energy.

FIGURE VI.1 Summary of amino acid metabolism. Dietary proteins are digested to amino acids in the stomach and intestine, which are absorbed by the intestinal epithelium, transferred to the circulation, and taken up by cells. Amino acids are used to synthesize proteins and other nitrogen-containing compounds. The carbon skeletons of amino acids are also oxidized for energy, and the nitrogen is converted to urea and other nitrogenous excretory products.

Protein synthesis, the translation of messenger ribonucleic acid (mRNA) on ribosomes (see Chapter 14), is a dynamic process. Within the body, proteins are constantly being synthesized and degraded, partially draining and then refilling the cellular amino acid pools.

Compounds derived from amino acids include cellular proteins, hormones, neurotransmitters, creatine phosphate, the heme of hemoglobin and the cytochromes, the skin pigment melanin, and the purine and pyrimidine bases of nucleotides and nucleic acids. In fact, all of the nitrogen-containing compounds of the body are synthesized from amino acids. Many of these pathways are outlined in the following chapters.

In addition to serving as the precursors for the nitrogen-containing compounds of the body and as the building blocks for protein synthesis, amino acids are also a source of energy. Either amino acids are oxidized directly or the amino acid carbons are converted to glucose and then oxidized or stored as glycogen. The amino acid carbons may also be converted to fatty acids and stored as adipose triacylglycerols. Glycogen and triacylglycerols are oxidized during periods of fasting. The liver is the major site of amino acid oxidation. However, most tissues, particularly the muscle, can oxidize the branched-chain amino acids (leucine, isoleucine, and valine).

Before the carbon skeletons of amino acids are oxidized, the nitrogen must be removed. Amino acid nitrogen forms ammonia, which is toxic to the body. In the liver, ammonia and the amino groups from amino acids are converted to urea, which is nontoxic, water-soluble, and readily excreted in the urine. The process by which urea is produced is known as the urea cycle. The liver is the organ responsible for producing urea. Branched-chain amino acids can be oxidized in many tissues, but the nitrogen must always travel to the liver for disposal.

Although urea is the major nitrogenous excretory product of the body, nitrogen is also excreted in other compounds (Table VI.1). Uric acid is the degradation product of the purine bases, creatinine is produced from creatine phosphate, and ammonia is released from glutamine, particularly by the kidney, where it helps to buffer the urine by reacting with protons to form ammonium ions (NH_4^+). These compounds are excreted mainly in the urine, but substantial amounts are also lost in the feces and through the skin. Small amounts of nitrogen-containing metabolites are formed from the degradation of neurotransmitters, hormones, and other specialized amino acid products and excreted in the urine. Some of these degradation products, such as bilirubin (formed from the degradation of heme), are excreted mainly in the feces.

TABLE VI.1 Major Nitrogenous Urinary Excretory Products

AMOUNT EXCRETED IN URINE PER DAY ^a		
Urea ^b	12–20 g urea nitrogen (12,000–20,000 mg)	
NH_4^+	140–1,500 mg ammonia nitrogen	
Creatinine	Men	14–26 mg/kg
	Women	11–20 mg/kg
Uric acid	250–750 mg	

^aThe amounts are expressed in the units that are generally reported by clinical laboratories. Note that the amounts for creatinine and uric acid are for the whole compound, whereas those for urea and ammonia are for the nitrogen content.

^bUnder normal circumstances, approximately 90% of the nitrogen excreted in the urine is in the form of urea. The exact amounts of each component vary, however, depending on dietary protein intake and physiologic state. For instance, NH_4^+ excretion increases during acidosis because the kidney secretes ammonia to bind protons in the urine.

The healthy human adult is in nitrogen balance; in other words, the amount of nitrogen excreted each day (mainly in the urine) equals the amount consumed (mainly as dietary protein). Negative nitrogen balance occurs when the amount of nitrogen excreted is greater than the amount consumed, and positive nitrogen balance occurs when the amount excreted is less than that consumed (see Chapter 1).

Eleven of the 20 amino acids used to form proteins are synthesized in the body if an adequate amount is not present in the diet (Table VI.2). Ten of these amino acids can be produced from glucose; the 11th, tyrosine, is

synthesized from the essential amino acid phenylalanine. It should be noted that cysteine, one of the 10 amino acids produced from glucose, obtains its sulfur atom from the essential amino acid methionine.

TABLE VI.2 Amino Acids Synthesized in the Body ^a	
FROM GLUCOSE	FROM AN ESSENTIAL AMINO ACID
Alanine	Tyrosine (from phenylalanine)
Arginine	
Asparagine	
Aspartate	
Cysteine ^b	
Glutamate	
Glutamine	
Glycine	
Proline	
Serine	

^aThese amino acids are called **nonessential** or **dispensable**, terms that refer to dietary requirements. Of course, within the body, they are necessary. We cannot survive without them.

^bAlthough the carbons of cysteine can be derived from glucose, its sulfur is obtained from the essential amino acid methionine.

Nine amino acids are essential in the human. “Essential” means that the carbon skeleton cannot be synthesized, and therefore, these amino acids are required in the diet (Table VI.3). The essential amino acids are also called the indispensable amino acids. Arginine is essential during periods of growth; in adults, it is no longer considered essential.

TABLE VI.3 Amino Acids Essential in the Diet
Histidine
Isoleucine
Leucine
Lysine
Methionine
Phenylalanine
Threonine
Tryptophan
Valine
Arginine (not required by the adult, but required for growth)

After nitrogen is removed from amino acids, the carbon skeletons are oxidized (Fig. VI.2). Most of the carbons are converted to pyruvate, intermediates of the tricarboxylic acid (TCA) cycle, or to acetyl coenzyme A (acetyl CoA). In the liver, particularly during fasting, these carbons may be converted to glucose or to ketone bodies and released into the blood. Other tissues then oxidize the glucose and ketone bodies. Ultimately, the carbons of the amino acids are converted to carbon dioxide (CO₂) and water (H₂O).

FIGURE VI.2 Overview of nitrogen metabolism. The metabolism of nitrogen-containing compounds is shown on the right and that of glucose and fatty acids is shown on the left. This figure shows a hypothetical, composite cell. No single cell type has all of these pathways. Many of the pathways shown are described in the next few chapters. α -KG, α -ketoglutarate; G 6-P, glucose 6-phosphate; G 1-P, glucose 1-phosphate; OAA, oxaloacetate; TCA, tricarboxylic acid.

Protein Digestion and Amino Acid Absorption

Proteolytic enzymes (also called **proteases**) break down dietary proteins into their constituent amino acids in the **stomach** and the **intestine**. Many of these digestive proteases are synthesized as larger, inactive forms known as **zymogens**. After zymogens are secreted into the digestive tract, they are cleaved to produce the active proteases.

In the stomach, **pepsin** begins the digestion of proteins by hydrolyzing them to smaller polypeptides. The contents of the stomach pass into the small intestine, where enzymes produced by the exocrine pancreas act. The pancreatic proteases (**trypsin**, **chymotrypsin**, **elastase**, and the **carboxypeptidases**) cleave the polypeptides into oligopeptides and amino acids.

Further cleavage of the oligopeptides to amino acids is accomplished by enzymes produced by the intestinal epithelial cells. These enzymes include **aminopeptidases** located on the brush border and other peptidases located within the cells. Ultimately, the amino acids produced by protein digestion are absorbed through the **intestinal epithelial cells** and enter the **blood**.

A large number of overlapping transport systems exist for amino acids in cells. Some systems contain **facilitative transporters**, whereas others express **sodium-linked transporters**, which allow the **active transport** of amino acids into cells. Defects in amino acid transport can lead to disease.

Proteins are also continually synthesized and degraded (**turnover**) in cells. A wide variety of proteases in cells carry out this activity. **Lysosomal proteases (cathepsins)** degrade proteins that enter lysosomes. Cytoplasmic proteins targeted for turnover are covalently linked to the small protein **ubiquitin**, which then interacts with a large protein complex, the **proteasome**, to degrade the protein in an adenosine triphosphate (ATP)–dependent process. The amino acids released from proteins during turnover can then be used for the synthesis of new proteins or for energy generation.

THE WAITING ROOM

Susan F., a young child with cystic fibrosis (see Chapter 16), has had repeated bouts of bronchitis/bronchiolitis caused by *Pseudomonas aeruginosa*. With each of these infections, her response to aerosolized antibiotics has been good. However, her malabsorption of food continues, resulting in foul-smelling, glistening, bulky stools. Her growth records show a slow decline. She is now in the 24th percentile for height and the 20th percentile for weight. She is often listless and irritable, and she tires easily. When her pediatrician discovered that her levels of the serum proteins albumin and prealbumin were low to low-normal (indicating protein malnutrition), **Susan F.** was given enteric-coated microspheres of pancreatic enzymes. Almost immediately, the character of **Susan F.**'s stools became more normal and she began gaining weight. Over the next 6 months, her growth curves showed improvement, and she seemed brighter, more active, and less irritable.

Kwashiorkor, a common problem of children in resource-limited countries, is caused by a deficiency of protein in a diet that is adequate in calories. Children with kwashiorkor suffer from muscle wasting and decreased concentration of plasma proteins, particularly albumin. The result is an increase in interstitial fluid that causes edema and a distended abdomen, which makes the children appear “plump” (see Chapter 43). The muscle wasting is caused by the lack of essential amino acids in the diet; existing proteins must be broken down to produce these amino acids for new protein synthesis. These problems may be compounded by a decreased ability to produce digestive enzymes and new intestinal epithelial cells because of a decreased availability of amino acids for the synthesis of new proteins.

For the first few months after a painful episode of renal colic, during which he passed a kidney stone (see Chapter 6), **David K.** had faithfully maintained a high daily fluid intake and had taken the medication required

to increase the pH of his urine. He had been diagnosed with cystinuria, a genetically determined amino acid substitution in the transport protein that normally reabsorbs cysteine, arginine, and lysine from the kidney lumen back into the renal tubular cells. Therefore, his urine contained high amounts of these amino acids. Cystine, which is less soluble than the other amino acids, precipitates in the urine to form renal stones (also known as calculi). The measures he was instructed to follow were necessary to increase the solubility of the large amounts of cystine present in his urine and thereby to prevent further formation of kidney stones. With time, however, it became difficult for him to keep up with his preventive program. After failing to take his medication for a month, he experienced another severe episode of renal colic with grossly bloody urine. Fortunately, he passed the stone spontaneously, after which he tried again to adhere to his treatment regimen.

Elastase is also found in neutrophils, which are white blood cells that engulf and destroy invading bacteria. Neutrophils frequently act in the lung, and elastase is sometimes released into the lung as the neutrophils work. In normal individuals, the released elastase is blocked from destroying lung cells by the action of circulating α -1-antitrypsin, a protease inhibitor that is synthesized and secreted by the liver. Certain individuals have a genetic mutation that leads to the production of an inactive α -1-antitrypsin protein (α -1-antitrypsin deficiency). The lack of this enzyme activity leads to the development of emphysema caused by proteolytic destruction of lung cells, which results in a reduction in the expansion/contraction capability of the lungs. Deficiency of α -1-antitrypsin can be measured using a dried blood spot. The blood is solubilized using a buffer, and then, various amounts of the blood sample are incubated with antibodies specific for α -1-antitrypsin. The antigen–antibody complexes formed will disperse light, and the extent of light scattering is proportional to the concentration of α -1-antitrypsin in the solution. This procedure is known as rate nephelometry. Obtaining blood samples from a finger prick and allowing the blood to dry on a card enable rapid screening of individuals for this disorder.

His mother heard that some dietary amino acids were not absorbed in patients with cystinuria and asked whether any dietary changes would reduce **David K.**'s chances of developing additional renal stones.

I. Protein Digestion

The digestion of proteins begins in the stomach and is completed in the intestine (Fig. 35.1). The enzymes that digest proteins are produced as inactive precursors (zymogens) that are larger than the active enzymes. The inactive zymogens are secreted from the cells in which they are synthesized and enter the lumen of the digestive tract, where they are cleaved to smaller forms that have proteolytic activity (Fig. 35.2). These active enzymes have different specificities; no single enzyme can completely digest a protein. However, by acting in concert, they can digest dietary proteins to amino acids and small peptides, which are cleaved by peptidases associated with intestinal epithelial cells.

FIGURE 35.1 Digestion of proteins. The proteolytic enzymes, pepsin, trypsin, chymotrypsin, elastase, and the carboxypeptidases, are produced as zymogens (the “pro” and “ogen,” in red, accompanying the enzyme name) that are activated by cleavage after they enter the gastrointestinal lumen (see Fig. 35.2). Pepsinogen is produced within the stomach and is activated within the stomach (to pepsin) as the pH drops due to HCl secretion. HCl, hydrochloric acid.

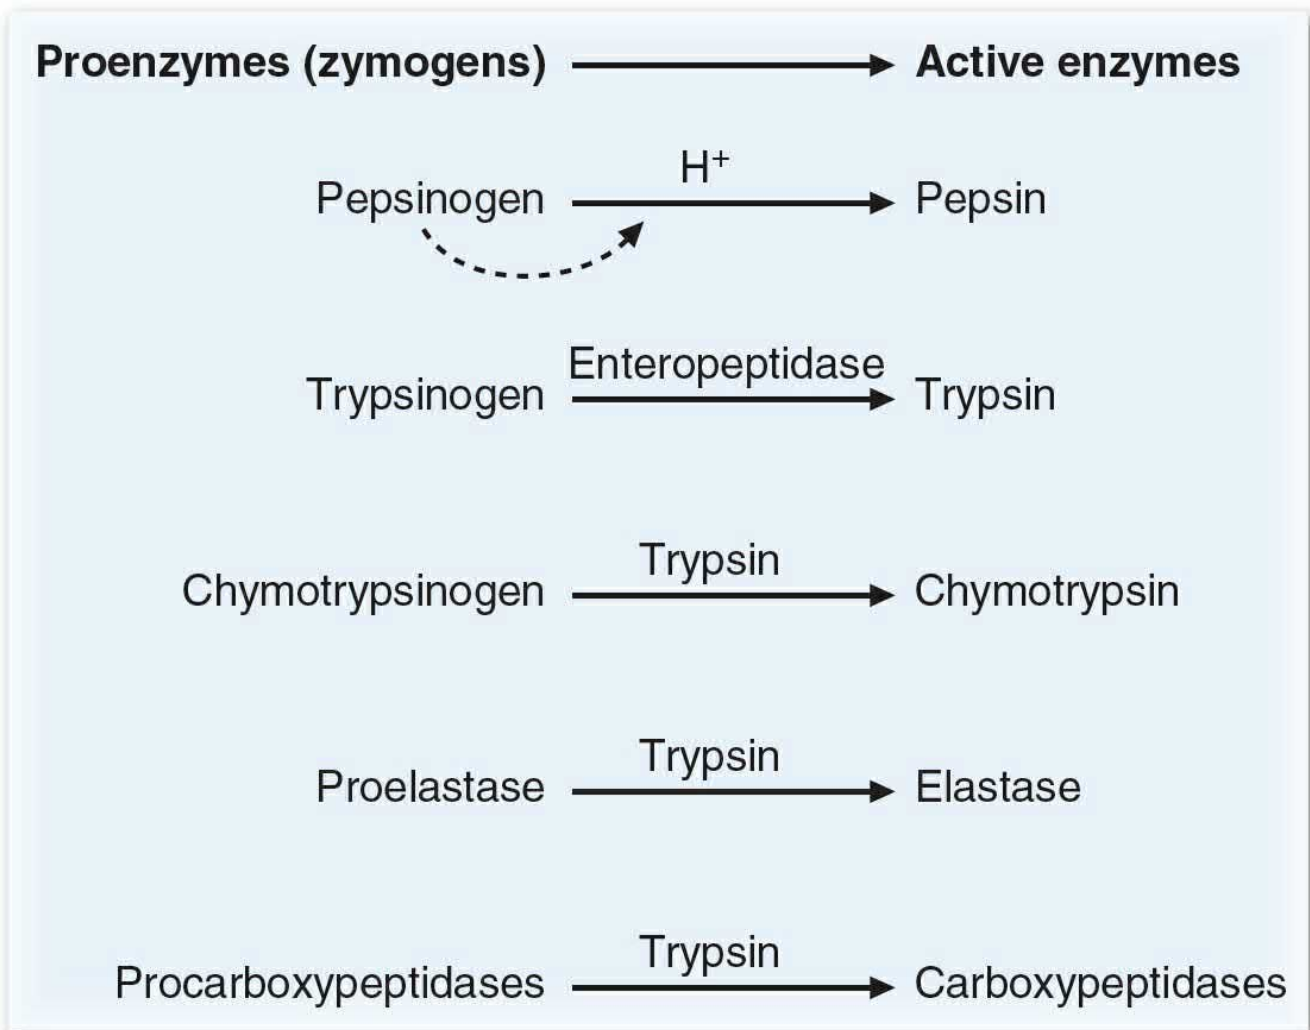

FIGURE 35.2 Activation of the gastric and pancreatic zymogens. Pepsinogen catalyzes its own cleavage as the pH of the stomach drops. Trypsinogen is cleaved by enteropeptidase in the intestine to form the active protease trypsin. Trypsin then plays a key role by catalyzing the cleavage and activation of the other pancreatic zymogens.

A. Digestion in the Stomach

Pepsinogen is secreted by the chief cells of the stomach. The gastric parietal cells secrete hydrochloric acid (HCl). The acid in the stomach lumen alters the conformation of pepsinogen so that it can cleave itself, producing the active protease pepsin. Thus, the activation of pepsinogen is autocatalytic.

Dietary proteins are denatured by the acid in the stomach. This inactivates the proteins and partially unfolds them so that they are better substrates for proteases. However, at the low pH of the stomach, pepsin is not denatured and acts as an endopeptidase, cleaving peptide bonds at various points within the protein chain. Although pepsin has fairly broad specificity, it tends to cleave peptide bonds in which the carboxyl group is provided by an aromatic or acidic amino acid (Fig. 35.3). Smaller peptides and some free amino acids are produced.

FIGURE 35.3 Action of the digestive proteases. Pepsin, trypsin, chymotrypsin, and elastase are endopeptidases; they hydrolyze peptide bonds within chains. The others are exopeptidases; aminopeptidases remove the amino acid at the *N* terminus, and the carboxypeptidases remove the amino acid at the C-terminus. For each proteolytic enzyme, the amino acid residues involved in the peptide bond that is cleaved are listed beside the R group to the *right* of the enzyme name.

B. Digestion by Enzymes from the Pancreas

As the gastric contents empty into the intestine, they encounter the secretions from the exocrine pancreas. Recall that the exocrine pancreas secretes amylase for starch digestion and lipase and colipase for dietary triacylglycerol digestion. Another pancreatic secretion is bicarbonate, which, in addition to neutralizing stomach acid, raises the pH so that the pancreatic proteases, which are also present in pancreatic secretions, can be active. As secreted, these pancreatic proteases are in the inactive proenzyme form (zymogens). Because the active forms of these enzymes can digest each other, it is important for their zymogen forms all to be activated within a short span of time. This is accomplished by the cleavage of trypsinogen to the active enzyme trypsin, which then cleaves the other pancreatic zymogens, producing their active forms (see Fig. 35.2).

The zymogen trypsinogen is cleaved to form trypsin by enteropeptidase (a protease, formerly called enterokinase) secreted by the brush border cells of the small intestine. Trypsin catalyzes the cleavages that convert chymotrypsinogen to the active enzyme chymotrypsin, proelastase to elastase, and the procarboxypeptidases to the carboxypeptidases. Thus, trypsin plays a central role in digestion because it both cleaves dietary proteins and activates other digestive proteases produced by the pancreas.

Trypsin, chymotrypsin, and elastase are serine proteases (see Chapter 9) that act as endopeptidases. Trypsin is the most specific of these enzymes, cleaving peptide bonds in which the carboxyl (carbonyl) group is provided by lysine or arginine (see Fig. 35.3). Chymotrypsin is less specific but favors residues that contain hydrophobic amino acids. Elastase cleaves not only elastin (for which it was named) but also other proteins at bonds in which the carboxyl group is contributed by amino acid residues with small side chains (alanine, glycine, and serine). The actions of these pancreatic endopeptidases continue the digestion of dietary proteins begun by pepsin in the stomach.

The smaller peptides formed by the action of trypsin, chymotrypsin, and elastase are attacked by exopeptidases, which are proteases that cleave one amino acid at a time from the end of the chain. Procarboxypeptidases, zymogens produced by the pancreas, are converted by trypsin to the active carboxypeptidases. These exopeptidases remove amino acids from the carboxyl ends of peptide chains. Carboxypeptidase A preferentially releases hydrophobic amino acids, whereas carboxypeptidase B releases basic amino acids (arginine and lysine).

C. Digestion by Enzymes from Intestinal Cells

Exopeptidases produced by intestinal epithelial cells act within the brush border and also within the cell. Aminopeptidases, located on the brush border, cleave one amino acid at a time from the amino end of peptides. Intracellular peptidases act on small peptides that are absorbed by the cells.

The concerted action of the proteolytic enzymes produced by cells of the stomach, pancreas, and intestine cleaves dietary proteins to amino acids. The digestive enzymes digest themselves as well as dietary protein. They also digest the intestinal cells that are regularly sloughed off into the lumen. These cells are replaced by cells that mature from precursor cells in the duodenal crypts. The amount of protein that is digested and absorbed each day from digestive juices and cells released into the intestinal lumen may be equal to, or greater than, the amount of protein consumed in the diet (50 to 100 g).

II. Absorption of Amino Acids

Amino acids are absorbed from the intestinal lumen through secondary active Na^+ -dependent transport systems and through facilitated diffusion.

A. Cotransport of Sodium Ions and Amino Acids

Amino acids are absorbed from the lumen of the small intestine principally by semispecific Na^+ -dependent transport proteins in the luminal membrane of the intestinal cell brush border, similar to that already seen for carbohydrate transport (Fig. 35.4). The cotransport of Na^+ and the amino acid from the outside of the apical

membrane to the inside of the cell is driven by the low intracellular Na^+ concentration. Low intracellular Na^+ concentration results from the pumping of Na^+ out of the cell by a Na^+ , K^+ -ATPase on the serosal membrane. Thus, the primary transport mechanism is the creation of a sodium gradient; the secondary transport process is the coupling of amino acids to the influx of sodium. This mechanism allows the cells to concentrate amino acids from the intestinal lumen. The amino acids are then transported out of the cell into the interstitial fluid principally by facilitated transporters in the serosal membrane (see Fig. 35.4).

FIGURE 35.4 Transepithelial amino acid transport. Na^+ -dependent carriers transport both Na^+ and an amino acid into the intestinal epithelial cell from the intestinal lumen. Na^+ is pumped out on the serosal side (across the basolateral membrane) in exchange for K^+ by the Na^+ , K^+ -ATPase. On the serosal side, the amino acid is carried by a facilitated transporter down its concentration gradient into the blood. This process is an example of secondary active transport. ADP, adenosine diphosphate;

ATP, adenosine triphosphate; P_i, inorganic phosphate.

 Patients with cystic fibrosis, such as **Susan F.**, have a genetically determined defect in the function of the chloride channels. In the pancreatic secretory ducts, which carry pancreatic enzymes into the lumen of the small intestine, this defect causes inspissation (drying and thickening) of pancreatic exocrine secretions, eventually leading to the obstruction of these ducts. One result of this problem is the inability of pancreatic enzymes to enter the intestinal lumen to digest dietary proteins (as well as fats and carbohydrates).

 The pancreas synthesizes and stores the zymogens in secretory granules. The pancreas also synthesizes a secretory trypsin inhibitor. The need for the inhibitor is to block any trypsin activity that may occur from accidental trypsinogen activation. If the inhibitor were not present, trypsinogen activation would lead to the activation of all of the zymogens in the pancreas, which would lead to the digestion of intracellular pancreatic proteins. Such episodes can lead to pancreatitis.

At least six different Na⁺-dependent amino acid carriers are located in the apical brush border membrane of the epithelial cells. These carriers have an overlapping specificity for different amino acids. One carrier preferentially transports neutral amino acids, another transports proline and hydroxyproline, a third preferentially transports acidic amino acids, and a fourth transports basic amino acids (lysine, arginine, and the urea cycle intermediate ornithine) and cystine (two cysteine residues linked by a disulfide bond). In addition to these Na⁺-dependent carriers, some amino acids are transported across the luminal membrane by facilitated transport carriers. Most amino acids are transported by more than one transport system.

 **Hartnup disease** is a genetically determined and relatively rare autosomal recessive disorder. It is caused by a defect in the transport of neutral amino acids across both intestinal and renal epithelial cells (the amino acid transport system B⁰, encoded by the gene SLC6A19, where SLC refers to the solute carrier family of transport proteins, of which there are 55, with a total of 362 different genes). The signs and symptoms are caused, in part, by a deficiency of essential amino acids (see “Clinical Comments”). **Cystinuria** (a defect in the amino acid transport system B^{0,+}, involving the genes SLC7A9 and SLC3A1, as the transporter is a heteromeric complex) and Hartnup disease involve defects in two different transport proteins. In each case, the defect is present both in intestinal cells, causing malabsorption of the amino acids from the digestive products in the intestinal lumen, and in kidney tubular cells, causing a decreased resorption of these amino acids from the glomerular filtrate and an increased concentration of the amino acids in the urine.

As with glucose transport, the Na⁺-dependent carriers of the apical membrane of the intestinal epithelial cells are also present in the renal epithelium. However, different isozymes are present in the cell membranes of other tissues. Conversely, the facilitated transport carriers in the serosal membrane of the intestinal epithelia are similar to those found in other cell types in the body. During starvation, the intestinal epithelia, like these other cells, take up amino acids from the blood to use as an energy source. Thus, amino acid transport across the serosal membrane is bidirectional.

B. Transport of Amino Acids into Cells

Amino acids that enter the blood are transported across cell membranes of the various tissues principally by Na⁺-dependent cotransporters and, to a lesser extent, by facilitated transporters (Table 35.1). In this respect, amino acid transport differs from glucose transport, which is Na⁺-dependent transport in the intestinal and renal epithelium but facilitated transport in other cell types. The Na⁺ dependence of amino acid transport in liver, muscle, and other tissues allows these cells to concentrate amino acids from the blood. These transport proteins have a different genetic basis, amino acid composition, and somewhat different specificity than those in the luminal membrane of intestinal epithelia. They also differ somewhat among tissues. For instance, the *N*-system for glutamine uptake is present in the liver, but either is not present in other tissues or is present as an isoform with different properties. As with the epithelial cell transporters, there is also some overlap in specificity of the transport proteins, with most amino acids being transported by more than one carrier.

TABLE 35.1 A Partial Listing of Amino Acid Transport Systems^a

SYSTEM NAME	SODIUM-DEPENDENT?	SPECIFICITY	TISSUES EXPRESSED
A	Yes	Small and polar neutral amino acids (Ala, Ser, Gln, Gly, Pro, Cys, Asn, His, Met)	Many
ASC	Yes	Small amino acids (Ala, Ser, Cys)	Many

N	Yes	Gln, Asn, His	Liver, basolateral membrane of kidney
L	No	Branched and aromatic amino acids (His, Met, Leu, Ile, Val, Phe, Tyr, Trp)	Many ^b
B ^{0,+}	Yes	Basic amino acids	Intestine (brush border) ^c and kidney
B ⁰	Yes	Zwitterionic amino acids (monoamino, monocarboxylic acid amino acids)	Intestine and kidney ^d
X _{AG} ⁻	Yes	Anionic amino acids (Asp, Glu)	Intestine (brush border) and kidney
Imino	Yes	Pro, hydroxyproline, Gly	Intestine (brush border) and kidney

^aNot all transport systems are listed.

^bThis transport system will be exploited in a treatment for phenylketonuria (PKU); see Chapter 37.

^cThis system is most likely defective in cystinuria.

^dThis system is most likely defective in Hartnup disease.

Why do patients with cystinuria and Hartnup disease have hyperaminoaciduria without associated hyperaminoacidemia?

III. Protein Turnover and Replenishment of the Intracellular Amino Acid Pool

The amino acid pool within cells is generated both from dietary amino acids and from the degradation of existing proteins within the cell. All proteins within cells have a half-life ($t_{1/2}$), a time at which 50% of the protein that was synthesized at a particular time will have been degraded. Some proteins are inherently short-lived, with half-lives of 5 to 20 min. Other proteins are present for extended periods, with half-lives of many hours or even days. Thus, proteins are continuously being synthesized and degraded in the body, using a variety of enzyme systems to do so (Table 35.2). Examples of proteins that undergo extensive synthesis and degradation are hemoglobin, muscle proteins, digestive enzymes, and the proteins of cells sloughed off from the gastrointestinal (GI) tract. Hemoglobin is produced in reticulocytes and reconverted to amino acids by the phagocytic cells that remove mature red blood cells from the circulation on a daily basis. Muscle protein is degraded during periods of fasting, and the amino acids are used for gluconeogenesis. After ingestion of protein in the diet, muscle protein is resynthesized. Adults cannot increase the amount of muscle or other body proteins by eating an excess amount of protein. If dietary protein is consumed in excess of our needs, it is converted to glycogen and triacylglycerols, which are then stored.

TABLE 35.2 Proteases Involved in Protein Turnover/Degradation

CLASSIFICATION	MECHANISM	ROLE
Cathepsins	Cysteine proteases	Lysosomal enzymes
Caspases	Cysteine proteases, which cleave after aspartate	Apoptosis; activated from pro-caspases (see Chapter 17)
Matrix metalloproteinases	Require zinc for catalysis	Model extracellular matrix components; regulated by tissue inhibitors of matrix metalloproteinases (TIMPs)
Proteasome	Large complex that degrades ubiquitin-tagged proteins	Protein turnover
Serine proteases	Active-site serine in a catalytic triad with histidine and aspartic acid	Digestion and blood clotting; activated usually from zymogens (see Chapter 43)
Calpains	Calcium-dependent cysteine proteases	Many different cellular roles

Trace amounts of polypeptides pass into the blood. They may be transported through intestinal epithelial cells, probably by pinocytosis, or they may slip between the cells that line the gut wall. This process is particularly troublesome for premature infants, because it can lead to allergies caused by proteins in their food.

David K. and other patients with cystinuria have a genetically determined defect in the transport of cystine and the basic amino acids, lysine, arginine, and ornithine, across the brush border membranes of cells in both their small intestine and renal tubules (system B^{0,+}). The transporter consists of a protein complex, and mutations in either the SLC3A1 or SLC7A9 genes can lead to the disorder. Patients with cystinuria, however, do not appear to have any symptoms of amino acid deficiency, in part because the amino acids cysteine (which is oxidized in blood and urine to form the disulfide cystine) and arginine can be synthesized in the body (i.e., they are “nonessential” amino acids). Ornithine (an amino acid that is not found in proteins but serves as an intermediate of the urea cycle) can also be synthesized. The most serious problem for these patients is the insolubility of cystine, which can form kidney stones that may lodge in the ureter, causing genitourinary bleeding, obstruction of the ureters, and severe pain known as renal colic.

A large amount of protein is recycled daily in the form of digestive enzymes, which are themselves degraded by digestive proteases. In addition, approximately one-fourth of the cells lining the walls of the GI tract are lost each day and replaced by newly synthesized cells. As cells leave the GI wall, their proteins and other components are digested by enzymes in the lumen of the gut, and the products are absorbed. Additionally, red blood cells have a life span of about 120 days. Every day, 3×10^{11} red blood cells die and are phagocytosed. The hemoglobin in these cells is degraded to amino acids by lysosomal proteases, and their amino acids are reutilized in the synthesis of new proteins. Only approximately 6% (roughly 10 g) of the protein that enters the digestive tract (including dietary proteins, digestive enzymes, and the proteins in sloughed-off cells) is excreted in the feces each day. The remainder is recycled.

A Patients with cystinuria and Hartnup disease have defective transport proteins in both the intestine and the kidney. These patients do not absorb the affected amino acids at a normal rate from the digestive products in the intestinal lumen. They also do not readily resorb these amino acids from the glomerular filtrate into the blood. Therefore, they do not have hyperaminoacidemia (a high concentration in the blood). Normally, only a small percent of the amino acids that enter the glomerular filtrate are excreted in the urine; most are resorbed. In these diseases, much larger amounts of the affected amino acids are excreted in the urine, resulting in hyperaminoaciduria.

Proteins are also recycled within cells. The differences in amino acid composition of the various proteins of the body, the vast range in turnover times ($t_{1/2}$), and the recycling of amino acids are all important factors that help to determine the requirements for specific amino acids and total protein in the diet. The synthesis of many enzymes is induced in response to physiologic demand (such as fasting or feeding). These enzymes are continuously being degraded. Intracellular proteins are also damaged by oxidation and other modifications that limit their function. Mechanisms for intracellular degradation of unnecessary or damaged proteins involve lysosomes and the ubiquitin–proteasome system.

A. Lysosomal Protein Turnover

Lysosomes participate in the process of autophagy, in which intracellular components are surrounded by membranes that fuse with lysosomes and endocytosis (see Chapter 10). Autophagy is a complex regulated process in which cytoplasm is sequestered into vesicles and delivered to the lysosomes. Within the lysosomes, the cathepsin family of proteases degrades the ingested proteins to individual amino acids. The recycled amino acids can then leave the lysosome and rejoin the intracellular amino acid pool. Although the details of how autophagy is induced are still being investigated, starvation of a cell is a trigger to induce this process. This will allow old proteins to be recycled and the newly released amino acids to be used for new protein synthesis, to enable the cell to survive starvation conditions. The mechanistic target of rapamycin (mTOR) kinase (see Chapter 34) plays a key role in regulating autophagy, as outlined in Figure 35.5.

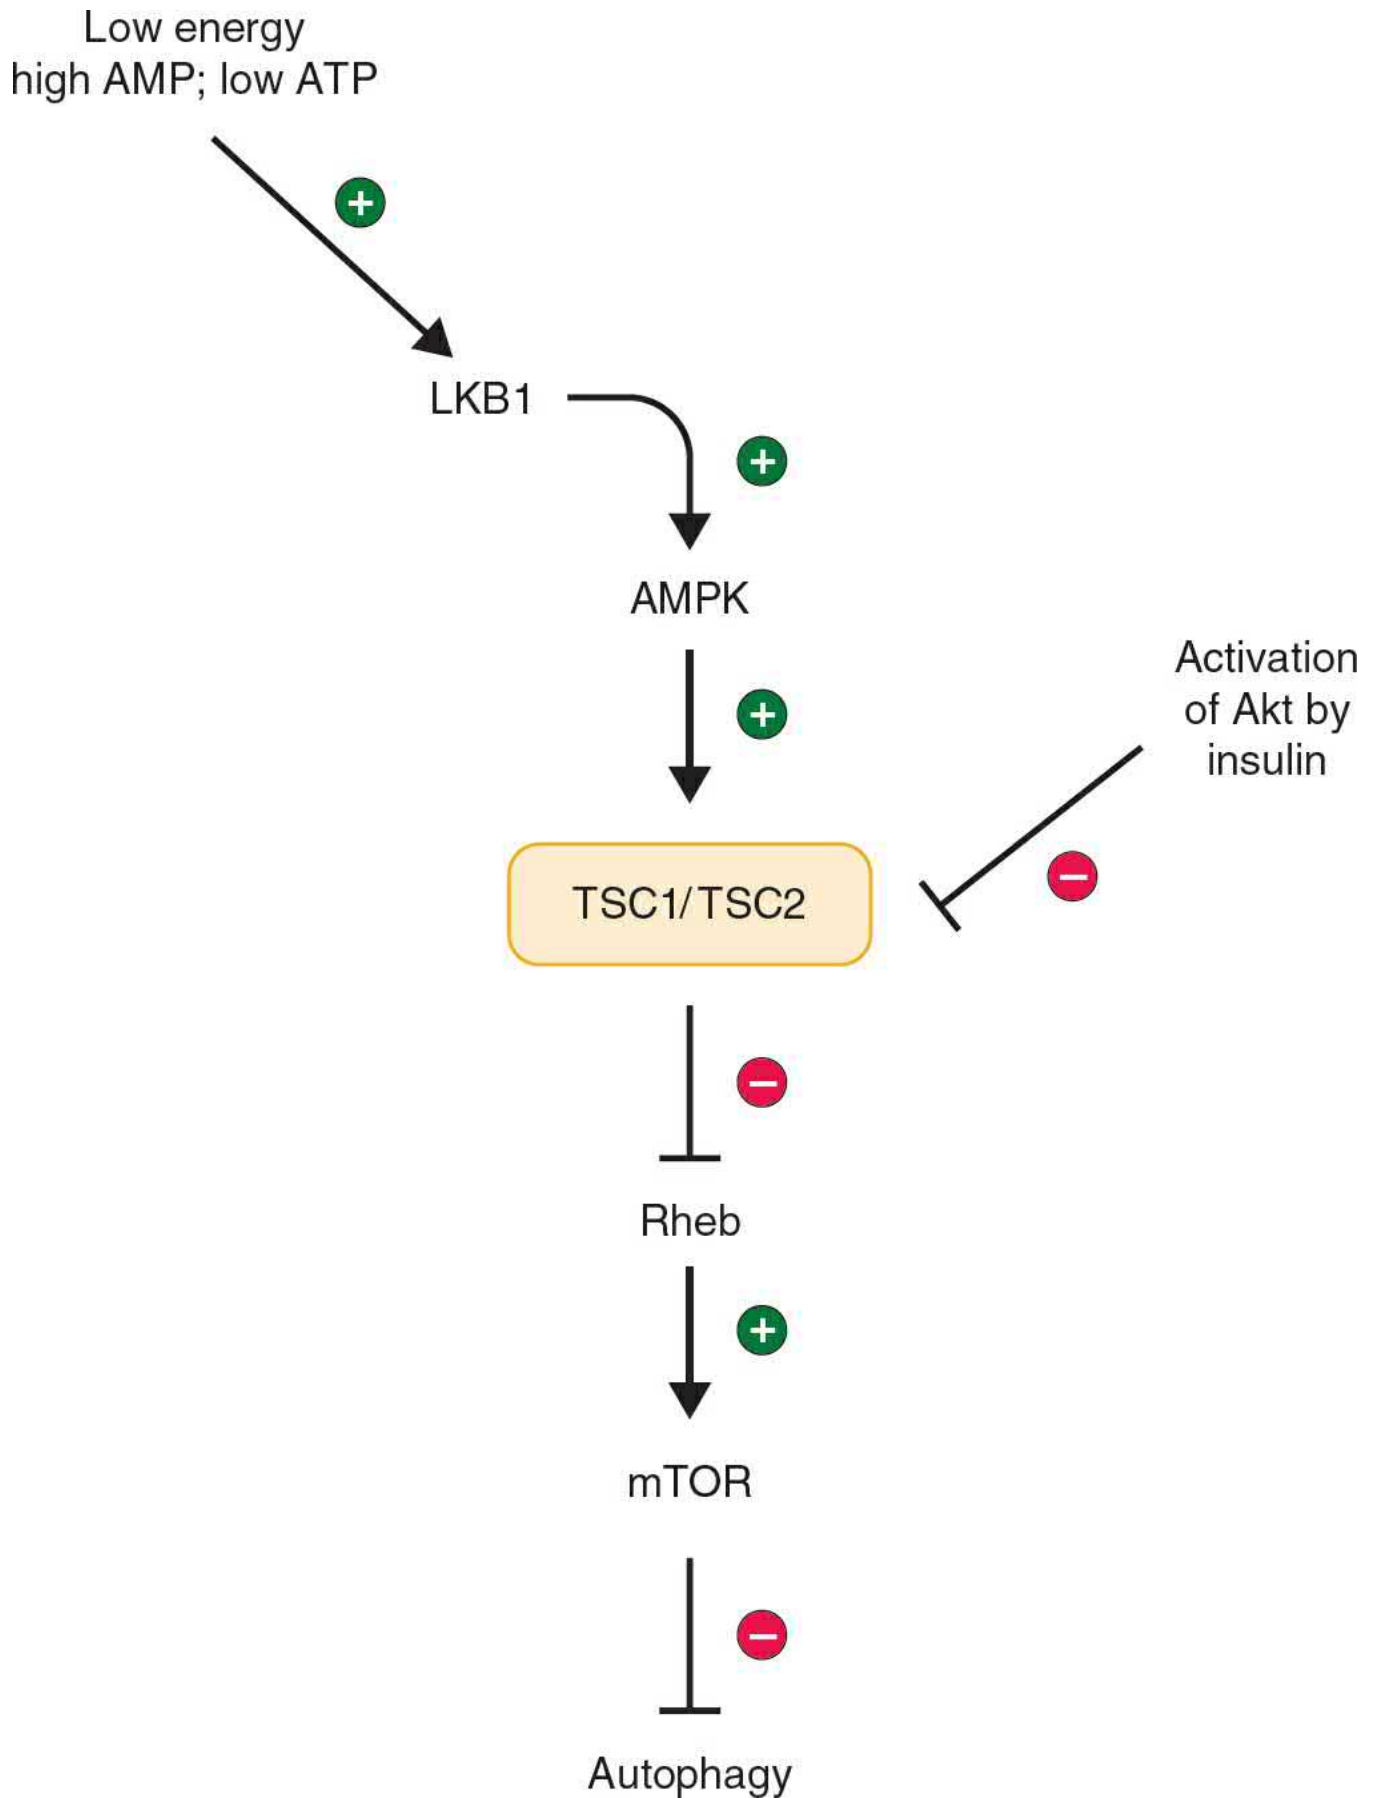

FIGURE 35.5 Overview of mTOR participation in autophagy. When active, the mTOR kinase will phosphorylate a protein crucial to the initiation of phagosome formation, which will inhibit autophagy. mTOR kinase is activated by Rheb-GTP. Under low-energy conditions (starvation), autophagy is favored as the AMPK is activated, which phosphorylates the TSC1/TSC2 complex, activating its Rheb-GTPase activating activity. This leads to the inactivation of Rheb (Rheb-GTP is converted to the

inactive Rheb-GDP), which leads to the inactivation of mTOR. When inactive, mTOR does not block autophagy, and self-proteolysis is favored, as is an inhibition of protein synthesis. In the presence of growth factors, such as insulin, which activate the Akt kinase, Akt phosphorylates the TSC1/TSC2 at a site distinct from the AMPK site. The phosphorylation event by Akt leads to an inhibition of the TSC1/TSC2 Rheb-GTPase activating activity, which allows Rheb to be active for extended periods of time. Active Rheb leads to activation of mTOR, inhibition of autophagy, and activation of protein synthesis. AMP, adenosine monophosphate; AMPK, AMP-activated protein kinase; ATP, adenosine triphosphate; GTP, guanosine triphosphate; LKB1, liver kinase B1; mTOR, mechanistic target of rapamycin; Rheb, Ras homolog enriched in brain; TSC, tuberous sclerosis complex.

B. The Ubiquitin-Proteasome Pathway

Ubiquitin is a small protein (76 amino acids) that is highly conserved. Its amino acid sequence in yeast and humans differs by only three residues. Ubiquitin targets intracellular proteins for degradation by covalently binding to the ϵ -amino group of lysine residues. This is accomplished by a three-enzyme system that adds ubiquitin to proteins targeted for degradation. Often, the target protein is polyubiquitinated, a process in which additional ubiquitin molecules are added to previous ubiquitin molecules, forming a long ubiquitin tail on the target protein. After polyubiquitination is complete, the targeted protein is released from the three-enzyme complex and is directed to the proteasome via a variety of mechanisms.

The three-enzyme system for conjugating ubiquitin to proteins consists of E1 (ubiquitin-activating enzyme), E2, and E3 (ubiquitin ligase). E1, in an ATP-dependent process, covalently links ubiquitin to a sulfhydryl group in E1. E1 then transfers the ubiquitin to a sulfhydryl group on E2, which complexes with E3 and the target protein. E3 then catalyzes the transfer of the ubiquitin from E2 to the target protein. E3 can continue to add ubiquitin molecules to the initial ubiquitin molecule on the target, creating polyubiquitylated proteins targeted for degradation. Interestingly, abnormal expression of certain ubiquitin ligases (E3), which regulate the turnover of cell cycle and apoptotic-specific proteins, can lead to uncontrolled cell proliferation and cancer.

A protease complex, known as the proteasome, then degrades the targeted protein, releasing intact ubiquitin that can again mark other proteins for degradation (Fig. 35.6). The basic proteasome is a cylindrical 20S protein complex with multiple internal proteolytic sites. ATP hydrolysis is used both to unfold the tagged protein and to push the protein into the core of the cylinder. The complex is regulated by four different types of regulatory particles (cap complexes), which bind the ubiquitylated protein (a step that requires ATP) and deliver them to the complex. After the target protein is degraded, the ubiquitin is released intact and recycled. The resulting amino acids join the intracellular pool of free amino acids.

FIGURE 35.6 The proteasome and regulatory proteins. The regulatory particle (shown in this figure as the 19S regulator; others are PA28 $\alpha\beta 1$, PA28 γ , and PA200) regulates the activity of this proteolytic complex by recruiting to the complex the substrates for proteolysis. The ATP requirement is to unfold and denature the proteins targeted for destruction. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

Many proteins that contain regions rich in the amino acids proline (P), glutamate (E), serine (S), and threonine (T) have short half-lives. These regions are known as PEST sequences, based on the one-letter abbreviations used for these amino acids. Most of the proteins that contain PEST sequences are hydrolyzed by the ubiquitin–proteasome system.

CLINICAL COMMENTS

Susan F.'s growth and weight curves were both subnormal until her pediatrician added pancreatic enzyme supplements to her treatment plan. These supplements digest dietary protein, releasing essential and other amino acids from the dietary protein, which are then absorbed by the epithelial cells of **Susan F.**'s small intestine, through which they are transported into the blood. A discernable improvement in her body weight and growth curves was noted within months of starting this therapy.

Besides the proportions of essential amino acids present in various foods, the quality of a dietary protein is also determined by the rate at which it is digested and, in a more general way, by its capacity to contribute to the growth of the infant. In this regard, the proteins in foods of animal origin are more digestible than are those derived from plants. For example, the digestibility of proteins in eggs is approximately 97%; that of meats, poultry, and fish is 85% to 100%, and that from wheat, soybeans, and other legumes ranges from 75% to 90%.

The official daily dietary **protein requirement** accepted by the U.S. and Canadian governments is 0.8 g of protein per kilogram of desirable body weight for adults (~56 g for an adult man and 44 g for an adult woman). On an average weight basis, the requirement per kilogram is much greater for infants and children. This fact underscores the importance of improving **Susan F.**'s protein digestion to optimize her potential for normal growth and development.

David K. In patients with cystinuria, such as **David K.**, the inability to normally absorb cystine and basic

amino acids from the gut and the increased loss of these amino acids in the urine may be expected to cause a deficiency of these compounds in the blood. However, because three of these amino acids can be synthesized in the body (i.e., they are nonessential amino acids), their concentrations in the plasma remain normal, and clinical manifestations of a deficiency state do not develop. It is not clear why symptoms related to a lysine deficiency have not been observed.

In another disorder with a transport defect, that was first observed in the Hartnup family and bears their name, the intestinal and renal transport defect involves the neutral amino acids (monoamine, monocarboxylic acids), including several essential amino acids (isoleucine, leucine, phenylalanine, threonine, tryptophan, and valine) as well as certain nonessential amino acids (alanine, serine, and tyrosine). A reduction in the availability of these essential amino acids may be expected to cause a variety of clinical disorders. Yet children with the Hartnup disorder, which can be identified by routine newborn urine screening, almost always remain clinically normal.

However, some patients with the Hartnup biochemical phenotype may eventually develop pellagra-like manifestations, which usually include a photosensitivity rash, ataxia, and neuropsychiatric symptoms. Pellagra results from a dietary deficiency of the vitamin niacin or the essential amino acid tryptophan, which are both precursors for the nicotinamide moiety of nicotinamide adenine dinucleotide (NAD) and NAD phosphate (NAD[P]). In asymptomatic patients, the transport abnormality may be incomplete and so subtle as to allow no phenotypic expression of Hartnup disease. These patients may also be capable of absorbing some small peptides that contain the neutral amino acids.

The only rational treatment for patients who have pellagra-like symptoms is to administer niacin (nicotinic acid) in oral doses up to 300 mg/day. Although the rash, ataxia, and neuropsychiatric manifestations of niacin deficiency may disappear, the hyperaminoaciduria and intestinal transport defect do not respond to this therapy. In addition to niacin, a high-protein diet may benefit some patients.

BIOCHEMICAL COMMENTS

The γ -Glutamyl Cycle. The γ -glutamyl cycle is necessary for the synthesis of glutathione, a compound that protects cells from oxidative damage (see Chapter 25). When it was first discovered, the cycle was thought to be important in amino acid transport, but its involvement in such transport is now thought to be limited to salvage of cysteine. The enzymes of the cycle are present in many tissues, although certain tissues lack one or more of the enzymes of the cycle.

The entire cycle is presented in Figure 35.7. In this case, the extracellular amino acid reacts with glutathione (γ -glutamyl-cysteinyl-glycine) in a reaction catalyzed by a transpeptidase present in the cell membrane. A γ -glutamyl amino acid is formed, which travels across the cell membrane and releases the amino acid into the cell. The other products of these two reactions are reconverted to glutathione.

FIGURE 35.7 The γ -glutamyl cycle. In cells of the intestine and kidney, amino acids can be transported across the cell membrane by reacting with glutathione (γ -glutamyl-cysteinyl-glycine) to form a γ -glutamyl amino acid. The amino acid is released into the cell, and glutathione is resynthesized. However, the major role of this cycle is glutathione synthesis, because many tissues lack the transpeptidase and 5-oxoprolinase activities. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i , inorganic phosphate.

The reactions that convert glutamate to glutathione in the γ -glutamyl cycle are the same reactions as those required for the synthesis of glutathione. The enzymes for glutathione synthesis, but not the transpeptidase, are found in most tissues. The oxoprolinase is also missing from many tissues, so the major role of this pathway is one of glutathione synthesis from glutamate, cysteine, and glycine. The transpeptidase is the only protease in the cell that can break the γ -glutamyl linkage in glutathione. Glutathione is also involved in reducing compounds such as hydrogen peroxide (see Chapter 25). It also protects cells, particularly erythrocytes, from oxidative damage, through formation of oxidized glutathione, two glutathione residues connected by a disulfide bond (see Chapter 25).

KEY CONCEPTS

- ◆ Proteases (proteolytic enzymes) break down dietary proteins into peptides and then their constituent amino acids in the stomach and intestine.
- ◆ Pepsin initiates protein breakdown in the stomach.
- ◆ Upon entering the small intestine, inactive zymogens secreted from the pancreas are activated to continue protein digestion.
- ◆ Enzymes produced by the intestinal epithelial cells are also required to fully degrade proteins.
- ◆ The amino acids generated by proteolysis in the intestinal lumen are transported into the intestinal epithelial cells, from which they enter the circulation for use by the tissues.
- ◆ Transport systems for amino acids are similar to transport systems for monosaccharides; both facilitative and active transport systems exist.

- ◆ There are several overlapping transport systems for amino acids in cells.
- ◆ Protein degradation (turnover) occurs continuously in all cells.
- ◆ Proteins can be degraded by lysosomal enzymes (cathepsins).
- ◆ Proteins are also targeted for destruction by being covalently linked to the small protein ubiquitin.
- ◆ The ubiquitin-tagged proteins interact with the proteasome, a large complex that degrades proteins to small peptides in an ATP-dependent process.
- ◆ Amino acids released from proteins during turnover can be used for the synthesis of new proteins, for energy generation, or for gluconeogenesis.
- ◆ Diseases discussed in the chapter are summarized in Table 35.3.

TABLE 35.3 Diseases Discussed in Chapter 35

DISEASE OR DISORDER	GENETIC OR ENVIRONMENTAL	COMMENTS
Cystic Fibrosis	Genetic	Patients with cystic fibrosis often experience a blockage of the pancreatic duct, which necessitates oral ingestion of digestive enzymes for appropriate nutrient degradation and absorption.
Cystinuria	Genetic	A mutation in a membrane transport protein (B^{0+}) for basic amino acids, including cystine, which is expressed in the kidney and intestine. Kidney stones may develop due to this disorder.
Kwashiorkor	Environmental	Protein–calorie malnutrition (diet is adequate in calories, but lacking in protein), leading to excessive protein degradation in the muscles and edema.
Hartnup disease	Genetic	A mutation in a membrane transport protein (B^0) for neutral amino acids, including tryptophan, which is expressed in both the kidney and intestine. Some patients may develop pellagra-like symptoms, due to the lack of tryptophan and inability to synthesize adequate amounts of $NAD(P)^+$.

NAD(P), nicotinamide adenine dinucleotide phosphate.

REVIEW QUESTIONS—CHAPTER 35

- An individual with a deficiency in the conversion of trypsinogen to trypsin would be expected to experience a more detrimental effect on protein digestion than an individual who was defective in any of the other digestive proteases. This is a result of which of the following?
 - Trypsin has a greater and wider range of substrates on which to act.
 - Trypsin activates pepsinogen, so digestion can begin in the stomach.
 - Trypsin activates the other zymogens that are secreted by the pancreas.
 - Trypsin activates enteropeptidase, which is needed to activate the other pancreatic zymogens.
 - Trypsin inhibits intestinal motility, so the substrates can be hydrolyzed for longer periods.
- An individual has been shown to have a deficiency in an intestinal epithelial cell amino acid transport system for leucine. However, the individual shows no symptoms of amino acid deficiency. This could be due to which of the following?
 - The body synthesizes leucine to compensate for the transport defect.
 - The kidney reabsorbs leucine and sends it to other tissues.
 - There are multiple transport systems for leucine.
 - Isoleucine takes the place of leucine in proteins.
 - Leucine is not necessary for bulk protein synthesis.
- Kwashiorkor can result from which one of the following?
 - Consuming a calorie-deficient diet that is also deficient in protein
 - Consuming a calorie-adequate diet that is deficient in carbohydrates
 - Consuming a calorie-adequate diet that is deficient in fatty acids
 - Consuming a calorie-adequate diet that is deficient in proteins
 - Consuming a calorie-deficient diet that is primarily proteins
- Which one of the following enzymes is activated through an autocatalytic process?
 - Enteropeptidase

- B. Trypsinogen
 - C. Pepsinogen
 - D. Aminopeptidase
 - E. Proelastase
5. Children with kwashiorkor usually have a fatty liver. This is due to which one of the following?
 - A. The high-fat content of their diet
 - B. The high-carbohydrate content of their diet
 - C. The high-protein content of their diet
 - D. The lack of substrates for gluconeogenesis in the liver
 - E. The lack of substrates for protein synthesis in the liver
 - F. The lack of substrates for glycogen synthesis in the liver
 6. All of the nitrogen-containing compounds of the human body are synthesized from amino acids. Which one of the following statements about amino acid degradation is correct?
 - A. Amino acid carbons can be stored only as glycogen.
 - B. The liver is the only site of amino acid oxidation.
 - C. The nitrogen of oxidized branched-chain amino acids must travel to the liver for disposal.
 - D. The nitrogen of amino acids is always excreted as urea.
 - E. The nitrogen of amino acids is only excreted by the kidney.
 7. Proteases break down dietary proteins, and their release from the pancreas to the small intestine is often blocked in individuals with cystic fibrosis. Which one of the following is an example of a pancreatic protease?
 - A. Pepsin
 - B. Elastase
 - C. Aminopeptidase
 - D. Cathepsin
 - E. Ubiquitin
 8. A 38-year-old patient has developed chronic obstructive pulmonary disease (COPD) caused by an α -1-antitrypsin deficiency. Which one of the following correctly describes α -1-antitrypsin?
 - A. It is synthesized by the lung.
 - B. It is a protease enhancer.
 - C. It enhances the action of trypsin in the lung.
 - D. It blocks the action of elastase in the lung.
 - E. It blocks the action of trypsin in the lung.
 9. Proteolytic enzymes must be secreted as zymogens that are activated or they would auto-digest themselves and the organs that produce them. Trypsinogen, a zymogen, is cleaved to form trypsin by a protease that is secreted by which one of the following?
 - A. Stomach
 - B. Pancreas
 - C. Colon
 - D. Liver
 - E. Small intestine
 0. An adult patient is trying to increase his amount of muscle by ingesting protein-rich drinks daily without increasing his daily exercise routine. Which one of the following correctly describes a problem with this approach?
 - A. Dietary proteins in excess of bodily needs pass unchanged and unabsorbed into the feces.
 - B. Dietary proteins in excess of bodily needs pass unchanged in the urine.
 - C. Dietary proteins in excess of bodily needs feedback and shut down pancreatic enzymes.
 - D. Dietary proteins in excess of bodily needs are stored as amino acids in the liver.
 - E. Dietary proteins in excess of bodily needs are converted to glycogen and triacylglycerols for storage.
 1. The denaturation of proteins in the stomach due to the reduced pH is most beneficial for which protease to function in the intestine?
 - A. Pepsin
 - B. Enteropeptidase
 - C. Trypsin
 - D. Chymotrypsin
 - E. Caspase

2. A scientist was conducting experiments with an intestinal organoid system, in which the transport of various compounds, from the lumen of the organoid and across the epithelial cells, could be studied. When the scientist treated the organoids with a drug that blocked the activity of the Na^+ , K^+ -ATPase, the transport of which of the following compounds would be reduced? Choose the one best answer.

	Basic Amino Acids	Neutral Amino Acids	Glucose	Fatty Acids
A	Yes	Yes	Yes	Yes
B	Yes	No	No	No
C	Yes	Yes	Yes	No
D	No	No	No	No
E	No	Yes	Yes	Yes
F	No	No	No	Yes

3. Proteins derived from vegetable sources are considered low quality for humans, whereas proteins from animal sources are considered high quality. The high-quality proteins contain greater levels of which one of the following as compared to low-quality protein?
- Alanine
 - Arginine
 - Glycine
 - Lysine
 - Serine
4. A 5-year-old girl, whose parents were going through a divorce, developed a red, scaly, photosensitive rash on her face, arms, and legs. She had recently been sick with a fever before the rash appeared. The pediatrician examining the child recognized the dermatitis as being similar to that seen with pellagra. In order to confirm her suspicions, the pediatrician ordered a urinalysis. Which one of the following is likely to be elevated in the urine if the pediatrician is correct?
- Branched-chain fatty acids
 - Odd-chain fatty acids
 - Glucose
 - Neutral amino acids
 - Basic amino acids
5. Cigarette smoke contains hydrogen peroxide, which can react with methionine side chains in proteins to generate methionine sulfoxide, which usually alters the function of the protein (loss of activity). When this occurs to circulating α -1-antitrypsin in the lung, the body has an inability to protect the lungs from which of the following?
- Trypsin
 - Hydrogen peroxide
 - Superoxide
 - Elastase
 - Chymotrypsin

1. **The answer is C.** Trypsinogen, which is secreted by the intestine, is activated by enteropeptidase, a protein found in the intestine (thus, D is backward and incorrect). Once trypsin is formed, it activates all of the other zymogens secreted by the pancreas. Trypsin does not activate pepsinogen (thus, B is incorrect), because pepsinogen is found in the stomach and autocatalyzes its own activation when the pH drops as a result of acid secretion. Trypsin has no effect on intestinal motility (hence, E is incorrect) and also does not have a much broader base of substrates than any other protease (trypsin cleaves on the carboxyl side of basic side chains, lysine, and arginine; thus, A is incorrect).
2. **The answer is C.** Leucine can be transported by a number of different amino acid systems. Leucine is an essential amino acid, so the body cannot synthesize it (thus, A is incorrect). If the intestine cannot absorb leucine, then the kidneys do not have a chance to reabsorb it, so B is incorrect. Leucine and isoleucine have different structures and cannot substitute for each other in all positions within a protein; thus, D is incorrect. Leucine is an important component of proteins and is required for protein synthesis; hence, E is incorrect.
3. **The answer is D.** Kwashiorkor is a disease that results from eating a calorie-sufficient diet that lacks protein. None of the other answers is correct.
4. **The answer is C.** Pepsinogen, under acidic conditions, autocatalyzes its conversion to pepsin in the stomach. Both enteropeptidase and aminopeptidases are synthesized in active form by the intestine (thus, A and D are incorrect). Enteropeptidase activates trypsinogen (thus, B is incorrect), which then activates proelastase (thus, E is incorrect).
5. **The answer is E.** Because of the lack of protein in the diet, protein synthesis in the liver is impaired (lack of essential amino acids). The liver can still synthesize fatty acids from carbohydrate or fat sources, but very-low-density lipoprotein (VLDL) particles cannot be assembled because of the shortage of apolipoprotein B-100. Thus, the fatty acids remain in the liver, leading to a fatty liver. None of the other answers explains this finding.
6. **The answer is C.** Branched-chain amino acids can be oxidized in many tissues, but the nitrogen must travel to the liver for disposal. The muscle is the primary site of branched-chain amino acid oxidation due to the high level of the branched-chain α -ketoacid dehydrogenase in that tissue. Amino acid carbons can be oxidized directly, converted to glucose and then oxidized or stored as glycogen, or converted to fatty acids and stored as adipose triacylglycerols. Although urea is the major nitrogenous excretory product, nitrogen is also excreted in other compounds such as uric acid, creatinine, and ammonia. These compounds are excreted mostly in the urine, but substantial amounts are lost in feces and through the skin.
7. **The answer is B.** Pepsin is synthesized in the stomach. Trypsin, chymotrypsin, elastase, and carboxypeptidases are secreted from the pancreas into the small intestine. Aminopeptidases are found on the brush border of intestinal epithelial cells. Cathepsins degrade proteins that enter lysosomes. Ubiquitin is a small protein that is covalently linked to proteins targeted for turnover in the cytoplasm.
8. **The answer is D.** Elastase, found in neutrophils, can be released into the lung where it causes proteolytic destruction of normal lung cells, leading to emphysema. α -1-Antitrypsin is a protease inhibitor synthesized in the liver and released into the circulation that blocks the action of elastase in the lung. Trypsin is not found in the lung. α -1-Antitrypsin was named due to the fact that it will also inhibit trypsin activity, although that is not its physiologic function.
9. **The answer is E.** Trypsinogen is cleaved by the enzyme enteropeptidase, which is secreted by the brush border cells of the small intestine. Trypsin then cleaves chymotrypsinogen, proelastase, and procarboxypeptidase to their active forms. Pepsinogen is essentially autocatalytic in the presence of acid and is found in the stomach. Pepsin does not activate zymogens in the small intestine.
10. **The answer is E.** Proteins are constantly being synthesized and degraded. Only about 6% of protein that enters the GI tract is excreted in feces each day. The remainder is recycled. Excess proteins above dietary and metabolic needs are converted to glycogen and triacylglycerols for storage. The patient will gain weight as adipose tissue instead of increasing muscle mass.
11. **The answer is D.** Chymotrypsin cleaves on the carboxyl side of phenylalanine and tyrosine, amino acids with a hydrophobic side chain. As such, the phenylalanine and tyrosine side chains are often in the interior of globular proteins (in a hydrophobic environment), and chymotrypsin would be ineffective in cleaving peptide bonds in native proteins. Denaturation, however, destroys the secondary and tertiary structures of the protein, exposing the hydrophobic amino acids to the active site of proteases, including chymotrypsin. Pepsin is only active in the stomach at a low pH. Pepsin activity is reduced in the higher

pH environment of the intestine. Enteropeptidase is on the surface of the intestinal epithelial cells and cleaves trypsinogen specifically at lysine or arginine residues and works on the nondenatured form of trypsinogen. Trypsin also recognizes the basic amino acids, which are on the surface of globular proteins, so denaturation is not required for trypsin to cleave proteins. Caspases are found in all cells and are involved in apoptosis. Caspases target peptide bonds containing an aspartic acid, which is usually on the surface of globular proteins.

12. **The answer is C.** Inhibition of the Na^+ , K^+ -ATPase will not allow a sodium gradient to be created across the intestinal epithelial cell membrane. The lack of the gradient would block sodium-dependent transport systems from working, which includes the basic amino acid transport system, neutral amino acid system, and glucose transport. Fatty acid transport across the membrane is not dependent upon a sodium gradient (in the intestine, it occurs using mixed micelles with the bile acids).
13. **The answer is D.** High-quality protein contains higher levels of the amino acids considered essential for the human diet. Of the amino acids listed, lysine is the only one that is essential for the human diet.
14. **The answer is D.** The child most likely has Hartnup disease, which results from a mutation in the B^0 system of amino acid transport (neutral amino acids). Pellagra is due to a lack of niacin in the diet (so there is difficulty in synthesizing NAD(P)^+). Tryptophan metabolism can also lead to nicotinamide synthesis, and when the tryptophan transport system is altered, there could be a deficiency in NAD(P) synthesis. Episodes of Hartnup disease can occur during stress (the child's parent undergoing a divorce) and during recovery from the disease (the fever the child had prior to the rash presenting).
15. **The answer is D.** Neutrophils in the lung utilize elastase to aid in destroying engulfed material, and occasionally, elastase can be released from the neutrophil into the lung. In order to protect the lung from being digested by the elastase, α -1-antitrypsin, synthesized and secreted from the liver into the blood, binds to the elastase and inactivates elastase activity. The loss of α -1-antitrypsin activity in smokers leads to the increased incidence of emphysema in smokers as compared to the general population. α -1-Antitrypsin does not protect against reactive oxygen species (such as hydrogen peroxide and superoxide), nor does it protect the lungs from trypsin or chymotrypsin, as those enzymes are not released in the lungs.

Fate of Amino Acid Nitrogen: Urea Cycle

In comparison with carbohydrate and lipid metabolism, the metabolism of amino acids is complex. We must be concerned not only with the fate of the carbon atoms of the amino acids but also with the fate of the **nitrogen**. During their metabolism, amino acids travel in the blood from one tissue to another. Ultimately, most of the nitrogen is converted to **urea** in the **liver** and the carbons are oxidized to CO_2 and H_2O by a number of tissues (Fig. 36.1).

FIGURE 36.1 Fate of amino acid carbons and nitrogen. Amino acid carbon can be used either for energy storage (glycogen, fatty acids) or for energy. Amino acid nitrogen is used for urea synthesis. One nitrogen of urea comes from NH_4^+ , the other from aspartate.

After a meal that contains protein, amino acids released by digestion (see Chapter 35) pass from the gut through the hepatic portal vein to the liver (see Fig. 36.2A). In a normal diet containing 60 to 100 g protein, most of the amino acids are used for the synthesis of proteins in the liver and in other tissues. Excess amino acids may be converted to glucose or triacylglycerol.

FIGURE 36.2 Roles of various tissues in amino acid metabolism. **A.** In the fed state, amino acids released by digestion of dietary proteins travel through the hepatic portal vein to the liver, where they are used for the synthesis of proteins, particularly the blood proteins, such as serum albumin. The carbon skeletons of excess amino acids are converted to glucose or to triacylglycerols. The latter are then packaged and secreted in VLDL. The glucose produced from amino acids in the fed state is stored as glycogen or released into the blood if blood glucose levels are low. Amino acids that pass through the liver are converted to proteins in cells of other tissues. **B.** During fasting, amino acids are released from muscle protein. Some enter the blood directly. Others are partially oxidized and the nitrogen stored in the form of alanine and glutamine, which enter the blood. In the kidney, glutamine releases ammonia into the urine and is converted to alanine and serine. In the cells of the gut, glutamine is converted to alanine. Alanine (the major gluconeogenic amino acid) and other amino acids enter the liver, where their nitrogen is converted to urea, which is excreted in the urine, and their carbons are converted to glucose and ketone bodies, which are oxidized by various tissues for energy. RBCs, red blood cells; TCA, tricarboxylic acid; VLDL, very-low-density lipoproteins.

During fasting, muscle protein is cleaved to amino acids. Some of the amino acids are partially oxidized to produce energy (see Fig. 36.2B). Portions of these amino acids are converted to **alanine** and **glutamine**, which, along with other amino acids, are released into the blood. Glutamine is oxidized by various tissues, including the **lymphocytes**, **gut**, and **kidney**, which convert some of the carbons and nitrogen to alanine. Alanine and other amino acids travel to the liver, where the carbons are converted to glucose and ketone bodies and the nitrogen is converted to urea, which is excreted by the kidneys. Glucose, produced by gluconeogenesis, is subsequently oxidized to CO_2 and H_2O by many tissues, and ketone bodies are oxidized by tissues such as muscle and kidney.

Several enzymes are important in the process of interconverting amino acids and in removing nitrogen so that the carbon skeletons can be oxidized. These include **dehydratases**, **transaminases**, **glutamate dehydrogenase**, **glutaminase**, and **deaminases**.

The conversion of amino acid nitrogen to urea occurs mainly in the liver. Urea is formed in the urea cycle from NH_4^+ , bicarbonate, and the nitrogen of **aspartate** (see Fig. 36.1). Initially, NH_4^+ , bicarbonate, and adenosine triphosphate (ATP) react to produce **carbamoyl phosphate**, which reacts with **ornithine** to form **citrulline**. Aspartate then reacts with citrulline to form **argininosuccinate**, which releases **fumarate**, forming **arginine**. Finally, **arginase** cleaves arginine to release urea and regenerate ornithine. The cycle is regulated in a **feed-forward** manner, such that when amino acid degradation is occurring, the rate of the cycle is increased. The urea cycle spans two compartments in the cell; the mitochondria (where carbamoyl phosphate and citrulline are produced) and the cytoplasm (where the remainder of the cycle takes place).

THE WAITING ROOM

Percy V. and his high school friend decided to take a Caribbean cruise, during which they sampled the cuisine of many of the islands on their itinerary. One month after their return to the United States, **Percy V.** complained of severe malaise, loss of appetite, nausea, vomiting, headache, and abdominal pain. He had a low-grade fever and noted a persistent and increasing pain in the area of his liver. After a few days, his urine turned the color of iced tea and his stool became a light-clay color. Soon after this, his friend noted a yellow discoloration of the whites of **Percy V.**'s eyes and skin. He went to see his family physician, who found his liver to be enlarged and tender. Liver function tests were ordered.

Serologic testing for viral hepatitis types B and C were nonreactive, but tests for antibodies to antigens of the hepatitis A virus (anti-HAV) in the serum were positive for the immunoglobulin M type.

A diagnosis of acute viral hepatitis type A was made, probably contracted from virus-contaminated food **Percy V.** had eaten while on his cruise. His physician explained that there was no specific treatment for type-A viral hepatitis but recommended symptomatic and supportive care and prevention of transmission to others by the fecal–oral route. He took acetaminophen three to four times a day for fever and headaches throughout his illness.

I. Fate of Amino Acid Nitrogen

A. Transamination Reactions

Transamination is the major process for removing nitrogen from amino acids. In most instances, the nitrogen is transferred as an amino group from the original amino acid to α -ketoglutarate, forming glutamate, whereas the original amino acid is converted to its corresponding α -keto acid (Fig. 36.3). For example, the amino acid aspartate can be transaminated to form its corresponding α -keto acid, oxaloacetate. In the process, the amino group is transferred to α -ketoglutarate, which is converted to its corresponding amino acid, glutamate.

A

B

FIGURE 36.3 Transamination. The amino group from one amino acid is transferred to another. Pairs of amino acids and their corresponding α -keto acids are involved in these reactions. α -Ketoglutarate and glutamate are usually one of the pairs. The reactions, which are readily reversible, use PLP as a cofactor. The enzymes are called transaminases or aminotransferases. **A.** A generalized reaction. **B.** The aspartate transaminase reaction. PLP, pyridoxal phosphate.

All amino acids except lysine and threonine undergo transamination reactions. The enzymes that catalyze these reactions are known as transaminases or aminotransferases. For most of these reactions, α -ketoglutarate and glutamate serve as one of the α -keto acid–amino acid pairs. Pyridoxal phosphate (PLP; derived from vitamin B₆) is the required cofactor for these reactions.

Overall, in a transamination reaction, an amino group from one amino acid becomes the amino group of a second amino acid. Because these reactions are readily reversible, they can be used to remove nitrogen from amino acids or to transfer nitrogen to α -keto acids to form amino acids. Thus, they are involved both in amino acid degradation and in amino acid synthesis. The mechanism of a transamination reaction is available online, in the supplemental material. 

B. Removal of Amino Acid Nitrogen as Ammonia

Cells in the body and bacteria in the gut release the nitrogen of certain amino acids as ammonia or ammonium ion (NH_4^+) (Fig. 36.4). Because these two forms of nitrogen can be interconverted, the terms are sometimes used interchangeably. Ammonium ion releases a proton to form ammonia by a reaction with a $\text{p}K_a$ of 9.3. Therefore, at physiologic pH, the equilibrium favors NH_4^+ by a factor of approximately 100/1 (see Chapter 4, the Henderson–Hasselbalch equation). However, it is important to note that NH_3 is also present in the body, because this is the form that can cross cell membranes. For example, NH_3 passes into the urine from kidney tubule cells and decreases the acidity of the urine by binding protons, forming NH_4^+ . Once the NH_4^+ is formed, the compound can no longer freely diffuse across membranes.

FIGURE 36.4 Summary of the sources of NH_4^+ for the urea cycle. All of the reactions are irreversible except that of GDH. Only the dehydratase reactions, which produce NH_4^+ from serine and threonine, require PLP as a cofactor. The reactions that are not shown occurring in the muscle or the gut can all occur in the liver, where the NH_4^+ generated can be converted to urea. The purine nucleotide cycle of the brain and muscle is described further in Chapter 39. GDH, glutamate dehydrogenase; NAD, nicotinamide adenine dinucleotide; PLP, pyridoxal phosphate.

Percy V.'s laboratory studies showed that his serum alanine transaminase (ALT) level was 875 U/L (reference range, 5 to 30 U/L), and his serum aspartate transaminase (AST) level was 801 U/L (reference range, 10 to 30 U/L). His serum alkaline phosphatase level was 313 U/L (reference range for an adult male, 40 to 125 U/L), and his serum total bilirubin was 9.6 mg/dL (reference range, 0.2 to 1.0 mg/dL). Bilirubin is a degradation product of heme, as described in Chapter 42.

Cellular enzymes such as AST, ALT, and alkaline phosphatase leak into the blood through the membranes of hepatic cells that have been damaged as a result of the inflammatory process. In acute viral hepatitis, the serum ALT level is often elevated to a greater extent than the serum AST level. Alkaline phosphatase, which is present on membranes between liver cells and the bile duct, is also elevated in the blood in acute viral hepatitis.

The rise in serum total bilirubin occurs as a result of the inability of the infected liver to conjugate bilirubin and of a partial or complete occlusion of the hepatic biliary drainage ducts caused by inflammatory swelling within the liver. In fulminant hepatic failure, the serum bilirubin level may exceed 20 mg/dL, a poor prognostic sign.

Glutamate is oxidatively deaminated by a reaction catalyzed by glutamate dehydrogenase that produces

ammonium ion and α -ketoglutarate (Fig. 36.5). Either NAD^+ or NADP^+ can serve as the cofactor. This reaction, which occurs in the mitochondria of most cells, is readily reversible; it can incorporate ammonia into glutamate or release ammonia from glutamate. Glutamate can collect nitrogen from other amino acids as a consequence of transamination reactions and then release ammonia through the glutamate dehydrogenase reaction. This process provides one source of the ammonia that enters the urea cycle. Glutamate dehydrogenase is one of four mammalian enzymes that can “fix” ammonia into organic molecules. The other three are glutamine synthetase, carbamoyl phosphate synthetase I (CPSI), and the glycine cleavage enzyme (also known as glycine synthase).

FIGURE 36.5 Reaction catalyzed by glutamate dehydrogenase. This reaction is readily reversible and can use either NAD^+ or NADP^+ as a cofactor. The oxygen on α -ketoglutarate is derived from H_2O . NAD, nicotinamide adenine dinucleotide.

In addition to glutamate, a number of amino acids release their nitrogen as NH_4^+ (see Fig. 36.4). Histidine may be directly deaminated to form NH_4^+ and urocanate. The deaminations of serine and threonine are dehydration reactions that require PLP and are catalyzed by serine dehydratase. Serine forms pyruvate, and threonine forms α -ketobutyrate. In both cases, NH_4^+ is released.

Glutamine and asparagine contain R-group amides that may be released as NH_4^+ by deamidation. Asparagine is deamidated by asparaginase, yielding aspartate and NH_4^+ . Glutaminase acts on glutamine, forming glutamate and NH_4^+ . The glutaminase reaction is particularly important in the kidney, where the ammonium ion produced is excreted directly into the urine, where it forms salts with metabolic acids, facilitating their removal in the urine.

 Vitamin B_6 deficiency symptoms include dermatitis, a microcytic, hypochromic anemia, weakness, irritability, and, in severe cases, seizures. Xanthurenic acid (a degradation product of tryptophan) and other compounds appear in the urine because of an inability to completely metabolize amino acids. A decreased ability to synthesize heme from glycine may cause the microcytic anemia (see Chapter 42), and decreased decarboxylation of amino acids to form neurotransmitters (see Chapter 46) may explain the convulsions. Although vitamin B_6 is required for a large number of reactions involved in amino acid metabolism, it is also required for the glycogen phosphorylase reaction (see Chapter 27).

In muscle and brain, but not in liver, the purine nucleotide cycle allows NH_4^+ to be released from amino acids (see Fig. 36.4). Nitrogen is collected by glutamate from other amino acids by means of transamination reactions. Glutamate then transfers its amino group to oxaloacetate to form aspartate, which supplies nitrogen to the purine nucleotide cycle (see Chapter 39). The reactions of the cycle release fumarate and NH_4^+ . The ammonium ion formed can leave the muscle in the form of glutamine.

In summary, NH_4^+ that enters the urea cycle is produced in the body by deamination or deamidation of amino acids (see Fig. 36.4). A significant amount of NH_4^+ is also produced by bacteria that live in the lumen of the intestinal tract. This ammonium ion enters the hepatic portal vein and travels to the liver.

C. Role of Glutamate in the Metabolism of Amino Acid Nitrogen

Glutamate plays a pivotal role in the metabolism of amino acids. It is involved in both synthesis and degradation.

Glutamate provides nitrogen for amino acid synthesis (Fig. 36.6). In this process, glutamate obtains its nitrogen either from other amino acids by transamination reactions or from NH_4^+ by the glutamate dehydrogenase reaction. Transamination reactions then serve to transfer amino groups from glutamate to α -keto acids to produce their corresponding amino acids.

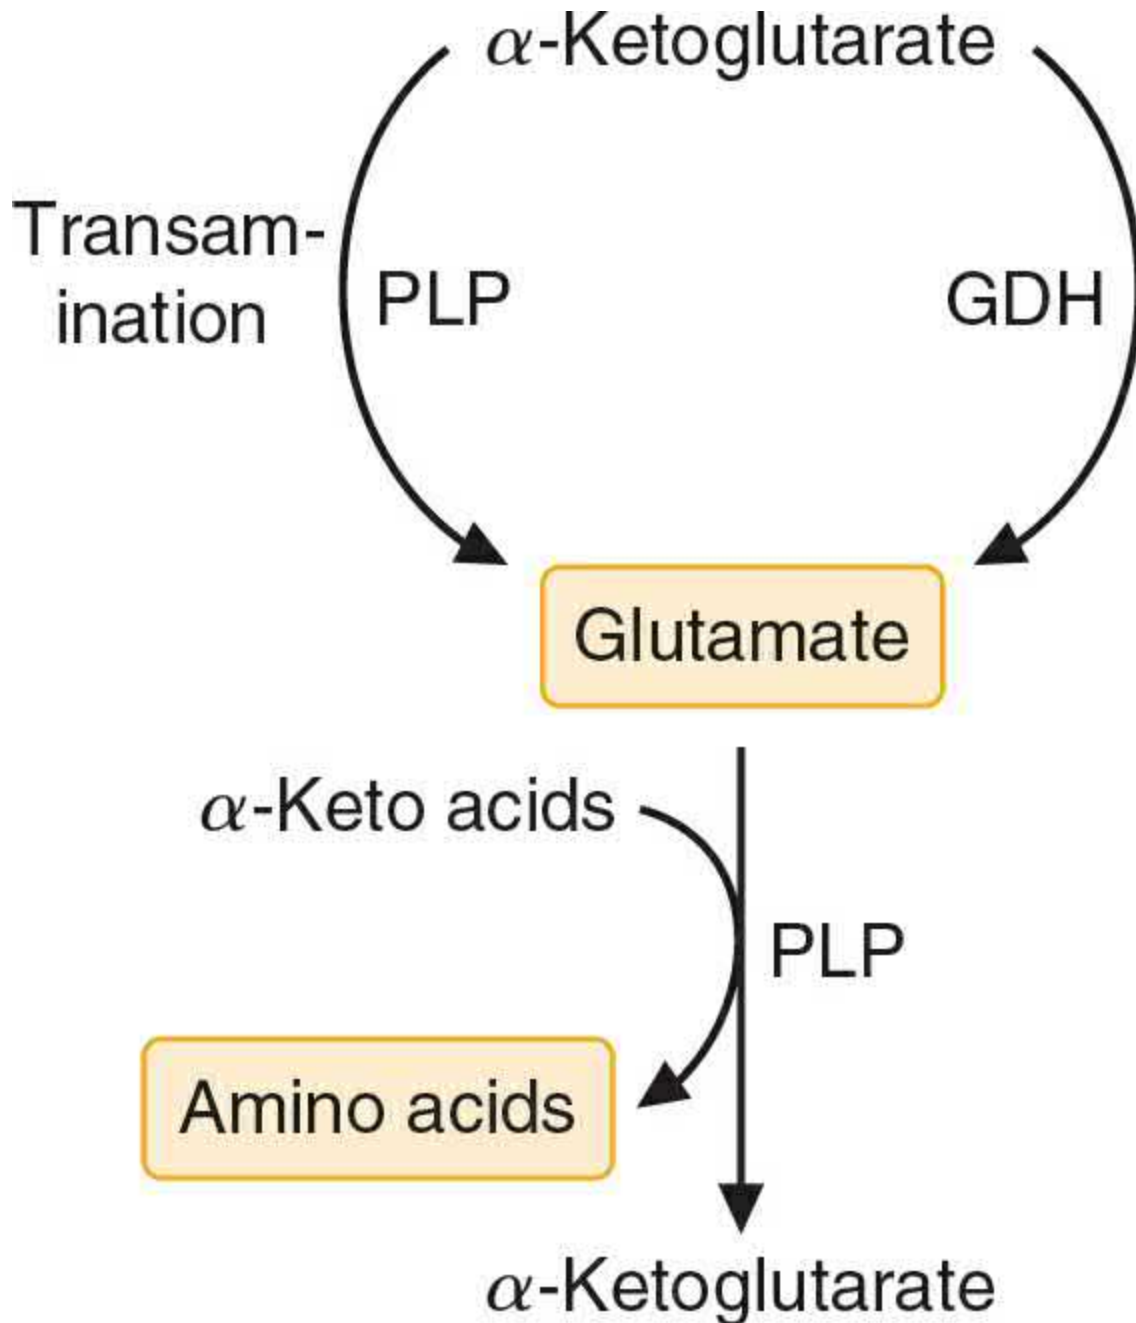

FIGURE 36.6 Role of glutamate in amino acid synthesis. Glutamate transfers nitrogen by means of transamination reactions to α -keto acids to form amino acids. This nitrogen is either obtained by glutamate from transamination of other amino acids or from NH_4^+ by means of the GDH reaction. GDH, glutamate dehydrogenase; PLP, pyridoxal phosphate, the active form of vitamin B₆ (pyridoxine).

When amino acids are degraded and urea is formed, glutamate collects nitrogen from other amino acids by transamination reactions. Some of this nitrogen is released as ammonia by the glutamate dehydrogenase

reaction, but much larger amounts of ammonia are produced from the other sources shown in Figure 36.4. NH_4^+ is one of the two forms in which nitrogen enters the urea cycle (Fig. 36.7).

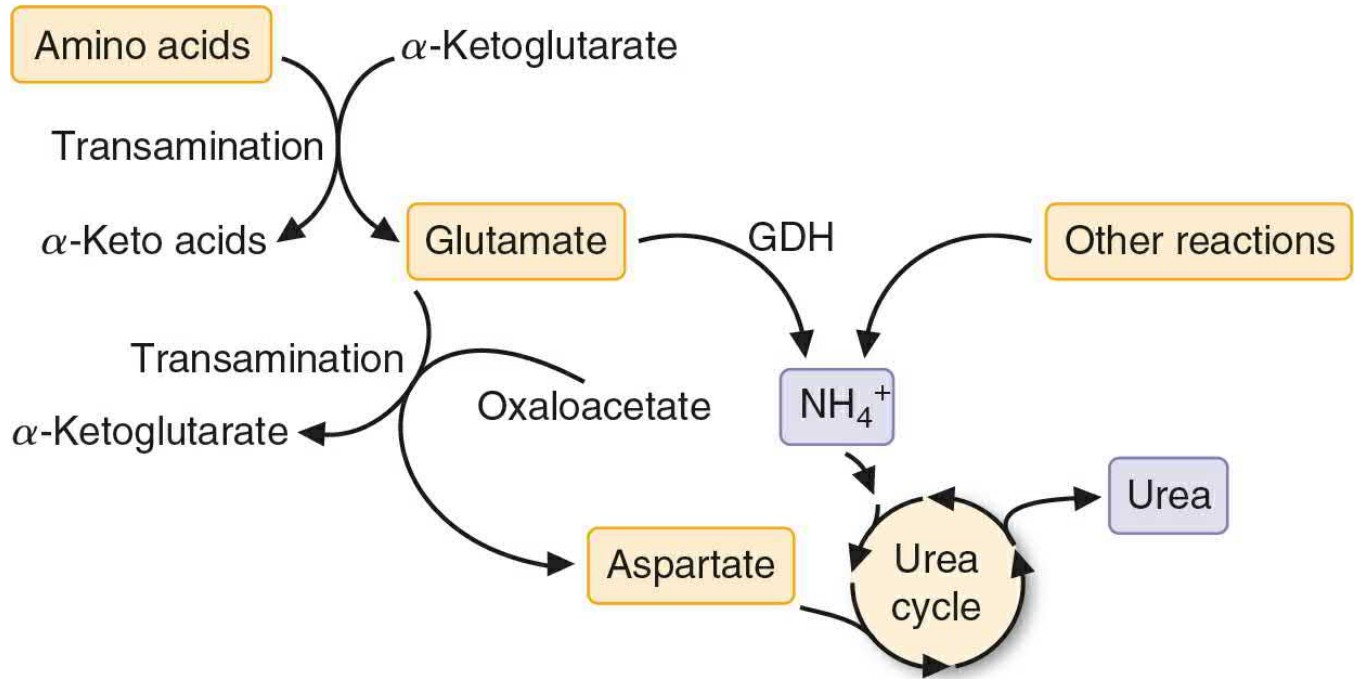

FIGURE 36.7 Role of glutamate in urea production. Glutamate collects nitrogen from other amino acids by transamination reactions. This nitrogen can be released as NH_4^+ by GDH. NH_4^+ is also produced by other reactions (see Fig. 36.4). NH_4^+ provides one of the nitrogens for urea synthesis. The other nitrogen comes from aspartate and is obtained from glutamate by transamination of oxaloacetate. GDH, glutamate dehydrogenase.

The second form of nitrogen for urea synthesis is provided by aspartate (see Fig. 36.7). Glutamate can be the source of the nitrogen. Glutamate transfers its amino group to oxaloacetate, and aspartate and α -ketoglutarate are formed.

D. Role of Alanine and Glutamine in Transporting Amino Acid Nitrogen to the Liver

Protein turnover and amino acid degradation occur in all tissues; however, the urea-cycle enzymes are active primarily in the liver (the intestine expresses low levels of activity of these enzymes; see Chapter 40). Thus, a mechanism needs to be in place to transport amino acid nitrogen to the liver. Alanine and glutamine are the major carriers of nitrogen in the blood. Alanine is primarily exported by muscle. Because the muscle is metabolizing glucose through glycolysis, pyruvate is available in the muscle. The pyruvate is transaminated by glutamate to form alanine, which travels to the liver (Fig. 36.8). The glutamate is formed by transamination of an amino acid that is being degraded. Upon arriving at the liver, alanine is transaminated to pyruvate, and the nitrogen is used for urea synthesis. The pyruvate formed is used for gluconeogenesis and the glucose exported to the muscle for use as energy. This cycle of moving carbons and nitrogen between the muscle and liver is known as the **glucose–alanine cycle**.

FIGURE 36.8 The glucose–alanine cycle. Within the muscle, amino acid degradation leads to the transfer of nitrogens to α -KG and pyruvate. The alanine formed travels to the liver, where the carbons of alanine are used for gluconeogenesis and the alanine nitrogen is used for urea biosynthesis. This could occur during exercise, when the muscle uses blood-borne glucose (see Chapter 45). α -KG, α -ketoglutarate.

Glutamine is synthesized from glutamate by the fixation of ammonia, requiring energy (ATP) and the enzyme glutamine synthetase (Fig. 36.9), which is a cytoplasmic enzyme found in all cells. In the liver, glutamine synthetase is located in cells surrounding the portal vein. Its major role is to convert any ammonia that has escaped from urea production into glutamine, so that free ammonia does not leave the liver and enter the circulation.

FIGURE 36.9 Synthesis of glutamine in peripheral tissues and its transport to the liver. Within the liver, glutaminase converts glutamine to glutamate. Note how α -KG can accept two molecules of ammonia to form glutamine. α -KG, α -ketoglutarate; ADP, adenosine diphosphate; ATP, adenosine triphosphate; GDH, glutamate dehydrogenase; P_i , inorganic phosphate.

Under conditions of rapid amino acid degradation within a tissue, so that ammonia levels increase, the glutamate that has been formed from transamination reactions accepts another nitrogen molecule to form glutamine. The glutamine travels to the liver, kidney, or intestines, where glutaminase (see Fig. 36.9) will remove the amide nitrogen to form glutamate plus ammonia. In the kidney, the release of ammonia, and the formation of ammonium ion, serves to form salts with metabolic acids in the urine. In the intestine, the glutamine is used as a fuel (see Chapter 40). In the liver, the ammonia is used for urea biosynthesis.

II. Urea Cycle

The normal human adult is in nitrogen balance; that is, the amount of nitrogen ingested each day, mainly in the form of dietary protein, is equal to the amount of nitrogen excreted. The major nitrogenous excretory product is urea, which exits from the body in the urine. This innocuous compound, produced mainly in the liver by the urea cycle, serves as the disposal form of ammonia, which is toxic, particularly to the brain and central nervous system (CNS). Normally, little ammonia (or NH_4^+) is present in the blood. The concentration ranges between 30 and 60 μM . Ammonia is rapidly removed from the blood and converted to urea by the liver. Nitrogen travels in the blood mainly in amino acids, particularly alanine and glutamine. The urea cycle was proposed in 1932 by Hans Krebs and a medical student, Kurt Henseleit, based on their laboratory observations. It was originally

called the Krebs–Henseleit cycle. Subsequently, Krebs used this concept of metabolic cycling to explain a second process that also bears his name, the Krebs (or tricarboxylic acid [TCA]) cycle.

Percy V.'s symptoms and laboratory abnormalities did not slowly subside over the next 6 weeks, as they usually do in uncomplicated viral hepatitis A infections. Instead, his serum total bilirubin, ALT, AST, and alkaline phosphatase levels increased further. His vomiting became intractable, and his friend noted jerking motions of his arms (asterixis), facial grimacing, restlessness, slowed mentation, and slight disorientation. He was admitted to the hospital with a diagnosis of acute liver failure with hepatic encephalopathy (brain dysfunction caused by accumulation of various toxins in the blood), a rare complication of acute type-A viral hepatitis alone. The possibility of a superimposed acute hepatic toxicity caused by the use of acetaminophen was considered.

A. Reactions of the Urea Cycle

Nitrogen enters the urea cycle as NH_4^+ and aspartate (Fig. 36.10). NH_4^+ forms carbamoyl phosphate, which reacts with ornithine to form citrulline. Ornithine is the compound that both initiates and is regenerated by the cycle (similar to oxaloacetate in the TCA cycle). Aspartate reacts with citrulline, eventually donating its nitrogen for urea formation. Arginine is formed in two successive steps. Cleavage of arginine by arginase releases urea and regenerates ornithine.

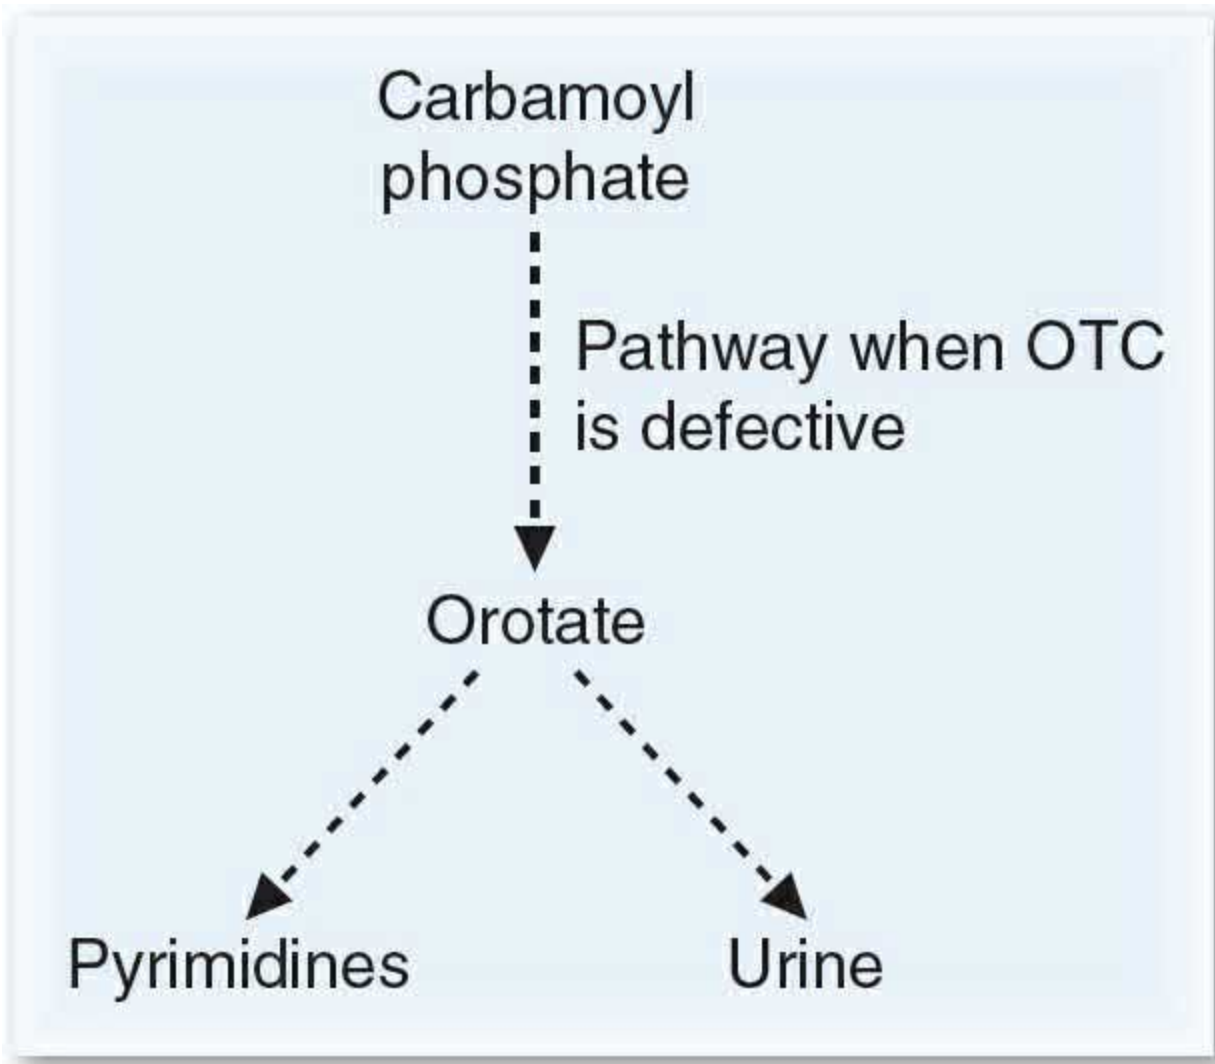

FIGURE 36.10 Urea cycle. The steps of the cycle are numbered 1 through 5. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; P_i , inorganic phosphate.

1. Synthesis of Carbamoyl Phosphate

In the first step of the urea cycle, NH_4^+ , bicarbonate, and ATP react to form carbamoyl phosphate (see Fig. 36.10). The cleavage of two molecules of ATP is required to form the high-energy phosphate bond of carbamoyl phosphate. CPSI, the enzyme that catalyzes this first step of the urea cycle, is found mainly in mitochondria of the liver and intestine. The Roman numeral suggests that another carbamoyl phosphate synthetase exists, and indeed, CPSII, located in the cytosol, produces carbamoyl phosphate for pyrimidine biosynthesis, using nitrogen from glutamine (see Chapter 39).

When OTC is deficient, the carbamoyl phosphate that normally would enter the urea cycle accumulates and floods the pathway for pyrimidine biosynthesis. Carbamoyl phosphate, produced by a cytoplasmic enzyme (CPSII), is the precursor for pyrimidine synthesis. Under these conditions, excess orotic acid (orotate), an intermediate in pyrimidine biosynthesis, is excreted in the urine. It produces no ill effects, but is indicative of a problem in the urea cycle.

2. Production of Arginine by the Urea Cycle

Carbamoyl phosphate reacts with ornithine to form citrulline (see Fig. 36.10). The high-energy phosphate bond of carbamoyl phosphate provides the energy required for this reaction, which occurs in mitochondria and is catalyzed by ornithine transcarbamoylase (OTC). The product citrulline is transported across the mitochondrial membranes in exchange for cytoplasmic ornithine and enters the cytosol. The carrier for this transport reaction catalyzes an electroneutral exchange of the two compounds.

In the cytosol, citrulline reacts with aspartate, the second source of nitrogen for urea synthesis, to produce argininosuccinate (see Fig. 36.10). This reaction, catalyzed by argininosuccinate synthetase, is driven by the hydrolysis of ATP to adenosine monophosphate (AMP) and pyrophosphate. Aspartate is produced by transamination of oxaloacetate.

Argininosuccinate is cleaved by argininosuccinate lyase to form fumarate and arginine (see Fig. 36.10). Fumarate is produced from the carbons of argininosuccinate provided by aspartate. Fumarate is converted to malate (using cytoplasmic fumarase), which is used either for the synthesis of glucose by the gluconeogenic pathway or for the regeneration of oxaloacetate by cytoplasmic reactions similar to those observed in the TCA cycle (Fig. 36.11). The oxaloacetate that is formed is transaminated to generate the aspartate that carries nitrogen into the urea cycle. Thus, the carbons of fumarate can be recycled to aspartate.

FIGURE 36.11 The Krebs bi-cycle, indicating the common steps between the TCA and urea cycles. All reactions shown occur in the cytoplasm except for the synthesis of citrulline, which occurs in the mitochondria. NAD, nicotinamide adenine dinucleotide; TCA, tricarboxylic acid.

3. Cleavage of Arginine to Produce Urea

Arginine, which contains nitrogens derived from NH_4^+ and aspartate, is cleaved by arginase, producing urea and regenerating ornithine (see Fig. 36.10). Urea is produced from the guanidinium group on the side chain of arginine. The portion of arginine originally derived from ornithine is reconverted to ornithine.

The reactions by which citrulline is converted to arginine and arginine is cleaved to produce urea occur in the cytosol. Ornithine, the other product of the arginase reaction, is transported into the mitochondrion in exchange for citrulline, where it can react with carbamoyl phosphate, initiating another round of the cycle.

B. Origin of Ornithine

Ornithine is an amino acid. However, it is not incorporated into proteins during the process of protein synthesis because no genetic codon exists for this amino acid. Although ornithine is normally regenerated by the urea cycle (as one of the products of the arginase reaction), ornithine also can be synthesized *de novo* if needed. The reaction is an unusual transamination reaction catalyzed by ornithine aminotransferase under specific conditions in the intestine (Fig. 36.12). The usual direction of this reaction is the formation of glutamate semialdehyde, which is the first step of the degradation pathway for ornithine.

The precise pathogenesis of the CNS signs and symptoms that accompany liver failure (hepatic encephalopathy) in patients such as **Percy V.** is not completely understood. These changes are, however, attributable in part to toxic materials that are derived from the metabolism of nitrogenous substrates by bacteria in the gut that circulate to the liver in the portal vein. These materials bypass their normal metabolism by the liver cells, however, because the acute inflammatory process of viral hepatitis severely limits the ability of liver cells to degrade these compounds to harmless metabolites. As a result, these toxins are shunted into the hepatic veins unaltered and eventually reach the brain through the systemic circulation (“portal–systemic encephalopathy”).

C. Regulation of the Urea Cycle

The human liver has a vast capacity to convert amino acid nitrogen to urea, thereby preventing toxic effects from ammonia, which would otherwise accumulate. In general, the urea cycle is regulated by substrate availability; the higher the rate of ammonia production, the higher is the rate of urea formation. Regulation by substrate availability is a general characteristic of disposal pathways, such as the urea cycle, which remove toxic compounds from the body. This is a type of feed-forward regulation, in contrast to the feedback regulation characteristic of pathways that produce functional end products.

Two other types of regulation control the urea cycle: allosteric activation of CPSI by *N*-acetylglutamate (NAG) and induction and repression of the synthesis of urea-cycle enzymes. NAG is formed specifically to activate CPSI; it has no other known function in mammals. The synthesis of NAG from acetyl coenzyme A (acetyl CoA) and glutamate, catalyzed by *N*-acetylglutamate synthase (NAGS), is stimulated by arginine (Fig. 36.13). Thus, as arginine levels increase within the liver, two important reactions are stimulated. The first is the synthesis of NAG, which increases the rate at which carbamoyl phosphate is produced. The second is to produce more ornithine (via the arginase reaction) such that the cycle can operate more rapidly.

FIGURE 36.13 Activation of CPSI. Arginine stimulates the synthesis of *N*-acetylglutamate, which activates CPSI. Acetyl CoA, acetyl coenzyme A; ADP, adenosine diphosphate; ATP, adenosine triphosphate; CPSI, carbamoyl phosphate synthetase I; P_i , inorganic phosphate.

The induction of urea-cycle enzymes occurs in response to conditions that require increased protein metabolism, such as a high-protein diet or prolonged fasting. In both of these physiologic states, as amino acid

carbon is converted to glucose, amino acid nitrogen is converted to urea. The induction of the synthesis of urea-cycle enzymes under these conditions occurs even though the uninduced enzyme levels are far in excess of the capacity required. The ability of a high-protein diet to increase urea-cycle enzyme levels is another type of feed-forward regulation.

 NH_4^+ is one of the toxins that results from the degradation of urea or proteins by intestinal bacteria and is not metabolized by the infected liver. The subsequent elevation of ammonia concentrations in the fluid bathing the brain causes depletion of TCA cycle intermediates and ATP in the CNS. α -Ketoglutarate, a TCA cycle intermediate, combines with ammonia to form glutamate in a reaction catalyzed by glutamate dehydrogenase. Glutamate subsequently reacts with ammonia to form glutamine. This effectively reduces α -ketoglutarate levels in the mitochondria, thereby reducing the rate at which the TCA cycle can operate.

The absolute level of ammonia and its metabolites, such as glutamine, in the blood or cerebrospinal fluid in patients with hepatic encephalopathy correlates only roughly with the presence or severity of the neurologic signs and symptoms. γ -Aminobutyric acid (GABA), an important inhibitory neurotransmitter in the brain, is also produced in the gut lumen and is shunted into the systemic circulation in increased amounts in patients with hepatic failure. In addition, other compounds (such as aromatic amino acids, false neurotransmitters, and certain short-chain fatty acids) bypass liver metabolism and accumulate in the systemic circulation, adversely affecting CNS function. Their relative importance in the pathogenesis of hepatic encephalopathy remains to be determined.

D. Function of the Urea Cycle during Fasting

During fasting, the liver maintains blood glucose levels. Amino acids from muscle protein are a major carbon source for the production of glucose by the pathway of gluconeogenesis. As amino acid carbons are converted to glucose, the nitrogens are converted to urea. Thus, the urinary excretion of urea is high during fasting (Fig. 36.14). As fasting progresses, however, the brain begins to use ketone bodies, sparing blood glucose. Less muscle protein is cleaved to provide amino acids for gluconeogenesis, and decreased production of glucose from amino acids is accompanied by decreased production of urea (see Chapter 28).

FIGURE 36.14 Nitrogen excretion during fasting. Human subjects were initially given IV glucose as indicated, then fasted.

Total nitrogen excretion was measured as well as the nitrogen in urea (*brown area*). IV, intravenous. (Based on Ruderman NB, Aoki TT, and Cahill GF, Jr. Gluconeogenesis and its disorders in man. In: Hanson RW, Mehliman MA, eds. *Gluconeogenesis: Its Regulation in Mammalian Species*. John Wiley & Sons; 1976:518.)

In addition to producing urea, the reactions of the urea cycle also serve as the pathway for the biosynthesis of arginine. Therefore, this amino acid is not required in the diet of the adult; however, it is required in the diet for growth. Urea is not cleaved by human enzymes. However, bacteria, including those in the human digestive tract, can cleave urea to ammonia and CO₂, using the enzyme urease. Urease is not produced by humans.

To some extent, humans excrete urea into the gut and saliva. Intestinal bacteria convert urea to ammonia. This ammonia, as well as ammonia produced by other bacterial reactions in the gut, is absorbed into the hepatic portal vein. It is normally extracted by the liver and converted to urea. Approximately one-fourth of the total urea released by the liver each day is recycled by bacteria.

The major amino acid substrate for gluconeogenesis is alanine, which is synthesized in peripheral tissues to act as a nitrogen carrier (see Fig. 36.8). Glucagon release, which is expected during fasting, stimulates alanine transport into the liver by activating the transcription of transport systems for alanine. Two molecules of alanine are required to generate one molecule of glucose. The nitrogen from the two molecules of alanine is converted to one molecule of urea (Fig. 36.15).

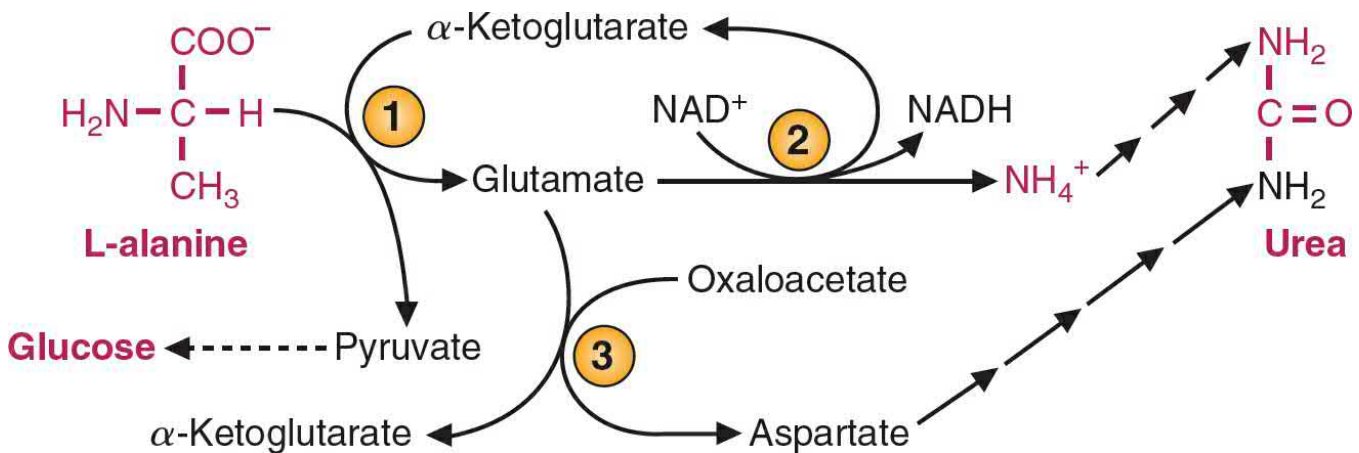

FIGURE 36.15 Conversion of alanine to glucose and urea. (1) Alanine, the key gluconeogenic amino acid, is transaminated to form pyruvate, which is converted to glucose. The nitrogen, now in glutamate, can be released as NH_4^+ (2) or transferred to oxaloacetate to form aspartate (3). NH_4^+ and aspartate enter the urea cycle, which produces urea. In summary, the carbons of alanine form glucose and the nitrogens form urea. Two molecules of alanine are required to produce one molecule of glucose and one molecule of urea. NAD, nicotinamide adenine dinucleotide.

Blood ammonia levels can be determined several ways. One is to use an ammonia-specific electrode. Another is to use enzyme-coupled reactions that result in either a color change or an absorbance change. One enzyme-coupled system takes advantage of glutamate dehydrogenase. The unknown sample is incubated with glutamate dehydrogenase, α -ketoglutarate, and NADPH. If ammonia is present, glutamate will be produced, as will NADP^+ . As NADPH is converted to NADP^+ , the absorbance of light at 340 nm will decrease, and because one NADP^+ is formed per ammonia molecule used, the concentration of ammonia can be determined.

Blood urea nitrogen (BUN) is a measurement for the urea content of the blood. The key to measuring BUN is to split urea into carbon dioxide and two ammonia molecules by the bacterial enzyme urease. The ammonia levels are then determined as described previously, or via a colorimetric assay based on pH indicator dyes. As ammonia is generated, it binds protons, forming ammonium ions, which raises the pH. The extent of the pH change will be proportional to the amount of ammonia generated. Once BUN is determined, the urea concentration can be determined (in milligrams per deciliter) by multiplying the nitrogen value by 2.14.

E. Disorders of the Urea Cycle

Disorders of the urea cycle are dangerous because of the accumulation of ammonia in the circulation. Ammonia is toxic to the nervous system, and its concentration in the body must be carefully controlled. Under normal conditions, free ammonia is rapidly fixed into either α -ketoglutarate (by glutamate dehydrogenase, to form glutamate) or glutamate (by glutamine synthetase, to form glutamine). The glutamine can be used by many tissues, including the liver; the glutamate donates nitrogens to pyruvate to form alanine, which travels to the

liver. Within the liver, as the nitrogens are removed from their carriers, CPSI fixes the ammonia into carbamoyl phosphate to initiate the urea cycle. However, when a urea-cycle enzyme is defective, the cycle is interrupted, which leads to an accumulation of urea-cycle intermediates before the block. Because of the block in the urea cycle, glutamine levels increase in the circulation, and because α -ketoglutarate is no longer being regenerated by removal of nitrogen from glutamine, the α -ketoglutarate levels are too low to fix more free ammonia, leading to elevated ammonia levels in the blood. Therefore, defects in any urea-cycle enzyme lead to elevated glutamine and ammonia levels in the circulation. However, the extent of the elevation depends on which enzyme is defective; see question 1 at the end of this chapter.

Ammonia toxicity will lead to brain swelling, caused, in part, to an osmotic imbalance owing to high levels of both ammonia and glutamine in the astrocytes. As ammonia levels increase in the astrocytes, more glutamine is produced (via glutamine synthetase), which only exacerbates the osmotic imbalance. The ammonia levels inhibit glutaminase, leading to glutamine elevation. Additionally, high levels of glutamine alter the permeability of the mitochondrial membrane, leading to an opening of the mitochondrial permeability transition pore, which leads to cell death (see Chapter 24). Another toxic effect of ammonia is a lowering of glutamate levels (owing to the high activity of the glutamine synthetase reaction). Glutamate is a neurotransmitter, and glutamatergic neurotransmission, if impaired, causes brain dysfunction because glutamate is one of the excitatory neurotransmitters, and in the absence of glutamate neurotransmission, lethargy and reduced nervous system activity can result.

The most common urea-cycle defect is OTC deficiency, which is an X-linked disorder. This disorder occurs with a frequency of about 1 in 80,000 people.

The major clinical problem in treating patients with urea-cycle defects is reducing the effects of excessive blood ammonia on the nervous system. High ammonia levels can lead to irreversible neuronal damage and intellectual disability. So how is hyperammonemia treated?

The key to treating patients with urea-cycle defects is to diagnose the disease early and then treat aggressively to remove nitrogen (ammonia) from the patient. Low-protein diets are essential to reduce the potential for excessive amino acid degradation. If the enzyme defect in the urea cycle comes after the synthesis of argininosuccinate, massive arginine supplementation has proved beneficial. Once argininosuccinate has been synthesized, the two nitrogen molecules destined for excretion have been incorporated into the substrate; the problem is that ornithine cannot be regenerated. If ornithine could be replenished to allow the cycle to continue, argininosuccinate could be used as the carrier for nitrogen excretion from the body. Thus, ingesting large levels of arginine leads to ornithine production by the arginase reaction, and nitrogen excretion via argininosuccinate in the urine can be enhanced.

Arginine therapy will not work for enzyme defects that exist in steps before the synthesis of argininosuccinate. For these disorders, drugs are used that form conjugates with amino acids. The conjugated amino acids are excreted, and the body then has to use its nitrogen to resynthesize the excreted amino acid. The two compounds most frequently used are benzoic acid and phenylbutyrate (the active component of phenylbutyrate is phenylacetate, its oxidation product. Phenylacetate has a bad odor, which makes it difficult to take orally). As indicated in Figure 36.16A, benzoic acid, after activation, reacts with glycine to form hippuric acid, which is excreted. As glycine is synthesized from serine, the body now uses nitrogens to synthesize serine, so more glycine can be produced. Phenylacetate (see Fig. 36.16B) forms a conjugate with glutamine, which is excreted. This conjugate removes two nitrogens per molecule and requires the body to resynthesize glutamine from glucose, thereby using another two nitrogen molecules.

FIGURE 36.16 The metabolism of benzoic acid **(A)** and phenylbutyrate **(B)**, two agents used to reduce nitrogen levels in patients with urea-cycle defects. AMP, adenosine monophosphate; ATP, adenosine triphosphate; CoA, coenzyme A; PPI, pyrophosphate.

Urea-cycle defects are excellent candidates for treatment by gene therapy. This is because the defect has to be repaired in only one cell type (in this case, the hepatocyte), which makes it easier to target the vector carrying the replacement gene. Preliminary gene therapy experiments had been carried out on individuals with OTC deficiency (the most common inherited defect of the urea cycle), but the experiments came to a halt when one of the patients died of a severe immunologic reaction to the vector used to deliver the gene. This incident led to a review and improvements of gene therapy protocols in the United States. Biochemical comments discuss three more disorders of the urea cycle, which are very rare in the population.

CLINICAL COMMENTS

Percy V. The two most serious complications of acute viral hepatitis found in patients such as **Percy V.** are massive hepatic necrosis leading to fulminant liver failure and the eventual development of chronic hepatitis. Both complications are rare in acute viral hepatitis type A, however, suggesting that acetaminophen toxicity may have contributed to **Percy V.**'s otherwise unexpectedly severe hepatocellular dysfunction and early hepatic encephalopathy.

Fortunately, bed rest, rehydration, parenteral nutrition, and therapy directed at decreasing the production of toxins that result from bacterial degradation of nitrogenous substrates in the gut lumen (e.g., administration of lactulose, which reduces gut ammonia levels by a variety of mechanisms, the use of enemas and certain antibiotics, such as rifaximin, to decrease the intestinal flora, a low-protein diet) prevented **Percy V.** from progressing to the later stages of hepatic encephalopathy. As with most patients who survive an episode of fulminant hepatic failure, recovery to his previous state of health occurred over the next 3 months. **Percy V.**'s liver function studies returned to normal, and a follow-up liver biopsy showed no histologic abnormalities.

BIOCHEMICAL COMMENTS

More disorders of the urea cycle. In addition to the enzymes that catalyze the reactions of the urea-cycle inactivating mutations in three other proteins can also lead to hyperammonemia. Two of these proteins are transporters in the inner mitochondrial membrane, and the third is NAGS, the enzyme which produces NAG.

NAGS deficiency. The symptoms exhibited by a patient with a mutation in NAGS is similar to a CPS1 deficiency, in that in the absence of NAG, CPS-1 cannot be fully activated, and insufficient carbamoyl phosphate can be produced to allow for effective running of the urea cycle. NAGS deficiency is an extremely rare syndrome, and if properly diagnosed can be partially treated with a NAG analog, carbamoyl glutamate. If NAGS has partial activity, then the patient exhibits episodes of hyperammonemia, usually under conditions of stress (which releases cortisol and which stimulates protein turnover).

Ornithine translocase (SLC25A15 gene, ORNT1 protein) deficiency: A lack of ORNT1 activity blocks the ability of ornithine to enter the mitochondria in exchange for citrulline produced in the mitochondria. The lack of ornithine in the mitochondria leads to hyperornithinemia (high ornithine in the blood), hyperammonemia (because of the inability to produce citrulline in the mitochondria), and hypocitrullinemia (low levels of citrulline in the blood because it cannot leave the mitochondria). This is also an extremely rare disorder, with approximately 100 cases described worldwide. Orotic aciduria also occurs, as carbamoyl phosphate accumulates in the mitochondria, enters the cytoplasm, and bypasses the regulated step of pyrimidine biosynthesis and stimulates orotic acid production (very similar to an OTC deficiency). Once properly diagnosed, treatment of this disorder requires a low-protein diet, coupled with citrulline or arginine supplementation. Ammonia-lowering drugs (sodium benzoate or sodium phenylbutyrate) are also prescribed. The patients also need to be monitored during times of stress (cortisol release, or when prescribed corticosteroids), as those agents increase protein turnover in the muscle.

Hypercitrullinemia type II: Hypercitrullinemia type I is caused by a defect in argininosuccinate synthetase. Hypercitrullinemia type II is caused by a defect in the protein citrin (the gene is SLC25A13), which is an isozyme of the glutamate–aspartate exchange carrier found in the inner mitochondrial membrane. This

carrier has a dual role, in that it functions as a key component of the malate–aspartate shuttle for transferring reducing equivalents across the inner mitochondrial membrane, and the carrier also provides aspartate for use in the urea cycle in the cytoplasm (the argininosuccinate synthetase reaction). Over 100 different mutations have been identified in the SLC25A13 gene and the symptoms exhibited by the individuals who inherit these mutations fall into two major classifications, with different phenotypes. The first is neonatal intrahepatic cholestasis (neonatal onset hypercitrullinemia type 2), and the second is adult onset hypercitrullinemia type 2. Intrahepatic cholestasis is an accumulation of conjugated bilirubin in the liver, because of a block in flow of bile components from the liver. The accumulation of the conjugated bilirubin leads to liver dysfunction, including a fatty liver, liver fibrosis, small stature, hypoproteinemia, and hypoglycemia in children <1 year of age. The cholestasis is usually transient and gradually disappears during the first 2 years of life. Such individuals may develop hypercitrullinemia again, between 20 and 50 years of age. Infants with this disorder are treated with a low-carbohydrate diet and medium-chain triglycerides supplemented with fat-soluble vitamins (recall, the infants have trouble producing bile for release from the gall bladder, leading to inefficient digestion of “normal” dietary fat). As the patients age, they develop an aversion to carbohydrates and prefer high-protein, high-fat diets. Recall, because the malate–aspartate shuttle is defective in these patients, the carbohydrate in the diet leads to elevated NADH levels in the cytoplasm (the reducing equivalents cannot be transferred into the mitochondria). The elevated NADH blocks gluconeogenesis from lactate, alanine, and glycerol and could lead to hypoglycemic symptoms in the patient. The patients also avoid alcohol, for the same reasons as avoiding carbohydrates. The high-protein diet provides aspartic acid in the cytoplasm for the argininosuccinate synthetase reaction to proceed and allow the urea cycle to function, thereby reducing the citrulline produced and leading to normal levels of citrulline in the circulation.

KEY CONCEPTS

- ◆ Amino acid catabolism generates urea, which is a nontoxic carrier of nitrogen atoms.
- ◆ Urea synthesis occurs in the liver. The amino acids alanine and glutamine carry amino acid nitrogen from peripheral tissues to the liver.
- ◆ Key enzymes involved in nitrogen disposal are transaminases, glutamate dehydrogenase, and glutaminase.
- ◆ The urea cycle consists of four steps and incorporates a nitrogen from ammonia and one from aspartate into urea.
- ◆ Disorders of the urea cycle lead to hyperammonemia, a condition that is toxic to nervous system health and development.
- ◆ Diseases discussed in this chapter are summarized in Table 36.1.

TABLE 36.1 Diseases Discussed in Chapter 36

DISEASE OR DISORDER	GENETIC OR ENVIRONMENTAL	COMMENTS
Viral hepatitis	Environmental	Infection of the liver by viral hepatitis may lead to liver failure.
Pyridoxamine deficiency	Environmental	The lack of vitamin B ₆ affects many systems, such as heme synthesis, glycogen phosphorylase activity, and neurotransmitter synthesis, leading to possibly dementia, dermatitis, anemia, weakness, and seizures.
Hepatic encephalopathy	Environmental	Liver failure leading to brain dysfunction, caused by the liver's inability to rid the body of toxins, including ammonia
Ammonia toxicity	Both	Ammonia accumulation interferes with energy production and neurotransmitter synthesis in the brain, altering brain function.
OTC deficiency	Genetic	Most common urea-cycle defect, leading to elevated blood ammonia and orotic acid levels, and will lead to mental impairment if not treated.
CPS1 deficiency, argininosuccinate	All genetic	Mutations in urea-cycle enzymes

CPS I deficiency, argininosuccinate synthetase deficiency, argininosuccinate lyase deficiency, and arginase deficiency

All genetic

Mutations in urea-cycle enzymes, leading to various degrees of hyperammonemia and inability to synthesize urea. Can be distinguished by the type of urea-cycle intermediates that accumulate in the blood.

CPSI, carbamoyl phosphate synthetase I; OTC, ornithine transcarbamoylase.

REVIEW QUESTIONS—CHAPTER 36

1. Deficiency diseases have been described that involve each of the five enzymes of the urea cycle. Clinical manifestations may appear in the neonatal period. Infants with defects in the first four enzymes usually appear normal at birth, but after 24 hours progressively develop lethargy, hypothermia, and apnea. They have high blood ammonia levels, and the brain becomes swollen. One possible explanation for the swelling is the osmotic effect of the accumulation of glutamine in the brain produced by the reactions of ammonia with α -ketoglutarate and glutamate. Arginase deficiency is not as severe as deficiencies of the other urea-cycle enzymes.

Given the following information about five newborn infants (identified as I through V) who appeared normal at birth but developed hyperammonemia after 24 hours, determine which urea-cycle enzyme might be defective in each case (for each infant, choose from the same five answers, lettered A through E). All infants had low levels of BUN. (Normal citrulline levels are 10 to 20 μM .)

Infant	Urine		Blood		
	Orotate	Blood Citrulline	Arginine	Blood NH_3	
I	Low	Low	Low	High	
II	—	High ($> 1,000 \mu\text{M}$)	Low	High	
III	—	—	High	Moderately high	
IV	High	Low	Low	High	
V	—	High ($200 \mu\text{M}$)	Low	High	

—, Value not determined; low, below normal; high, above normal.

- CPSI
 - OTC
 - Argininosuccinate synthetase
 - Argininosuccinate lyase
 - Arginase
2. The nitrogens in urea are derived directly from which of the following compounds?
- Ornithine and carbamoyl phosphate
 - Ornithine and aspartate
 - Ornithine and glutamate
 - Carbamoyl phosphate and aspartate
 - Carbamoyl phosphate and glutamine
 - Aspartate and glutamine
3. Which one of the following enzymes can fix ammonia into an organic molecule?

- A. Alanine–pyruvate aminotransferase
 - B. Glutaminase
 - C. Glutamate dehydrogenase
 - D. Arginase
 - E. Argininosuccinate synthetase
4. Under conditions of high rates of protein turnover, glutamine is used as a nitrogen carrier to deliver nitrogen to the liver for safe disposal as urea. The carbons of glutamine can then be used for gluconeogenesis, which would require which one of the following enzymes?
 - A. Malate dehydrogenase
 - B. Pyruvate dehydrogenase
 - C. Pyruvate carboxylase
 - D. Citrate synthase
 - E. Pyruvate kinase
 5. Drugs used to treat urea-cycle defects, such as sodium benzoate, and phenylbutyrate, need to be activated once they enter cells. The activation of these drugs is very similar to which one of the following reactions?
 - A. Formation of acetyl CoA by pyruvate dehydrogenase
 - B. Activation of glucose for the glycolytic pathway
 - C. Activation of fatty acids
 - D. Activation of glucose for glycogen synthesis
 - E. Activation of isoprene units
 6. Which one of the following foods is highest in the vitamin needed to form the required cofactor of transamination reactions?
 - A. Eggs
 - B. Dairy products
 - C. Citrus fruits
 - D. Dark green leafy vegetables
 - E. Carrots
 7. Release of amino acid nitrogen and NH_4^+ is an important step in generating precursors for the urea cycle. Which statement best describes this release of amino acid nitrogen as NH_4^+ from amino acids?
 - A. NH_4^+ freely diffuses across membranes.
 - B. Glutamate deamination by oxidation is readily reversible.
 - C. Serine deamination to pyruvate is readily reversible.
 - D. Glutamine deamination to glutamate is readily reversible.
 - E. NH_3 cannot freely diffuse across membranes.
 8. Under conditions of rapid amino acid degradation, ammonia levels increase and must be safely removed from the cells. Glutamate can accept a nitrogen (in the form of ammonia) to form glutamine. Which statement correctly describes what happens to the glutamine, and resulting ammonia and glutamate via the action of glutaminase, in various tissues?
 - A. In the liver, glutamine becomes part of the glucose/alanine cycle.
 - B. In the kidney, glutamate forms salts with metabolic acids in the urine.
 - C. In the intestine, glutamine is used as a fuel.
 - D. In the kidney, the glutamate is used for urea synthesis.
 - E. In the intestine, glutamine becomes part of the glucose/alanine cycle.
 9. The urea cycle is the major mechanism in the human body for removal of nitrogen. Which statement correctly describes steps of the urea cycle?
 - A. Three high-energy phosphate bonds are used for one complete cycle.
 - B. Citrulline is synthesized in the cytosol.
 - C. Citrulline initiates and is regenerated by the cycle.
 - D. Ornithine is generated in the mitochondria.
 - E. Citrulline is exchanged for ornithine across the mitochondrial membrane in an electroneutral exchange.
 10. During fasting, amino acids are a major carbon source for gluconeogenesis and the nitrogens are converted to urea. Which one of the following correctly describes alanine, the major amino acid substrate of gluconeogenesis from the muscle?
 - A. One molecule of alanine is converted to two molecules of glucose and two molecules of urea.
 - B. One molecule of alanine is converted to one molecule of glucose and one molecule of urea.

- C. One molecule of alanine is converted to one molecule of glucose and two molecules of urea.
 - D. Two molecules of alanine are required to generate one molecule of glucose and one molecule of urea.
 - E. Two molecules of alanine are required to generate three molecules of glucose and three molecules of urea.
1. Inhibition of the aspartate–glutamate carrier in the inner mitochondrial membrane leads to hyperammonemia. This is owing to reduced substrate availability for which one of the following enzymes?
- A. NAGS
 - B. Glutamate dehydrogenase
 - C. CPSI
 - D. OTC
 - E. Argininosuccinate synthetase

Questions 12 and 13 are based on the following case. *A newborn child was very lethargic 24 hours after birth, and a rapid blood analysis indicated significant hyperammonemia. The child was treated by stopping all protein intake and with an intravenous glucose drip.*

2. The rationale for the glucose infusion is best described by which one of the following?
- A. To promote catabolic pathways
 - B. To promote anabolic pathways
 - C. To block amino acid transport into the liver
 - D. To stimulate amino acid transport into the liver
 - E. To promote fatty acid biosynthesis
3. After 12 hours on the glucose infusion, the child's blood ammonia levels were still too high, so the glucose infusion was reduced and the patient was given sodium phenylbutyrate to aid in reducing ammonia levels. In order for this new treatment to be effective, which one of the following pathways needs to be active?
- A. Glycolysis
 - B. Gluconeogenesis
 - C. Fatty acid oxidation
 - D. Fatty acid synthesis
 - E. Hexose monophosphate shunt
4. One of the consequences of hyperammonemia is reduced energy production in neurons, which can lead to neuronal apoptosis. The reduced energy production is because of a primary reduction in concentration of which one of the following metabolites?
- A. Citrate
 - B. Pyruvate
 - C. Glutamate
 - D. α -Ketoglutarate
 - E. Alanine
5. The nitrogen in amino acids can be used to produce which of the following? Choose the one best answer.

	Creatine	Purines	Pyrimidines	Cholesterol	Sphingo- myelin
A	Yes	Yes	Yes	Yes	Yes
B	Yes	No	Yes	Yes	No
C	Yes	Ye	Yes	No	Yes
D	No	No	No	No	No
E	No	Yes	No	No	Yes
F	No	No	No	Yes	No

ANSWERS TO REVIEW QUESTIONS

- Infant I has a defect in CPSI (answer A), and infant IV has a defect in OTC (answer B).** Infants with high ammonia, low arginine, and low citrulline levels must have a defect in a urea-cycle enzyme before the step that produces citrulline; that is, CPSI or OTC. If CPSI is functional and carbamoyl phosphate is produced but cannot be further metabolized, more than the normal amount is diverted to the pathway for pyrimidine synthesis and the intermediate orotate appears in the urine. Therefore, infant I has a defect in CPSI (citrulline is low and less than the normal amount of orotate is in the urine). Infant IV has an OTC defect; carbamoyl phosphate is produced, but it cannot be converted to citrulline, so citrulline is low and orotate is present in the urine.

Infants II and V have high levels of citrulline but low levels of arginine. Therefore, they cannot produce arginine from citrulline. Argininosuccinate synthetase or argininosuccinate lyase is defective. The very elevated citrulline levels in infant II suggest that the block is in argininosuccinate synthetase (answer C). In infant V, citrulline levels are more moderately elevated, suggesting that citrulline can be converted to argininosuccinate and that the defect is in argininosuccinate lyase (answer D). Thus, the accumulated intermediates of the urea cycle are distributed between argininosuccinate and citrulline (both of which can be excreted in the urine). The high levels of arginine and more moderate hyperammonemia in infant III suggest that, in this case, the defect is in arginase (answer E).
- The answer is D.** The nitrogens in urea are derived from carbamoyl phosphate and aspartate directly during one turn of the cycle. The nitrogen in the side chain of ornithine is never incorporated into urea, because it stays with ornithine (thus, A, B, and C are incorrect). Glutamine does not donate a nitrogen directly during the urea cycle, so E and F are also incorrect.
- The answer is C.** Glutamate dehydrogenase fixes ammonia into α -ketoglutarate, generating glutamate, in a reversible reaction that also requires NAD(P)H. Alanine-pyruvate aminotransferase catalyzes the transfer of nitrogen from alanine to an α -keto acid acceptor but does not use ammonia as a substrate. Glutaminase converts glutamine to glutamate and ammonia, but the reaction is not reversible. Arginase splits arginine into urea and ornithine, and argininosuccinate synthetase forms argininosuccinate from citrulline and aspartate. The only other three enzymes that can fix ammonia into an organic compound are CPSI, glycine cleavage enzyme, and glutamine synthetase.
- The answer is A.** Glutamine is converted to ammonia and glutamate in the cytoplasm (glutaminase) and then to α -ketoglutarate and ammonia in the mitochondria (glutamate dehydrogenase). The α -ketoglutarate goes around the TCA cycle to form malate, which is then exported from the mitochondria to the cytoplasm. In the cytoplasm, the malate is converted to oxaloacetate by malate dehydrogenase. The oxaloacetate is converted to phosphoenolpyruvate (PEP) by PEP carboxykinase, and then the standard gluconeogenic pathway is followed to glucose production. Pyruvate dehydrogenase, pyruvate

carboxylase, citrate synthase, and pyruvate kinase are not required for these conversions to occur.

5. **The answer is C.** The activation of fatty acids requires a two-step reaction. In the first, ATP donates AMP to form a covalent bond with the carboxylic acid of the fatty acid, releasing pyrophosphate. In the second step, coenzyme A (CoA) displaces the AMP, forming a fatty acyl CoA. This is the exact same reaction pathway for the activation of these drugs, and the pathway uses enzymes similar to those for fatty acid activation. Activation of glucose for the glycolytic pathway requires phosphorylation (not addition of CoA). Activation of glucose for glycogen synthesis requires formation of a nucleotide sugar, not involving CoA. Formation of an activated isoprene requires two subsequent phosphorylations to create a pyrophosphate derivative (e.g., isopentenyl pyrophosphate). The formation of acetyl CoA, via pyruvate dehydrogenase, is an oxidative decarboxylation reaction, which is not similar to the fatty acid activation reactions or to those that activate the drugs used for treatment of urea-cycle disorders.
6. **The answer is A.** PLP is the required cofactor for transamination reactions and is derived from pyridoxine (B₆) found in chicken, fish, pork, eggs, noncitrus fruits, peanuts, and walnuts. Dairy products contain choline and vitamin D, citrus fruits contain vitamin C, carrots contain vitamin A, and leafy vegetables are rich in folate and vitamin K.
7. **The answer is B.** Glutamate deamination to α -ketoglutarate is readily reversible (via the enzyme glutamate dehydrogenase). The other deaminations listed are irreversible reactions (serine deamination requires vitamin B₆, and glutamine deamination is a simple hydrolysis reaction). NH₃ can freely diffuse cross membranes, but once NH₄⁺ is formed, it can no longer do so because of its charge.
8. **The answer is C.** In the intestine, glutamine is used as fuel. In the liver, glutamate can transaminate oxaloacetate to aspartate or release NH₄⁺, both of which join the urea cycle. Alanine, not glutamate, is part of the glucose/alanine cycle. In the kidney, the ammonia formed with glutamate from glutamine forms salts with metabolic acids. Urea is formed in the liver and transported to the kidney.
9. **The answer is E.** Citrulline is synthesized in the mitochondria, and ornithine is regenerated in the cytosol. A transporter exchanges these two amino acids via an electroneutral exchange. Ornithine is the compound that both initiates and is regenerated by the cycle. Four high-energy phosphate bonds are used for one complete cycle—2 ATP to produce carbamoyl phosphate from NH₄⁺, and two high-energy bonds (ATP to AMP) to form argininosuccinate from citrulline and aspartate.
10. **The answer is D.** Two molecules of alanine are required to generate one molecule of glucose and one molecule of urea. Glucose contains six carbons, and alanine only three carbons. Urea contains two nitrogen groups, and alanine only contains one nitrogen group. Thus, starting with two molecules of alanine, there are six carbons available for glucose production and two nitrogens available for urea synthesis.
11. **The answer is E.** When the aspartate–glutamate carrier (citrin) is inactive, aspartate cannot leave the mitochondria and the malate–aspartate shuttle for transferring reducing equivalents across the inner mitochondrial membrane is also defective. With less aspartate in the cytoplasm, one of the substrates for argininosuccinate synthetase is reduced in concentration (the other substrate is citrulline). The lack of aspartate in the cytoplasm will not alter the substrate availability of NAGS, glutamate dehydrogenase, CPSI, or OTC.
12. **The answer is B.** Raising blood glucose levels will stimulate the release of insulin, which will promote anabolic pathways, and stop protein catabolism, which would lead to increased ammonia levels. By blocking catabolic pathways the ammonia load will be reduced, and the need for a functional urea cycle can be alleviated. Glucose infusions do not alter amino acid transport. Although glucose infusions will promote fatty acid biosynthesis, the stimulation of fatty acid biosynthesis does not contribute to a reduction in ammonia production.
13. **The answer is C.** In order for phenylbutyrate to be effective, it must be activated to phenylbutyryl CoA and then undergo one round of β -oxidation to be converted into phenylacetyl CoA, which conjugates with glutamine to produce phenylacetylglutamine, which is excreted. None of the other pathways listed are required to activate phenylbutyrate to phenylacetate.
14. **The answer is D.** As ammonia diffuses across the blood–brain barrier and enters neurons, glutamate dehydrogenase in the mitochondria will convert α -ketoglutarate plus ammonia to glutamate (glutamate dehydrogenase), and because ammonia levels are high, the glutamate will react with ammonia to produce glutamine (via glutamine synthetase). This results in a reduction of mitochondrial α -ketoglutarate levels, slowing of the TCA cycle, and reduced energy production. As the TCA cycle slows, the levels of the other intermediates will also be reduced, but the primary event is the reduction of α -ketoglutarate levels.

15. **The answer is C.** Amino acids are used in the biosynthesis of creatine (glycine and arginine), purines (glycine, aspartic acid, and glutamine), pyrimidines (aspartic acid), and sphingomyelin (serine). There are no nitrogen groups in cholesterol.

Synthesis and Degradation of Amino Acids

Because each of the 20 common amino acids has a unique structure, their metabolic pathways differ. Despite this, some generalities do apply to both the synthesis and degradation of all amino acids. These are summarized in the following sections. Because a number of the amino acid pathways are clinically relevant, we present most of the diverse pathways that occur in humans. However, we will be as succinct as possible.

Important Coenzymes. **Pyridoxal phosphate** (derived from vitamin B₆) is the quintessential coenzyme of amino acid metabolism. In degradation, it is involved in the removal of amino groups, principally through **transamination reactions** and in donation of amino groups for various amino acid biosynthetic pathways. It is also required for certain reactions that involve the carbon skeleton of amino acids. **Tetrahydrofolate (FH₄)** is a coenzyme that is used to transfer one-carbon groups at various oxidation states. FH₄ is used in both amino acid degradation (e.g., serine and histidine) and biosynthesis (e.g., glycine). **Tetrahydrobiopterin (BH₄)** is a cofactor that is required for ring hydroxylation reactions (e.g., phenylalanine to tyrosine).

Synthesis of the Amino Acids. Eleven of the 20 common amino acids can be synthesized in the body (Fig. 37.1). The other nine are considered “**essential**” and must be obtained from the diet. Almost all of the amino acids that can be synthesized by humans are amino acids used for the synthesis of additional nitrogen-containing compounds. Examples include glycine, which is used for porphyrin and purine synthesis; glutamate, which is required for neurotransmitter synthesis; and aspartate, which is required for both purine and pyrimidine biosynthesis.

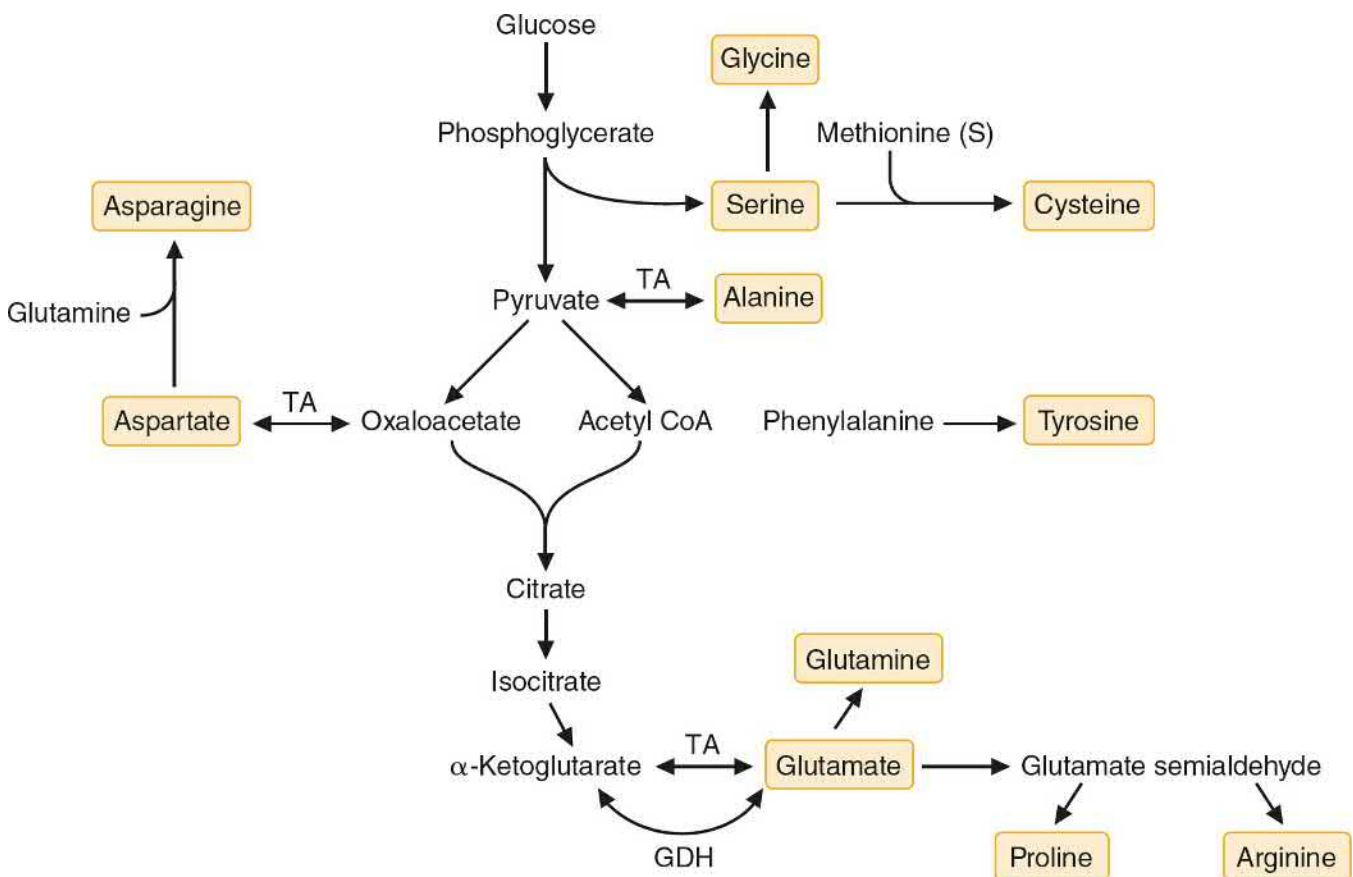

FIGURE 37.1 Overview of the synthesis of the nonessential amino acids. The carbons of 10 amino acids may be produced from glucose through intermediates of glycolysis or the TCA cycle. The 11th nonessential amino acid, tyrosine, is synthesized by hydroxylation of the essential amino acid phenylalanine. Only the sulfur of cysteine comes from the essential amino acid methionine; its carbons and nitrogen come from serine. Transamination (TA) reactions involve pyridoxal phosphate (PLP) and another amino acid- α -keto acid pair. Acetyl CoA, acetyl coenzyme A; GDH, glutamate dehydrogenase.

Nine of the 11 “**nonessential**” amino acids can be produced from glucose plus, of course, a source of nitrogen, such as another amino acid or ammonia. The other two nonessential amino acids, tyrosine and cysteine, require an essential amino acid for their synthesis (phenylalanine for tyrosine, methionine for cysteine). The carbons for cysteine synthesis come from glucose; the methionine donates only the sulfur.

The carbon skeletons of the 10 nonessential amino acids derived from glucose are produced from intermediates of **glycolysis** and the **tricarboxylic acid (TCA) cycle** (see Fig. 37.1). Four amino acids (**serine, glycine, cysteine, and alanine**) are produced from glucose through components of the **glycolytic pathway**. TCA cycle intermediates (which can be produced from glucose) provide carbon for synthesis of the six remaining nonessential amino acids. α -Ketoglutarate is the precursor for the synthesis of glutamate, glutamine, proline, and arginine. Oxaloacetate provides carbon for the synthesis of aspartate and asparagine.

Regulation of the biosynthesis of individual amino acids can be quite complex, but the overriding feature is that the **pathways are feedback-regulated** such that as the **concentration of free amino acid increases**, a key biosynthetic **enzyme is allosterically or transcriptionally inhibited**. Amino acid levels, however, are always maintained at a level such that the aminoacyl-tRNA synthetases can remain active, and protein synthesis can continue.

Degradation of Amino Acids. The **degradation pathways** for amino acids are, in general, **distinct from biosynthetic pathways**. This allows for separate regulation of the anabolic and catabolic pathways. Because protein is a fuel, almost every amino acid has a degradative pathway that can generate NADH, which is used as an electron source for oxidative phosphorylation. However, the energy-generating pathway may involve direct oxidation, oxidation in the TCA cycle, conversion to glucose and then oxidation, or conversion to **ketone bodies**, which are then oxidized.

The fate of the carbons of the amino acids depends on the physiological state of the individual and the tissue in which the degradation occurs. For example, in the liver during fasting, the carbon skeletons of the amino acids produce glucose, ketone bodies, and CO_2 . In the fed state, the liver can convert intermediates of amino acid metabolism to glycogen and triacylglycerols. Thus, the **fate of the carbons of the amino acids parallels that of glucose and fatty acids**. The **liver** is the only tissue that has all of the pathways of amino acid synthesis and degradation.

As amino acids are degraded, their **carbons** are converted to (1) **CO_2** , (2) compounds that produce **glucose** in the liver (pyruvate and the TCA cycle intermediates α -ketoglutarate, succinyl coenzyme A [succinyl CoA], fumarate, and oxaloacetate), and (3) **ketone bodies** or their precursors (acetoacetate and acetyl CoA) (Fig. 37.2). For simplicity, amino acids are considered to be **glucogenic** if their carbon skeletons can be converted to a precursor of glucose and **ketogenic** if their carbon skeletons can be converted directly to acetyl CoA or acetoacetate. Some amino acids contain carbons that produce a glucose precursor and other carbons that produce acetyl CoA or acetoacetate. These amino acids are both glucogenic and ketogenic.

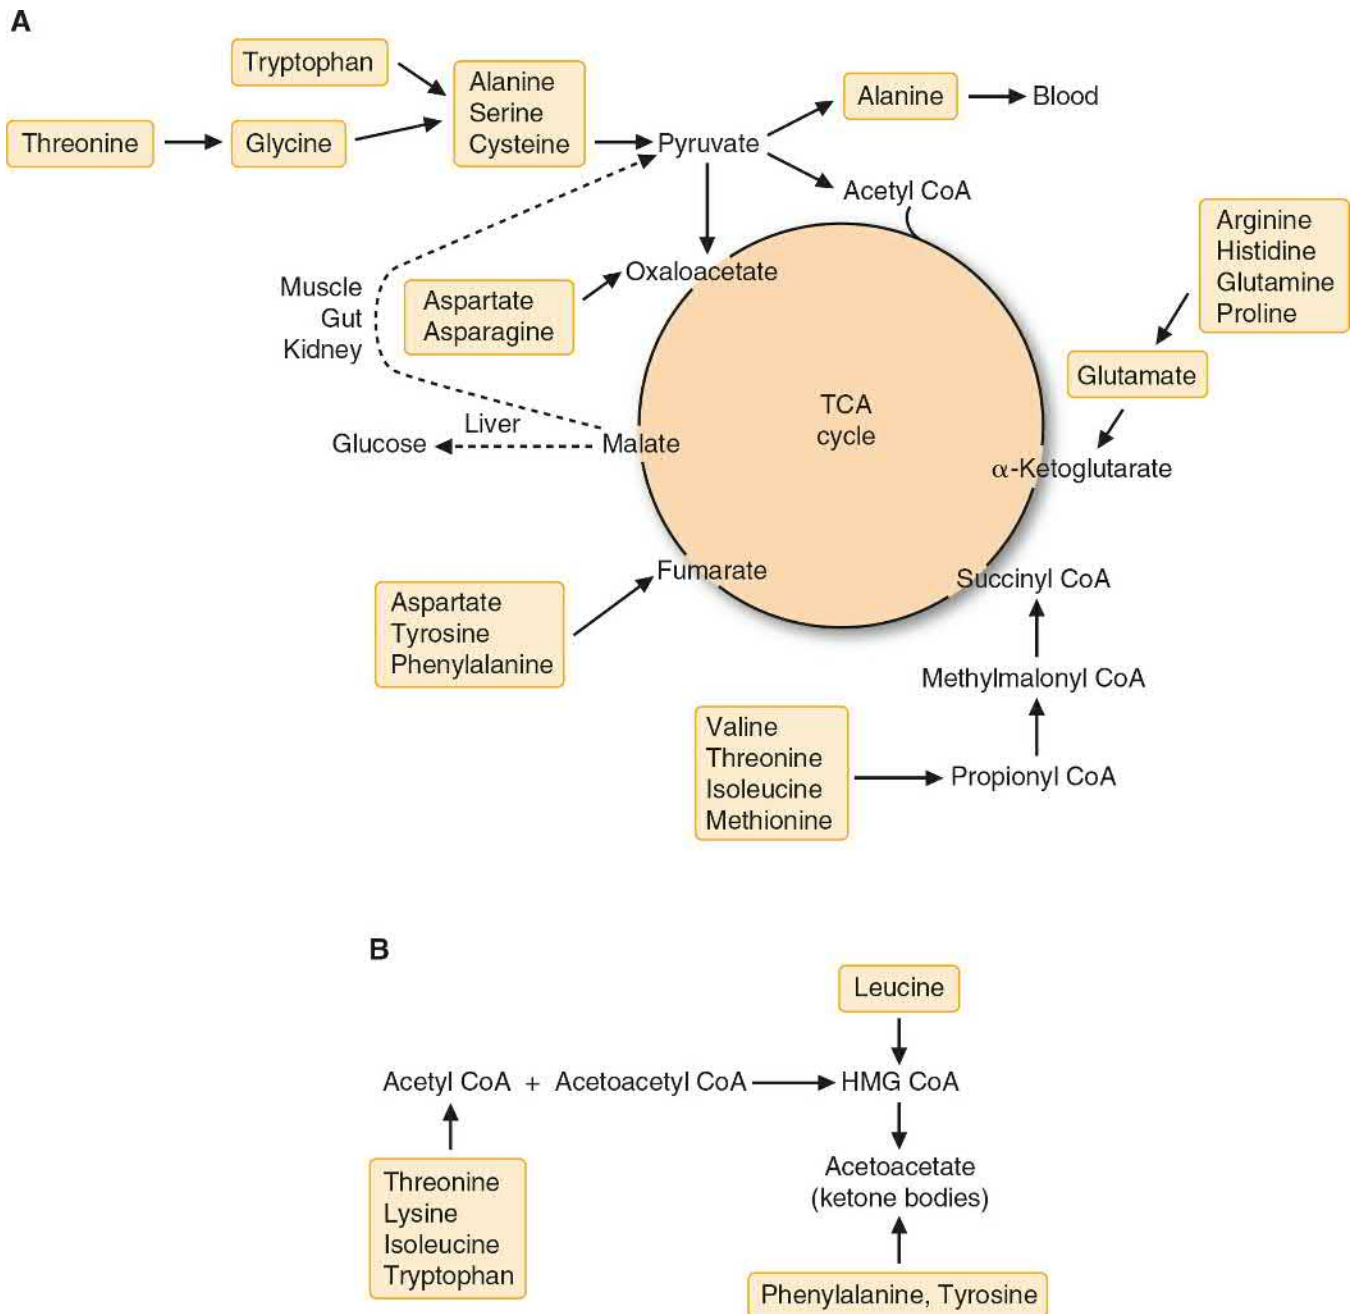

FIGURE 37.2 Degradation of amino acids. **A.** Amino acids that produce pyruvate or intermediates of the TCA cycle. These amino acids are considered glucogenic because they can produce glucose in the liver. The fumarate group of amino acids produces cytoplasmic fumarate. Potential mechanisms whereby the cytoplasmic fumarate can be oxidized are presented in Section III.C.1. **B.** Amino acids that produce acetyl CoA or ketone bodies. These amino acids are considered ketogenic. HMG-CoA, hydroxymethylglutaryl coenzyme A; Methylmalonyl CoA, methylmalonyl coenzyme A; propionyl CoA, propionyl coenzyme A; Succinyl CoA, succinyl coenzyme A.

The amino acids that are synthesized from intermediates of glycolysis (**serine, alanine, and cysteine**) plus certain other amino acids (**threonine, glycine, and tryptophan**) produce **pyruvate** when they are degraded. The amino acids synthesized from TCA cycle intermediates (**aspartate, asparagine, glutamate, glutamine, proline, and arginine**) are reconverted to these intermediates during degradation. **Histidine** is converted to **glutamate** and then to the TCA cycle intermediate **α-ketoglutarate**. **Methionine, threonine, valine, and isoleucine** form **succinyl CoA**, and **phenylalanine** (after conversion to **tyrosine**) forms **fumarate**. Because pyruvate and the TCA cycle intermediates can produce glucose in the liver, these amino acids are glucogenic.

Some amino acids with carbons that produce glucose also contain other carbons that produce ketone bodies. **Tryptophan, isoleucine, and threonine** produce **acetyl CoA**, and **phenylalanine and tyrosine** produce **acetoacetate**. These amino acids are both glucogenic and ketogenic.

Two of the essential amino acids (**lysine** and **leucine**) are strictly **ketogenic**. They do not produce glucose, only acetoacetate and acetyl CoA.

THE WAITING ROOM

Petria Y., a 4-month-old female infant, emigrated from the Ukraine with her French mother and Russian father 1 month ago. She was normal at birth but in the last several weeks was less than normally attentive to her surroundings. Her psychomotor development seemed to be delayed, and a tremor of her extremities had recently appeared. When her mother found her having gross twitching movements in her crib, she brought the infant to the hospital emergency room. A pediatrician examined **Petria Y.** and immediately noted a musty odor to the baby's wet diaper. A drop of her blood was obtained from a heel prick and used to perform a Guthrie bacterial inhibition assay using a special type of filter paper. This screening procedure was positive for the presence of an excess of phenylalanine in **Petria Y.**'s blood.

All states have enacted legislation requiring that newborns be screened for various metabolic abnormalities, of which PKU is one. A common screening procedure is the Guthrie bacterial inhibition assay. In this assay, spores of the organism *Bacillus subtilis* are plated on an agar plate containing β_2 -thienylalanine, an inhibitor of *B. subtilis* growth. The blood sample obtained from the infant (in the form of a dried blood spot on a filter disk) is placed on the agar plate. If the phenylalanine content of the blood is >2 to 4 mg/dL, the phenylalanine will counteract the effects of the β_2 -thienylalanine, and bacterial growth will occur. An alternative assay is a microfluorometric determination of phenylalanine, via its incorporation into a ninhydrin-copper complex in the presence of the dipeptide l-leucyl-l-alanine. Positive results with either assay then require verification and actual measurement of phenylalanine levels, using either HPLC (high-performance liquid chromatography) separation of the components of the blood or enzymatic and fluorometric assays.

Horace S., a 14-year-old boy, had a sudden weakness of the muscles on the left side of his face and of his left arm and leg. He was hospitalized with a tentative diagnosis of a cerebrovascular accident involving the right cerebral hemisphere.

Horace S.'s past medical history included a downward partial dislocation of the lenses of both eyes, for which he had had a surgical procedure. He also has a slight intellectual disability requiring placement in a special education group.

Horace S.'s left-sided neurological deficits cleared within 3 days, but a computerized axial tomogram (CT scan) showed changes consistent with a small infarct (a damaged area caused by a temporary or permanent loss of adequate arterial blood flow) in the right cerebral hemisphere. A neurologist noted that **Horace S.** had a slight waddling gait, which his mother said began several years earlier and was progressing with time. Further studies confirmed the decreased mineralization (decreased density) of the skeleton (called osteopenia if mild and osteoporosis if more severe) and high methionine and homocysteine but low cystine levels in the blood.

All of this information, plus the increased length of the long bones of **Horace S.**'s extremities and a slight curvature of his spine (scoliosis), caused his physician to suspect that **Horace S.** might have an inborn error of metabolism.

I. The Role of Cofactors in Amino Acid Metabolism

Amino acid metabolism requires the participation of three important cofactors. Pyridoxal phosphate (PLP) is the quintessential coenzyme of amino acid metabolism (Fig. 37.3). It is required for the following types of reactions involving amino acids: transamination, deamination, decarboxylation, β -elimination, racemization, and γ -elimination. Almost all pathways involving amino acid metabolism will require PLP at one step of the pathway.

FIGURE 37.3 Pyridoxal phosphate (PLP) attached covalently to an amino acid substrate. The arrows indicate which bonds are broken for the various types of reactions in which PLP is involved. X and Y represent chemical leaving groups that may be present on the amino acid (such as the hydroxyl group on serine or threonine).

The coenzyme tetrahydrofolate (FH_4), which is derived from the vitamin folate, is required in certain amino acid pathways to either accept or donate a one-carbon group. The carbon can be in various states of oxidation. Chapter 38 describes the reactions of FH_4 in much more detail.

The coenzyme tetrahydrobiopterin (BH_4) is required for ring hydroxylations. The reactions involve molecular oxygen, and one atom of oxygen is incorporated into the product. The second is found in water (see Chapter 24). BH_4 is important for the synthesis of tyrosine and neurotransmitters (see Chapter 46).

II. Amino Acids Derived from Intermediates of Glycolysis

Four amino acids are synthesized from intermediates of glycolysis: serine, glycine, cysteine, and alanine. Serine, which produces glycine and cysteine, is synthesized from 3-phosphoglycerate, and alanine is formed by transamination of pyruvate, the product of glycolysis (Fig. 37.4). When these amino acids are degraded, their carbon atoms are converted to pyruvate or to intermediates of the glycolytic/gluconeogenic pathway and, therefore, can produce glucose or be oxidized to CO_2 .

FIGURE 37.4 Amino acids derived from intermediates of glycolysis. These amino acids can be synthesized from glucose. Their carbons can be reconverted to glucose in the liver.

A. Serine

In the biosynthesis of serine from glucose, 3-phosphoglycerate is first oxidized to a 2-keto compound (3-phosphohydroxypyruvate), which is then transaminated to form phosphoserine (Fig. 37.5). Phosphoserine phosphatase removes the phosphate, forming serine. The major sites of serine synthesis are the liver and kidney.

FIGURE 37.5 The major pathway for serine synthesis from glucose is on the *left*, and for serine degradation on the *right*. Serine levels are maintained because serine causes repression (\downarrow) of 3-phosphoglycerate dehydrogenase synthesis. Serine also inhibits (\ominus) phosphoserine phosphatase. ADP, adenosine diphosphate; ATP, adenosine triphosphate; NAD, nicotinamide adenine dinucleotide; PEP, phosphoenolpyruvate; P_i , inorganic phosphate; PLP, pyridoxal phosphate.

Serine can be used by many tissues and is generally degraded by transamination to hydroxypyruvate, followed by reduction and phosphorylation to form 2-phosphoglycerate, an intermediate of glycolysis that forms phosphoenolpyruvate (PEP) and, subsequently, pyruvate. Serine also can undergo β -elimination of its hydroxyl group, catalyzed by serine dehydratase, to form pyruvate directly.

Regulatory mechanisms maintain serine levels in the body. When serine levels fall, serine synthesis is increased by induction of 3-phosphoglycerate dehydrogenase and by release of the feedback inhibition of phosphoserine phosphatase (caused by higher levels of serine). When serine levels rise, synthesis of serine decreases because synthesis of the dehydrogenase is repressed and the phosphatase is inhibited (see Fig. 37.5).

B. Glycine

Glycine can be synthesized from serine and, to a minor extent, threonine. The major route from serine is by a reversible reaction that involves FH_4 and PLP (Fig. 37.6). Tetrahydrofolate is a coenzyme that transfers one-

carbon groups at different levels of oxidation. It is derived from the vitamin folate and is discussed in more detail in Chapter 38. The minor pathway for glycine production involves threonine degradation (this is an aldolase-like reaction because threonine contains a hydroxyl group located two carbons from the carbonyl group).

FIGURE 37.6 Metabolism of glycine. Glycine can be synthesized from serine (major route) or threonine. Glycine forms serine or CO_2 and NH_4^+ by reactions that require tetrahydrofolate (FH_4). Glycine also forms glyoxylate, which is converted to oxalate or to CO_2 and H_2O . $\text{N}^5, \text{N}^{10}-\text{CH}_2-\text{FH}_4$, $\text{N}^5, \text{N}^{10}$ -methylene tetrahydrofolate (see Chapter 38); NAD, nicotinamide adenine dinucleotide; PLP, pyridoxal phosphate; TPP, thiamine pyrophosphate.

 Oxalate, produced from glycine or the small amount absorbed from the diet, forms precipitates with calcium. Kidney stones (renal calculi) are most often composed of calcium oxalate. A lack of the transaminase that can convert glyoxylate to glycine (see Fig. 37.6) leads to the disease primary oxaluria type I (PH 1). This disease has a consequence of renal failure attributable to excessive accumulation of calcium oxalate in the kidney.

The conversion of glycine to glyoxylate by the enzyme D-amino acid oxidase is a degradative pathway of glycine that is clinically relevant. Once glyoxylate is formed, it can be oxidized to oxalate, which is sparingly soluble and tends to precipitate in kidney tubules, leading to formation of kidney stones. Approximately 40% of oxalate formation in the liver comes from glycine metabolism. Dietary oxalate accumulation has been estimated to be a low contributor to excreted oxalate in the urine because of poor absorption of crystallized oxalate in the intestine.

 Cystathionuria, the presence of cystathionine in the urine, is relatively common in premature infants. As they mature, cystathionase levels rise, and the levels of cystathionine in the urine decrease. In adults, a genetic deficiency of cystathionase causes cystathionuria. Individuals with a genetically normal cystathionase can also develop cystathionuria from a dietary deficiency of pyridoxine (vitamin B_6) because cystathionase requires the cofactor pyridoxal phosphate. No characteristic clinical abnormalities have been observed in individuals with cystathionase deficiency, and it is probably a benign disorder.

Although glyoxalate can be transaminated back to glycine, this is not really considered a biosynthetic route for “new” glycine, because the primary route for glyoxylate formation is from glycine oxidation.

Generation of energy from glycine occurs through a dehydrogenase (glycine cleavage enzyme) that oxidizes glycine to CO_2 , ammonia, and a carbon that is donated to FH_4 .

C. Cysteine

The carbons and nitrogen for cysteine synthesis are provided by serine, and the sulfur is provided by methionine (Fig. 37.7). Serine reacts with homocysteine (which is produced from methionine) to form cystathionine. This reaction is catalyzed by cystathionine β -synthase. Cleavage of cystathionine by cystathionase produces cysteine and α -ketobutyrate, which forms succinyl CoA via propionyl CoA. Both cystathionine β -synthase (β -elimination) and cystathionase (γ -elimination) require PLP.

FIGURE 37.7 Synthesis and degradation of cysteine. Cysteine is synthesized from the carbons and nitrogen of serine and the sulfur of homocysteine (which is derived from methionine). During the degradation of cysteine, the sulfur is converted to sulfate and either excreted in the urine or converted to 3'-phosphoadenosine 5'-phosphosulfate (PAPS, the universal sulfate donor), and the carbons are converted to pyruvate. ATP, adenosine triphosphate; Methylmalonyl CoA, methylmalonyl coenzyme A; propionyl CoA, propionyl coenzyme A; PLP, pyridoxal phosphate; Succinyl CoA, succinyl coenzyme A.

Cystinuria and cystinosis are disorders involving two different transport proteins for cystine, the disulfide formed from two molecules of cysteine. Cystinuria is caused by a defect in the transport protein that carries cystine, lysine, arginine, and ornithine into intestinal epithelial cells and that permits resorption of these amino acids by renal tubular cells. Cystine, which is not very soluble in the urine, forms renal calculi (stones). **David K.**, a patient with cystinuria, developed cystine stones (see Chapter 35).

Cystinosis is a rare disorder caused by a defective carrier that normally transports cystine across the lysosomal membrane from lysosomal vesicles to the cytosol. Cystine accumulates in the lysosomes in many tissues and forms crystals, leading to a depletion of intracellular cysteine levels. Children with this disorder develop renal failure by 6 to 12 years of age, through a mechanism that has not yet been fully elucidated.

Cysteine inhibits cystathionine β -synthase and, therefore, regulates its own production to adjust for the dietary supply of cysteine. Because cysteine derives its sulfur from the essential amino acid methionine, cysteine becomes essential if the supply of methionine is inadequate for cysteine synthesis. Conversely, an adequate dietary source of cysteine “spares” methionine; that is, it decreases the amount that must be degraded to produce cysteine.

When cysteine is degraded, the nitrogen is converted to urea, the carbons to pyruvate, and the sulfur to sulfate, which has two potential fates (see Fig. 37.7; see also Chapter 40). Sulfate generation, in an aqueous medium, is essentially generating sulfuric acid, and both the acid and sulfate need to be disposed of in the urine. Sulfate is also used in most cells to generate an activated form of sulfate known as PAPS (3'-phosphoadenosine 5'-phosphosulfate), which is used as a sulfate donor in modifying carbohydrates or amino acids in various structures (glycosaminoglycans) and proteins in the body.

The conversion of methionine to homocysteine and homocysteine to cysteine is the major degradative route for these two amino acids. Because this is the only degradative route for homocysteine, vitamin B₆ deficiency or congenital cystathionine β -synthase deficiency can result in homocystinemia, which is associated with cardiovascular disease.

D. Alanine

Alanine is produced from pyruvate by a transamination reaction catalyzed by alanine aminotransaminase (ALT) and may be converted back to pyruvate by a reversal of the same reaction (see Fig. 37.4). Alanine is the major gluconeogenic amino acid because it is produced in many tissues for the transport of nitrogen to the liver.

III. Amino Acids Related to TCA Cycle Intermediates

Two groups of amino acids are synthesized from TCA cycle intermediates: one group from α -ketoglutarate and one from oxaloacetate (see Fig. 37.1). During degradation, four groups of amino acids are converted to the TCA cycle intermediates α -ketoglutarate, oxaloacetate, succinyl CoA, and fumarate (see Fig. 37.2A).

A. Amino Acids Related through α -Ketoglutarate/Glutamate

1. Glutamate

The five carbons of glutamate are derived from α -ketoglutarate either by transamination or by the glutamate dehydrogenase reaction (see Chapter 36). Because α -ketoglutarate can be synthesized from glucose, all of the carbons of glutamate can be obtained from glucose (see Fig. 37.1). When glutamate is degraded, it is likewise converted back to α -ketoglutarate either by transamination or by glutamate dehydrogenase. In the liver, α -ketoglutarate leads to the formation of malate, which produces glucose via gluconeogenesis. Thus, glutamate can be derived from glucose and reconverted to glucose (Fig. 37.8).

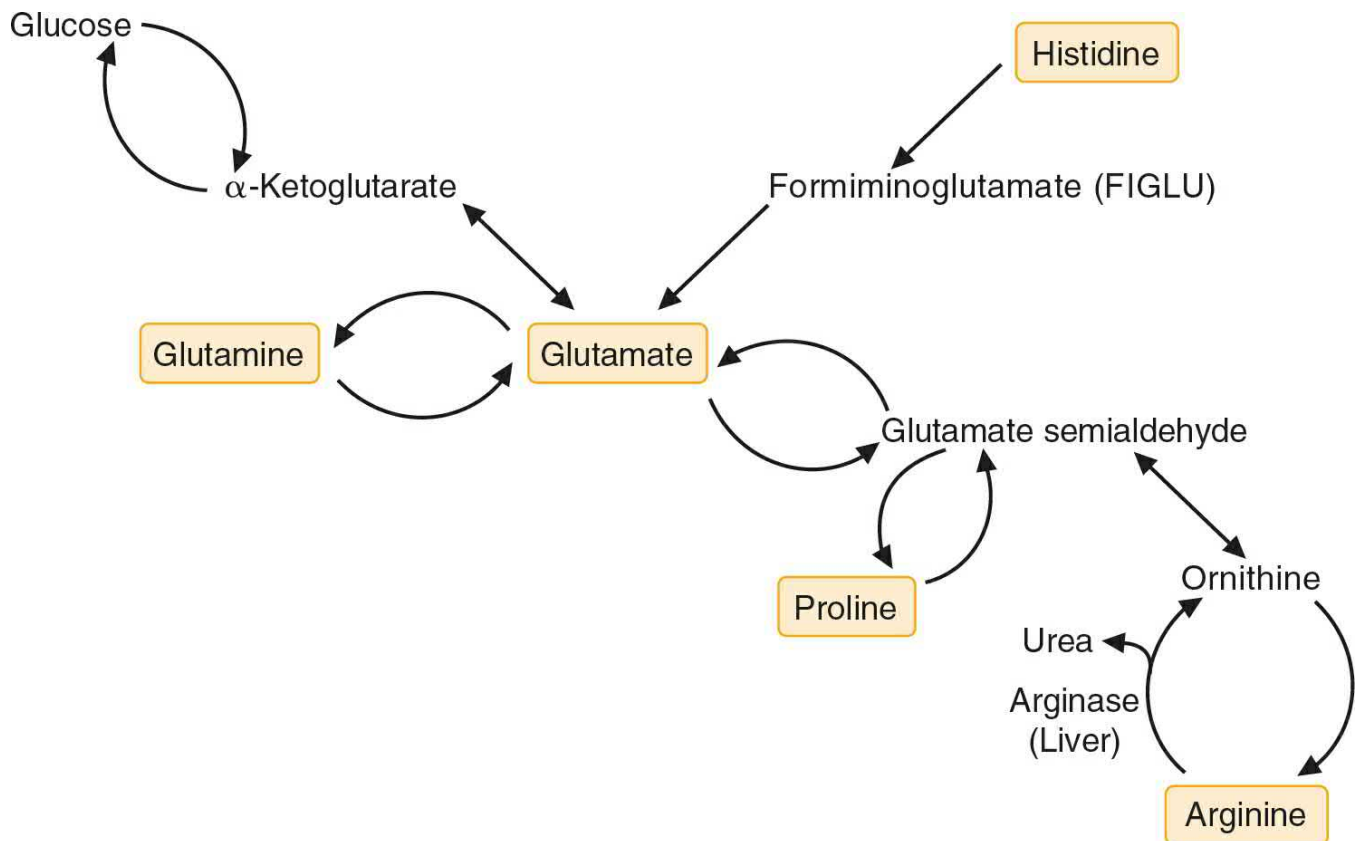

FIGURE 37.8 Amino acids related through glutamate. These amino acids contain carbons that can be reconverted to glutamate, which can be converted to glucose in the liver. All of these amino acids except histidine can be synthesized from glucose.

Homocysteine is oxidized to a disulfide, homocystine. To indicate that both forms are being considered, the term "homocyst(e)ine" is used.

Homocysteine

Homocysteine

Homocystine

Because a colorimetric screening test for urinary homocystine was positive, the doctor ordered several biochemical studies on **Horace S.**'s serum, which included tests for methionine, homocyst(e)ine (both free and protein-bound), cystine, vitamin B₁₂, and folate. The level of homocystine in a 24-hour urine collection was also measured.

The results were as follows: the serum methionine level was 980 μM (reference range, <30 μM); serum homocyst(e)ine (both free and protein-bound) was markedly elevated; cystine was not detected in the serum; the serum B₁₂ and folate levels were normal. A 24-hour urine homocystine level was elevated.

Based on these measurements, **Horace S.**'s doctor concluded that he had homocystinuria caused by an enzyme deficiency. What was the rationale for this conclusion?

Glutamate is used for the synthesis of a number of other amino acids (glutamine, proline, ornithine, and arginine) (see Fig. 37.8) and for providing the glutamyl moiety of glutathione (γ-glutamyl-cysteinyl-glycine; see "Biochemical Comments" in Chapter 35). Glutathione is an important antioxidant, as has been described previously (see Chapter 27).

2. Glutamine

Glutamine is produced from glutamate by glutamine synthetase, which adds NH_4^+ to the carboxyl group of the side chain, forming an amide (Fig. 37.9). This is one of only four human enzymes that can fix free ammonia into an organic molecule; the other three are glutamate dehydrogenase, glycine cleavage enzyme, and carbamoyl phosphate synthetase I (see Chapter 36). Glutamine is reconverted to glutamate by a different enzyme, glutaminase, which is particularly important in the kidney. The ammonia it produces enters the urine and can be used as an expendable cation to aid in the excretion of metabolic acids ($\text{NH}_3 + \text{H}^+ \rightarrow \text{NH}_4^+$), as discussed in Chapter 36.

Glutamine

FIGURE 37.9 Synthesis and degradation of glutamine. Different enzymes catalyze the addition and the removal of the amide nitrogen of glutamine. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i, inorganic phosphate.

3. Proline

In the synthesis of proline, glutamate is first phosphorylated and then converted to glutamate 5-semialdehyde by reduction of the side-chain carboxyl group to an aldehyde (Fig. 37.10). This semialdehyde spontaneously cyclizes (forming an internal Schiff base between the aldehyde and the α -amino group). Reduction of this cyclic compound yields proline. Hydroxyproline is formed only after proline has been incorporated into collagen (see Chapter 47) by the prolyl hydroxylase system, which uses molecular oxygen, iron, α -ketoglutarate, and ascorbic acid (vitamin C).

FIGURE 37.10 Synthesis and degradation of proline. Reactions 1, 3, and 4 occur in mitochondria. Reaction 2 occurs in the cytosol. Synthesis and degradation involve different enzymes. The cyclization reaction (formation of a Schiff base) is nonenzymatic; that is, it is spontaneous. ADP, adenosine diphosphate; ATP, adenosine triphosphate; FAD, flavin adenine dinucleotide; NAD, nicotinamide adenine dinucleotide; P_i, inorganic phosphate.

Proline is converted back to glutamate semialdehyde, which is oxidized to form glutamate. The synthesis and degradation of proline use different enzymes even though the intermediates are the same. Hydroxyproline, however, has an entirely different degradative pathway (not shown). The presence of the hydroxyl group in hydroxyproline allows an aldolase-like reaction to occur once the ring has been hydrolyzed, which is not possible with proline.

If the blood levels of methionine and homocysteine are very elevated and cystine is low, cystathionine β-synthase could be defective, but a cystathionase deficiency is also a possibility. With a deficiency of either of these enzymes, cysteine could not be synthesized and levels of homocysteine would rise. Homocysteine would be converted to methionine by reactions that require vitamin B₁₂ and tetrahydrofolate (see Chapter 38). In addition, it would be oxidized to homocystine, which would appear in the urine. The levels of cysteine (measured as its oxidation product cystine) would be low. A measurement of serum cystathionine levels would help to distinguish between a cystathionase or cystathionine β-synthase deficiency.

4. Arginine

Arginine is synthesized from glutamate via glutamate semialdehyde, which is transaminated to form ornithine, an intermediate of the urea cycle (see Fig. 36.12). This activity (ornithine aminotransferase) appears to be greatest in the epithelial cells of the small intestine (see Chapter 40). The reactions of the urea cycle then produce arginine. However, the quantities of arginine generated by the urea cycle are adequate only for the adult and are insufficient to support growth. Therefore, during periods of growth, arginine becomes an essential amino acid. It is important to realize that if arginine is used for protein synthesis, the levels of ornithine will drop, thereby slowing the urea cycle. This will stimulate the formation of ornithine from glutamate.

Arginine is cleaved by arginase to form urea and ornithine. If ornithine is present in amounts in excess of those required for the urea cycle, it is transaminated to glutamate semialdehyde, which is reduced to glutamate. The conversion of an aldehyde to a primary amine is a unique form of a transamination reaction and requires PLP.

5. Histidine

Although histidine cannot be synthesized in humans, five of its carbons form glutamate when it is degraded. In a series of steps, histidine is converted to formiminoglutamate (FIGLU). The subsequent reactions transfer one carbon of FIGLU to the FH₄ pool (see Chapter 38) and release NH₄⁺ and glutamate.

B. Amino Acids Related to Oxaloacetate (Aspartate and Asparagine)

Aspartate is produced by transamination of oxaloacetate. This reaction is readily reversible, so aspartate can be reconverted to oxaloacetate (Fig. 37.11).

Oxaloacetate

Aspartate

Asparagine

FIGURE 37.11 Synthesis and degradation of aspartate and asparagine. Note that the amide nitrogen of asparagine is derived from glutamine. (The amide nitrogen of glutamine comes from NH_4^+ ; see Fig. 37.8.) AMP, adenosine monophosphate; ATP, adenosine triphosphate; PP_i , pyrophosphate.

Asparagine is formed from aspartate by a reaction in which glutamine provides the nitrogen for formation of the amide group. Thus, this reaction differs from the synthesis of glutamine from glutamate, in which NH_4^+ provides the nitrogen. However, the reaction catalyzed by asparaginase, which hydrolyzes asparagine to NH_4^+ and aspartate, is analogous to the reaction catalyzed by glutaminase.

C. Amino Acids That Form Fumarate

1. Aspartate

Although the major route for aspartate degradation involves its conversion to oxaloacetate, carbons from aspartate can form fumarate in the urea cycle (see Chapter 36). This reaction generates cytosolic fumarate, which must be converted to malate (using cytoplasmic fumarase) for transport into the mitochondria for oxidative or anaplerotic purposes. An analogous sequence of reactions occurs in the purine nucleotide cycle. Aspartate reacts with inosine monophosphate (IMP) to form an intermediate (adenylosuccinate) that is then cleaved, forming adenosine monophosphate (AMP) and fumarate (see Chapter 39).

Certain types of tumor cells, particularly leukemic cells, require asparagine for their growth. Therefore, asparaginase has been used as an antitumor agent. It acts by converting asparagine to aspartate in the blood, decreasing the amount of asparagine available for tumor cell growth. Asparaginase has been utilized for over 30 years to treat acute lymphoblastic leukemia.

2. Phenylalanine and Tyrosine

Phenylalanine is converted to tyrosine by a hydroxylation reaction. Tyrosine, produced from phenylalanine or obtained from the diet, is oxidized, ultimately forming acetoacetate and fumarate. The oxidative steps required to reach this point are, surprisingly, not energy generating. The conversion of fumarate to malate, followed by the action of malic enzyme, allows the carbons to be used for gluconeogenesis. The conversion of phenylalanine to tyrosine and the production of acetoacetate are considered further in Section IV of this chapter.

D. Amino Acids That Form Succinyl CoA

The essential amino acids methionine, valine, isoleucine, and threonine are degraded to form propionyl CoA. The conversion of propionyl CoA to succinyl CoA is common to their degradative pathways. Propionyl CoA is also generated from the oxidation of odd-chain fatty acids.

Propionyl CoA is carboxylated in a reaction that requires biotin and forms D-methylmalonyl CoA. The D-methylmalonyl CoA is racemized to L-methylmalonyl CoA, which is rearranged in a vitamin B₁₂-requiring reaction to produce succinyl CoA, a TCA cycle intermediate (see Fig. 30.11).

1. Methionine

Methionine is converted to S-adenosylmethionine (SAM), which donates its methyl group to other compounds to form S-adenosylhomocysteine (SAH). SAH is then converted to homocysteine (Fig. 37.12). Methionine can be regenerated from homocysteine by a reaction that requires both FH_4 and vitamin B₁₂ (a topic that is considered in more detail in Chapter 38). Alternatively, by reactions that require PLP, homocysteine can provide the sulfur needed for the synthesis of cysteine (see Fig. 37.7). Carbons of homocysteine are then metabolized to α -ketobutyrate, which undergoes oxidative decarboxylation to propionyl CoA. The propionyl CoA is then converted to succinyl CoA (see Fig. 37.12).

FIGURE 37.12 Conversion of methionine and other amino acids to succinyl CoA. The amino acids methionine, threonine,

isoleucine, and valine, all of which form succinyl CoA via methylmalonyl CoA, are essential in the diet. The carbons of serine are converted to cysteine and do not form succinyl CoA by this pathway. Acetyl CoA, acetyl coenzyme A; B₁₂-CH₃, methylcobalamin; methylmalonyl CoA, methylmalonyl coenzyme A; N⁵-CH₃-FH₄, N⁵-methyltetrahydrofolate; PLP, pyridoxal phosphate; propionyl CoA, propionyl coenzyme A; SAM, S-adenosylmethionine; succinyl CoA, succinyl coenzyme A; TCA, tricarboxylic acid.

A biopsy specimen from **Horace S.**'s liver was sent to the hospital's biochemistry research laboratory for enzyme assays. Cystathionine β-synthase activity was reported to be 7% of that found in normal liver.

Homocystinuria is caused by deficiencies in the enzymes cystathionine β-synthase and cystathionase as well as by deficiencies of methyltetrahydrofolate (CH₃-FH₄) or of methyl-B₁₂. The deficiencies of CH₃-FH₄ or of methyl-B₁₂ are due either to an inadequate dietary intake of folate or vitamin B₁₂ or to defective enzymes involved in joining methyl groups to tetrahydrofolate (FH₄), transferring methyl groups from FH₄ to B₁₂, or passing them from B₁₂ to homocysteine to form methionine (see Chapter 38).

Is **Horace S.**'s homocystinuria caused by any of these problems?

Horace S.'s methionine levels are elevated, and his vitamin B₁₂ and folate levels are normal. Therefore, he does not have a deficiency of dietary folate or vitamin B₁₂ or of the enzymes that transfer methyl groups from tetrahydrofolate to homocysteine to form methionine. In these cases, homocysteine levels are elevated but methionine levels are low.

2. Threonine

In humans, threonine is primarily degraded by a PLP-requiring dehydratase to ammonia and α-ketobutyrate, which subsequently undergoes oxidative decarboxylation to form propionyl CoA, just as in the case for methionine (see Fig. 37.12).

3. Valine and Isoleucine

The branched-chain amino acids (valine, isoleucine, and leucine) are a universal fuel, and the degradation of these amino acids occurs at low levels in the mitochondria of most tissues, but the muscle carries out the highest level of branched-chain amino acid oxidation. The branched-chain amino acids make up almost 25% of the content of the average protein, so their use as fuel is quite significant. The degradative pathway for valine and isoleucine has two major functions, the first being energy generation and the second to provide precursors to replenish TCA cycle intermediates (anaplerosis). Both valine and isoleucine contain carbons that form succinyl CoA. The initial step in the degradation of the branched-chain amino acids is a transamination reaction. Although the enzyme that catalyzes this reaction is present in most tissues, the level of activity varies from tissue to tissue. Its activity is particularly high in muscle, however. In the second step of the degradative pathway, the α-keto analogs of these amino acids undergo oxidative decarboxylation by the α-keto acid dehydrogenase complex in a reaction similar in its mechanism and cofactor requirements to pyruvate dehydrogenase and α-ketoglutarate dehydrogenase (see Chapter 23). As with the first enzyme of the pathway, the highest level of activity for this dehydrogenase is found in muscle tissue. Subsequently, the pathways for degradation of these amino acids follow parallel routes (Fig. 37.13). The steps are analogous to those for β-oxidation of fatty acids, so NADH and FAD(2H) are generated for energy production.

FIGURE 37.13 Degradation of the branched-chain amino acids. Valine forms propionyl coenzyme A (propionyl CoA). Isoleucine forms propionyl CoA and acetyl coenzyme A (acetyl CoA). Leucine forms acetoacetate and acetyl CoA. FAD, flavin adenine dinucleotide; HMG-CoA, hydroxymethylglutaryl coenzyme A; Isobutyryl CoA, isobutyryl coenzyme A; Isovaleryl CoA, isovaleryl coenzyme A; Methylbutyryl CoA, methylbutyryl coenzyme A; Methylmalonyl CoA, methylmalonyl coenzyme A; NADH, reduced nicotinamide adenine dinucleotide; Succinyl CoA, succinyl coenzyme A.

What compounds form succinyl CoA via propionyl CoA and methylmalonyl CoA?

Thiamin deficiency will lead to an accumulation of α -keto acids in the blood because of an inability of pyruvate dehydrogenase, α -ketoglutarate dehydrogenase, and branched-chain α -keto acid dehydrogenase to catalyze their reactions (see Chapter 8). **AI M.** had a thiamin deficiency resulting from his chronic alcohol use disorder. His ketoacidosis resulted partly from the accumulation of these α -keto acids in his blood and partly from the accumulation of ketone bodies used for energy production. Beriberi is a disorder that results from thiamin deficiency.

In maple syrup urine disease, the branched-chain α -keto acid dehydrogenase that oxidatively decarboxylates the branched-chain amino acids is defective. As a result, the branched-chain amino acids and their α -keto analogs (produced by transamination) accumulate. They appear in the urine, giving it the odor of maple syrup or burnt sugar. The accumulation of α -keto analogs leads to neurological complications. This condition is difficult to treat by dietary restriction, because abnormalities in the metabolism of three essential amino acids contribute to the disease.

Valine and isoleucine are converted to succinyl CoA (see Fig. 37.12). Isoleucine also forms acetyl CoA. Leucine, the third branched-chain amino acid, does not produce succinyl CoA. It forms acetoacetate and acetyl CoA and is strictly ketogenic.

IV. Amino Acids That Form Acetyl CoA and Acetoacetate

Seven amino acids produce acetyl CoA or acetoacetate and, therefore, are categorized as ketogenic. Of these, isoleucine, threonine, and the aromatic amino acids (phenylalanine, tyrosine, and tryptophan) are converted to compounds that produce both glucose and acetyl CoA or acetoacetate (Fig. 37.14). Leucine and lysine do not produce glucose; they produce acetyl CoA and acetoacetate.

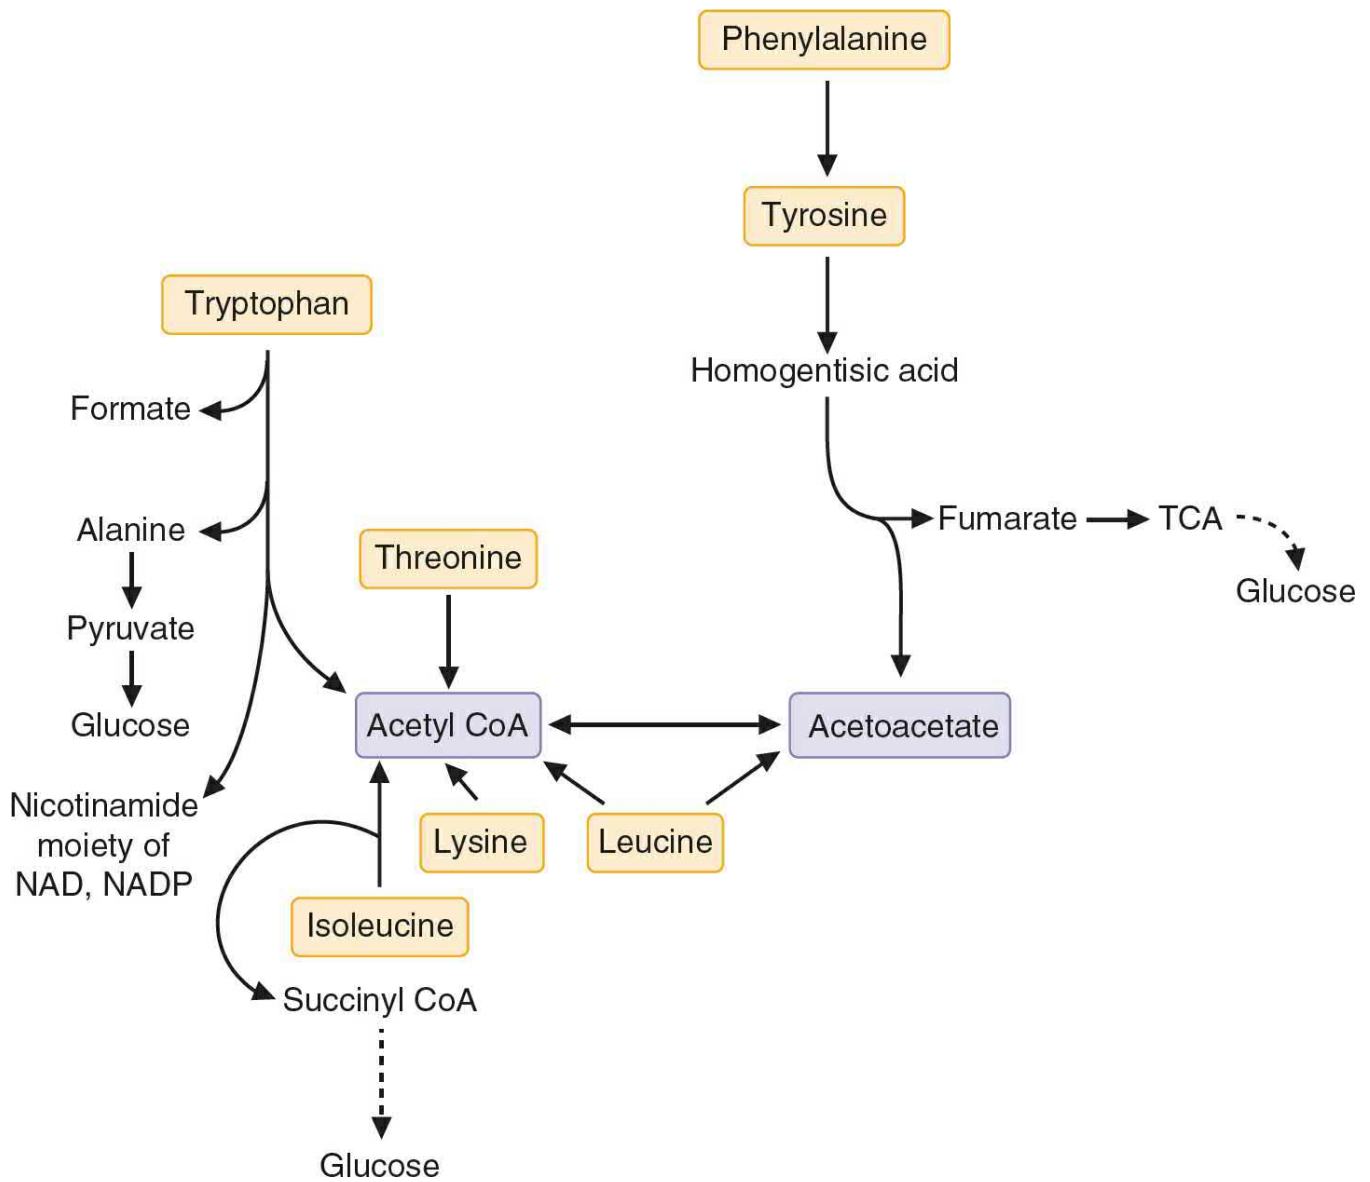

FIGURE 37.14 Ketogenic amino acids. Some of these amino acids (tryptophan, phenylalanine, and tyrosine) also contain carbons that can form glucose. Leucine and lysine are strictly ketogenic; they do not form glucose. Acetyl CoA, acetyl coenzyme A; NAD, nicotinamide adenine dinucleotide; Succinyl CoA, succinyl coenzyme A; TCA, tricarboxylic acid.

A. Phenylalanine and Tyrosine

Phenylalanine is converted to tyrosine, which undergoes oxidative degradation (Fig. 37.15). The last step in the pathway produces both fumarate and the ketone body acetoacetate. Deficiencies of different enzymes in the pathway result in phenylketonuria (PKU), tyrosinemia, and alkaptonuria.

Phenylalanine

Tyrosine

P-Hydroxyphenylpyruvate

Homogentisate

FIGURE 37.15 Degradation of phenylalanine and tyrosine. The carboxyl carbon forms CO_2 , and the other carbons form fumarate or acetoacetate as indicated. Deficiencies of enzymes (dark bars) result in the indicated diseases. PKU, phenylketonuria; PLP, pyridoxal phosphate.

 Alkaptonuria occurs when homogentisate, an intermediate in tyrosine metabolism, cannot be further oxidized because the next enzyme in the pathway, homogentisate oxidase, is defective. Homogentisate accumulates and auto-oxidizes, forming a dark pigment, which discolors the urine and stains the diapers of affected infants. Later in life, the chronic accumulation of this pigment in cartilage may cause arthritic joint pain.

Phenylalanine is hydroxylated to form tyrosine by a mixed-function oxidase, phenylalanine hydroxylase (PAH), which requires molecular oxygen and tetrahydrobiopterin (Fig. 37.16). The cofactor tetrahydrobiopterin is converted to quinonoid dihydrobiopterin by this reaction. Tetrahydrobiopterin is not synthesized from a vitamin; it can be synthesized in the body from guanosine triphosphate (GTP). However, as is the case with other cofactors, the body contains limited amounts. Therefore, dihydrobiopterin must be reconverted to tetrahydrobiopterin for the reaction to continue to produce tyrosine.

FIGURE 37.16 Hydroxylation of phenylalanine. Phenylalanine hydroxylase (PAH) is a mixed-function oxidase; that is, molecular oxygen (O_2) donates one atom to water and one to the product, tyrosine. The cofactor, tetrahydrobiopterin (BH_4), is oxidized to dihydrobiopterin (BH_2) and must be reduced back to BH_4 for phenylalanine hydroxylase (PAH) to continue forming tyrosine. BH_4 is synthesized in the body from guanosine triphosphate (GTP). The disorder phenylketonuria (PKU) results from deficiencies of PAH (the classic form), dihydropteridine reductase, or enzymes in the biosynthetic pathway for BH_4 .

 In addition to methionine, threonine, isoleucine, and valine (see Fig. 37.12), the last three carbons at the ω -end of odd-chain fatty acids form succinyl CoA by this route (see Chapter 30).

 Transient tyrosinemia is frequently observed in newborn infants, especially those that are premature. For the most part, the condition appears to be benign and dietary restriction of protein returns plasma tyrosine levels to normal. The biochemical defect is most likely a low level, attributable to immaturity, of 4-hydroxyphenylpyruvate dioxygenase. Because this

enzyme requires ascorbate, ascorbate supplementation also aids in reducing circulating tyrosine levels.

Other types of tyrosinemia are related to specific enzyme defects (see Fig. 37.15). Tyrosinemia II is caused by a genetic deficiency of tyrosine aminotransferase (TAT) and may lead to lesions of the eye and skin as well as neurological problems. Patients are treated with a low-tyrosine, low-phenylalanine diet.

Tyrosinemia I (also called tyrosinosis) is caused by a genetic deficiency of fumarylacetoacetate hydrolase. The acute form is associated with liver failure and death within the first year of life.

A small subset of patients with hyperphenylalaninemia show an appropriate reduction in plasma phenylalanine levels with dietary restriction of this amino acid; however, these patients can still develop progressive neurological symptoms and seizures ("malignant" hyperphenylalaninemia). These infants exhibit normal phenylalanine hydroxylase (PAH) activity but have a deficiency in dihydropteridine reductase (DHPR), an enzyme required for the regeneration of tetrahydrobiopterin (BH₄), a cofactor of PAH (see Fig. 37.17). Less frequently, DHPR activity is normal but a defect in the biosynthesis of BH₄ exists. In either case, dietary therapy with administration of BH₄ corrects the hyperphenylalaninemia. However, BH₄ is also a cofactor for two other hydroxylations required in the synthesis of neurotransmitters in the brain: the hydroxylation of tryptophan to 5-hydroxytryptophan and of tyrosine to L-DOPA (see Chapter 46). Because BH₄ does not penetrate the CNS as well, patients also need replacement therapy for the neurotransmitters. However, patients will often still have neurological deficits.

FIGURE 37.17 Degradation of tryptophan. One of the ring carbons (in red) produces formate. The nonring portion (indicated by the box) forms alanine. Kynurenine is an intermediate, which can be converted to a number of urinary excretion products (e.g., xanthurenate), degraded to CO₂ and acetyl coenzyme A (acetyl CoA), or converted to the nicotinamide moiety of nicotinamide adenine dinucleotide (NAD) and NADP, which also can be formed from the vitamin niacin. PLP, pyridoxal phosphate.

B. Tryptophan

Tryptophan is oxidized to produce alanine (from the nonring carbons), formate, and acetyl CoA. Tryptophan is, therefore, both glucogenic and ketogenic (Fig. 37.17).

 If the dietary levels of niacin and tryptophan are insufficient, the condition known as pellagra results. The symptoms of pellagra are dermatitis, diarrhea, dementia, and, finally, death. In addition, abnormal metabolism of tryptophan occurs in a vitamin B₆ deficiency. Kynurenine intermediates in tryptophan degradation cannot be cleaved because kynureninase requires PLP derived from vitamin B₆. Consequently, these intermediates enter a minor pathway for tryptophan metabolism that produces xanthurenic acid, which is excreted in the urine.

NAD⁺ and NADP⁺ can be produced from the ring structure of tryptophan. Therefore, tryptophan “saves” the dietary requirement for niacin. The higher the dietary levels of tryptophan, the lower are the levels of niacin required to prevent symptoms of deficiency.

C. Threonine, Isoleucine, Leucine, and Lysine

As discussed previously, the major route of threonine degradation in humans is by threonine dehydratase (see Section III.D.2). In a minor pathway, threonine degradation by threonine aldolase produces glycine and acetyl CoA in the liver.

Isoleucine produces both succinyl CoA and acetyl CoA (see Section III.D.3).

 On more definitive testing of **Petria Y.**'s blood, the plasma level of phenylalanine was elevated at 25 mg/dL (reference range, <1.2). Several phenyl ketones and other products of phenylalanine metabolism, which give the urine a characteristic odor, were found in significant quantities in the baby's urine.

Phenylalanine

Transamination

Phenylpyruvate

Phenylacetate

Phenyllactate

Leucine is purely ketogenic and produces hydroxymethylglutaryl CoA (HMG-CoA), which is cleaved to form acetyl CoA and the ketone body acetoacetate (see Figs. 37.13 and 37.14). Most of the tissues in which it is oxidized can use ketone bodies, with the exception of the liver. As with valine and isoleucine, leucine is a universal fuel, with its primary metabolism occurring in muscle.

Lysine cannot be directly transaminated at either of its two amino groups. Lysine is degraded by a complex pathway in which saccharopine, α -ketoacid, and crotonyl CoA are intermediates. During the degradation pathway, NADH and FADH₂ are generated for energy. Ultimately, lysine generates acetyl CoA (see Fig. 37.14) and is strictly ketogenic.

CLINICAL COMMENTS

Petria Y. The overall incidence of phenylketonuria (PKU), leading to hyperphenylalaninemia, is approximately 1 per 10,000 births, with a wide geographic and ethnic variation. PKU occurs by autosomal-recessive transmission of a defective PAH gene, causing accumulation of phenylalanine in the blood that is well above the normal concentration in young children and adults (<1 to 2 mg/dL). In the newborn, the upper limit of normal is almost twice this value. Values >20 mg/dL are usually found in patients, such as **Petria Y.**, with “classic” PKU.

Patients with classic PKU usually appear normal at birth. If the disease is not recognized and treated within the first month of life, the infant gradually develops varying degrees of irreversible intellectual disability (IQ scores frequently <50), delayed psychomotor maturation, tremors, seizures, eczema, and hyperactivity. The neurological sequelae may result in part from the competitive interaction of phenylalanine with brain amino acid transport systems and inhibition of neurotransmitter synthesis. A successful dietary therapy for PKU includes a reduction in phenylalanine intake and, in adults, can include supplementation of the diet with large, neutral amino acids (such as tryptophan, tyrosine, histidine, and leucine). These large, neutral amino acids share a transport system (the L system) with phenylalanine and can overcome the high levels of phenylalanine in the blood, allowing the neurotransmitter precursors to enter the nervous system. If the disease is not recognized in time, the biochemical alterations lead to impaired myelin synthesis and delayed neuronal development, which result in the clinical picture in patients such as **Petria Y.** Because of the simplicity of the test for PKU (elevated phenylalanine levels in the blood), all newborns in the United States are required to have a PKU test at birth. Early detection of the disease can lead to early treatment, and if followed, the neurological consequences of the disease can be avoided.

To restrict dietary levels of phenylalanine, special semisynthetic preparations (such as Lofenalac, Periflex, or PhenylAde) are used in the United States. Use of these preparations reduces dietary intake of phenylalanine to 250 to 500 mg/day while maintaining normal intake of all other dietary nutrients. Although it is generally agreed that scrupulous adherence to this regimen is mandatory for the first decade of life, less consensus exists regarding its indefinite use. Evidence suggests, however, that without lifelong compliance with dietary restriction of phenylalanine, even adults will develop at least neurological sequelae of PKU. A pregnant woman with PKU must be particularly careful to maintain satisfactory plasma levels of phenylalanine throughout gestation to avoid the adverse effects of hyperphenylalaninemia on the fetus. The use of glycomacropeptide from whey is a promising development in PKU treatment. This protein, when pure, contains no phenylalanine but as isolated has a very low-phenylalanine content (due to contaminants), while providing adequate levels of the other amino acids. The use of glycomacropeptide in PKU diet preparation is expanding and provides alternatives to the dietary therapy not previously available.

A liver biopsy was sent to the special chemistry research laboratory, where it was determined that the level of activity of phenylalanine hydroxylase (PAH) in **Petria Y.**'s liver was <1% of that found in normal infants. A diagnosis of “classic” phenylketonuria (PKU) was made. Until gene therapy allows substitution of the defective PAH gene with its normal counterpart *in vivo*, the mainstay of therapy in classic PKU is to maintain levels of phenylalanine in the blood between 3 and 12 mg/dL through dietary restriction of this essential amino acid.

Petria Y.'s parents were given thorough dietary instruction, which they followed carefully. Although her pediatrician was not optimistic, it was hoped that the damage done to her nervous system before dietary therapy was minimal and that her subsequent psychomotor development would allow her to lead a relatively normal life.

Horace S. The most characteristic biochemical features of the disorder that affects **Horace S.**, a cyst β -synthase deficiency, are the presence of an accumulation of both homocyst(e)ine and methionine in the blood. Because renal tubular reabsorption of methionine is highly efficient, this amino acid may not appear in the urine. Homocystine, the disulfide of homocysteine, is less efficiently reabsorbed, and amounts in excess of 1 mmol may be excreted in the urine each day.

In the type of homocystinuria in which the patient is deficient in cystathionine β -synthase, the elevation in serum methionine levels is presumed to be the result of enhanced rates of conversion of homocysteine to methionine, caused by increased availability of homocysteine (see Fig. 37.12). In type II and type III homocystinuria, in which there is a deficiency in the synthesis of methyl cobalamin and of N^5 -methyltetrahydrofolate, respectively (both required for the methylation of homocysteine to form methionine), serum homocysteine levels are elevated but serum methionine levels are low (see Fig. 37.12).

The pathologic findings that underlie the clinical features manifested by **Horace S.** are presumed (but not proved) to be the consequence of chronic elevations of homocysteine (and perhaps other compounds, e.g., methionine) in the blood and tissues. The zonular fibers that normally hold the lens of the eye in place become frayed and break, causing dislocation of the lens. The skeleton reveals a loss of bone density (i.e., osteoporosis), which may explain the curvature of the spine. The elongation of the long bones beyond their normal genetically determined length leads to tall stature.

Animal experiments suggest that increased concentrations of homocysteine and methionine in the brain may trap adenosine as *S*-adenosylhomocysteine, diminishing adenosine levels. Because adenosine normally acts as a central nervous system depressant, its deficiency may be associated with a lowering of the seizure threshold as well as a reduction in cognitive function.

Acute vascular events are common in these patients. Thrombi (blood clots) and emboli (clots that have broken off and traveled to a distant site in the vascular system) have been reported in almost every major artery and vein as well as in smaller vessels. These clots result in infarcts in vital organs such as the liver, the myocardium (heart muscle), the lungs, the kidneys, and many other tissues. Although increased serum levels of homocysteine have been implicated in enhanced platelet aggregation and damage to vascular endothelial cells (leading to clotting and accelerated atherosclerosis), no generally accepted mechanism for these vascular events has yet emerged.

Treatment is directed toward early reduction of the elevated levels of homocysteine and methionine in the blood. In addition to a diet that is low in methionine, very high oral doses of pyridoxine (vitamin B_6) have significantly decreased the plasma levels of homocysteine and methionine in some patients with cystathionine β -synthase deficiency. (Genetically determined “responders” to pyridoxine treatment make up ~50% of type I homocystinurics.) PLP serves as a cofactor for cystathionine β -synthase; however, the molecular properties of the defective enzyme that confer the responsiveness to vitamin B_6 therapy are not known.

The terms **hypermethioninemia**, **homocystinuria** (or -emia), and **cystathioninuria** (or -emia) designate biochemical abnormalities and are not specific clinical diseases. Each may be caused by more than one specific genetic defect. For example, at least seven distinct genetic alterations can cause increased excretion of homocystine in the urine. A deficiency of cystathionine β -synthase is the most common cause of homocystinuria; more than 600 such proven cases have been studied.

BIOCHEMICAL COMMENTS

Phenylketonuria. Many enzyme deficiency diseases have been discovered that affect the pathways of amino acid metabolism. These deficiency diseases have helped researchers to elucidate the pathways in humans, in whom experimental manipulation is, at best, unethical. These spontaneous mutations (“experiments” of nature), although devastating to patients, have resulted in an understanding of these diseases that now permit treatment of inborn errors of metabolism that were once considered to be untreatable.

Classic PKU is caused by mutations in the gene located on chromosome 12 that encodes the enzyme PAH. This enzyme normally catalyzes the hydroxylation of phenylalanine to tyrosine, the rate-limiting step in the major pathway by which phenylalanine is catabolized.

In early experiments, sequence analysis of mutant clones indicated a single base substitution in the gene, with a G-to-A transition at the canonical 5' donor splice site of intron 12 and expression of a truncated unstable protein product. This protein lacked the C-terminal region, a structural change that yielded <1% of the normal activity of PAH.

Since these initial studies, DNA analysis has shown >100 mutations (missense, nonsense, insertions, and deletions) in the PAH gene, associated with PKU and non-PKU hyperphenylalaninemia. That PKU is a heterogeneous phenotype is supported by studies measuring PAH activity in needle biopsy samples taken from the livers of a large group of patients with varying degrees of hyperphenylalaninemia. PAH activity varied from <1% of normal in patients with classic PKU to up to 35% of normal in those with a non-PKU form of hyperphenylalaninemia (such as a defect in BH₄ production; see Chapter 46).

The genetic diseases affecting amino acid degradation that have been discussed in this chapter are summarized in Table 37.1. This is just a partial listing of disorders in amino acid metabolism; there are many others that are less common and were not discussed in this chapter.

AMINO ACID DEGRADATION PATHWAY	MISSING ENZYME	PRODUCT THAT ACCUMULATES	DISEASE	SYMPTOMS
Phenylalanine	Phenylalanine hydroxylase	Phenylalanine	PKU (classical)	Intellectual disability
	Dihydropteridine reductase	Phenylalanine	PKU (nonclassical)	Intellectual disability
	Homogentisate oxidase	Homogentisic acid	Alkaptonuria	Black urine, arthritis
	Fumarylacetoacetate hydrolase	Fumarylacetoacetate	Tyrosinemia I	Liver failure, death early
Tyrosine	Tyrosine aminotransferase	Tyrosine	Tyrosinemia II	Neurological defects
Methionine	Cystathionase	Cystathionine	Cystathioninuria	Benign
	Cystathionine β-synthase	Homocysteine	Homocysteinemia	Cardiovascular complications and neurological problems
Glycine	Glycine transaminase	Glyoxylate	Primary oxaluria type I	Renal failure due to stone formation
Branched-chain amino acids (leucine, isoleucine, valine)	Branched-chain α-keto acid dehydrogenase	α-Keto acids of the branched-chain amino acids	Maple syrup urine disease	Intellectual disability

KEY CONCEPTS

- ◆ Humans can synthesize only 11 of the 20 amino acids required for protein synthesis; the other 9 are considered to be essential amino acids in the diet.
- ◆ Amino acid metabolism utilizes, to a large extent, the cofactors PLP, tetrahydrobiopterin, and tetrahydrofolate.
 - ◆ PLP is required primarily for transamination reactions.
 - ◆ Tetrahydrobiopterin is required for ring hydroxylation reactions.
 - ◆ Tetrahydrofolate is required for one-carbon metabolism and is discussed further in Chapter 38.
- ◆ The nonessential amino acids can be synthesized from glycolytic intermediates (serine, glycine, cysteine, and alanine), TCA cycle intermediates (aspartate, asparagine, glutamate, glutamine, proline, arginine, and ornithine), or from existing amino acids (tyrosine from phenylalanine).
- ◆ When amino acids are degraded, the nitrogen is converted to urea, and the carbon skeletons are classified as either glucogenic (a precursor of glucose) or ketogenic (a precursor of ketone bodies).
- ◆ Defects in amino acid degradation pathways can lead to disease.
 - ◆ Glycine degradation can lead to oxalate production, which may lead to one class of kidney stone formation.
 - ◆ Defects in methionine degradation can lead to hyperhomocysteinemia, which has been linked to blood clotting disorders and heart disease.
 - ◆ A defect in branched-chain amino acid degradation leads to maple syrup urine disease, which has severe neurological consequences.
 - ◆ Defects in phenylalanine and tyrosine degradation lead to PKU, alkaptonuria, tyrosinemia I and II, and albinism.
- ◆ Table 37.2 summarizes in a slightly different format than Table 37.1 the diseases discussed in this chapter.

DISEASE OR ENVIRONMENTAL

DISORDER	OR GENETIC	COMMENTS
PKU	Genetic	Classical PKU is due to a defect in phenylalanine hydroxylase, whereas nonclassical PKU is due to a defect in dihydropteridine reductase (or an inability to synthesize tetrahydrobiopterin). Both forms of PKU will lead to intellectual disability if treatment is not initiated at an early age.
Alkaptonuria	Genetic	Alkaptonuria is due to a defect in homogentisate oxidase, leading to an accumulation of homogentisic acid. Arthritis may develop later in life.
Tyrosinemia	Genetic	Tyrosinemia type 1 is a defect in fumarylacetoacetate hydrolase, leading to liver failure and early death. Tyrosinemia type 2 is a defect in tyrosine aminotransferase, leading to skin lesions and neurological defects.
Cystathionuria	Genetic	Defect in cystathionase, leading to an accumulation of cystathionine. No major complications result from this mutation.
Homocysteinemia	Genetic	A defect in cystathionine β -synthase leads to accumulation of homocysteine, which can result in cardiac and neurological complications in the patient.
Primary oxaluria type 1	Genetic	Defect in glycine transaminase leading to oxalate accumulation, and renal failure due to stone formation within the kidney.
Maple syrup urine disease	Genetic	A defect in the branched-chain α -keto acid dehydrogenase, leading to an accumulation of the α -keto acids of the branched-chain amino acids, resulting in intellectual disability.
Cystinosis	Genetic	A defect in the transport protein that carries cystine across lysosomal membranes, with three forms of diseases. Cystine accumulates in lysosomes, interfering with and ultimately destroying their function and affecting different organs.
Thiamin deficiency	Environmental	A thiamin deficiency leads to accumulation of α -keto acids because the enzymes that catalyze oxidative decarboxylation reactions will not function in the absence of this vitamin. This will interfere with energy production and lead to a ketoacidosis.

PKU, phenylketonuria.

REVIEW QUESTIONS—CHAPTER 37

- If an individual has a vitamin B₆ deficiency, which one of the following amino acids could still be synthesized and be considered nonessential?
 - Tyrosine
 - Serine
 - Alanine
 - Cysteine
 - Aspartate
- The degradation of amino acids can be classified into families, which are named after the end product of the degradative pathway. Which one of the following is such an end product?
 - Citrate
 - Glyceraldehyde 3-phosphate
 - Fructose 6-phosphate
 - Malate
 - Succinyl CoA
- A newborn infant has elevated levels of phenylalanine and phenylpyruvate in her blood. Which one of the following enzymes might be deficient in this baby?
 - Phenylalanine dehydrogenase
 - Phenylalanine oxidase
 - Dihydropteridine reductase
 - Tyrosine hydroxylase
 - Tetrahydrofolate synthase
- PLP is required for which one of the following reaction pathways or individual reactions?
 - Phenylalanine \rightarrow tyrosine
 - Methionine \rightarrow cysteine + α -ketobutyrate

- C. Propionyl CoA → succinyl CoA
 - D. Pyruvate → acetyl CoA
 - E. Glucose → glycogen
5. A folic acid deficiency would interfere with the synthesis of which one of the following amino acids from the indicated precursors?
 - A. Aspartate from oxaloacetate and glutamate
 - B. Glutamate from glucose and ammonia
 - C. Glycine from glucose and alanine
 - D. Proline from glutamate
 - E. Serine from glucose and alanine
 6. A newborn displayed symptoms of maple syrup urine disease, but also displayed elevated levels of lactic acid in their blood (lactic acidosis). Assuming that this is an inherited disorder, with a single gene mutation, which one of the following is a likely substrate for the mutated protein?
 - A. α -Keto acids
 - B. Amino acids
 - C. Monosaccharides
 - D. Nucleotides
 - E. Nucleosides
 - F. Dicarboxylic acids
 7. A child was recently diagnosed with classic PKU. Part of the treatment plan for the child was supplementation with large doses of tryptophan, leucine, and tyrosine. The rationale for such treatment is which one of the following?
 - A. To inhibit PAH activity
 - B. To increase neurotransmitter synthesis
 - C. To activate PAH activity
 - D. To stimulate protein synthesis
 - E. To inhibit protein synthesis
 - F. To decrease neurotransmitter biosynthesis
 8. An individual has been diagnosed with Hartnup disease and is experiencing symptoms consistent with niacin deficiency. In this patient, which amino acid is no longer able to “spare” the dietary requirement for niacin?
 - A. Alanine
 - B. Tryptophan
 - C. Glutamine
 - D. Leucine
 - E. Methionine
 9. Amino acids are an important substrate for gluconeogenesis during fasting. Which one of the following is the major gluconeogenic amino acid received by the liver from the muscle?
 - A. Alanine
 - B. Glycine
 - C. Cysteine
 - D. Pyruvate
 - E. Tryptophan
 10. Which amino acid is involved in producing glutathione, an important antioxidant?
 - A. Glutamine
 - B. Glutamate
 - C. Proline
 - D. Ornithine
 - E. Arginine
 1. Under conditions of stress, the release of cortisol stimulates muscle protein degradation to provide carbons for gluconeogenesis and glycogen synthesis in the liver. The amino acid least likely to provide carbons for the liver’s function under these conditions is which one of the following?
 - A. Alanine
 - B. Valine
 - C. Isoleucine
 - D. Leucine
 - E. Histidine

2. Nitisinone is a drug used to treat patients with alkaptonuria or tyrosinemia, type 1. It is not effective as a treatment for tyrosinemia, type 2. The use of the drug significantly reduces the accumulation of products normally seen in alkaptonuria or type 1 tyrosinemia. The drug most likely blocks the production of which one of the following?
- Tyrosine
 - Phenylalanine
 - Tryptophan
 - Para-hydroxyphenyl pyruvate
 - Homogentisic acid
3. The complete oxidation of the valine carbons to carbon dioxide requires which of the following vitamins or cofactors? Choose the one best answer.

	B6	B12	B1	Biotin	BH₄
A	No	No	No	Yes	No
B	No	Yes	No	No	Yes
C	No	No	Yes	No	Yes
D	Yes	Yes	Yes	Yes	Yes
E	Yes	No	No	No	No
F	Yes	Yes	Yes	Yes	No

Questions 14 and 15 refer to the following case: A 25-year-old man developed kidney stones, and after treatment was advised to reduce his dietary consumption of oxalate. The man did some research, and learned there is a controversy in the literature concerning the effect of dietary oxalate on stone formation. Foods high in oxalate levels include spinach, in which a 100 g serving (either raw or cooked) contains approximately 1 g of oxalate. The man then was trying to decide how to proceed with dietary changes, if any.

4. Assume that 5% of the ingested oxalate is absorbed through the intestinal epithelial cells and into the blood. The dietary oxalate will add to the oxalate produced from the initial step of a transamination of which one of the following amino acids?
- Alanine
 - Glycine
 - Glutamate
 - Serine
 - Threonine
5. Dietary absorption of oxalate is altered by which one of the following in the diet?
- Calcium
 - Copper
 - Iron
 - Magnesium
 - Sodium

ANSWERS TO REVIEW QUESTIONS

1. **The answer is A.** Tyrosine is derived from phenylalanine, which requires BH₄ but not vitamin B₆. Vitamin B₆ is required in the synthesis of serine (transamination), of alanine (another transamination),

cysteine (β -elimination, β -addition, γ -elimination), and aspartate (transamination).

2. **The answer is E.** In addition to succinyl CoA, the other family members of amino acid degradation are acetoacetate, acetyl CoA, fumarate, oxaloacetate, α -ketoglutarate, and pyruvate.
3. **The answer is C.** The classical form of PKU, a deficiency of PAH, results in elevations of phenylalanine and phenylpyruvate. However, this enzyme is not an answer choice. In the nonclassical variant of PKU, there is a problem in either synthesizing or regenerating BH_4 . The enzyme that converts BH_2 to BH_4 is dihydropteridine reductase (DHPR).
4. **The answer is B.** The reaction pathway in which methionine goes to cysteine and α -ketobutyrate requires PLP at two steps, the cystathionine β -synthase reaction and the cystathionase reaction. Phenylalanine to tyrosine requires BH_4 ; propionyl CoA to succinyl CoA requires B_{12} ; pyruvate to acetyl CoA requires thiamin pyrophosphate, lipoic acid, NAD, FAD, and coenzyme A; and glucose to glycogen does not require a cofactor, but glycogen phosphorylase, the enzyme that degrades glycogen to glucose 1-phosphate, does require PLP.
5. **The answer is C.** Folic acid is required for the conversion of serine to glycine (the serine hydroxymethyl transferase reaction) and the serine is produced from 3-phosphoglycerate and alanine. Folic acid is not needed to synthesize aspartate (from oxaloacetate by transamination), glutamate (from α -ketoglutarate by transamination), proline (from glutamate by a series of steps that do not require folic acid), or serine (from 3-phosphoglycerate, with no one-carbon metabolism needed).
6. **The answer is A.** Maple syrup urine disease is due to a dysfunctional branched-chain α -keto acid dehydrogenase, such that the α -keto acids of all three branched-chain amino acids accumulate in the blood. The fact that lactic acidosis is also present (indicating high pyruvate and lactate levels) suggests that pyruvate dehydrogenase (the enzyme that converts pyruvate to acetyl CoA) is also defective. The common link between the branched-chain α -keto acid dehydrogenase and pyruvate dehydrogenase is the E3 subunit of the enzymes, which are the same. The E3 subunit is the dihydrolipoyl dehydrogenase subunit, and it is present in all of the enzymes that catalyze oxidative decarboxylation reactions. Such reactions require, as substrates, α -keto acids. The reaction does not utilize as substrates amino acids, monosaccharides, nucleotides, nucleosides, or dicarboxylic acids.
7. **The answer is B.** A child with classic PKU has a deficiency in PAH, which blocks the conversion of the essential amino acid phenylalanine to tyrosine. This leads to phenylalanine accumulation in the blood, and the high phenylalanine levels saturate the "L" amino acid transport system (for large, neutral, amino acids) such that the nervous system is "starved" for tryptophan, leucine, and tyrosine. As tryptophan and tyrosine are precursors for neurotransmitter synthesis (serotonin and the catecholamines, respectively), neuronal dysfunction will occur. By saturating the system with large, neutral amino acids, the tryptophan, leucine, and tyrosine can compete with the high phenylalanine levels to get into the nervous system, such that neurotransmitter synthesis can proceed. High levels of tryptophan, leucine, and tyrosine do not alter the activity of PAH, nor do they allosterically stimulate, or inhibit, protein synthesis.
8. **The answer is B.** The niacin requirement for the synthesis of NAD^+ and $NADP^+$ can be "spared" by the presence of tryptophan, which can be degraded and produce the nicotinamide component of these cofactors. In Hartnup disease, the neutral amino acid transporter is defective, leading to reduced uptake of tryptophan from the intestine. With less tryptophan available, the dietary requirement for niacin is increased. None of the other amino acids listed (alanine, glutamine, leucine, and methionine) as answers can produce the ring component of NAD^+ and $NADP^+$.
9. **The answer is A.** Pyruvate is not an amino acid. Alanine is produced from pyruvate in a reversible transamination reaction. Alanine is the major gluconeogenic amino acid because it is produced in multiple tissues as a transport mechanism for nitrogen to the liver. Once in the liver, the alanine is transaminated to pyruvate, which enters gluconeogenesis, and the nitrogen (now attached to glutamate) is utilized by the urea cycle for excretion of the nitrogen. Under conditions of starvation, glutamine is also a major nitrogen carrier in the blood (due to its ability to bind two nitrogen groups), but glutamine was not offered as an answer to this question. Glycine, cysteine, and tryptophan are not utilized as nitrogen carriers during fasting, or any other conditions.
10. **The answer is B.** Glutathione is a tripeptide consisting of glutamate, cysteine, and glycine. The glutamate is linked to the cysteine via a peptide bond using the side-chain carboxylic acid of glutamate and the nitrogen group of cysteine. Glutamate is also used as a precursor for the synthesis of all the other amino acids listed as possible answers.
11. **The answer is D.** Leucine and lysine are the only two amino acids which are strictly ketogenic, in that their degradation products can only be used to produce ketone bodies, or fatty acids, but not glucose.

Alanine, valine, and histidine are strictly glucogenic, whereas isoleucine can give rise to carbons that form glucose, as well as carbons that form acetyl CoA.

12. **The answer is E.** Nitisinone blocks the formation of homogentisic acid, allowing para-hydroxyphenyl pyruvate to accumulate. The accumulation of para-hydroxyphenyl pyruvate does not lead to disease, whereas the accumulation of homogentisic acid leads to alkaptonuria, and the accumulation of fumarylacetoacetate (produced from homogentisic acid) leads to tyrosinemia, type 1. Nitisinone has no effect on the tryptophan degradative pathway, and it does not alter phenylalanine synthesis, as phenylalanine is an essential amino acid.
13. **The answer is F.** Valine is a strictly glucogenic amino acid, which first undergoes transamination (which requires vitamin B6, PLP). The next step, as it is for all the branched-chain amino acids, is an oxidative decarboxylation of the α -keto acid product of the transamination reaction. Oxidative decarboxylation reactions require five cofactors, one of which is vitamin B1 (thiamin). Eventually propionyl CoA is produced, which is carboxylated (requiring biotin) to form D-methylmalonyl CoA, which is isomerized to L-methylmalonyl CoA, and then rearranged in a vitamin B12–requiring reaction to form succinyl CoA. Tetrahydrobiopterin (BH_4) is required for ring hydroxylation reactions, which does not occur in the degradation of valine.
14. **The answer is B.** Transamination of glycine will generate glyoxylate, which is then oxidized to form oxalate. When alanine is transaminated, it produces pyruvate, and transamination of glutamate produces α -ketoglutarate. Serine and threonine undergo dehydration, or β -elimination, but not transamination.
15. **The answer is A.** Calcium oxalate is very insoluble, and it is calcium oxalate that forms stones in the kidney. However, if both oxalate and calcium are in the diet, calcium oxalate forms in the intestinal tract, and the oxalate cannot be absorbed, and the precipitate is excreted in the feces. This is a major reason why dietary absorption of oxalate is low. The other answer choices (copper, iron, magnesium, and sodium) do not form insoluble complexes with oxalate, and do not interfere with the absorption of oxalate from the diet.

Tetrahydrofolate, Vitamin B₁₂, and S-Adenosylmethionine

Groups that contain a single-carbon atom can be transferred from one compound to another. These carbon atoms may be in a number of different oxidation states. The most oxidized form, CO₂, is transferred by biotin. One-carbon groups at lower levels of oxidation than CO₂ are transferred by reactions involving tetrahydrofolate (FH₄), vitamin B₁₂, and S-adenosylmethionine (SAM).

Tetrahydrofolate. Tetrahydrofolate, which is produced from the vitamin **folate**, is the primary one-carbon carrier in the body. This vitamin obtains one-carbon units from serine, glycine, histidine, formaldehyde, and formate (Fig. 38.1). While these carbons are attached to FH₄, they can be either oxidized or reduced. As a result, folate can exist in a variety of chemical forms. Once a carbon has been reduced to the methyl level (methyl-FH₄); however, it cannot be reoxidized. Collectively, these one-carbon groups attached to their carrier FH₄ are known as the **one-carbon pool**. The term “folate” is used to represent a water-soluble B-complex vitamin that functions in transferring single-carbon groups at various stages of oxidation.

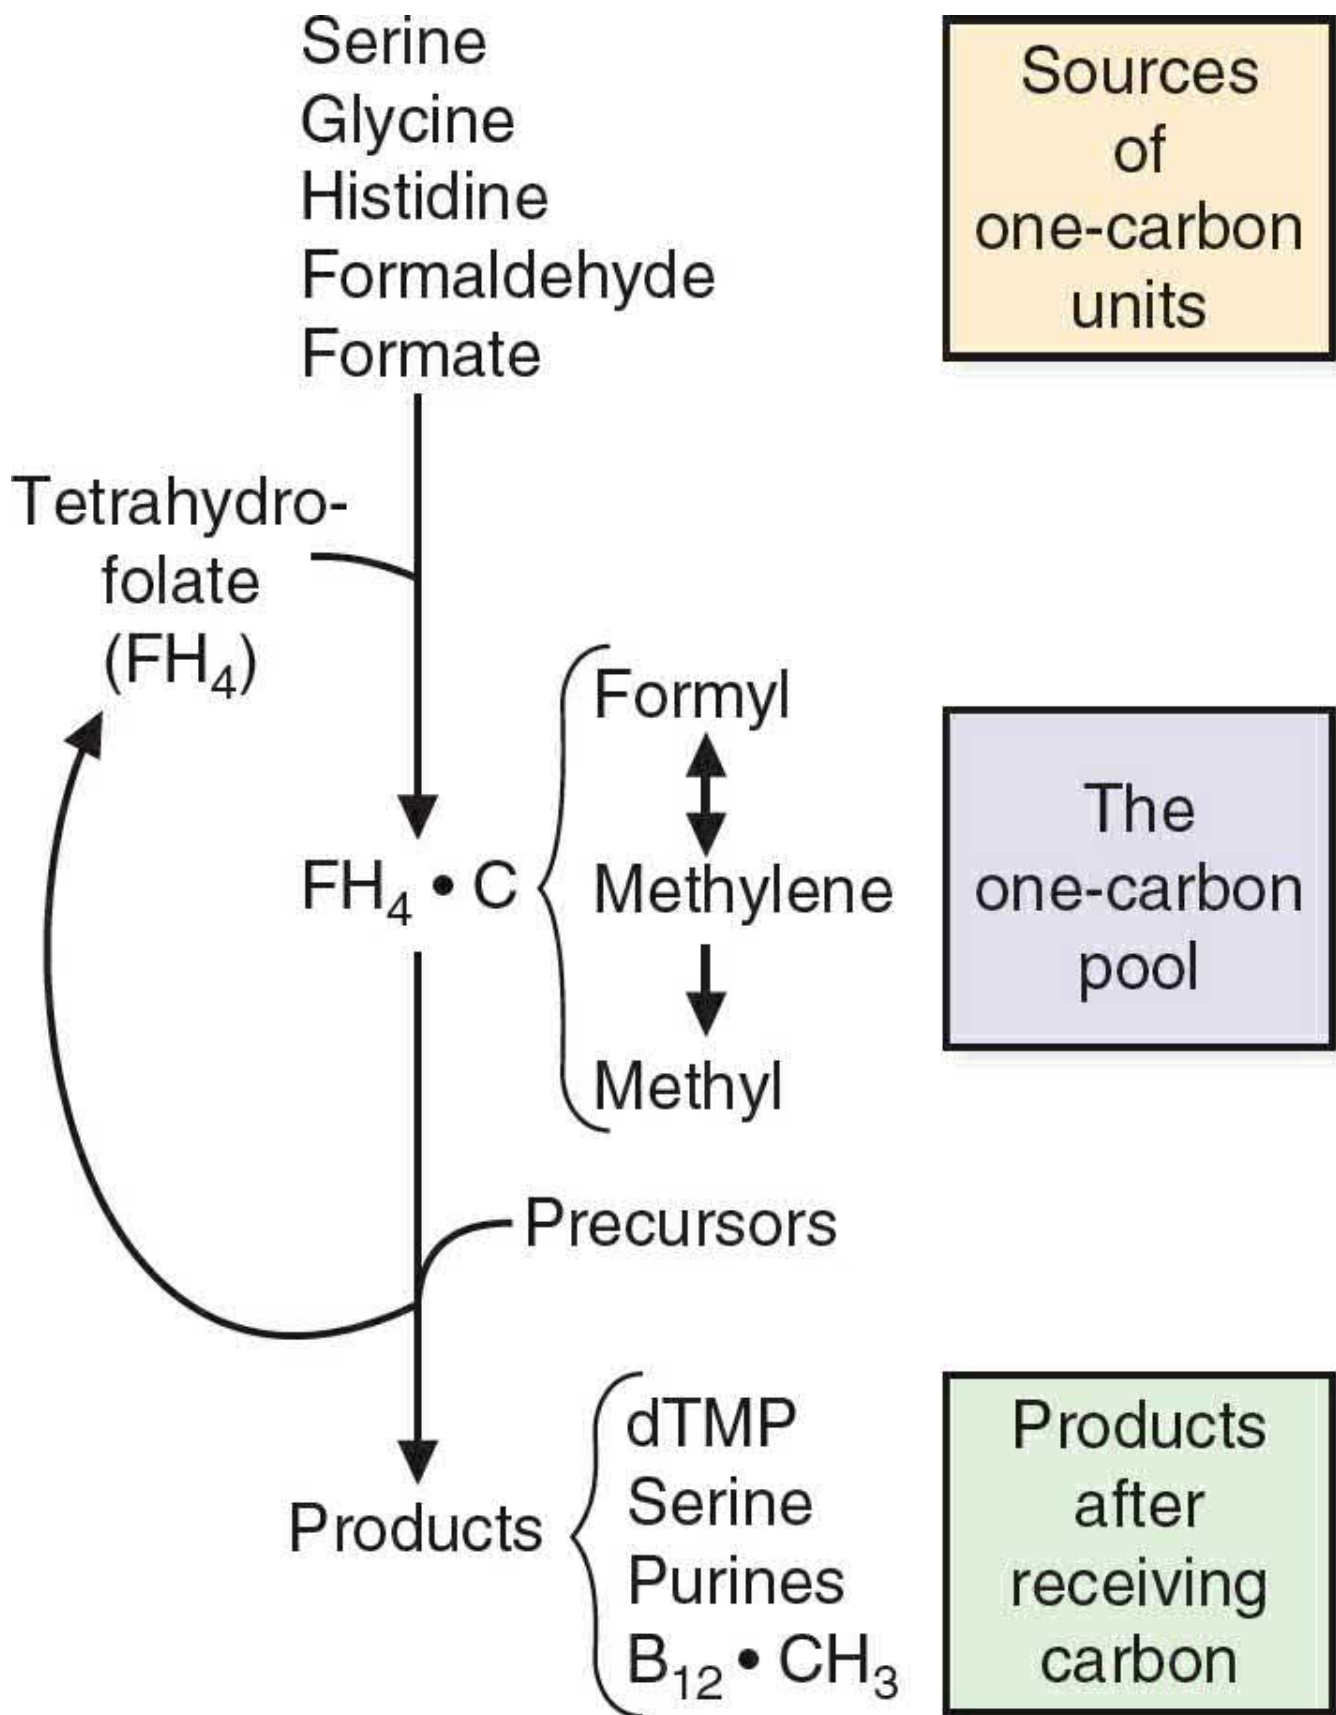

FIGURE 38.1 Overview of the one-carbon pool. $\text{FH}_4 \cdot \text{C}$ indicates tetrahydrofolate (FH_4) containing a one-carbon unit that is at the formyl, methylene, or methyl level of oxidation (see Fig. 38.3). The origin of the carbons is indicated, as are the final products after a one-carbon transfer. dTMP, deoxythymidine monophosphate.

The one-carbon groups carried by FH_4 are used for many biosynthetic reactions. For example,

one-carbon units are transferred to the pyrimidine base of deoxyuridine monophosphate (**dUMP**) to form deoxythymidine monophosphate (**dTMP**), to the amino acid **glycine** to form **serine**, to precursors of the purine bases to produce carbons C2 and C8 of the **purine ring**, and to **vitamin B₁₂**.

Vitamin B₁₂. Vitamin B₁₂ is involved in two reactions in the body. It participates in the rearrangement of the methyl group of L-methylmalonyl coenzyme A (L-methylmalonyl CoA) to form succinyl CoA, and it transfers a methyl group, obtained from FH₄, to homocysteine, forming methionine.

S-adenosylmethionine. SAM, produced from methionine and adenosine triphosphate (ATP), transfers the methyl group to precursors that form a number of compounds, including creatine, phosphatidylcholine, epinephrine, melatonin, methylated nucleotides, methylated histones, and methylated DNA.

Methionine metabolism is very dependent on both FH₄ and vitamin B₁₂. **Homocysteine** is derived from methionine metabolism and can be converted back into methionine by using both methyl-FH₄ and vitamin B₁₂. This is the only reaction in which methyl-FH₄ can donate the methyl group. If the enzyme that catalyzes this reaction is defective, or if vitamin B₁₂ or FH₄ levels are insufficient, homocysteine will accumulate. Elevated homocysteine levels have been linked to cardiovascular and neurological disease. A vitamin B₁₂ deficiency can be brought about by the lack of **intrinsic factor**, a gastric protein required for the absorption of dietary B₁₂. A consequence of vitamin B₁₂ deficiency is the accumulation of methyl-FH₄ and a decrease in other folate derivatives. This is known as the **methyl-trap hypothesis**, in which, because of the B₁₂ deficiency, most of the carbons in the FH₄ pool are trapped in the methyl-FH₄ form, which is the most stable. The carbons cannot be released from the folate because the one reaction in which they participate cannot occur because of the B₁₂ deficiency. This leads to a functional folate deficiency, even though total levels of folate are normal. A folate deficiency (whether functional or actual) leads to **megaloblastic anemia** caused by an inability of blood cell precursors to synthesize DNA and, therefore, to divide. This leads to large, partially replicated cells being released into the blood to attempt to replenish the cells that have died. Folate deficiencies also have been linked to an increased incidence of **neural tube defects**, such as spina bifida, in mothers who become pregnant while folate deficient.

 In the past, the gold standard for determining if someone was B₁₂ deficient was the Schilling test. This test consists of the patient ingesting radioactive (⁵⁷Co) crystalline vitamin B₁₂, after which a 24-hour urine sample was collected. The radioactivity in the urine sample is compared with the input radioactivity, and the difference represents the amount of B₁₂ absorbed through the digestive tract. Such tests could distinguish between problems in removing B₁₂ from bound dietary proteins or if the deficiency is due to a lack of intrinsic factor, or other proteins involved in transporting B₁₂ throughout the body. Another method to determine if intrinsic factor activity is reduced is to determine the levels of anti-intrinsic factor antibodies in the blood. Autoantibodies toward intrinsic factor commonly develop in individuals with lack of intrinsic factor activity, and the levels of such antibodies can be determined in an ELISA using recombinant human intrinsic factor bound to plastic wells as the antigen. The Schilling test has been replaced by a competitive binding luminescent assay. This new test has recently been criticized for being unreliable, particularly if a patient exhibits anti-intrinsic factor antibodies. Suspected B₁₂ deficiencies can also be determined by assaying blood levels of methylmalonic acid or homocysteine.

THE WAITING ROOM

After resection of the cancer in his large intestine and completion of a course of postoperative chemotherapy with 5-fluorouracil (5-FU) and oxaliplatin, **Clark T.** returned to his gastroenterologist for a routine follow-up colonoscopy. His colon was completely normal, with excellent healing at the site of the anastomosis. His physician expressed great optimism about a possible cure of **Clark T.**'s previous malignancy but cautioned him about the need for regular colonoscopies and surveillance CT scans over the next

few years.

Beatrice T., a 75-year-old woman, went to see her physician because of numbness and tingling in her legs. A diet history indicated a normal and healthy diet, but she was not taking any supplemental vitamin pills. Laboratory results indicated a low level of serum B₁₂.

The initial laboratory profile, determined when **Jean T.** first presented to her physician with evidence of early alcohol-induced hepatitis, included a hematologic analysis that showed that **Jean T.** was anemic. Her hemoglobin was 11.0 g/dL (reference range, 12 to 16 g/dL for an adult woman). The erythrocyte (red blood cell) count was 3.6 million cells/mm³ (reference range, 4.0 to 5.2 million cells/mm³ for an adult woman). The average volume of her red blood cells (mean corpuscular volume [MCV]) was 108 fL (reference range = 80 to 100 fL; 1 fL = 10⁻¹² mL), and the hematology laboratory reported a striking variation in the size and shape of the red blood cells in a smear of her peripheral blood (see Chapter 42). The nuclei of the circulating granulocytic leukocytes had increased nuclear segmentation (polysegmented neutrophils). Because these findings are suggestive of a macrocytic anemia (in which blood cells are larger than normal), measurements of serum folate and vitamin B₁₂ (cobalamin) levels were ordered.

Folate deficiencies occur frequently in people with chronic alcohol use disorder. Several factors are involved: inadequate dietary intake of folate; direct damage to intestinal cells and brush border enzymes, which interferes with absorption of dietary folate; a defect in the enterohepatic circulation, which reduces the absorption of folate; liver damage that causes decreased hepatic production of plasma proteins; and interference with kidney reabsorption of folate.

Hematopoietic precursor cells, when exposed to too little folate and/or vitamin B₁₂, show slowed cell division, but cytoplasmic development occurs at a normal rate. Hence, the megaloblastic cells tend to be large, with an increased ratio of RNA to DNA. Megaloblastic erythroid progenitors are usually destroyed in the bone marrow (although some reach the circulation). Thus, marrow cellularity is often increased but production of red blood cells is decreased, a condition called **ineffective erythropoiesis**.

Therefore, **Jean T.** has megaloblastic anemia, characteristic of folate or B₁₂ deficiency.

I. Tetrahydrofolate (FH₄)

A. Structure and Forms of FH₄

Folates exist in many chemical forms. The coenzyme form that functions in accepting one-carbon groups is tetrahydrofolate polyglutamate (Fig. 38.2), generally referred to as just tetrahydrofolate or FH₄. It has three major structural components, a bicyclic pteridine ring, *para*-aminobenzoic acid, and a polyglutamate tail consisting of several glutamate residues joined in amide linkage. The one-carbon group that is accepted by the coenzyme and then transferred to another compound is bound to N⁵, to N¹⁰, or both.

FIGURE 38.2 Reduction of folate to tetrahydrofolate (FH₄). The same enzyme, dihydrofolate reductase, catalyzes both reactions. Multiple glutamate residues are added within cells ($n \sim 5$). Plants can synthesize folate, but humans cannot. Therefore, folate is a dietary requirement. R is the portion of the folate molecule shown to the right of N¹⁰. The different precursors of FH₄ are indicated in the figure. NADP, nicotinamide adenine dinucleotide phosphate; PABA, *para*-aminobenzoic acid.

Different forms of folate may differ in the oxidation state of the one-carbon group, in the number of glutamate residues attached, or in the degree of oxidation of the pteridine ring. When the term “folate” or “folic acid” is applied to a specific chemical form, it is the most oxidized form of the pteridine ring (see Fig. 38.2). Folate is reduced to dihydrofolate and then to tetrahydrofolate by dihydrofolate reductase present in cells. Reduction is the favored direction of the reaction; therefore, most of the folate present in the body is present as the reduced coenzyme form, FH₄.

B. The Vitamin Folate

Folates are synthesized in bacteria and higher plants and ingested in green leafy vegetables, fruits, and legumes in the diet. The vitamin was named for its presence in green, leafy vegetables (foliage). Most of the dietary folate derived from natural food sources is present in the reduced coenzyme form. However, vitamin supplements and fortified foods contain principally the oxidized form of the pteridine ring.

 **Jean T.**'s serum folic acid level was 3.1 ng/mL (reference range, 6 to 15 ng/mL), and her serum B₁₂ level was 210 ng/L (reference range, 180 to 914 ng/L). Her serum iron level was normal. It was clear, therefore, that her megaloblastic anemia was caused by a folate deficiency (although her B₁₂ levels were in the low range of normal). The management of a pure folate deficiency in a patient with alcohol use disorder includes cessation of alcohol intake and a diet that is rich in folate.

 Sulfa drugs, which are used to treat certain bacterial infections, are analogs of *para*-aminobenzoic acid. They prevent growth and cell division in bacteria by interfering with the synthesis of folate. Because we cannot synthesize folate, sulfa drugs do not affect human cells in this way.

 The current U.S. Recommended Dietary Allowance (RDA) for folate equivalents is approximately 400 μg for adult men and women. In addition to being prevalent in green leafy vegetables, other good sources of this vitamin are liver, yeast, legumes, and some fruits. Protracted cooking of these foods, however, can destroy up to 90% of their folate content. A standard U.S. diet provides 50 to 500 μg of absorbable folate each day. Folate deficiency in pregnant women, especially during the month before conception and the month after, increases the risk of neural tube defects, such as spina bifida, in the fetus. To reduce the potential risk of neural tube defects for women capable of becoming pregnant, the recommendation is to take 400 μg of folic acid daily in a multivitamin pill (some organizations recommend 400 to 800 μg daily). If the woman has a history of having a child with a neural tube defect, this amount is increased to 4,000 μg/day for the month before and the month after conception. Flour-containing products in the United States are now supplemented with folate to reduce the risk of neural tube defects in newborns.

As dietary folates pass into the proximal third of the small intestine, folate conjugases in the brush border of the lumen cleave off glutamate residues to produce the monoglutamate form of folate, which is then absorbed (see Fig. 38.2, upper structure, when $n = 1$). Within the intestinal cells, folate is converted principally to N⁵-methyl-FH₄, which enters the portal vein and goes to the liver. Smaller amounts of other forms of folate also follow this route.

The liver, which stores half of the body's folate, takes up much of the folate from the portal circulation; uptake may be through active transport or receptor-mediated endocytosis. Within the liver, FH₄ is reconstituted to the polyglutamate form before being used in reactions. A small amount of the folate is partially degraded, and the components enter the urine. A relatively large portion of the folate enters the bile and is subsequently reabsorbed (very similar to the fate of bile salts in the enterohepatic circulation).

N⁵-Methyl-FH₄, the major form of folate in the blood, is loosely bound to plasma proteins, particularly serum albumin.

C. Oxidation and Reduction of the One-Carbon Groups of Tetrahydrofolate

One-carbon groups transferred by FH₄ are attached either to N⁵ or N¹⁰, or they form a bridge between N⁵ and N¹⁰. The collection of one-carbon groups attached to FH₄ is known as the one-carbon pool. While they are

attached to FH_4 , these one-carbon units can be oxidized and reduced (Fig. 38.3). Thus, reactions that require a carbon in a particular oxidation state may use carbon from the one-carbon pool that was donated in a different oxidation state.

A**Tetrahydrofolate (FH₄)****B****FH₄****N¹⁰-Formyl-FH₄****N⁵,N¹⁰-Methenyl-FH₄****N⁵,N¹⁰-Methylene-FH₄****N⁵-Methyl-FH₄**

FIGURE 38.3 One-carbon units attached to FH₄. **A.** The active form of FH₄. For definition of R, see Figure 38.2. **B.** Interconversions of one-carbon units of FH₄. Only the portion of FH₄ from N⁵ to N¹⁰ is shown, which is indicated by the green box in A. After a formyl group forms a bridge between N⁵ and N¹⁰, two reductions can occur. Note that N⁵-methyl-FH₄ cannot be reoxidized. The most oxidized form of FH₄ is at the top of the figure, whereas the most reduced form is at the bottom. ADP, adenosine diphosphate; ATP, adenosine triphosphate; NAD, nicotinamide adenine dinucleotide; Pi, inorganic phosphate.

 Hereditary folate malabsorption is a rare disease due to a mutation in a proton-coupled folate transporter (PCFT, gene SLC46A1). Loss of PCFT activity in the intestinal proximal jejunum and duodenum lead to systemic folate deficiency. Newborns begin to exhibit symptoms of folate deficiency after a few months of life, after the folate obtained from the mother has been excreted. The children develop anemia, diarrhea, and become immunocompromised (due to the reduction in blood cell differentiation). High-dose oral folate can be used to treat the patients, as another folate transporter (the reduced folate carrier, gene SLC19A1) can absorb sufficient folate when folate is present at high concentrations.

 A deficiency of folate results in the accumulation of FIGLU, which is excreted in the urine. A histidine load test can be used to detect folate deficiency. Patients are given a test dose of histidine (a histidine load), and the amount of FIGLU that appears in the urine is measured and compared to normal values. Values greater than normal indicate folate deficiency.

The concentration of folate in serum can also be determined by a microbiological test. Certain strains of bacteria require folate for growth, and if these bacteria are plated on a medium that lacks folate, they will not grow. Folate levels can be quantitated by preparing a standard curve using plates containing different levels of folate and determining the level of growth of the bacteria at that folate level. The unknown sample is then tested for bacterial growth and the extent of growth compared to the standard curve, to determine the amount of folate in the unknown sample. Other tests for folate include measuring the binding of folate to certain proteins, and use of immunologic reagents that specifically bind to and identify folate.

The individual steps for the reduction of the one-carbon group are shown in Figure 38.3. The most oxidized form is N¹⁰-formyl-FH₄. The most reduced form is N⁵-methyl-FH₄. Once the methyl group is formed, it is not readily reoxidized back to N⁵,N¹⁰-methylene-FH₄, and thus N⁵-methyl-FH₄ tends to accumulate in the cell.

D. Sources of One-Carbon Groups Carried by FH₄

Carbon sources for the one-carbon pool include serine, glycine, formaldehyde, histidine, and formate (Fig. 38.4). These donors transfer the carbons to folate in different oxidation states. Serine is the major carbon source of one-carbon groups in the human. Its hydroxymethyl group is transferred to FH₄ in a reversible reaction, catalyzed by the enzyme serine hydroxymethyltransferase. This reaction produces glycine and N⁵,N¹⁰-methylene-FH₄. Because serine can be synthesized from 3-phosphoglycerate, an intermediate of glycolysis, dietary carbohydrate can serve as a source of carbon for the one-carbon pool. The glycine that is produced may be further degraded by the donation of a carbon to folate. Additional donors that form N⁵,N¹⁰-methylene-FH₄ are listed in Table 38.1.

TABLE 38.1 One-Carbon Pool: Sources and Recipients of Carbon

SOURCE ^a	FORM OF ONE-CARBON DONOR PRODUCED ^b	RECIPIENT	FINAL PRODUCT
Formate	N ¹⁰ -formyl-FH ₄	Purine precursor	Purine (C2 and C8)
Serine	N ⁵ ,N ¹⁰ -methylene-FH ₄	dUMP	dTMP
Glycine		Glycine	Serine
Formaldehyde			
N ⁵ ,N ¹⁰ -methylene-FH ₄	N ⁵ -methyl FH ₄	Vitamin B ₁₂	Methylcobalamin
Histidine	N ⁵ -formimino-FH ₄ is converted to N ⁵ ,N ¹⁰ -methenyl-FH ₄		
Choline	Betaine	Homocysteine	Methionine and dimethylglycine
Methionine	S-adenosylmethionine (SAM)	Glycine (there are many others; see Fig. 38.9B)	N-methylglycine (sarcosine)

dUMP, deoxyuridine monophosphate; dTMP, deoxythymidine monophosphate; FH₄, tetrahydrofolate; SAM, S-adenosylmethionine.

^aThe major source of carbon is serine.

^bThe carbon unit attached to FH₄ can be oxidized and reduced (see Fig. 38.3). At the methyl level, reoxidation does not occur.

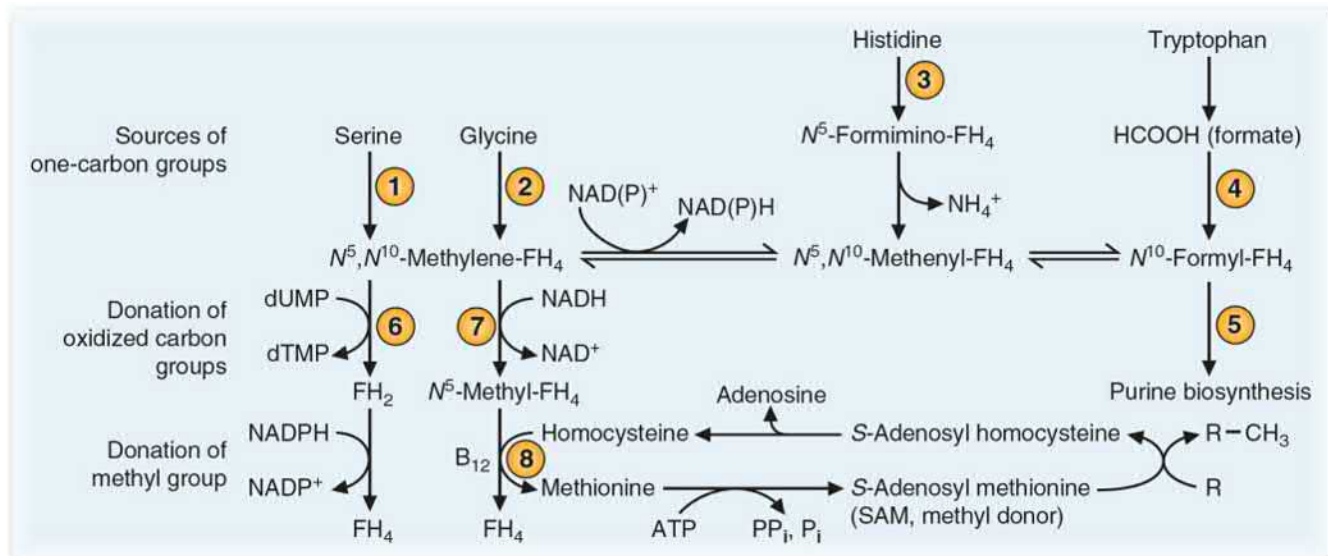

FIGURE 38.4 Sources of carbon (reactions 1 to 4) for the FH₄ pool and the recipients of carbon (reactions 5 to 8) from the pool. See Figure 38.3 to view the FH₄ derivatives involved in each reaction. ATP, adenosine triphosphate; dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate; NAD, nicotinamide adenine dinucleotide; P_i, inorganic phosphate; PP_i, pyrophosphate.

Histidine and formate provide examples of compounds that donate carbon in different oxidation levels (see Fig. 38.4). Degradation of histidine produces formiminoglutamate (FIGLU), which reacts with FH₄ to donate a carbon and nitrogen (generating N⁵-formimino-FH₄), thereby releasing glutamate. Formate, produced from tryptophan oxidation, can react with FH₄ and generate N¹⁰-formyl-FH₄, the most oxidized folate derivative.

E. Recipients of One-Carbon Groups

The one-carbon groups on FH₄ may be oxidized or reduced (see Fig. 38.3) and then transferred to other compounds (see Fig. 38.4 and Table 38.1). Transfers of this sort are involved in the synthesis of glycine from serine, the synthesis of the base thymine required for DNA synthesis, the purine bases required for both DNA and RNA synthesis, and the transfer of methyl groups to vitamin B₁₂.

 FH₄ is required for the synthesis of deoxythymidine monophosphate and the purine bases used to produce the precursors for DNA replication. Therefore, FH₄ is required for cell division. Blockage of the synthesis of thymine and the purine bases, either by a dietary deficiency of folate or by drugs that interfere with folate metabolism, results in a decreased rate of cell division and growth.

Because the conversion of serine to glycine is readily reversible, glycine can be converted to serine by drawing carbon from the one-carbon pool.

The nucleotide deoxythymidine monophosphate (dTMP) is produced from deoxyuridine monophosphate (dUMP) by a reaction in which dUMP is methylated to form dTMP (Fig. 38.5). The source of carbon is N⁵,N¹⁰-methylene-FH₄. Two hydrogen atoms from FH₄ are used to reduce the donated carbon to the methyl level. Consequently, dihydrofolate (FH₂) is produced. Reduction of FH₂ by NADPH in a reaction catalyzed by dihydrofolate reductase (DHFR) regenerates FH₄. This is the only reaction involving FH₄ in which the folate group is oxidized as the one-carbon group is donated to the recipient. Recall that DHFR is also required to reduce the oxidized form of the vitamin, which is obtained from the diet (see Fig. 38.2). Thus, DHFR is

essential for regenerating FH_4 both in the tissues and from the diet. These reactions contribute to the effect of folate deficiency on DNA synthesis because dTMP is required only for the synthesis of DNA.

FIGURE 38.5 Transfer of a one-carbon unit from N^5, N^{10} -methylene- FH_4 to deoxyuridine monophosphate (dUMP) to form deoxythymidine monophosphate (dTMP). Tetrahydrofolate (FH_4) is oxidized to dihydrofolate [FH_2] in this reaction. FH_2 is reduced to FH_4 by dihydrofolate reductase and FH_4 is converted to N^5, N^{10} -methylene FH_4 using serine as a carbon donor. Shaded bars indicate the steps at which the antimetabolites 5-fluorouracil (5-FU) and methotrexate act. 5-Fluorouracil (5-FU) inhibits thymidylate synthase. Methotrexate inhibits dihydrofolate reductase. Deoxyribose-P, deoxyribose phosphate; NADP, nicotinamide adenine dinucleotide phosphate.

Individuals with non-Hodgkin lymphoma receive a number of drugs to treat the tumor, including methotrexate. The structure of methotrexate is shown below.

What compound does methotrexate resemble?

During the synthesis of the purine bases, carbons 2 and 8 are obtained from the one-carbon pool (see Chapter 39). N^{10} -formyl-FH₄ provides both carbons. Folate deficiency would also hinder these reactions, contributing to an inability to replicate DNA because of the lack of precursors.

After the carbon group carried by FH₄ is reduced to the methyl level, it is transferred to vitamin B₁₂. This is the only reaction through which the methyl group can leave FH₄ (recall that the reaction that creates N^5 -methyl-FH₄ is not reversible).

II. Vitamin B₁₂

A. Structure and Forms of Vitamin B₁₂

The structure of vitamin B₁₂ (also known as cobalamin) is complex (Fig. 38.6). It contains a corrin ring, which is similar to the porphyrin ring found in heme. The corrin ring differs from heme, however, in that two of the four pyrrole rings are joined directly rather than by a methylene bridge. Its most unusual feature is the presence of cobalt, coordinated with the corrin ring (similar to the iron coordinated with the porphyrin ring). This cobalt can form a bond with a carbon atom. In the body, it reacts with the carbon of a methyl group, forming methylcobalamin, or with the 5'-carbon of 5'-deoxyadenosine, forming 5'-deoxyadenosylcobalamin (note that in this case, the “deoxy” designation refers to the 5'-carbon, not the 2'-carbon as is the case in the sugar found in DNA). The form of B₁₂ found in vitamin supplements is cyanocobalamin, in which a CN group is linked to the cobalt.

FIGURE 38.6 Vitamin B₁₂. When X is 5'-deoxyadenosine the vitamin is deoxyadenosylcobalamin; when X is a methyl group the vitamin is methylcobalamin; and when X is CN the vitamin is cyanocobalamin (the commercial form found in vitamin tablets).

 A better understanding of the structure and function of the purine and pyrimidine bases and of folate metabolism led to the development of compounds having antimetabolic and antifolate action useful for treatment of neoplastic disease. For example, **Clark T.** was successfully treated for colon cancer with a combination of chemotherapy including 5-fluorouracil (5-FU) (see Chapter 11 and Fig. 38.5). 5-FU is a pyrimidine analog, which is converted in cells to the nucleotide fluorodeoxyuridylylate (FdUMP). FdUMP causes a “thymineless death,” especially for tumor cells that have a rapid turnover rate. It prevents the growth of cancer cells by blocking the thymidylate synthase reaction, that is, the conversion of dUMP to dTMP.

 **Jean T.**'s megaloblastic anemia was treated in part with folate supplements (see Clinical Comments). Within 48 hours of the initiation of folate therapy, megaloblastic or “ineffective” erythropoiesis usually subsides, and effective

erythropoiesis begins.

Megaloblastic anemia is caused by a decrease in the synthesis of thymine and the purine bases. These deficiencies lead to an inability of hematopoietic (and other) cells to synthesize DNA and, therefore, to divide. Their persistently thwarted attempts at normal DNA replication, DNA repair, and cell division produce abnormally large cells (called megaloblasts) with abundant cytoplasm capable of protein synthesis, but with clumping and fragmentation of nuclear chromatin (see Chapter 42). Some of these large cells, although immature, are released early from the marrow in an attempt to compensate for the anemia. Thus, peripheral blood smears also contain megaloblasts. Many of the large immature cells, however, are destroyed in the marrow and never reach the circulation.

Methotrexate has the same structure as folate except that it has an amino group on C4 and a methyl group on N10. Anticancer drugs such as methotrexate are folate analogs that act by inhibiting dihydrofolate reductase, thereby preventing the conversion of FH_2 to FH_4 (see Fig. 38.5). Thus, the cellular pools of FH_4 are not replenished, and reactions that require FH_4 cannot proceed.

B. Absorption and Transport of Vitamin B₁₂

Although vitamin B₁₂ is produced by bacteria, it cannot be synthesized by higher plants or animals. The major source of vitamin B₁₂ is dietary meat, eggs, dairy products, fish, poultry, and seafood. The animals that serve as the source of these foods obtain B₁₂ mainly from the bacteria in their food supply. The absorption of B₁₂ from the diet is a complex process (Fig. 38.7).

FIGURE 38.7 Absorption, transport, and storage of vitamin B₁₂. Dietary B₁₂ binds to R-binders (haptocorrins) in the stomach and travels to the intestine, where the R-binders are destroyed by pancreatic proteases. The freed B₁₂ then binds to intrinsic factor (IF). B₁₂ is absorbed in the ileum and carried by proteins named transcobalamins (TC) to the liver, where B₁₂ is stored.

The average daily diet in Western countries contains 5 to 30 µg of vitamin B₁₂, of which 1 to 5 µg is absorbed into the blood (The RDA is 2.4 µg/day.). Total body content of this vitamin in an adult is approximately 2 to 5 mg, of which 1 mg is present in the liver. As a result, a dietary deficiency of B₁₂ is uncommon and is observed only after a number of years on a diet that is deficient in this vitamin.

In spite of **Jean T.**'s relatively malnourished state because of her chronic alcohol use disorder, her serum cobalamin level was still within the low-to-normal range. If her undernourished state had continued, a cobalamin deficiency would eventually have developed.

Ingested B₁₂ can exist in two forms, either free or bound to dietary proteins. If free, the B₁₂ binds to proteins known as R-binders (haptocorrins, also known as transcobalamin I), which are secreted by the salivary glands and the gastric mucosa, in either the saliva or the stomach. If the ingested B₁₂ is bound to proteins, it must be released from the proteins by the action of digestive proteases in both the stomach and small intestine. Once the B₁₂ is released from its bound protein, it binds to the haptocorrins. In the small intestine, the pancreatic proteases digest the haptocorrins, and the released B₁₂ then binds to intrinsic factor, a glycoprotein secreted by the parietal cells of the stomach when food enters the stomach. The intrinsic factor–B₁₂ complex attaches to specific receptors in the terminal segment of the small intestine known as the ileum, after which the complex is internalized.

Pernicious anemia, a deficiency of intrinsic factor, is a relatively common problem that results in malabsorption of dietary cobalamin. It may result from an inherited defect that leads to decreased ability of gastric parietal cells to synthesize intrinsic factor or from partial resection of the stomach or of the ileum. Production of intrinsic factor often declines with age and may be low in elderly individuals. An alternative circumstance that leads to the development of a B₁₂ deficiency is pancreatic insufficiency or a high intestinal pH, which results from too little acid being produced by the stomach. Both of these conditions prevent the degradation of the R-binder–B₁₂ complex; as a result, B₁₂ is not released from the R-binder protein and, therefore, cannot bind to intrinsic factor. The protein receptor for the B₁₂–intrinsic factor complex is named *cubilin*, and the internalization of the B₁₂–intrinsic factor–cubilin complex requires the activity of a transmembrane protein named *amnionless*. Congenital malabsorption of B₁₂ can also arise from inherited mutations in either **cubilin** or **amnionless**.

The B₁₂ within the enterocyte complexes with transcobalamin II before it is released into the circulation. The transcobalamin II - B₁₂ complex delivers B₁₂ to the tissues, which contain specific receptors for this complex. The liver takes up approximately 50% of the vitamin B₁₂, and the remainder is transported to other tissues. The amount of the vitamin stored in the liver is large enough that 3 to 6 years pass before symptoms of a dietary deficiency occur.

C. Functions of Vitamin B₁₂

Vitamin B₁₂ is involved in two reactions in the body: the transfer of a methyl group from N⁵-methyl-FH₄ to homocysteine to form methionine; and the rearrangement of L-methylmalonyl CoA to form succinyl CoA (Fig. 38.8).

A**Homocysteine****Methionine****B****Methylmalonyl CoA****Succinyl CoA**

FIGURE 38.8 The two reactions involving vitamin B₁₂ in humans. Methylmalonyl CoA, methylmalonyl coenzyme A; succinyl CoA, succinyl coenzyme A.

Tetrahydrofolate receives a one-carbon group from serine or from other sources. This carbon is reduced to the methyl level and transferred to vitamin B₁₂, forming methyl-B₁₂ (or methylcobalamin). Methylcobalamin transfers the methyl group to homocysteine, which is converted to methionine by the enzyme methionine synthase. Methionine can then be activated to SAM to transfer the methyl group to other compounds (Fig. 38.9).

FIGURE 38.9 Relationships among tetrahydrofolate (FH_4), B₁₂, and S-adenosylmethionine (SAM). **A.** Overall scheme. **B.** Some specific reactions that require SAM. ATP, adenosine triphosphate; P_i, inorganic phosphate.

Vitamin B₁₂ also participates in the conversion of L-methylmalonyl CoA to succinyl CoA. In this case, the active form of the coenzyme is 5'-deoxyadenosylcobalamin. This reaction is part of the metabolic route for the conversion of carbons from valine, isoleucine, threonine, and the last three carbons of odd-chain fatty acids, all of which form propionyl CoA, to the tricarboxylic acid (TCA) cycle intermediate succinyl CoA (see Chapter

37).

How should vitamin B₁₂ be administered to a patient with pernicious anemia?

There are two major clinical manifestations of cobalamin (B₁₂) deficiency. One such presentation is hematopoietic (caused by the adverse effects of a B₁₂ deficiency on folate metabolism), and the other is neurological (caused by hypomethylation and myelin destabilization in the nervous system). The hematopoietic problems associated with a B₁₂ deficiency are identical to those observed in a folate deficiency and, in fact, result from a folate deficiency secondary to (i.e., caused by) the B₁₂ deficiency (i.e., the methyl-trap hypothesis). As the FH₄ pool is exhausted, deficiencies of the FH₄ derivatives needed for purine and dTMP biosynthesis develop, leading to the characteristic megaloblastic anemia.

The classical clinical presentation of the neurological dysfunction associated with a B₁₂ deficiency includes symmetric numbness and tingling of the feet (and less so the hands), diminishing vibratory and position sense, and progression to a spastic gait disturbance. The patient may develop dementia and depression. Rarely, they develop psychosis (“megaloblastic madness”). Other rare symptoms include the development of blind spots in the central portions of the visual fields, and alterations in gustatory (taste) and olfactory (smell) function. This is thought to be due to two factors. The first is hypomethylation within the nervous system, brought about by an inability to recycle homocysteine to methionine and from there to S-adenosylmethionine. The latter is the required methyl donor in these reactions. The nervous system lacks the betaine pathway of methionine regeneration (see Fig. 38.10) and is dependent on the B₁₂ system for regenerating SAM. With a B₁₂ deficiency, this pathway is inoperable in the nervous system and DNA and histones are hypomethylated. The second factor is the accumulation of methylmalonic acid, which leads to myelin destabilization and loss of protection of the neurons. This occurs due to methylmalonyl CoA being used in place of malonyl CoA in fatty acid synthesis. This generates branched-chain fatty acids that are incorporated into phospholipids and eventually the myelin sheath.

FIGURE 38.10 Reaction pathways that involve homocysteine. Defects in numbered enzymes (1, methionine synthase; 2, N⁵,N¹⁰-methylene-FH₄ reductase; 3, cystathionine β-synthase) lead to elevated homocysteine. Recall that as cysteine accumulates, there is feedback inhibition on cystathionine β-synthase to stop further cysteine production. ATP, adenosine triphosphate; FH₄, tetrahydrofolate; NAD, nicotinamide adenine dinucleotide; P_i, inorganic phosphate; PP_i, pyrophosphate; SAM, S-adenosylmethionine.

III. S-Adenosylmethionine

S-adenosylmethionine (SAM) participates in the synthesis of many compounds that contain methyl groups. It is used in reactions that add methyl groups to either oxygen or nitrogen atoms in the acceptor (contrast that to folate derivatives, which can add one-carbon groups to sulfur or to carbon). As examples, SAM is required for the conversion of phosphatidylethanolamine to phosphatidylcholine, guanidinoacetate to creatine, norepinephrine to epinephrine, acetylserotonin to melatonin, and nucleotides to methylated nucleotides (see Fig. 38.9B). It is also required for the inactivation of catecholamines and serotonin (see Chapter 46). More than 35 reactions in humans require methyl donation from SAM.

SAM is synthesized from methionine and ATP. As with the activation of vitamin B₁₂, ATP donates the adenosine. With the transfer of its methyl group, SAM forms S-adenosylhomocysteine, which is subsequently hydrolyzed to form homocysteine and adenosine.

Methionine, required for the synthesis of SAM, is obtained from the diet or produced from homocysteine, which accepts a methyl group from vitamin B₁₂ (see Fig. 38.9A). Thus, the methyl group of methionine is regenerated. The portion of methionine that is essential in the diet is the homocysteine moiety. If we had an adequate dietary source of homocysteine, methionine would not be required in the diet. However, there is no good dietary source of homocysteine, whereas methionine is plentiful in the diet.

Homocysteine provides the sulfur atom for the synthesis of cysteine (see Chapter 37). In this case, homocysteine reacts with serine to form cystathionine, which is cleaved, yielding cysteine and α -ketobutyrate. The first reaction in this sequence is inhibited by cysteine. Thus, methionine, via homocysteine, is not used for cysteine synthesis unless the levels of cysteine in the body are lower than required for its metabolic functions. An adequate dietary supply of cysteine, therefore, can “spare” (or reduce) the dietary requirement for methionine.

IV. Relationships among Folate, Vitamin B₁₂, and SAM

A. The Methyl-Trap Hypothesis

If one analyzes the flow of carbon in the folate cycle, the equilibrium lies in the direction of the N⁵-methyl-FH₄ form. This appears to be the most stable form of carbon attached to the vitamin. However, in only one reaction can the methyl group be removed from N⁵-methyl-FH₄, and that is the methionine synthase reaction, which requires vitamin B₁₂. Thus, if vitamin B₁₂ is deficient, or if the methionine synthase enzyme is defective, N⁵-methyl-FH₄ accumulates. Eventually, most folate forms in the body become “trapped” in the N⁵-methyl form. A functional folate deficiency results because the carbons cannot be removed from the folate. The appearance of a functional folate deficiency caused by a lack of vitamin B₁₂ is known as the methyl-trap hypothesis, and its clinical implications are discussed in the following sections.

Because the problem in pernicious anemia is a lack of intrinsic factor, which results in an inability to absorb vitamin B₁₂ from the gastrointestinal (GI) tract, B₁₂ can be administered by injection. More recently, studies have shown that B₁₂ deficiency can be effectively treated with very high doses of oral B₁₂ because of another transport system lower in the GI tract that does not require intrinsic factor.

B. Hyperhomocysteinemia

Elevated homocysteine levels have been linked to cardiovascular and neurological disease. Homocysteine levels can accumulate in a number of ways, which are related to both folic acid and vitamin B₁₂ metabolism. Homocysteine is derived from S-adenosyl homocysteine, which arises when SAM donates a methyl group (Fig. 38.10). Because SAM is frequently donating methyl groups, there is constant production of S-adenosyl homocysteine, which leads to constant production of homocysteine. Recall from Chapter 37 that homocysteine has two biochemical fates. The homocysteine produced can be either remethylated to methionine or condensed with serine to form cystathionine. There are two routes to methionine production. The major one is methylation by N⁵-methyl-FH₄, which requires vitamin B₁₂. The liver also contains a second pathway in which betaine (derived from choline) can donate a methyl group to homocysteine to form methionine, but this is a minor pathway (see section V of this chapter). The conversion of homocysteine to cystathionine requires pyridoxal phosphate (PLP). Thus, if an individual is deficient in vitamin B₁₂, the conversion of homocysteine to

methionine by the major route is inhibited. This directs homocysteine to produce cystathionine, which eventually produces cysteine. As cysteine levels accumulate, the enzyme that makes cystathionine undergoes feedback inhibition, and that pathway is also inhibited (see Fig. 38.10). This, overall, leads to the accumulation of homocysteine, which is released into the blood.

Many health food stores in the United States now sell SAME, a stabilized version of *S*-adenosylmethionine. In Europe, SAME is a prescription drug. SAME has been hypothesized to relieve depression because the synthesis of certain neurotransmitters requires methylation by SAM (see Chapter 46). This has led to the hypothesis that by increasing SAM levels in the nervous system, the biosynthesis of these neurotransmitters will be accelerated. This in turn might alleviate the feelings of depression. There have been reports in the literature indicating that this may occur, but its efficacy as an antidepressant must be confirmed. The major questions that must be addressed include the stability of SAME in the digestive system and the level of uptake of SAME by cells of the nervous system. SAME has also been used to alleviate the pain of osteoarthritis.

Homocysteine also accumulates in the blood if a mutation is present in the enzyme that converts N^5,N^{10} -methylene-FH₄ to N^5 -methyl-FH₄. When this occurs, the levels of N^5 -methyl-FH₄ are too low to allow homocysteine to be converted to methionine. The loss of this pathway, coupled with the feedback inhibition by cysteine on cystathionine formation, also leads to elevated homocysteine levels in the blood.

A third way in which serum homocysteine levels can be elevated is by a mutated cystathionine β -synthase or a deficiency in vitamin B₆, the required cofactor for that enzyme. These defects block the ability of homocysteine to be converted to cystathionine, and the homocysteine that does accumulate cannot all be accommodated by conversion to methionine. Thus, an accumulation of homocysteine results.

C. Neural Tube Defects

Folate deficiency during pregnancy has been associated with an increased risk of neural tube defects in the developing fetus. This risk is significantly reduced if women take folic acid supplements periconceptually. The link between folate deficiency and neural tube defects was first observed in women with hyperhomocysteinemia brought about by a thermolabile variant of N^5,N^{10} -methylene-FH₄ reductase. This form of the enzyme, which results from a single nucleotide change (C to T) in position 677 of the gene that encodes the protein, is less active at body temperature than at lower temperatures. This results in a reduced level of N^5 -methyl-FH₄ being generated and, therefore, an increase in the levels of homocysteine. Along with the elevated homocysteine, the women were also folate deficient. The folate deficiency and the subsequent inhibition of DNA synthesis lead to neural tube defects. The elevated homocysteine is one indication that such a deficit is present. These findings have led to the recommendation that women considering getting pregnant begin taking folate supplements before conception occurs and during pregnancy. The U.S. Department of Agriculture has, in fact, mandated that folate be added to flour-containing products in the United States.

D. Folate Deficiencies and DNA Synthesis

Folate deficiencies result in decreased availability of the deoxythymidine and purine nucleotides that serve as precursors for DNA synthesis. The decreased concentrations of these precursors affect not only the DNA synthesis that occurs during replication before cell division but also the DNA synthesis that occurs as a step in the processes that repair damaged DNA.

Decreased methylation of dUMP to form dTMP, a reaction that requires N^5,N^{10} -methylene-FH₄ as a coenzyme (see Fig. 38.5), leads to an increase in the intracellular dUTP/dTTP ratio. This ratio change causes a significant increase in the incorporation of uracil into DNA. Although much of this uracil can be removed by DNA-repair enzymes, the lack of available dTTP blocks the step of DNA repair that is catalyzed by DNA polymerase. The result is fragmentation of DNA as well as blockade of normal DNA replication.

These abnormal nuclear processes are responsible for the clumping and polysegmentation seen in the nuclei of neutrophilic leukocytes in the bone marrow and in the peripheral blood of patients with megaloblastic anemia caused either by a primary folate deficiency or one that is secondary to B₁₂ deficiency. The abnormalities in DNA synthesis and repair lead to an irreversible loss of the capacity for cell division and eventually to cell death.

V. Choline and One-Carbon Metabolism

Other compounds involved in one-carbon metabolism are derived from degradation products of choline. Choline, an essential component of certain phospholipids, is oxidized to form betaine aldehyde, which is further oxidized to betaine (trimethylglycine). In the liver, betaine can donate a methyl group to homocysteine to form methionine and dimethyl glycine. This allows the liver to have two routes for homocysteine conversion to methionine. This is in contrast to the nervous system, which only expresses the primary B₁₂-requiring pathway. Under conditions in which SAM accumulates, glycine can be methylated to form sarcosine (*N*-methyl glycine). This route of glycine metabolism is used when methionine levels are high and excess methionine needs to be metabolized (Fig. 38.11).

FIGURE 38.11 A. Choline and one-carbon metabolism. B. Sarcosine synthesis from glycine.

CLINICAL COMMENTS

Jean T. developed a folate deficiency and is on the verge of developing a cobalamin (vitamin B₁₂) deficiency as a consequence of prolonged, moderately severe malnutrition related to chronic alcohol use disorder. Before folate therapy is started, the physician must ascertain that the megaloblastic anemia is not caused by a pure B₁₂ deficiency or a combined deficiency of folate and B₁₂.

If folate is given without cobalamin to a B₁₂-deficient patient, the drug only partially corrects the megaloblastic anemia, because it will “bypass” the methyl-folate trap and provide adequate FH₄ coenzyme for the conversion of dUMP to dTMP and for a resurgence of purine synthesis. As a result, normal DNA synthesis, DNA repair, and cell division occur. However, the neurological syndrome, resulting from hypomethylation in nervous tissue, and accumulation of methylmalonic acid, may progress unless the physician realizes that B₁₂ supplementation is required. In **Jean T.**’s case, in which the serum B₁₂ concentration was borderline low and in which the dietary history supported the possibility of a B₁₂ deficiency, a combination of folate and B₁₂ supplements is required to avoid this potential therapeutic trap.

Clark T. continued to do well and returned faithfully for his regular colonoscopic examinations.

Beatrice T. was diagnosed with a decreased ability to absorb dietary B₁₂. One of the consequences of aging is a reduced acid production by the gastric mucosa (atrophic gastritis), which limits the ability of pepsin to work on dietary protein. Reduced pepsin efficiency then reduces the amount of bound B₁₂ released from dietary protein, as a result of which the B₁₂ is not available for absorption. Her condition can be treated by taking high-dose vitamin B₁₂ supplements orally.

BIOCHEMICAL COMMENTS

A potential mechanism relating to folate deficiencies and neural tube defects. As indicated in Section IV.C of this chapter, neural tube defects in newborns have been associated with folate deficiency during pregnancy. While the mechanism leading to neural tube defects is vague, recent research has indicated that the induction of micro RNAs (miRNAs) may play a role in altering the normal developmental pattern of neural tube closure.

Under conditions of a folate deficiency hypomethylation occurs in the nervous system, affecting membrane phospholipid biosynthesis (such as phosphatidylcholine), myelin basic protein (see Chapter 46), and neurotransmitter biosynthesis (see Chapter 46). The reduced levels of neurotransmitters may interfere with normal gene expression during embryogenesis. DNA methylation is also reduced, due to reduced SAM levels when folate is limiting. Hypomethylation is also the result of increased levels of *S*-adenosylhomocysteine (SAH), which accumulates during a folate deficiency. SAH will inhibit DNA methyltransferase enzymes by tightly binding to the enzyme, and preventing the normal substrate, SAM, from binding to the enzyme. The enzymes affinity for SAH is higher than that of SAM, contributing to the hypomethylation observed.

MicroRNA genes are frequently in close proximity to CpG islands in DNA, and it has been predicted that alterations in cytosine methylation may be a means of regulating miRNA expression. Experimentally, a cell line in which two DNA methyltransferase genes were knocked out (inactivated) resulted in a significant reduction in global genomic methylation, and the differential expression of 13 miRNAs (seven of those genes were overexpressed, whereas the other six displayed a reduction in expression). A similar result was obtained with another cell line that was placed in folate-deficient media, as global hypomethylation and alterations in miRNA expression were observed.

As an example, miR-222 was identified as a potential miRNA that is upregulated under conditions of folate deprivation. A predicted target of miR-222 is the DNMT-1 gene (a DNA methyltransferase), whose activity is critical for the maintenance of methylation patterns in DNA. Overexpression of miR-222 would reduce DNMT-1 gene expression, thereby altering methylation patterns in the cell. A reduction of DNMT-1 activity has been shown to increase the expression of a number of genes, including β -catenin (see Chapter 17). This will lead to enhanced cell proliferation and inhibition of differentiation in the nervous system (all leading to a failure to close the neural tube). To date, using cell culture models of either folate deprivation or folate stimulation, over 30 different miRNA molecules have been shown to have their expression altered by folate treatment.

Such studies as those described above are in their infancy but produce a promising start for unraveling the effects of DNA methylation, and miRNA expression, on cell growth and differentiation in the nervous system.

KEY CONCEPTS

- ◆ One-carbon groups at lower oxidation states than carbon dioxide (which is carried by biotin) are transferred by reactions that involve tetrahydrofolate, vitamin B₁₂, and *S*-adenosylmethionine.
- ◆ Tetrahydrofolate is produced from the vitamin folate and obtains one-carbon units from serine, glycine, histidine, formaldehyde, and formic acid.
- ◆ The carbon attached to FH₄ can be oxidized or reduced, thus producing several different forms of FH₄. However, once a carbon has been reduced to the methyl level, it cannot be reoxidized.
- ◆ The carbons attached to FH₄ are known collectively as the one-carbon pool.
- ◆ The carbons carried by folate are used in a limited number of biochemical reactions, but they are very important in forming dTMP and the purine rings.

- ◆ Vitamin B₁₂ participates in two reactions in the body: conversion of L-methylmalonyl CoA to succinyl CoA, and conversion of homocysteine to methionine.
- ◆ S-adenosylmethionine, formed from ATP and methionine, transfers the methyl group to precursors of a variety of methylated compounds.
- ◆ Both vitamin B₁₂ and methyl-FH₄ are required in methionine metabolism; a deficiency of vitamin B₁₂ leads to overproduction and trapping of folate in the methyl form, leading to a functional folate deficiency. Such deficiencies can lead to
 - ◆ Megaloblastic anemia
 - ◆ Neural tube defects in newborns
- ◆ Diseases discussed in this chapter are summarized in Table 38.2.

TABLE 38.2 Diseases Discussed in Chapter 38

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Colon cancer	Both	Colon cancer can be treated by drugs which block the action of thymidylate synthase, blocking DNA synthesis by reducing the supply of dTTP.
Pernicious anemia	Both	Pernicious anemia is due to the lack of intrinsic factor, which leads to a B ₁₂ deficiency. The B ₁₂ deficiency indirectly interferes with DNA synthesis. In cells of the erythroid lineage, cell size increases without cell division, leading to megaloblastic anemia.
Alcohol-induced megaloblastic anemia	Environmental	Alcohol-induced malnutrition, which can lead to folate and/or B ₁₂ deficiencies. The folate and/or B ₁₂ deficiency will lead to the development of megaloblastic anemia.
Neural tube defects	Both	A lack of folate derivatives leads to reduced methylation in the nervous system, altering gene expression and increasing the risk of neural tube defects.

dTTP, deoxythymidine triphosphate.

REVIEW QUESTIONS—CHAPTER 38

1. Which one of the following reactions requires N^5,N^{10} -methylene-FH₄ as a carbon donor?
 - A. Homocysteine to methionine
 - B. Serine to glycine
 - C. Betaine to dimethylglycine
 - D. dUMP to dTMP
 - E. The de novo biosynthesis of the purine ring
2. Propionic acid accumulation from amino acid degradation will result from a deficiency of which one of the following vitamins?
 - A. Vitamin B₆
 - B. Biotin
 - C. Folic acid
 - D. Vitamin B₁
 - E. Vitamin B₂
3. A child with an acute otitis media (middle ear infection) is treated with a sulfa antibiotic. This medication interferes with the bacterial synthesis of which one of the following?
 - A. Vitamin B₁₂
 - B. S-adenosylmethionine (SAM)
 - C. Folic acid
 - D. Vitamin B₆
 - E. Homocysteine
4. Which one of the following forms of FH₄ is required for the synthesis of methionine from homocysteine?

- A. N^5, N^{10} -methylene FH_4
 - B. N^5 -methyl FH_4
 - C. N^5, N^{10} -methenyl FH_4
 - D. N^{10} -formyl FH_4
 - E. N^5 -formimino FH_4
5. An alternative method to methylate homocysteine to form methionine is which one of the following?
- A. Using glycine and FH_4 as the methyl donor
 - B. Using dimethylglycine as the methyl donor
 - C. Using choline as the methyl donor
 - D. Using sarcosine as the methyl donor
 - E. Using betaine as the methyl donor
6. Both folic acid and B_{12} deficiencies will lead to the observation of hypomethylation in the nervous system. These two cofactors are most closely linked via which one of the following proteins?
- A. Transcobalamin II
 - B. Methionine synthase
 - C. Cystathionine β -synthase
 - D. N^5, N^{10} methylene FH_4 reductase
 - E. DNA methyltransferase
7. A very strict vegan, who has not eaten animal products for over 5 years, nor taken exogenous vitamins, slowly develops tiredness and lethargy, and also notes occasional tingling in the feet. An analysis of total folate indicated normal amounts. In which form would this folate most likely be found?
- A. N^5 -methyl- FH_4
 - B. N^5, N^{10} methylene- FH_4
 - C. N^{10} -formyl- FH_4
 - D. N^5 -formimino- FH_4
 - E. N^5, N^{10} methenyl- FH_4
8. A patient presents to a clinic with symptoms of lethargy and tingling in the extremities. Blood work demonstrates a megaloblastic anemia. Measurement of which one of the following metabolites in the blood will aid in determining the cause of these symptoms in this patient?
- A. Lactic acid
 - B. Pyruvic acid
 - C. Methionine
 - D. Methylmalonic acid
 - E. Histidine
9. Which one of the following patients would be in danger of developing a vitamin B_{12} deficiency?
- A. A lacto-ovo vegetarian
 - B. A patient with an inability to secrete gastrin
 - C. A person who had their duodenum surgically removed
 - D. A patient with Crohn disease affecting the terminal ileum
 - E. A patient with a biliary duct obstruction
10. Methotrexate is a medication that has been used as an anticancer drug and currently is used in treatment of psoriasis and Rheumatoid Arthritis. This folate analog directly inhibits which one of the following conversions?
- A. Dihydrofolate (FH_2) to tetrahydrofolate (FH_4)
 - B. FH_2 to folate
 - C. Deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP)
 - D. Serine to glycine
 - E. Homocysteine to methionine

The following case is the basis for questions 11 to 13: A 65-year-old patient, who has been a strict vegan for the past 8 years, visits their physician due to tiredness, lethargy, and intermittent tingling in both hands and feet. During the history component of the examination, it was determined that the patient has not taken any supplements since switching to a vegan diet. A complete blood count indicated a red blood cell count below the normal range, with an increased mean corpuscular volume of the red cells (indicating

larger than normal red blood cells).

1. The red blood cell number is most likely reduced due to which of the following? Choose the one best answer.

	A Mutated DNA Polymerase	A Reduction in Precursors for DNA Synthesis	An Inhibition of Membrane Biosynthesis	An Increased Hemolysis of Red Blood Cells
A	No	Yes	No	No
B	No	No	Yes	No
C	No	Yes	No	Yes
D	Yes	No	Yes	Yes
E	Yes	Yes	No	No
F	Yes	No	Yes	Yes

2. A medical student rotating with the physician who saw the patient suggested giving the patient large doses of N^5 -methyl-FH₄. If this suggestion were followed which of the following symptoms exhibited by the patient would be likely alleviated? Choose the one best answer.

	Tiredness/Lethargy	Reduction in Number of Red Blood Cells	Increased Corpuscular Volume	Tingling in the Hands and Feet
A	Yes	Yes	Yes	Yes
B	Yes	No	Yes	Yes
C	Yes	Yes	Yes	No
D	No	No	No	No
E	No	Yes	No	Yes
F	No	No	No	No

3. The tingling and numbness exhibited by the patient is due, in part, to the accumulation of which one of the following?

- A. Citrate
 - B. Odd-chain fatty acids
 - C. Branched-chain fatty acids
 - D. S-adenosyl methionine
 - E. 2-hydroxyglutarate
4. While methionine is an essential amino acid for the human diet, carbons from glucose can be found as the methyl carbon in intracellular methionine. This occurs through the participation of which one of the following molecules?
- A. Citrate
 - B. Leucine
 - C. Lysine
 - D. Pyruvate
 - E. Serine
5. Hypermethioninemia, in certain cases, can lead to neurological problems, including delays in motor skills. A mutation in which one of the following enzymes would lead to hypermethioninemia?
- A. Cystathionine β -synthase
 - B. N^5,N^{10} methylene-FH₄ reductase
 - C. Methionine synthase
 - D. Methionine adenosyltransferase
 - E. Serine hydroxymethyltransferase

ANSWERS TO REVIEW QUESTIONS

1. **The answer is D.** The conversion of dUMP to dTMP requires N^5,N^{10} methylene-FH₄. The homocysteine-to-methionine reaction requires N^5 -methyl-FH₄; serine to glycine requires free FH₄ and generates N^5,N^{10} -methylene-FH₄; betaine donates a methyl group to homocysteine to form methionine without the participation of FH₄; and the purine ring requires N^{10} -formyl-FH₄ in its biosynthesis.
2. **The answer is B.** Propionic acid is derived from an accumulation of propionyl CoA. The normal pathway for the degradation of propionyl CoA is, first, a biotin-dependent carboxylation to D-methylmalonyl CoA, racemization to L-methylmalonyl CoA, and then, the B₁₂-dependent rearrangement to succinyl CoA.
3. **The answer is C.** Sulfa drugs are analogs of para-aminobenzoic acid and prevent growth and cell division in bacteria by interfering with the synthesis of folic acid (which is needed to produce FH₄). Humans cannot synthesize folate de novo and must obtain folate from the diet. Due to this, the sulfa drugs do not affect human metabolism.
4. **The answer is B.** The only three forms of folate that transfer carbons are the N^5 -methyl-FH₄ form, the N^5,N^{10} -methylene-FH₄ form, and the N^{10} -formyl form. None of the other forms participates in reactions in which the carbon is transferred. It is the N^5 -methyl form that transfers the methyl group to form methionine from homocysteine.
5. **The answer is E.** Choline, derived from phosphatidylcholine, is converted to betaine (trimethylglycine). Betaine can donate a methyl group to homocysteine to form methionine plus dimethylglycine. Sarcosine is N-methylglycine, which is formed when excess SAM methylates glycine, but it is not used as a methyl donor in this reaction.
6. **The answer is B.** The conversion of homocysteine to methionine, catalyzed by methionine synthase, requires vitamin B₁₂ as a cofactor, and N^5 -methyl-FH₄ as a substrate. This is the only mammalian reaction in which N^5 -methyl-FH₄ can donate its carbon. Once methionine is generated, it is converted to S-adenosylmethionine (SAM), which acts as a methyl donor for neurotransmitter synthesis, myelin synthesis, phospholipid synthesis, and DNA modifications. Inability to catalyze the methionine synthase reaction, either due to B₁₂ or folate deficiency, would lead to a reduction of SAM levels, and hypomethylation in the nervous system. The liver does not exhibit hypomethylation due to the betaine pathway, in which betaine can donate a methyl group to homocysteine to form methionine, also forming dimethyl glycine once betaine loses a methyl group. Transcobalamin II carries B₁₂ in the circulation and does not interact with folate. Cystathionine β -synthase catalyzes the conversion of homocysteine and

serine to cystathionine, and requires vitamin B₆, but not B₁₂ or folate. *N*⁵,*N*¹⁰ methylene-FH₄ reductase converts *N*⁵,*N*¹⁰ methylene-FH₄ to *N*⁵-methyl-FH₄, and requires NADH, but not vitamin B₁₂. DNA methyltransferases require SAM to methylate cytosine residues in DNA, but folic acid is not required as a cofactor for that reaction.

7. **The answer is A.** The patient is suffering from a B₁₂ deficiency. B₁₂ can only be obtained from meat and dairy products in the diet, and while the body may have a 2- to 3-year store of the vitamin, given the patient's diet, and lack of vitamins, B₁₂ has become deficient. The tiredness and lethargy is due to the development of megaloblastic anemia, and the tingling is due to nervous system dysfunction due to hypomethylation and methylmalonic acid in the nervous system. In the absence of vitamin B₁₂, folate will be trapped as *N*⁵-methyl-FH₄, as the methionine synthase reaction will be unable to proceed. Once *N*⁵-methyl-FH₄ is formed it cannot be converted back into the other folate forms. As this is the most stable folate form, the other variants of folate will slowly be converted to this form and trapped.
8. **The answer is D.** The megaloblastic anemia can be caused by a deficiency of either B₁₂ or folic acid. A B₁₂ deficiency will block two reactions, homocysteine to methionine, and methyl malonyl CoA to succinyl CoA. A B₁₂ deficiency, therefore, will lead to elevated methylmalonic acid since the methyl malonyl CoA produced cannot be further metabolized to succinyl CoA. The lack of B₁₂ also traps folate as the *N*⁵-methyl-FH₄ form (since the methyl group cannot be transferred to homocysteine), leading to a functional folate deficiency. The folate deficiency interferes with purine and thymidine synthesis, leading to an overall cessation of DNA synthesis in rapidly growing cells, such as reticulocytes. This leads to megaloblast development and ineffective erythropoiesis. If the patient had a folate deficiency FIGLU would accumulate in the urine (a degradation product of histidine). Accumulation of lactate, or pyruvate, does not occur with B₁₂ or folate deficiencies. Methionine might accumulate (due to high homocysteine levels), but it usually stays fairly level, and would not be diagnostic for determining between a B₁₂ or folate deficiency. Histidine would also not accumulate, as FIGLU accumulates in a folate deficiency, and would be able to distinguish between B₁₂ and folate deficiencies.
9. **The answer is D.** Lacto-ovo vegetarians eat eggs and dairy products. Eggs are a dietary source of B₁₂. Stomach intrinsic factor binds released B₁₂, but stomach gastrin has no role in B₁₂ absorption. B₁₂ bound to intrinsic factor is absorbed in the terminal ileum, not the duodenum. The ileum is involved in Crohn disease, which then interferes with B₁₂ absorption. Biliary duct obstruction would block bile acid release from the gall bladder into the intestine, which would interfere with dietary fat absorption but not B₁₂ absorption, which is a water-soluble vitamin.
10. **The answer is A.** Methotrexate inhibits dihydrofolate reductase (DHFR), which blocks the conversion of FH₂ to FH₄. The reduction of cellular pools of FH₄ would then indirectly affect reactions that require FH₄. 5-fluorouracil directly (5-FU) inhibits the conversion of dUMP to dTMP. The conversion of homocysteine to methionine requires vitamin B₁₂ and *N*⁵-methyl-FH₄. The *N*⁵-methyl-FH₄ levels will be low due to the folate being trapped as dihydrofolate due to the direct inhibition of dihydrofolate reductase by methotrexate.
11. **The answer is A.** The patient has a B₁₂ deficiency due to their diet (lacking meat and dairy products) and not taking supplemental vitamins while on the restrictive diet. With a B₁₂ deficiency, folate is trapped as *N*⁵-methyl-FH₄, due to an inability to transfer the methyl group to homocysteine to regenerate methionine (the methionine synthase reaction requires vitamin B₁₂). The functional folate deficiency leads to reduced DNA synthesis due to an inability to produce deoxy TMP (which requires *N*⁵,*N*¹⁰-methylene-FH₄), or purines (carbons 2 and 8 of the purine ring require *N*¹⁰-formyl-FH₄). The lack of DNA synthesis leads to fewer red blood cells in circulation (an anemia, leading to the tiredness and lethargy) and larger red blood cell precursors (a megaloblastic anemia). The anemia is not due to alterations in DNA polymerase, or lack of membrane biosynthesis, or increased hemolysis of red blood cells (fewer red cells are produced; one sees red blood cell hemolysis in an individual with a glucose 6-phosphate dehydrogenase deficiency in the presence of oxidizing agents).
12. **The answer is C.** The patient has a vitamin B₁₂ deficiency, not a folate deficiency. Folate levels would be adequate in an individual on a strict vegan diet (folates are found in leafy green vegetables, beans, fruits, broccoli, and asparagus as examples), but in the absence of B₁₂ (which is only obtained from meats and

dairy products), the patient would develop a functional folate deficiency, leading to manifestations of a folate deficiency (a megaloblastic anemia). However, the numbness and tingling of the extremities exhibited by the patient are not due to the functional folate deficiency, rather, to the accumulation of methylmalonic acid and propionic acid, as a result of the B₁₂ deficiency. Thus, giving the patient folate instead of B₁₂ would resolve the megaloblastic anemia, but would not resolve the neurologic effects exhibited by the patient.

13. **The answer is C.** A B₁₂ deficiency leads to neurologic complications, in part, due to the synthesis of branched-chain fatty acids in the nervous system that get incorporated into phospholipids in the myelin sheath, which alters myelin's ability to protect the neuron and allow action potentials to be sent, and received, normally. The branched-chain fatty acid synthesis occurs from the use of methylmalonyl CoA in the cytoplasm, as a result of the B₁₂ deficiency. Methylmalonyl CoA is derived from the degradation of a variety of amino acids (methionine, threonine, isoleucine, valine), and if it cannot be converted to succinyl CoA (a reaction that requires B₁₂) it will accumulate. The fatty acid synthase can utilize methylmalonyl CoA in place of malonyl CoA for fatty acid synthesis, leading to the production of branched-chain fatty acids. When incorporated into phospholipids, and then into membranes, the permeability properties of the membrane are altered due to inappropriate packing of the fatty acid tails of the phospholipids, which can lead to membrane dysfunction. A B₁₂ deficiency will not lead to an accumulation of 2-hydroxyglutarate (that requires a mutated isocitrate dehydrogenase enzyme), or citrate (an inactive aconitase can lead to increased citrate), or S-adenosylmethionine (a B₁₂ deficiency may lead to a reduction in SAM, due to an inability to convert homocysteine to methionine). Odd-chain fatty acids may be synthesized, due to an accumulation of propionyl CoA, but the incorporation of odd-chain fatty acids into phospholipids in membranes will not significantly alter the physical properties of those membranes, as would a branched-chain fatty acid.
14. **The answer is E.** The pathway for methionine degradation is to convert methionine to S-adenosylmethionine, then SAM donates a methyl group to form S-adenosyl homocysteine, which has the adenosine removed by hydrolysis to form homocysteine. The homocysteine can be converted to methionine in a reaction requiring both B₁₂ and N⁵-methyl-FH₄. Thus, the regenerated methionine has a methyl group that came from the one-carbon pool associated with tetrahydrofolate. Serine is derived from 3-phosphoglycerate, which is an intermediate of glycolysis. Once serine is synthesized it can be converted to glycine, with one carbon being picked up by FH₄, to form N⁵,N¹⁰-methylene-FH₄. The N⁵,N¹⁰-methylene-FH₄ can be reduced to N⁵-methyl-FH₄, which can then add the methyl carbon to homocysteine to form methionine. Citrate and pyruvate do not donate carbons to the one-carbon pool, Leucine and lysine degradation is strictly ketogenic, so none of the carbons from those amino acids can also be used to produce N⁵-methyl-FH₄.
15. **The answer is D.** Hypermethioninemia is an excess of methionine in the blood. Of the answer choices listed only methionine adenosyltransferase deficiency would lead to an excess of methionine (the enzyme converts methionine to SAM; in the absence of this activity methionine cannot be degraded and would accumulate). Defects in cystathionine β-synthase and N⁵,N¹⁰-methylene-FH₄ reductase would lead to accumulations of homocysteine, not methionine. A defect in serine hydroxymethyltransferase would not affect methionine levels but would affect serine and glycine levels.

Purine and Pyrimidine Metabolism

Purines and pyrimidines are required for synthesizing **nucleotides** and **nucleic acids**. These molecules can be synthesized either from scratch, **de novo**, or **salvaged** from existing bases. Dietary uptake of purine and pyrimidine bases is low because most of the ingested nucleic acids are metabolized by the intestinal epithelial cells.

The de novo pathway of purine synthesis is complex, consisting of 11 steps and requiring six molecules of adenosine triphosphate (ATP) for every purine synthesized. The precursors that donate components to produce purine nucleotides include **glycine**, **ribose 5-phosphate**, **glutamine**, **aspartate**, **carbon dioxide**, and **N¹⁰-formyltetrahydrofolate (N¹⁰-formyl-FH₄)** (Fig. 39.1). Purines are synthesized as **ribonucleotides**, with the initial purine synthesized being **inosine monophosphate (IMP)**. Adenosine monophosphate (AMP) and guanosine monophosphate (GMP) are each derived from IMP in two-step reaction pathways.

FIGURE 39.1 Origin of the atoms of the purine base. FH₄, tetrahydrofolate; RP, ribose 5'-phosphate. FH₄, tetrahydrofolate; RP, ribose 5'-phosphate.

The purine nucleotide salvage pathway allows free purine bases to be converted into nucleotides, nucleotides into nucleosides, and nucleosides into free bases. Enzymes included in this pathway are **AMP** and **adenosine deaminase (ADA)**, **adenosine kinase**, **purine nucleoside phosphorylase**, **adenine phosphoribosyltransferase (APRT)**, and **hypoxanthine-guanine phosphoribosyltransferase (HGPRT)**. Mutations in a number of these enzymes lead to serious diseases. Deficiencies in purine nucleoside phosphorylase and ADA lead to **immunodeficiency disorders**. A deficiency in HGPRT leads to **Lesch-Nyhan syndrome**. The **purine nucleotide cycle**, in which aspartate carbons are converted to fumarate to replenish tricarboxylic acid (TCA)-cycle intermediates in working muscle, and the aspartate nitrogen is released as ammonia, uses components of the purine nucleotide salvage pathway.

Pyrimidine bases are first synthesized as the free base and then converted to a nucleotide.

Aspartate and **carbamoyl phosphate** form all components of the pyrimidine ring. Ribose 5-phosphate, which is converted to **5'-phosphoribosyl-1'-pyrophosphate (PRPP)**, is required to donate the sugar phosphate to form a nucleotide. The first pyrimidine nucleotide produced is **orotidine monophosphate (OMP)**. The OMP is converted to **uridine monophosphate (UMP)**, which becomes the precursor for both **cytidine triphosphate (CTP)** and **deoxythymidine monophosphate (dTMP)** production.

The formation of deoxyribonucleotides requires **ribonucleotide reductase** activity, which catalyzes the reduction of ribose on nucleotide diphosphate substrates to 2'-deoxyribose. Substrates for the enzyme include adenosine diphosphate (ADP), guanosine diphosphate (GDP), cytidine diphosphate (CDP), and uridine diphosphate (UDP). Regulation of the enzyme is complex. There are two major allosteric sites. One controls the overall activity of the enzyme, whereas the other determines the substrate specificity of the enzyme. All deoxyribonucleotides are synthesized using this one enzyme.

The **regulation** of de novo purine nucleotide biosynthesis occurs at four points in the pathway. The enzymes **PRPP synthetase**, **amidophosphoribosyltransferase**, **IMP dehydrogenase**, and **adenylosuccinate synthetase** are regulated by allosteric modifiers, as they occur at key branch points through the pathway. Pyrimidine synthesis is regulated at the first committed step, which is the synthesis of cytoplasmic carbamoyl phosphate, by the enzyme **carbamoyl phosphate synthetase II (CPSII)**.

Purines, when degraded, cannot generate energy, nor can the purine ring be substantially modified. The end product of purine ring degradation is **uric acid**, which is excreted in the urine. Uric acid has limited solubility, and if it were to accumulate, uric acid crystals would precipitate in tissues of the body that have a reduced temperature (such as the big toe). This condition of acute painful inflammation of specific soft tissues and joints is called **gout**. Pyrimidines, when degraded, however, give rise to water-soluble compounds, such as urea, carbon dioxide, and water and do not lead to a disease state if pyrimidine catabolism is increased.

THE WAITING ROOM

The initial acute inflammatory process that caused **Lotta T.** to experience a painful attack of gouty arthritis responded quickly to colchicine therapy (see Chapter 10). Several weeks after the inflammatory signs and symptoms in her right great toe subsided, **Lotta T.** was placed on allopurinol (while continuing colchicine), a drug that reduces uric acid synthesis. Her serum uric acid level gradually fell from a pretreatment level of 9.2 mg/dL into the normal range (2.5 to 8.0 mg/dL). She remained free of gouty symptoms when she returned to her physician for a follow-up office visit.

I. Purines and Pyrimidines

As has been seen in previous chapters, nucleotides serve numerous functions in different reaction pathways. For example, nucleotides are the activated precursors required for DNA and RNA synthesis. Nucleotides form the structural moieties of many coenzymes (examples include reduced nicotinamide adenine dinucleotide [NADH], flavin adenine dinucleotide [FAD], and coenzyme A). Nucleotides are critical elements in energy metabolism (adenosine triphosphate [ATP], guanosine triphosphate [GTP]). Nucleotide derivatives are frequently activated intermediates in many biosynthetic pathways. For example, UDP-glucose and CDP-diacylglycerol are precursors of glycogen and phosphoglycerides, respectively. S-adenosylmethionine carries an activated methyl group. In addition, nucleotides act as second messengers in intracellular signaling (e.g., cyclic adenosine monophosphate [cAMP], cyclic guanosine monophosphate [cGMP]). Finally, nucleotides and nucleosides act as metabolic allosteric regulators. Think about all of the enzymes that have been studied that are regulated by levels of ATP, ADP, and AMP.

Dietary uptake of purine and pyrimidine bases is minimal. The diet contains nucleic acids, and the exocrine pancreas secretes deoxyribonuclease and ribonuclease, along with the proteolytic and lipolytic enzymes. This enables digested nucleic acids to be converted to nucleotides. The intestinal epithelial cells contain alkaline

phosphatase activity, which converts nucleotides to nucleosides. Other enzymes within the epithelial cells tend to metabolize the nucleosides to uric acid (which is released into the circulation), or to salvage them for their own needs. Approximately 5% of ingested nucleotides make it into the circulation, either as the free base or as a nucleoside. Because of the minimal dietary uptake of these important molecules, de novo synthesis of purines and pyrimidines is required.

II. Purine Biosynthesis

The purine bases are produced de novo by pathways that use amino acids as precursors and produce nucleotides. Most de novo synthesis occurs in the liver (Fig. 39.2), and the nitrogenous bases and nucleosides are then transported to other tissues by red blood cells. The brain also synthesizes significant amounts of nucleotides. Because the de novo pathway requires at least six high-energy bonds per purine produced, a salvage pathway, which is used by many cell types, can convert free bases and nucleosides to nucleotides.

FIGURE 39.2 Overview of purine production, starting with glutamine, ribose 5-phosphate, and ATP. The steps that require ATP are also indicated in this figure. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; dADP, deoxyadenosine diphosphate; dATP, deoxyadenosine triphosphate; dGDP, deoxyguanosine diphosphate; dGTP, deoxyguanosine triphosphate; FH₄, tetrahydrofolate; GMP, guanosine monophosphate; GTP, guanosine triphosphate; IMP, inosine monophosphate; PRPP, 5-phosphoribosyl 1-pyrophosphate; RR, ribonucleotide reductase.

A. De Novo Synthesis of the Purine Nucleotides

1. Synthesis of Inosine Monophosphate

As purines are built on a ribose base (see Fig. 39.2), an activated form of ribose is used to initiate the purine biosynthetic pathway. 5'-Phosphoribosyl-1'-pyrophosphate (PRPP) is the activated source of the ribose moiety. It is synthesized from ATP and ribose 5'-phosphate (Fig. 39.3), which is produced from glucose through the pentose phosphate pathway (see Chapter 27). The enzyme that catalyzes this reaction, PRPP synthetase, is a regulated enzyme (see Section II.A.5); however, this step is not the committed step of purine biosynthesis. PRPP has many other uses, which are described as the chapter progresses.

Ribose 5-phosphate

5-Phosphoribosyl 1-pyrophosphate (PRPP)

FIGURE 39.3 Synthesis of PRPP. Ribose 5-phosphate is produced from glucose by the pentose phosphate pathway. AMP, adenosine monophosphate; ATP, adenosine triphosphate; PRPP, 5-phosphoribosyl 1-pyrophosphate.

In the first committed step of the purine biosynthetic pathway, PRPP reacts with glutamine to form 5'-phosphoribosyl 1'-amine (Fig. 39.4). This reaction, which produces nitrogen 9 of the purine ring, is catalyzed by glutamine phosphoribosylamidotransferase, a highly regulated enzyme.

PRPP

5-Phosphoribosyl 1-amine

FIGURE 39.4 The first step in purine biosynthesis. The purine base is built on the ribose moiety. The availability of the substrate PRPP is a major determinant of the rate of this reaction. P_{Pi}, pyrophosphate; PRPP, 5-phosphoribosyl 1-pyrophosphate.

In the next step of the pathway, the entire glycine molecule is added to the growing precursor. Glycine provides carbons 4 and 5 and nitrogen 7 of the purine ring (Fig. 39.5). This step requires energy in the form of ATP.

5-Phosphoribosyl 1-amine

**Glycinamide
ribosyl 5-phosphate**

FIGURE 39.5 Incorporation of glycine into the purine precursor. The ATP is required for the condensation of the glycine carboxylic acid group with the 1'-amino group of phosphoribosyl 1-amine. ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, inorganic phosphate.

Subsequently, carbon 8 is provided by N_{10} -formyltetrahydrofolate (N^{10} -formyl-FH₄), nitrogen 3 by glutamine, carbon 6 by CO₂, nitrogen 1 by aspartate, and carbon 2 by N^{10} -formyl-FH₄ (see Fig. 39.1). Note that six high-energy bonds of ATP are required (starting with ribose 5-phosphate) to synthesize the first purine nucleotide, IMP. This nucleotide contains the base hypoxanthine joined by an *N*-glycosidic bond from nitrogen 9 of the purine ring to carbon 1 of the ribose (Fig. 39.6). Hypoxanthine is not found in DNA, but it is the precursor for the other purine bases. However, hypoxanthine is found in the anticodon of tRNA molecules (see Chapter 14) and is a critical component for allowing wobble base pairs to form.

FIGURE 39.6 Structure of IMP. The base is hypoxanthine. IMP, inosine monophosphate.

2. Synthesis of Adenosine Monophosphate

IMP serves as the branch point from which both adenine and guanine nucleotides can be produced (see Fig. 39.2). Adenosine monophosphate is derived from IMP in two steps (Fig. 39.7). In the first step, aspartate is added to IMP to form adenylosuccinate, a reaction similar to the one catalyzed by argininosuccinate synthetase in the urea cycle. Note that this reaction requires a high-energy bond, donated by GTP. Fumarate is then released from the adenylosuccinate by the enzyme adenylosuccinate lyase to form AMP. This is similar to the aspartate-to-fumarate conversion seen in the urea cycle (see Chapter 38). In both cases, aspartate donates a nitrogen to the product, whereas the carbons of aspartate are released as fumarate.

FIGURE 39.7 The conversion of IMP to AMP. Note that GTP is required for the synthesis of AMP. The first enzyme is adenylosuccinate synthetase; the second enzyme is adenylosuccinate lyase. AMP, adenosine monophosphate; GTP, guanosine triphosphate; IMP, inosine monophosphate; GDP, guanosine diphosphate; Pi, inorganic phosphate; R5P, ribose 5-phosphate.

3. Synthesis of Guanosine Monophosphate

GMP is also synthesized from IMP in two steps (Fig. 39.8). In the first step, the hypoxanthine base is oxidized by IMP dehydrogenase to produce the base xanthine and the nucleotide xanthosine monophosphate (XMP). Glutamine then donates the amide nitrogen to XMP to form GMP in a reaction that is catalyzed by GMP synthetase. This second reaction requires energy, in the form of ATP.

synthetase

GMP

FIGURE 39.8 The conversion of IMP to GMP. Note that ATP is required for the synthesis of GMP. AMP, adenosine monophosphate; ATP, adenosine triphosphate; GMP, guanosine monophosphate; IMP, inosine monophosphate; NAD, nicotinamide adenine dinucleotide; PPi, pyrophosphate; R5P, ribose 5-phosphate; XMP, xanthosine monophosphate.

4. Phosphorylation of AMP and GMP

AMP and GMP can be phosphorylated to the diphosphate and triphosphate levels. The production of nucleoside diphosphates requires specific nucleoside monophosphate kinases, whereas the production of nucleoside triphosphates requires nucleoside diphosphate kinases, which are active with a wide range of nucleoside diphosphates. The purine nucleoside triphosphates are also used for energy-requiring processes in the cell and also as precursors for RNA synthesis (see Fig. 39.2).

5. Regulation of Purine Synthesis

Regulation of purine synthesis occurs at several sites (Fig. 39.9). Four key enzymes are regulated: PRPP synthetase, amidophosphoribosyltransferase, adenylosuccinate synthetase, and IMP dehydrogenase. The first two enzymes regulate IMP synthesis; the last two regulate the production of AMP and GMP, respectively.

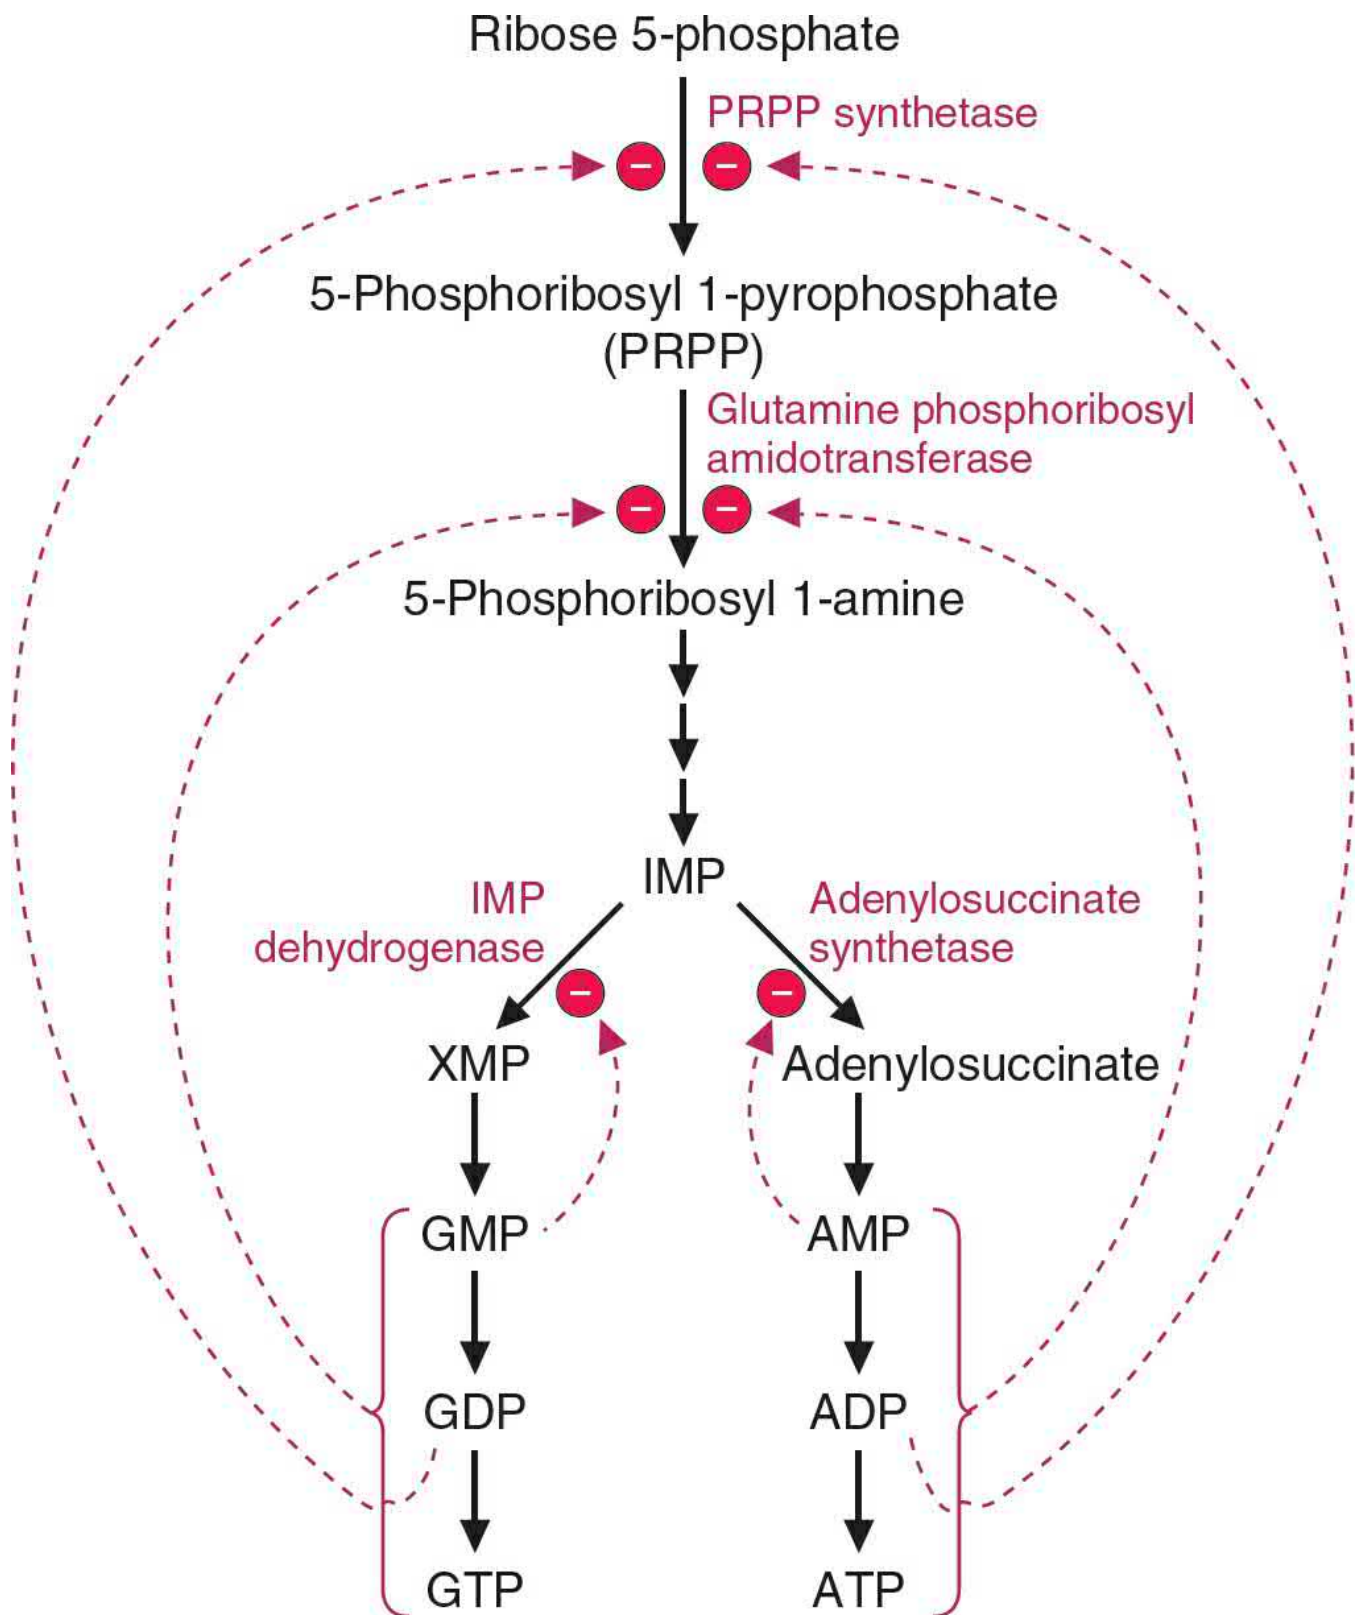

FIGURE 39.9 The regulation of purine synthesis. PRPP synthetase can be inhibited by ADP or GDP binding to a single allosteric site. Glutamine phosphoribosylamidotransferase contains adenine nucleotide- and guanine nucleotide-binding sites; the monophosphates are the most important, although the diphosphates and triphosphates will also bind to and inhibit the enzyme. Adenylosuccinate synthetase is inhibited by AMP; IMP dehydrogenase is inhibited by GMP. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; GDP, guanosine diphosphate; GTP, guanosine triphosphate; PRPP, 5-phosphoribosyl 1-pyrophosphate; XMP, xanthosine monophosphate.

A primary site of regulation is the synthesis of PRPP. PRPP synthetase is negatively affected by GDP and ADP. Thus, the binding of either an oxypurine (e.g., GDP) or an aminopurine (e.g., ADP) can occur, with the

result being an inhibition of the enzyme. This enzyme is not the committed step of purine biosynthesis; PRPP is also used in pyrimidine synthesis and both the purine and pyrimidine salvage pathways.

The committed step of purine synthesis is the formation of 5'-phosphoribosyl 1'-amine by glutamine phosphoribosylamidotransferase. This enzyme is strongly inhibited by GMP and AMP (the end products of the purine biosynthetic pathway) by binding to distinct allosteric sites. The enzyme is also inhibited by the corresponding nucleoside diphosphates and triphosphates, but under cellular conditions, these compounds probably do not play a central role in regulation. The active enzyme is a monomer of 133,000 Da but is converted to an inactive dimer (270,000 Da) by binding of the end products. Cellular concentrations of PRPP and glutamine are usually below their K_m for glutamine phosphoribosylamidotransferase. Thus, any situation that leads to an increase in their concentration can lead to an increase in de novo purine biosynthesis.

The enzymes that convert IMP to XMP and adenylosuccinate are both regulated. GMP inhibits the activity of IMP dehydrogenase, and AMP inhibits adenylosuccinate synthetase. Note that the synthesis of AMP is dependent on GTP (of which GMP is a precursor), whereas the synthesis of GMP is dependent on ATP (which is made from AMP). This serves as a type of positive regulatory mechanism to balance the pools of these precursors. When the levels of ATP are high, GMP will be made; when the levels of GTP are high, AMP synthesis will take place. GMP and AMP act as negative effectors at these branch points, a classic example of feedback inhibition.

B. Purine Salvage Pathways

Most of the de novo synthesis of the bases of nucleotides occurs in the liver, and to some extent in the brain, neutrophils, and other cells of the immune system. Within the liver, nucleotides can be converted to nucleosides or free bases, which can be transported to other tissues via the red blood cells in the circulation. In addition, the small amounts of dietary bases or nucleosides that are absorbed also enter cells in this form. Thus, most cells can salvage these bases to generate nucleotides for RNA and DNA synthesis. For certain cell types, such as lymphocytes, the salvage of bases is the major form of nucleotide generation.

A deficiency in purine nucleoside phosphorylase activity leads to an immune disorder in which T cell immunity is compromised. B-cell immunity, conversely, may be only slightly compromised or even normal. This is thought to occur because of significantly higher levels of dGTP or deoxyguanosine in the thymus as compared to the bone marrow, where the B cells are formed. Children who lack purine nucleoside phosphorylase activity have recurrent infections, and more than half display neurologic complications. Symptoms of the disorder first appear at between 6 months and 4 years of age. It is an extremely rare autosomal recessive disorder.

The overall picture of salvage is shown in Figure 39.10. The pathways allow free bases, nucleosides, and nucleotides to be easily interconverted. The major enzymes required are purine nucleoside phosphorylase, phosphoribosyltransferases, and deaminases.

FIGURE 39.10 Salvage of bases. The purine bases hypoxanthine and guanine react with PRPP to form the nucleotides inosine and guanosine monophosphate, respectively. The enzyme that catalyzes the reaction is HGPRT. Adenine forms AMP in a reaction that is catalyzed by APRT. Nucleotides are converted to nucleosides by 5'-nucleotidase. Free bases are generated from nucleosides by purine nucleoside phosphorylase (although adenosine is not a substrate of this enzyme). Deamination of the base adenine occurs with AMP and adenosine deaminase. Of the purines, only adenosine can be phosphorylated directly back to a nucleotide, by adenosine kinase. ADP, adenosine diphosphate; APRT, adenine phosphoribosyltransferase; ATP, adenosine triphosphate; GMP, guanosine monophosphate; HGPRT, hypoxanthine–guanine phosphoribosyltransferase; IMP, inosine monophosphate; P_i, inorganic phosphate; PP_i, pyrophosphate; PRPP, 5-phosphoribosyl 1-pyrophosphate.

M ADA activity is measured by coupling the deamination of adenosine (to inosine) with purine nucleoside phosphorylase, which will generate hypoxanthine and ribose 1-phosphate from inosine. The hypoxanthine generated then reacts with xanthine oxidase, generating uric acid and hydrogen peroxide. The hydrogen peroxide produced is then measured in the presence of peroxidase and a colorless dye. The oxidation of the colorless dye creates a colored dye, and the intensity of the color (which is directly proportional to the amount of inosine produced) can be determined spectrophotometrically.

Purine nucleoside phosphorylase catalyzes a phosphorolysis reaction of the *N*-glycosidic bond that attaches the base to the sugar moiety in the nucleosides guanosine and inosine (Fig. 39.11A). Thus, guanosine and inosine are converted to guanine and hypoxanthine, respectively, along with ribose 1-phosphate. The ribose 1-phosphate can be isomerized to ribose 5-phosphate, and the free bases then salvaged or degraded, depending on cellular needs.

FIGURE 39.11 **A.** The purine nucleoside phosphorylase reaction, which converts guanosine or inosine to ribose 1-phosphate plus the free base guanine or hypoxanthine. **B.** The phosphoribosyltransferase reaction. APRT uses the free-base adenine; HGPRT can use either hypoxanthine or guanine as a substrate. AMP, adenosine monophosphate; APRT, adenine phosphoribosyltransferase; GDP, guanosine diphosphate; GTP, guanosine triphosphate; HGPRT, hypoxanthine–guanine phosphoribosyltransferase; IMP, inosine monophosphate; Pi, inorganic phosphate; PPi, pyrophosphate.

The phosphoribosyltransferase enzymes catalyze the addition of a ribose 5-phosphate group from PRPP to a free base, generating a nucleotide and pyrophosphate (see Fig. 39.11B). Two enzymes do this for purine metabolism: adenine phosphoribosyltransferase (APRT) and hypoxanthine–guanine phosphoribosyltransferase (HGPRT). The reactions they catalyze are the same, differing only in their substrate specificity.

Adenosine and AMP can be deaminated by adenosine deaminase (ADA) and AMP deaminase, respectively, to form inosine and IMP (see Fig. 39.10). Adenosine is also the only nucleoside to be directly phosphorylated to a nucleotide by adenosine kinase. Guanosine and inosine must be converted to free bases by purine nucleoside phosphorylase before they can be converted to nucleotides by HGPRT.

Lesch–Nyhan syndrome is caused by a defective HGPRT (see Fig. 39.11B). In this condition, purine bases cannot be salvaged. Instead, they are degraded, forming excessive amounts of uric acid, leading to gout. Boys (it is x-linked recessive) with the severe form of this syndrome suffer from developmental delays and intellectual disabilities. They are also prone to self-injury, including biting and head banging.

A portion of the salvage pathway that is important in muscle is the purine nucleotide cycle (Fig. 39.12). The net effect of these reactions is the deamination of aspartate to fumarate (as AMP is synthesized from IMP and then deaminated back to IMP by AMP deaminase). Under conditions in which the muscle must generate energy, the fumarate derived from the purine nucleotide cycle is used anaplerotically to replenish TCA-cycle intermediates and to allow the cycle to operate at high speed. Deficiencies in enzymes of this cycle lead to muscle fatigue during exercise.

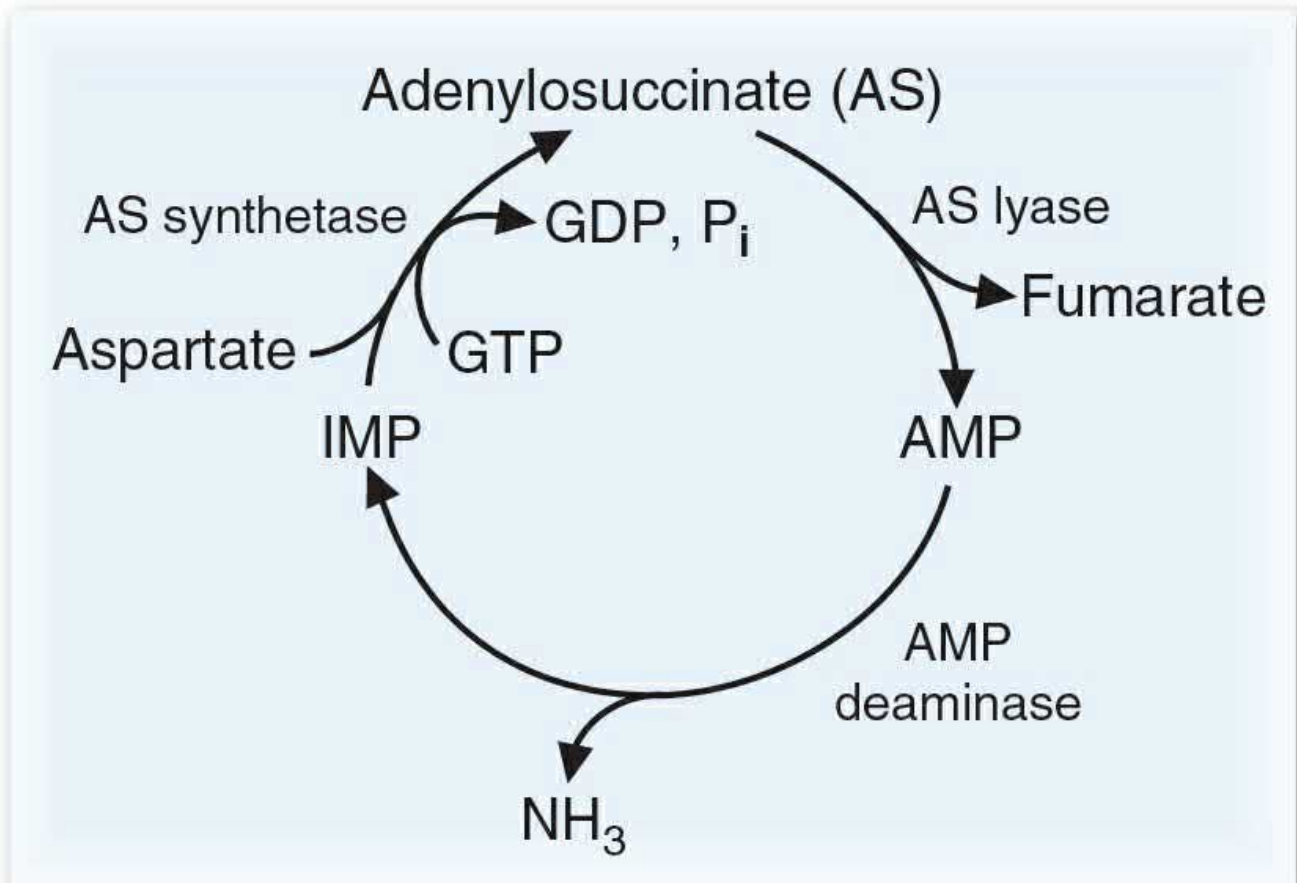

FIGURE 39.12 The purine nucleotide cycle. Using a combination of biosynthetic and salvage enzymes, the net effect is the conversion of aspartate to fumarate plus ammonia, with the fumarate playing an anaplerotic role in the muscle. AMP, adenosine monophosphate; AS, adenylosuccinate; GDP, guanosine diphosphate; GTP, guanosine triphosphate; IMP, inosine monophosphate; Pi, inorganic phosphate.

III. Synthesis of the Pyrimidine Nucleotides

A. De Novo Pathways

In the synthesis of the pyrimidine nucleotides, the base is synthesized first, and then it is attached to the ribose 5'-phosphate moiety (Fig. 39.13). The origin of the atoms of the ring (aspartate and carbamoyl phosphate, which is derived from carbon dioxide and glutamine) is shown in Figure 39.14. In the initial reaction of the pathway, glutamine combines with bicarbonate and ATP to form carbamoyl phosphate. This reaction is analogous to the first reaction of the urea cycle, except that it uses glutamine as the source of the nitrogen (rather than ammonia) and it occurs in the cytosol (rather than in mitochondria). The reaction is catalyzed by carbamoyl phosphate synthetase II (CPSII), which is the regulated step of the pathway. The analogous reaction in urea synthesis is catalyzed by carbamoyl phosphate synthetase I (CPSI), which is activated by *N*-acetylglutamate. The similarities and differences between these two carbamoyl phosphate synthetase enzymes are described in Table 39.1.

TABLE 39.1 Comparison of Carbamoyl Phosphate Synthetases (CPSI and CPSII)

	CPSI	CPSII
Pathway	Urea cycle	Pyrimidine biosynthesis
Source of nitrogen	NH ₄ ⁺	Glutamine
Location	Mitochondria	Cytosol
Activator	<i>N</i> -acetylglutamate	PRPP
Inhibitor	—	UTP

CPSI, carbamoyl phosphate synthetase I; CPSII, carbamoyl phosphate synthetase II; PRPP, 5'-phosphoribosyl-1'-pyrophosphate; UTP, uridine triphosphate.

FIGURE 39.13 Synthesis of the pyrimidine bases. ATP, adenosine triphosphate; CDP, cytidine diphosphate; CPSII, carbamoyl phosphate synthetase II; CTP, cytidine triphosphate; dCDP, deoxycytidine diphosphate; dCMP, deoxycytidine monophosphate; dCTP, deoxycytidine triphosphate; dTDP, deoxythymidine diphosphate; dTMP, deoxythymidine monophosphate; dTTP, deoxythymidine triphosphate; dUDP, deoxyuridine diphosphate; dUMP, deoxyuridine monophosphate; FH₂, dihydrofolate; FH₄, tetrahydrofolate; Pi, inorganic phosphate; PRPP, 5-phosphoribosyl 1-pyrophosphate; RR, ribonucleotide reductase; UDP, uridine diphosphate; UMP, uridine monophosphate; UTP, uridine triphosphate[⊕], stimulated by; ⊖, inhibited by.

FIGURE 39.14 The origin of the atoms in the pyrimidine ring.

In the next step of pyrimidine biosynthesis, the entire aspartate molecule adds to carbamoyl phosphate in a reaction that is catalyzed by aspartate transcarbamoylase (Fig. 39.15). The molecule subsequently closes to produce a ring (catalyzed by dihydroorotase), which is oxidized to form orotic acid (or its anion, orotate) through the actions of dihydroorotate dehydrogenase. The enzyme orotate phosphoribosyltransferase catalyzes the transfer of ribose 5-phosphate from PRPP to orotate, producing orotidine 5'-phosphate, which is decarboxylated by orotidylic acid decarboxylase to form uridine monophosphate (UMP) (see Fig. 39.15). In mammals, the first three enzymes of the pathway (CPSII, aspartate transcarbamoylase, and dihydroorotase) are located on the same polypeptide, designated as CAD. The last two enzymes of the pathway are similarly located on a polypeptide known as UMP synthase (the orotate phosphoribosyltransferase and orotidylic acid decarboxylase activities).

FIGURE 39.15 Conversion of carbamoyl phosphate and aspartate to UMP. The defective enzymes in hereditary orotic aciduria are indicated by the *dark bar*. OMP, orotate monophosphate; Orotidine 5-P, orotidine 5-phosphate; P_i, inorganic phosphate; PP_i, pyrophosphate; PRPP, 5-phosphoribosyl 1-pyrophosphate.

UMP is phosphorylated to uridine triphosphate (UTP) in two steps. An amino group, derived from the amide of glutamine, is added to carbon 4 to produce CTP by the enzyme CTP synthetase (this reaction cannot occur at the nucleotide monophosphate level). UTP and CTP are precursors for the synthesis of RNA (see Fig. 39.13). The synthesis of deoxythymidine triphosphate (dTTP) is described in Section IV.

B. Salvage of Pyrimidine Bases

Pyrimidine bases are normally salvaged by a two-step route. First, a relatively nonspecific pyrimidine nucleoside phosphorylase converts the pyrimidine bases to their respective nucleosides (Fig. 39.16). Notice that the preferred direction for this reaction is the reverse phosphorylase reaction, in which phosphate is released and is not being used as a nucleophile to release the pyrimidine base from the nucleoside. The more specific nucleoside kinases then react with the nucleosides, forming nucleotides (Table 39.2). As with purines, further phosphorylation is carried out by increasingly more specific kinases. The nucleoside phosphorylase–nucleoside kinase route for synthesis of pyrimidine nucleoside monophosphates is relatively inefficient for salvage of pyrimidine bases because of the very low concentration of the bases in plasma and tissues.

TABLE 39.2 Salvage Reactions for Conversion of Pyrimidine Nucleosides to Nucleotides	
ENZYME	REACTION
Uridine-cytidine kinase	Uridine + ATP → UMP + ADP
	Cytidine + ATP → CMP + ADP
Deoxythymidine kinase	Deoxythymidine + ATP → dTMP + ADP
Deoxycytidine kinase	Deoxycytidine + ATP → dCMP + ADP

ADP, adenosine diphosphate; ATP, adenosine triphosphate; CMP, cytidine monophosphate; dCMP, deoxycytidine monophosphate; dTMP, deoxythymidine monophosphate; UMP, uridine monophosphate.

FIGURE 39.16 Salvage reactions for pyrimidine nucleoside production. Thymine phosphorylase uses deoxyribose 1-phosphate as a substrate, so ribothymidine is rarely formed. P_i, inorganic phosphate.

Pyrimidine nucleoside phosphorylase can use all of the pyrimidines but has a preference for uracil and is sometimes called **uridine phosphorylase**. The phosphorylase uses cytosine fairly well but has a very, very low affinity for thymine; therefore, a ribonucleoside containing thymine is almost never made in vivo. A second phosphorylase, **thymine phosphorylase**, has a much higher affinity for thymine and adds a deoxyribose residue (see Fig. 39.16).

Of the various ribonucleosides and deoxyribonucleoside kinases, one that merits special mention is thymidine kinase (TK). This enzyme is allosterically inhibited by dTTP. Activity of thymidine kinase in a given cell is closely related to the proliferative state of that cell. During the cell cycle, the activity of TK rises dramatically as cells enter S-phase, and in general, rapidly dividing cells have high levels of this enzyme. Radiolabeled thymidine is widely used for isotopic labeling of DNA, for example, in radioautographic investigations or to estimate rates of intracellular DNA synthesis.

C. Regulation of De Novo Pyrimidine Synthesis

The regulated step of pyrimidine synthesis in humans is CPSII. The enzyme is inhibited by UTP and activated by PRPP (see Fig. 39.13). Thus, as pyrimidines decrease in concentration (as indicated by UTP levels), CPSII is activated and pyrimidines are synthesized. The activity is also regulated by the cell cycle. As cells approach S-phase, CPSII becomes more sensitive to PRPP activation and less sensitive to UTP inhibition. At the end of S-phase, the inhibition by UTP is more pronounced, and the activation by PRPP is reduced. These changes in the allosteric properties of CPSII are related to its phosphorylation state. Phosphorylation of the enzyme at a specific site by a mitogen-activated protein (MAP) kinase leads to a more easily activated enzyme. Phosphorylation at a second site by the cAMP-dependent protein kinase leads to a more easily inhibited enzyme.

In hereditary orotic aciduria, an extremely rare disorder, orotic acid is excreted in the urine because the enzymes that

convert it to UMP, orotate phosphoribosyltransferase and orotidine 5'-phosphate decarboxylase, are defective (see Fig. 39.16). Pyrimidines cannot be synthesized and, therefore, normal growth does not occur. Oral administration of uridine is used to treat this condition. Uridine, which is converted to UMP, bypasses the metabolic block and provides the body with a source of pyrimidines, as both CTP and dTMP can be produced from UMP.

IV. The Production of Deoxyribonucleotides

For DNA synthesis to occur, the ribose moiety must be reduced to deoxyribose (Fig. 39.17). This reduction occurs at the diphosphate level and is catalyzed by ribonucleotide reductase, which requires the protein thioredoxin. The deoxyribonucleoside diphosphates can be phosphorylated to the triphosphate level and used as precursors for DNA synthesis (see Figs. 39.2 and 39.13).

FIGURE 39.17 Reduction of ribose to deoxyribose. Reduction occurs at the nucleoside diphosphate level. A ribonucleoside diphosphate (NDP) is converted to a dNDP. Thioredoxin is oxidized to a disulfide, which must be reduced for the reaction to continue producing dNDP. dNDP, deoxyribonucleoside diphosphate; NADP, nicotinamide adenine dinucleotide phosphate.

 When ornithine transcarbamoylase is deficient (urea-cycle disorder), excess carbamoyl phosphate from the mitochondria leaks into the cytoplasm. The elevated levels of cytoplasmic carbamoyl phosphate lead to pyrimidine production, as the regulated step of the pathway, the reaction catalyzed by carbamoyl synthetase II, is being bypassed. Thus,

orotic aciduria results.

The regulation of ribonucleotide reductase is quite complex. The enzyme contains two allosteric sites, one controlling the activity of the enzyme and the other controlling the substrate specificity of the enzyme. ATP bound to the activity site activates the enzyme; deoxyadenosine triphosphate (dATP) bound to this site inhibits the enzyme. Substrate specificity is more complex. ATP bound to the substrate specificity site activates the reduction of pyrimidines (CDP and UDP), to form deoxycytidine diphosphate (dCDP) and deoxyuridine diphosphate (dUDP). The dUDP is not used for DNA synthesis; rather, it is used to produce dTMP (see below). Once dTMP is produced, it is phosphorylated to dTTP, which then binds to the substrate specificity site and induces the reduction of GDP. As dGTP accumulates, it replaces dTTP in the substrate specificity site and allows ADP to be reduced to dADP. This leads to the accumulation of dATP, which inhibits the overall activity of the enzyme. These allosteric changes are summarized in Table 39.3.

TABLE 39.3 Effectors of Ribonucleotide Reductase Activity

PREFERRED SUBSTRATE	EFFECTOR BOUND TO OVERALL ACTIVITY SITE	EFFECTOR BOUND TO SUBSTRATE SPECIFICITY SITE
None	dATP	Any nucleotide
CDP	ATP	ATP or dATP
UDP	ATP	ATP or dATP
GDP	ATP	dTTP
ADP	ATP	dGTP

ADP, adenosine diphosphate; ATP, adenosine triphosphate; CDP, cytidine diphosphate; dATP, deoxyadenosine triphosphate; dTTP, deoxythymidine triphosphate; GDP, guanosine diphosphate; dGTP, deoxyguanosine triphosphate; UDP, uridine diphosphate.

dUDP can be dephosphorylated to form deoxyuridine monophosphate (dUMP), or, alternatively, deoxycytidine monophosphate (dCMP) can be deaminated to form dUMP. Methylene-FH₄ transfers a methyl group to dUMP to form dTMP (see Fig. 38.5). Phosphorylation reactions produce dTTP, a precursor for DNA synthesis and a regulator of ribonucleotide reductase.

V. Degradation of Purine and Pyrimidine Bases

A. Purine Bases

The degradation of the purine nucleotides (AMP and GMP) occurs mainly in the liver (Fig. 39.18). Salvage enzymes are used for most of these reactions. AMP is first deaminated to produce IMP (AMP deaminase). Then IMP and GMP are dephosphorylated (5'-nucleotidase), and the ribose is cleaved from the base by purine nucleoside phosphorylase. Hypoxanthine, the base produced by cleavage of IMP, is converted by xanthine oxidase to xanthine, and guanine is deaminated by the enzyme guanase to produce xanthine. The pathways for the degradation of adenine and guanine merge at this point. Xanthine is converted by xanthine oxidase to uric acid, which is excreted in the urine. Xanthine oxidase is a molybdenum-requiring enzyme that uses molecular oxygen and produces hydrogen peroxide (H₂O₂). Another form of xanthine oxidase uses NAD⁺ as the electron acceptor (see Chapter 25).

FIGURE 39.18 Degradation of the purine bases. The reactions inhibited by allopurinol are indicated. A second form of xanthine oxidase exists that uses NAD^+ instead of O_2 as the electron acceptor. AMP, adenosine monophosphate; GMP, guanosine monophosphate; IMP, inosine monophosphate; NAD, nicotinamide adenine dinucleotide; P_i , inorganic phosphate.

Uric acid has a pK of 5.4. It is ionized in the body to form urate. Urate is not very soluble in an aqueous environment. The concentration of urate in normal human blood is very close to the solubility constant.

Gout is caused by excessive uric acid levels in the blood and tissues. In studies to determine whether a person with gout has developed this problem because of overproduction of purine nucleotides or because of a decreased ability to excrete uric acid, an oral dose of a ^{15}N -labeled amino acid is sometimes used. Which amino acid would be most appropriate to use for this purpose?

Note how little energy is derived from the degradation of the purine ring. Thus, it is to the cell's advantage to recycle and salvage the ring, because it costs energy to produce and not much is obtained in return.

B. Pyrimidine Bases

The pyrimidine nucleotides are dephosphorylated, and the nucleosides are cleaved to produce ribose 1-phosphate and the free pyrimidine bases cytosine, uracil, and thymine. Cytosine is deaminated, forming uracil, which is converted to CO_2 , NH_4^+ , and β -alanine. Thymine is converted to CO_2 , NH_4^+ , and β -aminoisobutyrate. These products of pyrimidine degradation are excreted in the urine or converted to CO_2 , H_2O , and NH_4^+ (which forms urea). They do not cause any problems for the body, in contrast to urate, which is produced from the purines and can precipitate, causing gout. As with the purine degradation pathway, little energy can be generated by pyrimidine degradation.

Normally, as cells die, their purine nucleotides are degraded to hypoxanthine and xanthine, which are converted to uric acid by xanthine oxidase (see Fig. 39.18). Allopurinol (a structural analog of hypoxanthine) is a substrate for xanthine oxidase. It is converted to oxypurinol (also called alloxanthine), which remains tightly bound to the enzyme, preventing further catalytic activity (see Fig. 8.15). Thus, allopurinol is a suicide inhibitor. It reduces the production of uric acid and hence its concentration in the blood and tissues (e.g., the synovial lining of the joints in **Lotta T.**'s great toe). Xanthine and hypoxanthine accumulate, and urate levels decrease. Overall, the amount of purine being degraded is spread over three products rather than appearing in only one. Therefore, none of the compounds exceeds its solubility constant, precipitation does not occur, and acute gout attacks decrease.

CLINICAL COMMENTS

Lotta T. Hyperuricemia in **Lotta T.**'s case arose as a consequence of overproduction of uric acid. Treatment with allopurinol not only inhibits xanthine oxidase, lowering the formation of uric acid with an increase in the excretion of hypoxanthine and xanthine, but also decreases the overall synthesis of purine nucleotides. Hypoxanthine and xanthine produced by purine degradation are often salvaged (i.e., converted to nucleotides) by reactions that require the consumption of PRPP. PRPP is a substrate for the glutamine phosphoribosylamidotransferase reaction that initiates purine biosynthesis. Because the normal cellular levels of PRPP and glutamine are below the K_m of the enzyme, changes in the level of either substrate can accelerate or reduce the rate of the reaction. Therefore, decreased levels of PRPP cause decreased synthesis of purine nucleotides.

BIOCHEMICAL COMMENTS

ADA deficiency. A deficiency in ADA activity leads to severe combined immunodeficiency disease (SCID). In the severe form of combined immunodeficiency, T cells (which provide cell-based immunity, see Chapter 42) and B cells (which produce antibodies) are both deficient, leaving the individual without a functional immune system. Children born with this disorder do not develop a mature thymus gland and suffer from many opportunistic infections because of their lack of a functional immune system. In order to avoid infection, which can be lethal, affected children must avoid exposure to infectious agents. Treatment with hematopoietic stem cell transplantation or gene therapy is recommended. If neither is

possible, administration of polyethylene glycol–modified ADA has been successful in treating the disorder. The question that remains, however, is that even though all the cells of the body lack ADA activity, why are the immune cells specifically targeted for destruction?

The specific immune disorder is not caused by any defect in purine salvage pathways, as children with Lesch–Nyhan syndrome have a functional immune system, although there are other major problems in those children. This suggests that perhaps the accumulation of precursors to ADA lead to toxic effects. Three hypotheses have been proposed and are outlined below.

In the absence of ADA activity, both adenosine and deoxyadenosine accumulate. When deoxyadenosine (dA) accumulates, adenosine kinase can convert it to deoxyadenosine monophosphate (dAMP). Other kinases then allow dATP to accumulate in the lymphocytes. How could this lead to a lack of functional T and B cells?

 The entire glycine molecule is incorporated into the precursor of the purine nucleotides. The nitrogen of this glycine also appears in uric acid, the product of purine degradation. ^{15}N -labeled glycine could be used, therefore, to determine whether purines are being overproduced.

T cell development occurs in the thymus (see Chapter 42). There is a significant level of apoptosis within the thymus during T-cell activation and development. The death of a significant number of cells leads to the release of dA, which then affect the surviving cells by being taken up, activated to dATP, and then inhibiting ribonucleotide reductase, reducing overall DNA synthesis in the cells. This leads to further cell death, with the net result being very few mature T-cells are formed.

B-cell development occurs in the marrow, and there appears to be reduced apoptosis in the marrow as compared to the thymus. Analysis of B-cell development and differentiation in ADA-deficient patients has indicated a block in differentiation, rather than an overall inhibition of DNA synthesis because of an inactive ribonucleotide reductase. It has been hypothesized that in the B cells, the accumulation of deoxyadenosine leads to an inhibition of *S*-adenosylhomocysteine (SAH) hydrolase, the enzyme that converts SAH to homocysteine and adenosine. This would lead to a reduction of *S*-adenosylmethionine (SAM) levels, and altered epigenetic regulation (hypomethylation) and an accumulation of SAH. The hypomethylation would alter the differentiation signals in the B-cell, leading to an inhibition of mature B-cell formation.

 Once nucleotide biosynthesis and salvage was understood at the pathway level, it was quickly realized that one way to inhibit cell proliferation would be to block purine or pyrimidine synthesis. Thus, drugs were developed that would interfere with a cell's ability to generate precursors for DNA synthesis, thereby inhibiting cell growth. This is particularly important for cancer cells, which have lost their normal growth-regulatory properties. Such drugs have been introduced previously with a number of different patients. **Clark T.** was treated with 5-fluorouracil, which inhibits thymidylate synthase (dUMP-to-TMP synthesis). **Charles F.** was treated with a combination of drugs (R-CHOP) for his leukemia. These drugs all interfere with DNA synthesis via a variety of mechanisms. Development of these drugs would not have been possible without an understanding of the biochemistry of both purine and pyrimidine salvage and synthesis and DNA replication. Such drugs also affect rapidly dividing normal cells, which brings about a number of the side effects of chemotherapeutic regimens.

ADA deficiency also leads to an accumulation of adenosine. Elevated adenosine levels will lead to inappropriate activation of adenosine receptors. Adenosine, acting as a signaling molecule, results in activation of protein kinase A and elevated cAMP levels in thymocytes. Elevated levels of cAMP in these cells triggers both apoptosis and developmental arrest of the cell.

Although it is still not clear which potential mechanism best explains the arrested development of immune cells, it is clear that elevated levels of adenosine and deoxyadenosine are toxic to both B- and T-cell development, in contrast to purine nucleoside phosphorylase (PNP) deficiency, which does block T-cell development but may only partially, if at all, affect B-cell development.

KEY CONCEPTS

- ◆ Purine and pyrimidine nucleotides can both be synthesized from scratch (de novo) or salvaged from existing bases.
- ◆ De novo purine synthesis is complex, requiring 11 steps and six molecules of ATP for every purine synthesized. Purines are initially synthesized in the ribonucleotide form.
- ◆ The precursors for de novo purine synthesis are glycine, ribose 5-phosphate, glutamine, aspartate, carbon dioxide, and N^{10} -formyl-FH₄.

- ◆ The initial purine ribonucleotide synthesized is IMP. AMP and GMP are each derived from IMP.
- ◆ Because de novo purine synthesis requires a large amount of energy, purine nucleotide salvage pathways exist such that free purine bases can be converted to nucleotides.
- ◆ Mutations in purine salvage enzymes are associated with severe diseases, such as Lesch–Nyhan syndrome and SCID.
- ◆ Pyrimidine bases are initially synthesized as the free base and then converted to nucleotides.
- ◆ Aspartate and cytoplasmic carbamoyl phosphate are the precursors for pyrimidine ring synthesis.
- ◆ The initial pyrimidine nucleotide synthesized is orotidine monophosphate, which is converted to UMP. The other pyrimidine nucleotides are derived from a uracil-containing intermediate.
- ◆ Deoxyribonucleotides are derived by reduction of ribonucleotides, as catalyzed by ribonucleotide reductase. The regulation of ribonucleotide reductase is complex.
- ◆ Degradation of purine containing nucleotides results in production of uric acid, which is eliminated in the urine. Elevated uric acid levels in the blood can lead to gout.
- ◆ Diseases discussed in this chapter are summarized in Table 39.4.

TABLE 39.4 Diseases Discussed in Chapter 39

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Gout	Both	Painful joints because of the precipitation of uric acid in the joint space
PNP deficiency	Genetic	A defect in a purine salvage enzyme, leading to a loss of T-cell function, with near normal B-cell function and a partial immunodeficiency disease. Purine nucleosides will accumulate.
Lesch–Nyhan syndrome (lack of HGPRT activity)	Genetic	The loss of HGPRT activity leads to the accumulation of purines and uric acid, with intellectual disability and self-injury resulting in severe cases. Gout will also appear in these individuals.
Hereditary orotic aciduria	Genetic	A defect in UMP synthase, leading to orotic acid accumulation and delay in growth
ADA deficiency	Genetic	The loss of ADA activity leads to SCID, with a loss of both T- and B-cell function. dA and derivatives of dA accumulate in the blood and blood-based cells.
Cancer	Both	The use of drugs that interfere with DNA replication will destroy rapidly dividing cells at a faster rate than normal cells.

ADA, adenosine deaminase; dA, deoxyadenosine; HGPRT, hypoxanthine–guanine phosphoribosyltransferase; PNP, purine nucleoside phosphorylase; SCID, severe combined immunodeficiency disease; UMP, uridine monophosphate.

REVIEW QUESTIONS—CHAPTER 39

- Similarities between CPSI and CPSII include which one of the following?
 - Carbon source
 - Intracellular location
 - Nitrogen source
 - Regulation by *N*-acetyl glutamate
 - Regulation by UMP
- Gout can result from a reduction in activity of which one of the following enzymes?
 - Glutamine phosphoribosylamidotransferase
 - HGPRT
 - Glucose 6-phosphate dehydrogenase
 - PRPP synthetase
 - Purine nucleoside phosphorylase
- A 2-year old boy is exhibiting developmental delay and has started to bite his lips and fingers. Orange-colored “sand” is found in his diapers. This child has an inability to metabolize which one of the following molecules?
 - Uric acid
 - Thymine

- C. Adenine
 - D. Uracil
 - E. Hypoxanthine
4. Allopurinol can be used to treat gout because of its ability to inhibit which one of the following reactions?
 - A. AMP to XMP
 - B. Xanthine to uric acid
 - C. Inosine to hypoxanthine
 - D. IMP to XMP
 - E. XMP to GMP
 5. The regulation of ribonucleotide reductase is quite complex. Assuming that an enzyme deficiency leads to highly elevated levels of dGTP, what effect would you predict on the reduction of ribonucleotides to deoxyribonucleotides under these conditions?
 - A. Elevated levels of dCDP will be produced.
 - B. The formation of dADP will be favored.
 - C. AMP will begin to be reduced.
 - D. Reduced thioredoxin will become rate-limiting, thereby reducing the activity of ribonucleotide reductase.
 - E. dGTP will bind to the overall activity site and inhibit the functioning of the enzyme.
 6. A patient with von Gierke disease displays the symptoms of gout. This most likely occurs owing to the overproduction of which one of the following molecules?
 - A. PRPP
 - B. Aspartate
 - C. Glucose
 - D. NADPH
 - E. UDP-glucose
 7. A patient with ornithine transcarbamoylase deficiency exhibits orotic aciduria. This occurs owing to which one of the following?
 - A. Activation of the regulated step of de novo pyrimidine biosynthesis
 - B. Bypassing the regulated step of de novo pyrimidine biosynthesis
 - C. Inhibition of the regulated step of de novo pyrimidine biosynthesis
 - D. Activation of the CAD complex by carbamoyl phosphate
 - E. Activation of the UMP synthase complex by carbamoyl phosphate
 8. Purines and pyrimidines are necessary for the synthesis of DNA. Of the substances that donate atoms to the purine base and pyrimidine ring, which one of the following directly donates atoms to both the purine base and pyrimidine ring?
 - A. CO₂
 - B. Glycine
 - C. Carbamoyl phosphate
 - D. Aspartate
 - E. Glutamine
 9. Which one of the following statements is correct concerning purine and pyrimidine metabolism?
 - A. Pyrimidines, when degraded, yield uric acid.
 - B. Excess pyrimidine degradation can lead to gout.
 - C. Purines cannot be degraded to generate energy.
 - D. Purines degrade to CO₂ and water.
 - E. An excess of urea leads to gout.
 10. Allopurinol is used to treat gout. The drug is a suicide inhibitor that leads to a reduction in the amount of uric acid produced. Instead of accumulating uric acid, which other compound would accumulate in the presence of allopurinol?
 - A. Hypoxanthine
 - B. Ribose 1-phosphate
 - C. IMP
 - D. Guanine
 - E. Adenine
 1. Adenine nucleotides have roles other than for nucleic acid synthesis. Which of the following compounds contain adenine as part of their structure? Choose the one best answer.

	Coenzyme A	NADP ⁺	FAD(2H)	SAM	Ubiquitin
A	Yes	Yes	Yes	No	No
B	Yes	No	Yes	No	Yes
C	Yes	Yes	Yes	Yes	No
D	No	No	No	Yes	Yes
E	No	Yes	No	No	No
F	No	No	No	Yes	Yes

2. The biosynthesis of adenine and guanine nucleotides is balanced by which one of the following?
 - A. ATP inhibition of both adenylosuccinate synthase and IMP dehydrogenase
 - B. Complete inhibition of glutamine amidophosphoribosyltransferase activity by GTP
 - C. The use of GTP for AMP synthesis, and ATP for GMP synthesis
 - D. AMP inhibition of IMP dehydrogenase and GMP inhibition of adenylosuccinate synthetase
 - E. PRPP stimulation of both IMP dehydrogenase and adenylosuccinate synthetase
3. A 6-month-old boy has had recurrent infections and is not progressing along a normal growth curve. Analysis of the blood indicated an abnormally high level of deoxyadenosine. One of the abnormal effects in this boy's cells is caused by which one of the following?
 - A. Stimulation of ribonucleotide reductase
 - B. Overproduction of ATP, inhibiting many key metabolic pathways
 - C. Hyperproliferation because of increased DNA synthesis
 - D. Alteration of epigenetic regulation
 - E. Loss of cytokine receptor activity

Questions 14 and 15 are based on the following case: *A 3-month-old child was lethargic and fussy, and after having trouble waking the child one morning, the parents took the child to the nearest pediatric emergency department. A battery of tests indicated that the child had a megaloblastic anemia, with normal ammonia, blood folate and vitamin B₁₂ levels. Urinalysis indicated elevated levels of orotic acid. The child was diagnosed and given uridine triacetate to manage the disorder.*

4. The defective enzyme in this child is most likely which one of the following?
 - A. CPSI
 - B. CPSII
 - C. CAD protein
 - D. Ornithine transcarbamoylase
 - E. UMP synthase
5. Uridine triacetate is an appropriate treatment for this patient owing to which of the following? Choose the one best answer.

	Inhibition of CPSII	Provide a Substrate to Produce CTP	Provide a Substrate to Make dTTP	Provide a Substrate to Regenerate FH₄
A	Yes	Yes	No	No
B	Yes	No	Yes	Yes
C	Yes	Yes	Yes	No
D	No	No	No	Yes
E	No	Yes	Yes	No
F	No	No	No	Yes

ANSWERS TO REVIEW QUESTIONS

- The answer is A.** Both CPSI and CPSII use carbon dioxide as the carbon source in the production of carbamoyl phosphate. CPSI is located in the mitochondria, whereas CPSII is in the cytoplasm (thus, B is incorrect). CPSI can fix ammonia; CPSII requires glutamine as the nitrogen source (thus, C is incorrect). *N*-acetyl glutamate activates CPSI; CPSII is activated by PRPP (thus, D is incorrect). UMP inhibits CPSII, but has no effect on CPSI (thus, E is also incorrect).
- The answer is B.** A lack of HGPRT activity (Lesch–Nyhan syndrome) leads to an accumulation of PRPP, which induces increased purine synthesis, leading to excessive levels of purines in the cells. The degradation of the extra purines leads to uric acid production and gout. A loss of either PRPP synthetase activity or glutamine phosphoribosylamidotransferase activity would lead to reduced purine synthesis and hypouricemia (thus, A and D are incorrect). A lack of glucose 6-phosphate dehydrogenase would hinder ribose 5-phosphate production and thus would not lead to excessive purine synthesis. A lack of purine nucleoside phosphorylase would hinder the salvage pathway, leading to an accumulation of nucleosides. Purine nucleoside phosphorylase activity is required to synthesize uric acid, so in the absence of this enzyme, less uric acid would be produced (thus, E is incorrect).
- The answer is E.** The child has Lesch–Nyhan syndrome, a deficiency of HGPRT activity. As such, hypoxanthine cannot be converted to IMP, and guanine cannot be converted to GMP. One consequence of this is elevated uric acid levels, owing to an accumulation of hypoxanthine and guanine. Pyrimidine metabolism is not altered in Lesch–Nyhan patients, so thymine and uracil metabolism is normal. Adenine is converted to AMP by APRT, so a loss of HGPRT activity does not alter adenine metabolism.
- The answer is B.** Allopurinol inhibits the conversion of both hypoxanthine to xanthine and xanthine to uric acid. This occurs because both of those reactions are catalyzed by xanthine oxidase, the target of allopurinol. Answer A is incorrect because AMP is not converted directly to XMP (AMP, when degraded, is deaminated to form IMP, which loses its phosphate to become inosine, which undergoes phosphorolysis to generate hypoxanthine and ribose 1-phosphate). Answer C is incorrect because the inosine-to-hypoxanthine conversion, catalyzed by nucleoside phosphorylase, is not inhibited by allopurinol. Answer D is incorrect because the conversion of hypoxanthine to xanthine occurs at the free-base level, not at the nucleotide level. Answer E is incorrect because GMP is converted first to guanosine (loss of phosphate), the guanosine is converted to guanine and ribose 1-phosphate, and the guanine is then converted to xanthine by guanase.
- The answer is B.** If dGTP were to accumulate in cells, the dGTP would bind to the substrate specificity

site of ribonucleotide reductase and direct the synthesis of dADP. This would lead to elevations of dATP levels, which would inhibit the activity of ribonucleotide reductase. The inhibition of ribonucleotide reductase leads to a cessation of cell proliferation, as the supply of deoxyribonucleotides for DNA synthesis become limiting. Answer A is incorrect because ATP would need to bind to the substrate specificity site to direct the synthesis of dCDP. That would not occur under these conditions of elevated dGTP levels. Answer C is incorrect because the enzyme works only on diphosphates; AMP would never be a substrate for this enzyme. Answer D is incorrect because the thioredoxin is always regenerated and does not become rate-limiting for the reductase reaction. Answer E is incorrect because dGTP does not bind to the activity site of the reductase; only ATP (activator) or dATP (inhibitor) is capable of binding to the activity site.

6. **The answer is A.** A patient with von Gierke disease is lacking glucose 6-phosphatase activity, and glucose 6-phosphate cannot be converted to free glucose. Under conditions of gluconeogenesis and glycogenolysis, in the liver, glucose 6-phosphate will accumulate. The high glucose 6-phosphate levels will drive the hexose monophosphate (HMP) shunt pathway to produce additional ribose 5-phosphate, which will stimulate PRPP synthetase to produce more PRPP. The elevated PRPP leads to increased activity of amidophosphoribosyltransferase, producing more AMP and GMP. As the AMP and GMP are not required by the cell, they are degraded and produce uric acid, which accumulates, precipitates, and leads to the symptoms of a gout attack. Elevated levels of NADPH may occur due to an increase in the oxidative steps of the HMP shunt, but will not lead to an increase in uric acid production. Glucose levels will not increase because of the defect in glucose 6-phosphatase. UDP-glucose levels may increase, but if they do, glycogen synthesis will be stimulated and this will not affect uric acid production. Aspartate levels may increase (owing to increased protein turnover to provide substrates for gluconeogenesis) in patients with von Gierke disease, but higher aspartate will not lead to uric acid production (as aspartate will not stimulate purine ring synthesis).
7. **The answer is B.** The regulated step of de novo pyrimidine synthesis is the CPSII step (CPSII, which uses the amide nitrogen of glutamine, the carbon and oxygen of carbon dioxide, and two high-energy bonds, to produce carbamoyl phosphate). UTP will inhibit the activity of this enzyme, signifying high levels of pyrimidines in the cell. A patient with a lack of ornithine transcarbamoylase activity will accumulate carbamoyl phosphate in the mitochondria (as produced by CPS1). As the concentration of carbamoyl phosphate in the mitochondria increases, the molecule will escape from the mitochondria and enter the cytoplasm and be used for de novo pyrimidine synthesis. This is bypassing the regulated step of pyrimidine biosynthesis. It is not an activation of the regulated step or an inhibition of the regulated step of pyrimidine biosynthesis. CAD is not a regulated enzyme and neither is UMP synthase.
8. **The answer is D.** Aspartate and carbamoyl phosphate (generated from carbon dioxide and glutamine) form all of the components of the pyrimidine ring, whereas aspartate, CO₂, glycine, glutamine, and N¹⁰-formyl-FH₄ all donate atoms to form the purine base. The direct donor of a carbon and nitrogen to pyrimidine ring biosynthesis is carbamoyl phosphate, not the glutamine and carbon dioxide required to synthesize the carbamoyl phosphate.
9. **The answer is C.** Purine degradation leads to uric acid formation and does not generate any energy. An excess of uric acid leads to gout (precipitation of the uric acid in joints). Pyrimidines are degraded to water-soluble compounds such as urea, CO₂, and water, although not much energy is obtained from pyrimidine degradation as well.
10. **The answer is A.** Allopurinol is a structural analog of hypoxanthine that reduces production of uric acid (by inhibition of the enzyme xanthine oxidase) allowing xanthine and hypoxanthine to accumulate as uric acid levels decrease. None of the other breakdown products will accumulate in the presence of allopurinol because the end products are water-soluble and are removed from the body in the urine.
11. **The answer is C.** Adenine is part of Coenzyme A (along with the vitamin pantothenic acid), NAD and NADP⁺ (nicotinamide adenine dinucleotide), FAD(2H) (reduced FAD), and SAM (universal methyl donor, S-adenosylmethionine). Ubiquitin (the molecule targeting proteins for proteolysis by the proteasome) does not contain adenine as part of its structure, as ubiquitin is a protein consisting of 76 amino acids.
12. **The answer is C.** GTP is required for AMP synthesis (at the adenylosuccinate synthetase step), and ATP is required for GMP synthesis (at the GMP synthetase step). AMP inhibits adenylosuccinate synthetase, whereas GMP inhibits IMP dehydrogenase (not ATP). Glutamine amidophosphoribosyltransferase is regulated by all adenine and guanine nucleotides, and both need to be present for complete inhibition of

the enzyme. PRPP does not regulate IMP dehydrogenase and adenylosuccinate synthetase.

13. **The answer is D.** The child has ADA deficiency, which is an inability to convert adenosine (or deoxyadenosine) to inosine (or deoxyinosine). Because of this enzyme defect, deoxyadenosine will accumulate, both in and outside of cells (i.e., in the blood). Although one consequence of this is the conversion of dA to dATP within cells, with the subsequent inhibition of ribonucleotide reductase, and inhibition of DNA synthesis, there are other consequences as well. A second major consequence of ADA deficiency, and the accumulation of deoxyadenosine, is the inhibition of SAH hydrolase, which converts SAH to homocysteine and adenosine. The inhibition of this enzyme leads to a reduction of SAM levels, which leads to alterations in epigenetic regulation. There is another form of SCID, which is due to the loss of cytokine receptor activity, but in that disorder (X-linked SCID) deoxyadenosine does not accumulate as ADA activity is not affected.
14. **The answer is E.** The child has hereditary orotic aciduria, which is because of a loss of function mutation in UMP synthase (either the orotidine phosphoribosyltransferase (ORPT) or decarboxylase activity). A defect in the CAD protein would not lead to orotic acid synthesis (those three activities are required to produce orotic acid). A lack of CPSII activity would block any pyrimidine production, and a CPSI or ornithine transcarbamoylase deficiency would show elevated ammonia in the blood. The megaloblastic anemia is because of the block in DNA synthesis (because pyrimidines cannot be formed) as the vitamin B₁₂ and folate levels are normal.
15. **The answer is C.** Uridine triacetate would be converted to uridine in the cell, and then to UMP (by uridine kinase). The UMP can be converted to UDP (a nucleoside monophosphate kinase), and UDP to UTP (a nucleoside diphosphate kinase). The UTP is converted to CTP by transferring the nitrogen from glutamine to UTP to produce CTP. Alternatively, the UTP is an inhibitor of CPSII, the committed and regulated step of pyrimidine production. Additionally, UDP is a substrate for ribonucleotide reductase, generating dUDP, which is converted to dUMP. dUMP is then converted to dTMP by thymidylate synthase, leading to dTTP synthesis. Uridine cannot donate a carbon to the THF pool or regenerate FH₄ (tetrahydrofolate).

Intertissue Relationships in the Metabolism of Amino Acids

The body maintains a relatively large free amino acid pool in the blood, even during fasting. As a result, tissues have continuous access to individual amino acids for the synthesis of proteins and essential amino acid derivatives, such as neurotransmitters. The amino acid pool also provides the liver with **amino acid substrates** for **gluconeogenesis** and provides several other cell types with a source of **fuel**. The **free amino acid pool** is derived from **dietary amino acids** and the **turnover of proteins** in the body. During an **overnight fast** and during **hypercatabolic states**, **degradation** of labile **protein**, particularly that in **skeletal muscle**, is the major source of free amino acids.

The liver is the major site of amino acid metabolism in the body and the major site of **urea synthesis**. The liver is also the major site of amino acid degradation. Hepatocytes partially oxidize most amino acids, converting the carbon skeleton to glucose, ketone bodies, or CO_2 . Because ammonia is toxic, the liver converts most of the nitrogen from amino acid degradation to urea, which is excreted in the urine. The nitrogen derived from amino acid catabolism in other tissues is transported to the liver as **alanine** or **glutamine** and converted to urea.

The **branched-chain amino acids**, or BCAAs (valine, isoleucine, and leucine), are oxidized principally in **skeletal muscle** and other tissues and not in the liver. In skeletal muscle, the carbon skeletons and some of the nitrogen are converted to glutamine, which is released into the blood. The remainder of the nitrogen is incorporated into alanine, which is taken up by the liver and converted to urea and glucose.

The formation and release of glutamine from skeletal muscle and other tissues serves several functions. In the kidney, the NH_4^+ carried by glutamine is excreted into the urine. This process removes protons formed during fuel oxidation and helps to maintain the body's pH, especially during metabolic acidosis. **Glutamine** also provides a **fuel** for the **kidney** and **gut**. In rapidly dividing cells (e.g., lymphocytes and macrophages), glutamine is required as a fuel, as a nitrogen donor for biosynthetic reactions, and as a substrate for protein synthesis.

During conditions of **sepsis** (the presence of various pathogenic organisms, or their toxins, in the blood or tissues), **trauma**, **injury**, or **burns**, the body enters a **catabolic state** characterized by a **negative nitrogen balance** (Fig. 40.1). Increased net protein degradation in skeletal muscle increases the availability of glutamine and other amino acids for cell division and protein synthesis in cells involved in the immune response and wound healing. In these conditions, increased release of glucocorticoids from the adrenal cortex stimulates proteolysis.

FIGURE 40.1 Amino acid flux in sepsis and trauma. In sepsis and traumatic injury, glutamine and other amino acids are released from skeletal muscle for uptake by tissues involved in the immune response and tissue repair, such as macrophages, lymphocytes, fibroblasts, and the liver. Nitrogen excretion as urea and NH_4^+ results in negative nitrogen balance.

THE WAITING ROOM

Katherine B., a 62-year-old homeless woman, was found by a neighborhood child who heard **Katherine B.**'s moans coming from an abandoned building. The child's mother called the police, who took **Katherine B.** to the hospital emergency room. The patient was semicomatose, incontinent of urine, and her clothes were stained with vomitus. She had a fever of 103°F, was trembling uncontrollably, appeared to be severely dehydrated, and had marked muscle wasting. Her heart rate was very rapid, and her blood pressure was low (85/46 mm Hg). Her abdomen was distended and without bowel sounds. She responded to moderate pressure on her abdomen with moaning and grimacing.

Blood was sent for a broad laboratory profile, and cultures of her urine and blood were taken. Intravenous saline with thiamine and folate, glucose, and parenteral broad-spectrum antibiotics were begun. Radiography performed after her vital signs were stabilized suggested a bowel perforation. These findings were compatible with a diagnosis of a ruptured viscus (e.g., an infected colonic diverticulum that perforated, allowing colonic bacteria to infect the tissues of the peritoneal cavity, causing peritonitis). Further studies confirmed that a diverticulum had ruptured, and appropriate surgery was performed. All of the blood cultures grew out *Escherichia coli*, indicating that **Katherine B.** also had a gram-negative infection of her blood (septicemia) that had been seeded by the proliferating organisms in her peritoneal cavity. Intensive fluid and electrolyte therapy and antibiotic coverage were continued. The medical team (surgeons, internists, and nutritionists) began developing a complex therapeutic plan to reverse **Katherine B.**'s severely catabolic state.

I. Maintenance of the Free Amino Acid Pool in Blood

The body maintains a relatively large free amino acid pool in the blood, even in the absence of an intake of dietary protein. The large free amino acid pool ensures the continuous availability of individual amino acids to tissues for the synthesis of proteins, neurotransmitters, and other nitrogen-containing compounds (Fig. 40.2). In a normal, well-fed, healthy individual, approximately 300 to 600 g of body protein is degraded per day. At the same time, roughly 100 g of protein is consumed in the diet per day, which adds additional amino acids. From this pool, tissues use amino acids for the continuous synthesis of new proteins (300 to 600 g) to replace those degraded. The continuous turnover of proteins in the body makes the complete complement of amino acids available for the synthesis of new and different proteins, such as antibodies. Protein turnover allows shifts in the quantities of different proteins produced in tissues in response to changes in physiologic state and continuously removes modified or damaged proteins. It also provides a complete pool of specific amino acids that can be used as oxidizable substrates; precursors for gluconeogenesis and for heme, creatine phosphate, purine, pyrimidine, and neurotransmitter synthesis; for ammoniogenesis to maintain blood pH levels; and for numerous other functions.

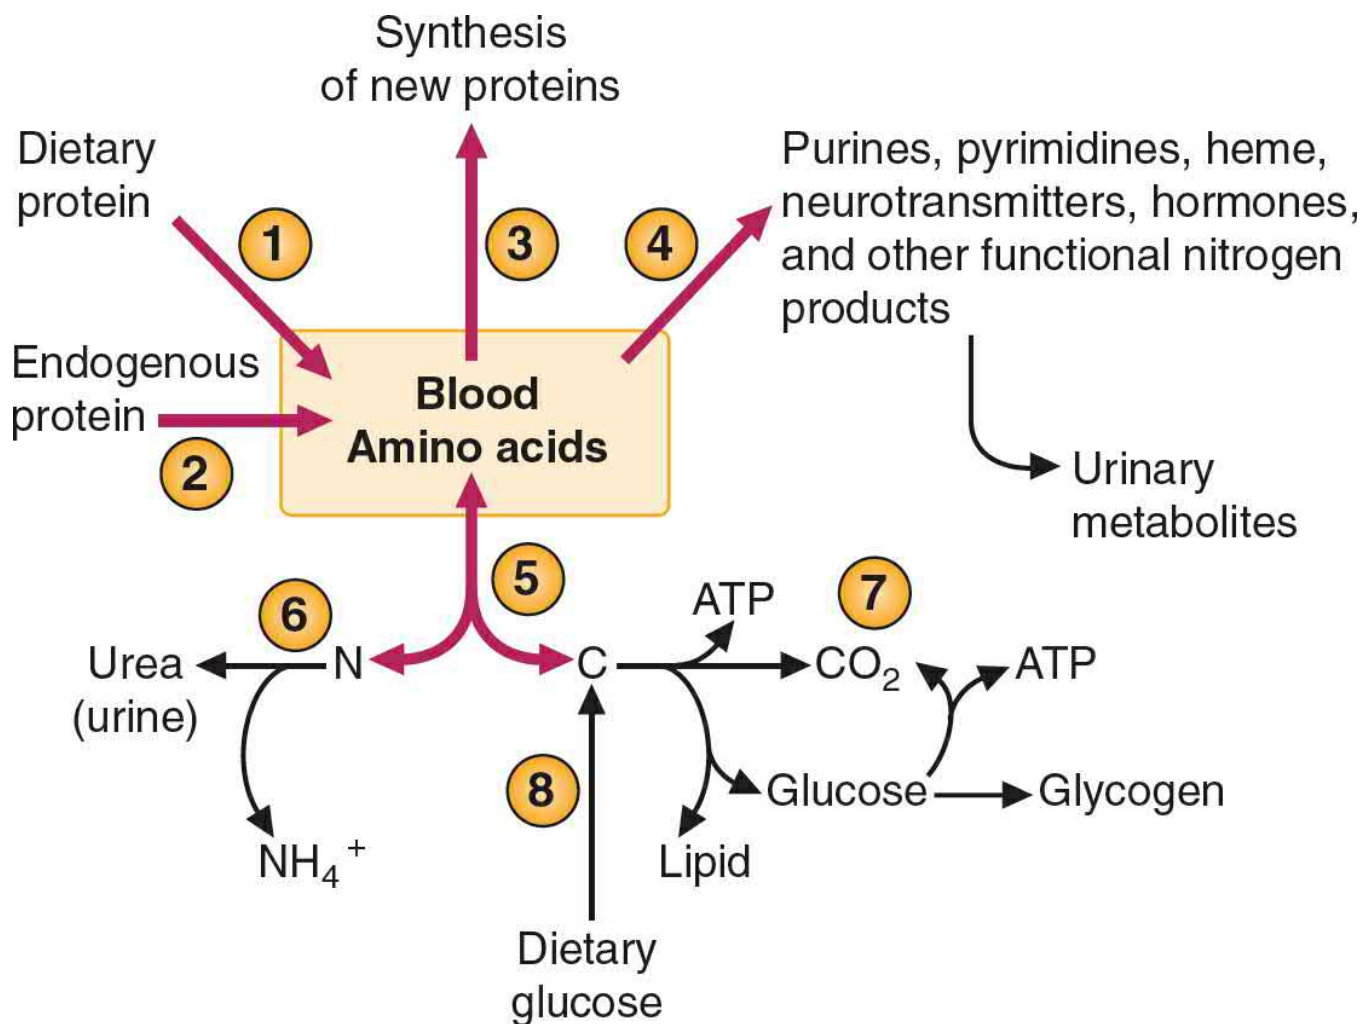

FIGURE 40.2 Maintenance of the blood amino acid pool. Dietary protein (1) and degradation of endogenous protein (2) provide a source of essential amino acids (those that cannot be synthesized in the human). (3) The synthesis of new protein is the major use of amino acids from the free amino acid pool. (4) Compounds synthesized from amino acid precursors are essential for physiological functions. Many of these compounds are degraded to nitrogen-containing urinary metabolites and do not return to the free amino acid pool. (5) In tissues, the nitrogen is removed from amino acids by transamination and deamination reactions. (6) The nitrogen from amino acid degradation appears in the urine primarily as urea or NH_4^+ , the ammonium ion. Ammonia excretion is necessary to maintain the pH of the blood. (7) Amino acids are used as fuels either directly or after being converted to glucose by gluconeogenesis. (8) Some amino acids can be synthesized in humans, provided that glucose and a nitrogen source are available. ATP, adenosine triphosphate.

The concentration of free amino acids in the blood is not nearly as rigidly controlled as blood glucose levels. The free amino acid pool in the blood is only a small part (0.5%) of the total amino acid pool in whole-body protein. Because of the large skeletal muscle mass, approximately 80% of the body's total protein is in skeletal muscle. Consequently, the concentration of individual amino acids in the blood is strongly affected by the rates of protein synthesis and degradation in skeletal muscle, as well as the rate of uptake and utilization of individual amino acids for metabolism in liver and other tissues. For the most part, changes in the rate of protein synthesis and degradation take place over a span of hours.

A. Interorgan Flux of Amino Acids in the Postabsorptive State

The fasting state provides an example of the interorgan flux of amino acids necessary to maintain the free amino acid pool in the blood and supply tissues with their required amino acids (Fig. 40.3). During an overnight fast, protein synthesis in the liver and other tissues continues, but at a diminished rate compared with the postprandial state. Net degradation of labile protein occurs in skeletal muscle (which contains the body's largest protein mass) and other tissues.

FIGURE 40.3 Interorgan amino acid exchange after an overnight fast. After an overnight fast (the postabsorptive state), the utilization of amino acids for protein synthesis, for fuels, and for the synthesis of essential functional compounds continues. The free amino acid pool is supported largely by net degradation of skeletal muscle protein. Glutamine and alanine serve as amino group carriers from skeletal muscle to other tissues. Glutamine brings NH_4^+ to the kidney for the excretion of protons and serves as a fuel for the kidney, gut, and cells of the immune system. Alanine transfers amino groups from skeletal muscle, the kidney, and the gut to the liver, where they are converted to urea for excretion. The brain continues to use amino acids for neurotransmitter synthesis.

What changes in hormone levels and fuel metabolism occur during an overnight fast?

1. Release of Amino Acids from Skeletal Muscle during Fasting

The efflux of amino acids from skeletal muscle supports the essential amino acid pool in the blood (see Fig. 40.3). Skeletal muscle oxidizes the BCAAAs (valine, leucine, isoleucine) to produce energy and glutamine. The amino groups of the BCAAAs, and of aspartate and glutamate, are transferred out of skeletal muscle in alanine and glutamine. Alanine and glutamine account for approximately 50% of the total α -amino nitrogen released by skeletal muscle.

The release of amino acids from skeletal muscle is stimulated during an overnight fast by the decrease of insulin and increase of glucocorticoid (such as cortisol) levels in the blood (see Chapters 28 and 41). Insulin promotes the uptake of amino acids and the general synthesis of proteins. The mechanisms for the stimulation of protein synthesis in human skeletal muscle are not all known, but probably include an activation of the A system for amino acid transport (a modest effect), a general effect on initiation of translation, and an inhibition of lysosomal proteolysis. The fall of blood insulin levels during an overnight fast results in net proteolysis and release of amino acids. As glucocorticoid release from the adrenal cortex increases an induction of ubiquitin synthesis and increase of ubiquitin-dependent proteolysis also occur.

2. Amino Acid Metabolism in Liver during Fasting

The major site of alanine uptake is the liver, which disposes of the amino nitrogen by incorporating it into urea

(see Fig. 40.3). The liver also extracts free amino acids, α -keto acids, and some glutamine from the blood. Alanine and other amino acids are oxidized and their carbon skeletons converted principally to glucose. Glucagon and glucocorticoids stimulate the uptake of amino acids into liver and increase gluconeogenesis and ureagenesis (Fig. 40.4). Alanine transport into the liver, in particular, is enhanced by glucagon. The induction of the synthesis of gluconeogenic enzymes by glucagon and glucocorticoids during the overnight fast correlates with an induction of many of the enzymes of amino acid degradation (e.g., tyrosine aminotransferase) and an induction of urea cycle enzymes (see Chapter 36). Urea synthesis also increases because of the increased supply of NH_4^+ from amino acid degradation in the liver.

FIGURE 40.4 Hormonal regulation of hepatic amino acid metabolism in the postabsorptive state. Induction of urea cycle enzymes occurs both during fasting and after a high-protein meal. Because many individuals in the United States normally have a high-protein diet, the levels of urea cycle enzymes may not fluctuate to any great extent. ⊕, glucagon-mediated activation of enzymes or proteins; ↑, induction of enzyme synthesis mediated by glucagon and glucocorticoids.

A The hormonal changes that occur during an overnight fast include a decrease of blood insulin levels and an increase of glucagon relative to levels after a high-carbohydrate meal. Glucocorticoid levels also increase in the blood. These hormones coordinate the changes of fat, carbohydrate, and amino acid metabolism. Fatty acids are released from adipose triacylglycerols and are used as the major fuel by heart, skeletal muscle, liver, and other tissues. The liver converts some of

the fatty acids to ketone bodies. Liver glycogen stores and gluconeogenesis maintain blood glucose levels for glucose-dependent tissues. The major precursors of gluconeogenesis include amino acids released from skeletal muscle, lactate, and glycerol.

3. Metabolism of Amino Acids in Other Tissues during Fasting

Glucose, produced by the liver, is used for energy by the brain and other glucose-dependent tissues, such as erythrocytes. The muscle, under conditions of exercise, when the adenosine monophosphate (AMP)-activated protein kinase is active, also oxidizes some of this glucose to pyruvate, which is used for the carbon skeleton of alanine (the glucose–alanine cycle; see Chapter 36).

Glutamine is generated in skeletal muscle from the oxidation of BCAAs and by the lungs and brain for the removal of NH_4^+ formed from amino acid catabolism or entering from the blood. The kidney, the gut, and cells with rapid turnover rates, such as those of the immune system, are the major sites of glutamine uptake (see Fig. 40.3). Glutamine serves as a fuel for these tissues, as a nitrogen donor for purine synthesis, and as a substrate for ammoniogenesis in the kidney. Much of the unused nitrogen from glutamine is transferred to pyruvate to form alanine in these tissues. Alanine then carries the unused nitrogen back to the liver.

 The body normally produces approximately 1 mmol of protons per kilogram of body weight per day. Nevertheless, the pH of the blood and extracellular fluid is normally maintained between 7.36 and 7.44. The narrow range is maintained principally by the bicarbonate (HCO_3^-), phosphate (HPO_4^-), and hemoglobin buffering systems, and by the excretion of an amount of acid equal to that produced. The excretion of protons by the kidney regenerates bicarbonate, which can be reclaimed from the glomerular filtrate.

The acids are produced from normal fuel metabolism. The major acid is carbonic acid, which is formed from water and CO_2 produced in the TCA cycle and other oxidative pathways. The oxidation of sulfur-containing amino acids (methionine and cysteine) ultimately produces sulfuric acid (H_2SO_4), which dissociates into $2\text{H}^+ + \text{SO}_4^{2-}$, and the protons and sulfate are excreted. The hydrolysis of phosphate esters produces the equivalent of phosphoric acid. What other acids produced during metabolism appear in the blood?

 **Katherine B.** was in a severe stage of negative nitrogen balance on admission, which was caused by both her malnourished state and her intra-abdominal infection complicated by sepsis. The physiological response to advanced catabolic status includes a degradation of muscle protein with the release of amino acids into the blood. This release is coupled with an increased uptake of amino acids for acute-phase protein synthesis by the liver (systemic response) and other cells involved in the immune response to general and severe infection.

The brain is glucose dependent, but, like many cells in the body, can use BCAAs for energy. The BCAAs also provide a source of nitrogen for neurotransmitter synthesis during fasting. Other amino acids released from skeletal muscle protein degradation also serve as precursors of neurotransmitters.

B. Principles Governing Amino Acid Flux between Tissues

The pattern of interorgan flux of amino acids is strongly affected by conditions that change the supply of fuels (e.g., the overnight fast, a mixed meal, a high-protein meal) and by conditions that increase the demand for amino acids (metabolic acidosis, surgical stress, traumatic injury, burns, wound healing, and sepsis). The flux of amino acid carbon and nitrogen in these different conditions is dictated by several considerations:

1. Ammonia (NH_3) is toxic. Consequently, it is transported between tissues as alanine or glutamine. Alanine is the principal carrier of amino acid nitrogen from other tissues back to the liver, where the nitrogen is converted to urea and subsequently excreted into the urine by the kidneys. The amount of urea synthesized is proportional to the amount of amino acid carbon that is being oxidized as a fuel.

The differences in amino acid metabolism between tissues are dictated by the types and amounts of different enzyme and transport proteins present in each tissue and the ability of each tissue to respond to different regulatory messages (hormones and neural signals).

2. The pool of glutamine in the blood serves several essential metabolic functions (Table 40.1). It provides ammonia for excretion of protons in the urine as NH_4^+ . It serves as a fuel for the gut, the kidney, and the cells of the immune system. Glutamine is also required by the cells of the immune system and other rapidly dividing cells in which its amide group serves as the source of nitrogen for biosynthetic reactions. In the brain, the formation of glutamine from glutamate and NH_4^+ provides a means of removing ammonia and of transporting glutamate between different cell types within the brain. The utilization of the blood glutamine

pool is prioritized. During metabolic acidosis, the kidney becomes the predominant site of glutamine uptake, at the expense of glutamine utilization in other tissues. Conversely, during sepsis, in the absence of acidosis, cells involved in the immune response (macrophages, hepatocytes) become the preferential sites of glutamine uptake.

TABLE 40.1 Functions of Glutamine

Protein synthesis
Ammoniogenesis for proton excretion
Nitrogen donor for synthesis of:
Purines
Pyrimidines
NAD ⁺
Amino sugars
Asparagine
Other compounds
Glutamate donor for synthesis of:
Glutathione
γ-Aminobutyric acid (GABA)
Ornithine
Arginine
Proline
Other compounds

Lactic acid is produced from glucose and amino acid metabolism. The ketone bodies (acetoacetate and β-hydroxybutyrate) produced during fatty acid oxidation are also acids. Many α-keto acids, formed from transamination reactions, are also found in the blood.

- The BCAAs (valine, leucine, and isoleucine) form a significant portion of the composition of the average protein and can be converted to tricarboxylic acid (TCA) cycle intermediates and used as fuels by almost all tissues. Valine and isoleucine are also the major precursors of glutamine. Except for the BCAAs and alanine, aspartate, and glutamate, the catabolism of amino acids occurs principally in the liver.

The ability to convert four-carbon intermediates of the TCA cycle to pyruvate is required for oxidation of both BCAAs and glutamine. This sequence of reactions requires phosphoenolpyruvate (PEP) carboxykinase or decarboxylating malate dehydrogenase (malic enzyme). Most tissues have one, or both, of these enzymes.

- Amino acids are major gluconeogenic substrates, and most of the energy obtained from their oxidation is derived from the oxidation of the glucose formed from their carbon skeletons. A much smaller percentage of amino acid carbon is converted to acetyl coenzyme A (acetyl CoA) or to ketone bodies and oxidized. The use of amino acids for glucose synthesis for the brain and other glucose-requiring tissues is subject to the hormonal regulatory mechanisms of glucose homeostasis (see Chapters 28 and 34).
- The relative rates of protein synthesis and degradation (protein turnover) determine the size of the free amino acid pools available for the synthesis of new proteins and for other essential functions. For example, the synthesis of new proteins to mount an immune response is supported by the net degradation of other proteins in the body.

II. Utilization of Amino Acids in Individual Tissues

Because tissues differ in their physiological functions, they have different amino acid requirements and contribute differently to whole-body nitrogen metabolism. However, all tissues share a common requirement for essential amino acids for protein synthesis, and protein turnover is an ongoing process in all cells.

A. The Kidney

One of the primary roles of amino acid nitrogen is to provide ammonia in the kidney for the excretion of protons in the urine. NH_4^+ is released from glutamine by glutaminase and from glutamate by glutamate dehydrogenase, resulting in the formation of α -ketoglutarate (Fig. 40.5). α -Ketoglutarate is used as a fuel by the kidney and is oxidized to CO_2 , converted to glucose for use in cells in the renal medulla, or converted to alanine to return ammonia to the liver for urea synthesis.

FIGURE 40.5 Renal glutamine metabolism. Renal tubule cells preferentially oxidize glutamine. During metabolic acidosis, it is the major fuel for the kidney. Conversion of glutamine to α -ketoglutarate generates NH_4^+ . Ammonium ion excretion helps to buffer systemic acidemia.

Glutamine is used as a fuel by the kidney in the normal fed state and, to a greater extent, during fasting and metabolic acidosis (Table 40.2). The carbon skeleton forms α -ketoglutarate, which is oxidized to CO_2 , converted to glucose, or released as the carbon skeleton of serine or alanine (Fig. 40.6). α -Ketoglutarate can be

converted to oxaloacetate by TCA cycle reactions, and oxaloacetate is converted to PEP by PEP carboxykinase. PEP can then be converted to pyruvate and subsequently acetyl CoA, alanine, serine, or glucose. The glucose is used principally by the cells of the renal medulla, which have a relatively high dependence on anaerobic glycolysis because of their lower oxygen supply and mitochondrial capacity. The lactate released from anaerobic glycolysis in these cells is taken up and oxidized in the renal cortical cells, which have a higher mitochondrial capacity and a greater blood supply.

TABLE 40.2 Major Fuel Sources for the Kidney

PERCENT OF TOTAL CO ₂ FORMED IN DIFFERENT PHYSIOLOGICAL STATES			
FUEL	NORMAL	ACIDOSIS	FASTED
Lactate	45	20	15
Glucose ^a	25	20	0
Fatty acids	15	20	60
Glutamine	15	40	25

^aGlucose used in the renal medulla is produced in the renal cortex.

FIGURE 40.6 Metabolism of glutamine and other fuels in the kidney. To completely oxidize glutamate carbon to CO₂, it must enter the TCA cycle as acetyl CoA. Carbon entering the TCA cycle as α-ketoglutarate (α-KG) exits as oxaloacetate and is converted to phosphoenolpyruvate (PEP) by PEP carboxykinase. PEP is converted to pyruvate, which may be oxidized to acetyl CoA. PEP also can be converted to serine, glucose, or alanine. acetyl CoA; acetyl coenzyme A; GDH, glutamate dehydrogenase; OAA, oxaloacetate; PEP, phosphoenolpyruvate; PEPCK, phosphoenolpyruvate carboxykinase; TA,

transaminase; TCA, tricarboxylic acid.

B. Skeletal Muscle

Skeletal muscle, because of its large mass, is a major site of protein synthesis and degradation in the human. After a high-protein meal, insulin promotes the uptake of certain amino acids and stimulates net protein synthesis. The insulin stimulation of protein synthesis is dependent on an adequate supply of amino acids to undergo protein synthesis. During fasting and other catabolic states, a net degradation of skeletal muscle protein and release of amino acids occur (see Fig. 40.3). The net degradation of protein affects functional proteins, such as myosin, which are sacrificed to meet more urgent demands for amino acids in other tissues. During sepsis, degradation of skeletal muscle protein is stimulated by the glucocorticoid cortisol. The effect of cortisol is exerted through the activation of ubiquitin-dependent proteolysis. During fasting, the decrease of blood insulin levels and the increase of blood cortisol levels increase net protein degradation.

Skeletal muscle is a major site of glutamine synthesis, thereby satisfying the demand for glutamine during the postabsorptive state, during metabolic acidosis, and during septic stress and trauma. The carbon skeleton and nitrogen of glutamine are derived principally from the metabolism of BCAAs. Amino acid degradation in skeletal muscle is also accompanied by the formation of alanine, which transfers amino groups from skeletal muscle to the liver in the glucose–alanine cycle.

When the carbon skeleton of alanine is derived from glucose, the efflux of alanine from skeletal muscle and its uptake by liver provide no net transfer of amino acid carbon to the liver for gluconeogenesis. However, some of the alanine carbon is derived from sources other than glucose. Which amino acids can provide carbon for alanine formation? (Hint: see Fig. 40.7.)

FIGURE 40.7 Metabolism of the carbon skeletons of BCAAs in skeletal muscle. (1) The first step in the metabolism of BCAAs is transamination (TA). (2) Carbon from valine and isoleucine enters the TCA cycle as succinyl CoA and is converted to pyruvate by decarboxylating malate dehydrogenase (malic enzyme). (3) The oxidative pathways generate NADH and FAD(2H) even before the carbon skeleton enters the TCA cycle. The rate-limiting enzyme in the oxidative pathways is the α -keto acid dehydrogenase complex. The carbon skeleton also can be converted to glutamate and alanine, shown in red. α -KG, α -ketoglutarate; FAD(2H), flavin adenine dinucleotide; HMG-CoA, hydroxymethylglutaryl coenzyme A; NADH, nicotinamide adenine dinucleotide; OAA, oxaloacetate; succinyl CoA, succinyl coenzyme A; TCA, tricarboxylic acid

1. Oxidation of Branched-Chain Amino Acids in Skeletal Muscle

The BCAAs play a special role in muscle and most other tissues because they are the major amino acids that can be oxidized in tissues other than the liver. However, all tissues can interconvert amino acids and TCA cycle intermediates through transaminase reactions, that is, alanine \leftrightarrow pyruvate, aspartate \leftrightarrow oxaloacetate, and α -ketoglutarate \leftrightarrow glutamate. The first step of the pathway, transamination of the BCAAs to α -keto acids, occurs principally in brain, heart, kidney, and skeletal muscles. These tissues have a high content of BCAA transaminase relative to the low levels in liver. The α -keto acids of the BCAAs are then either released into the blood and taken up by liver, or oxidized to CO_2 or glutamine within the muscle or other tissue (Fig. 40.7). They can be oxidized by all tissues that contain mitochondria.

Some of the alanine released from skeletal muscle is derived directly from protein degradation. The carbon skeletons of valine, isoleucine, aspartate, and glutamate, which are converted to malate and oxaloacetate in the TCA cycle, can be converted to pyruvate and subsequently transaminated to alanine. The extent to which these amino acids contribute carbon to alanine efflux differs between different types of muscles in the human. These amino acids also may contribute to alanine efflux from the gut.

The oxidative pathways of the BCAAs convert the carbon skeleton to either succinyl CoA or acetyl CoA (see Chapter 37 and Fig. 40.7). The pathways generate NADH and FAD(2H) for adenosine triphosphate (ATP) synthesis before the conversion of carbon into intermediates of the TCA cycle, thus providing the muscle with energy without loss of carbon as CO_2 . Leucine is “ketogenic” in that it is converted to acetyl CoA and acetoacetate. Skeletal muscle, adipocytes, and most other tissues are able to use these products and, therefore, oxidize leucine directly to CO_2 . The portion of isoleucine that is converted to acetyl CoA is also oxidized directly to CO_2 . For the portion of valine and isoleucine that enters the TCA cycle as succinyl CoA to be completely oxidized to CO_2 , it must first be converted to acetyl CoA. To form acetyl CoA, succinyl CoA is oxidized to malate in the TCA cycle, and malate is then converted to pyruvate by malic enzyme (malate + $\text{NADP}^+ \rightarrow$ pyruvate + $\text{NADPH} + \text{H}^+$) (see Fig. 40.7). Pyruvate can then be oxidized to acetyl CoA. Alternatively, pyruvate can form alanine or lactate.

2. Conversion of Branched-Chain Amino Acids to glutamine

The major route of valine and isoleucine catabolism in skeletal muscle is to enter the TCA cycle as succinyl CoA and exit as α -ketoglutarate to provide the carbon skeleton for glutamine formation (see Fig. 40.7). Some of the glutamine and CO_2 that is formed from net protein degradation in skeletal muscle may also arise from the carbon skeletons of aspartate and glutamate. These amino acids are transaminated and become part of the pool of four-carbon intermediates of the TCA cycle.

The purine nucleotide cycle is found in skeletal muscle and brain but is absent in liver and many other tissues. One of its functions in skeletal muscle is to respond to the rapid utilization of ATP during exercise. During exercise, the rapid hydrolysis of ATP increases AMP levels, resulting in an activation of AMP deaminase (see Fig. 40.9). As a consequence, the cellular concentration of IMP increases and ammonia is generated. IMP, like AMP, activates muscle glycogen phosphorylase during exercise (see Chapter 26). The ammonia that is generated may help to buffer the increased lactic acid production that occurs in skeletal muscles during strenuous exercise.

FIGURE 40.9 Purine nucleotide cycle. In skeletal muscle, the purine nucleotide cycle can convert the amino groups of the BCAAs to NH_3 , which is incorporated into glutamine. Compare this to Figure 39.12, in which the fumarate generated is utilized in an anaplerotic role in the muscle. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; BCAAs, branched-chain amino acids; IMP, inosine monophosphate; P_i , inorganic phosphate.

Glutamine nitrogen is derived principally from the BCAAs (Fig. 40.8). The α -amino group arises from transamination reactions that form glutamate from α -ketoglutarate, and the amide nitrogen is formed from the addition of free ammonia to glutamate by glutamine synthetase. Free ammonia in skeletal muscle arises principally from the deamination of glutamate by glutamate dehydrogenase or from the purine nucleotide cycle.

FIGURE 40.8 Formation of glutamine from the amino groups of BCAAs. The BCAAs are first transaminated with α -ketoglutarate to form glutamate and the branched-chain α -keto acids. The glutamate nitrogen can then follow either of two paths leading to glutamine formation. α -KG, α -ketoglutarate; BCAAs, branched-chain amino acids; OAA, oxaloacetate; TA, transamination.

In the purine nucleotide cycle (Fig. 40.9), the deamination of AMP to inosine monophosphate (IMP) releases NH_4^+ . AMP is resynthesized with amino groups provided from aspartate. The aspartate amino groups can arise from the BCAAs through transamination reactions. The fumarate can be used to replenish TCA cycle intermediates (see Fig. 39.12).

3. The Glucose–Alanine Cycle

The nitrogen arising from the oxidation of BCAAs in skeletal muscle can also be transferred back to the liver as alanine in the glucose–alanine cycle (Fig. 40.10; see also Fig. 36.8). The amino group of the BCAAs is first

transferred to α -ketoglutarate to form glutamate and then transferred to pyruvate to form alanine by sequential transamination reactions. The pyruvate arises principally from glucose via the glycolytic pathway. The alanine released from skeletal muscle is taken up principally by the liver, where the amino group is incorporated into urea, and the carbon skeleton can be converted back to glucose through gluconeogenesis. Although the amount of alanine formed varies with dietary intake and physiological state, the transport of nitrogen from skeletal muscle to liver as alanine occurs almost continuously throughout our daily fasting–feeding cycle.

FIGURE 40.10 Glucose–alanine cycle. The pathway for transfer of the amino groups from BCAAs in skeletal muscle to urea in the liver is shown in red.

C. The Gut

Amino acids are an important fuel for the intestinal mucosal cells after a protein-containing meal and in catabolic states such as fasting or surgical trauma (Fig. 40.11). During fasting, glutamine is one of the major amino acids used by the gut. The principal fates of glutamine carbon in the gut are oxidation to CO_2 and conversion to the carbon skeletons of lactate, citrulline, and ornithine. The gut also oxidizes BCAAs. Nitrogen derived from amino acid degradation is converted to citrulline, alanine, NH_4^+ , and other compounds that are released into the blood and taken up by the liver. Although most of the carbon in this alanine is derived from glucose, the oxidation of glucose to CO_2 is not a major fuel pathway for the gut. Fatty acids are also not a significant source of fuel for the intestinal mucosal cells, although they do use ketone bodies.

FIGURE 40.11 Amino acid metabolism in the gut. The pathways of glutamine metabolism in the gut are the same whether it is supplied by the diet (postprandial state) or from the blood (postabsorptive state). Cells of the gut also metabolize aspartate, glutamate, and BCAAs. Glucose is converted principally to the carbon skeleton of alanine. $\alpha\text{-KG}$, α -ketoglutarate; Acetyl CoA, acetyl coenzyme A; BCAAs, branched-chain amino acids; GDH, glutamate dehydrogenase; TA, transaminase; TCA, tricarboxylic acid.

Even though the liver is the organ that generates urea, the intestine also contains the enzymes for the urea cycle (including carbamoyl synthetase I). However, within the intestine, the V_{max} values for argininosuccinate synthetase and argininosuccinate lyase are very low, suggesting that the primary role of the urea cycle enzymes in the gut is to produce citrulline from the carbons of glutamine (glutamine \rightarrow glutamate \rightarrow glutamate semialdehyde \rightarrow ornithine \rightarrow citrulline). The citrulline is released in the circulation for use by the liver.

After a protein meal, dietary glutamine is a major fuel for the gut, and the products of glutamine metabolism are similar to those seen in the postabsorptive state. The gut also uses dietary aspartate and glutamate, which enter the TCA cycle. Colonocytes (the cells of the colon) also use short-chain fatty acids, derived from bacterial action in the lumen.

The importance of the gut in whole-body nitrogen metabolism arises from the high rate of division and death of intestinal mucosal cells and the need to continuously provide these cells with amino acids to sustain the high rates of protein synthesis needed for cellular division. Not only are these cells important for the uptake of nutrients, they maintain a barrier against invading bacteria from the gut lumen and are, therefore, part of our passive defense system. As a result of these important functions, the intestinal mucosal cells are supplied with the amino acids required for protein synthesis and fuel oxidation at the expense of the more expendable skeletal muscle protein. However, glutamine use by the gut is diminished by metabolic acidosis compared with the postabsorptive or postprandial state. During metabolic acidosis, the uptake of glutamine by the kidney is

increased and blood glutamine levels decrease. As a consequence, the gut takes up less glutamine.

D. The Liver

The liver is the major site of amino acid metabolism. It is the major site of amino acid catabolism and converts most of the carbon in amino acids to intermediates of the TCA cycle or the glycolytic pathway (which can be converted to glucose or oxidized to CO_2), or to acetyl CoA and ketone bodies. The liver is also the major site for urea synthesis. It can take up both glutamine and alanine and convert the nitrogen to urea for disposal (see Chapter 36). Other pathways in the liver give it an unusually high amino acid requirement. The liver synthesizes plasma proteins, such as serum albumin, transferrin, and the proteins of the blood coagulation cascade. It is a major site for the synthesis of nonessential amino acids, the conjugation of xenobiotic compounds with glycine, the synthesis of heme and purine nucleotides, and the synthesis of glutathione.

E. Brain and Nervous Tissue

1. The Amino Acid Pool and Neurotransmitter Synthesis

A major function of amino acid metabolism in neural tissue is the synthesis of neurotransmitters. More than 40 compounds are believed to function as neurotransmitters, and all of these contain nitrogen derived from precursor amino acids. They include amino acids, which are themselves neurotransmitters (e.g., glutamate, glycine), the catecholamines derived from tyrosine (dopamine, epinephrine, and norepinephrine), serotonin (derived from tryptophan), γ -aminobutyric acid (GABA; derived from glutamate), acetylcholine (derived from choline synthesized in the liver and acetyl CoA), and many peptides. In general, neurotransmitters are formed in the presynaptic terminals of axons and stored in vesicles until they are released by a transient change in electrochemical potential along the axon. Subsequent catabolism of some of the neurotransmitters results in the formation of a urinary excretion product. The rapid metabolism of neurotransmitters requires the continuous availability of a precursor pool of amino acids for de novo neurotransmitter synthesis (see Chapter 46).

2. Metabolism of Glutamine in the Brain

The brain is a net glutamine producer owing principally to the presence of glutamine synthetase in astroglial cells, a supporting cell type of the brain (see Chapter 46). Glutamate and aspartate are synthesized in these cells, using amino groups donated by the BCAAs (principally valine) and TCA cycle intermediates formed from glucose and from the carbon skeletons of BCAAs (Fig. 40.12). The glutamate is converted to glutamine by glutamine synthetase, which incorporates NH_4^+ released from deamination of amino acids and deamination of AMP in the purine nucleotide cycle in the brain. This glutamine may efflux from the brain, carrying excess NH_4^+ into the blood, or serve as a precursor of glutamate in neuronal cells.

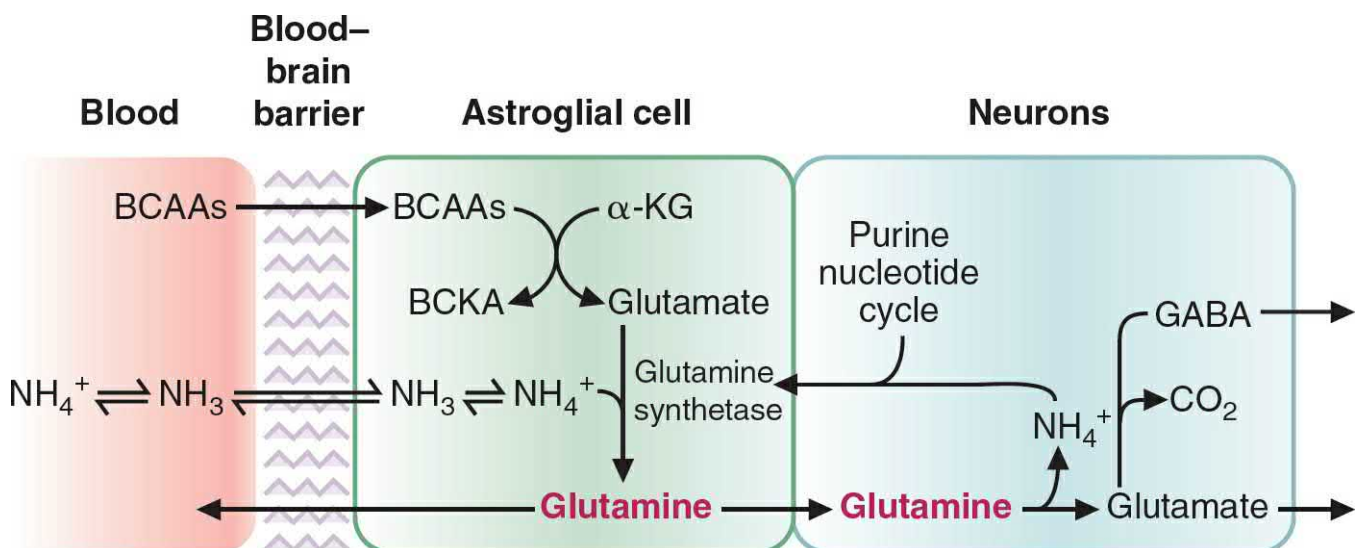

FIGURE 40.12 Role of glutamine in the brain. Glutamine serves as a nitrogen transporter in the brain for the synthesis of many different neurotransmitters. Different neurons convert glutamine to γ -aminobutyric acid (GABA) or to glutamate. Glutamine also transports excess NH_4^+ from the brain into the blood. $\alpha\text{-KG}$, α -ketoglutarate; BCAAs, branched-chain amino acids; BCKA,

branched-chain α -keto acids.

During hyperammonemia, ammonia (NH_3) can diffuse into the brain from the blood. The ammonia is able to inhibit the neural isozyme of glutaminase, thereby decreasing additional ammonia formation in the brain and inhibiting the formation of glutamate and its subsequent metabolism to GABA. This effect of ammonia might contribute to the lethargy associated with the hyperammonemia found in patients with end-stage liver disease.

Glutamine synthesized in the astroglial cells is a precursor of glutamate (an excitatory neurotransmitter) and GABA (an inhibitory neurotransmitter) in the neuronal cells (see Fig. 40.12). It is converted to glutamate by a neuronal glutaminase isozyme. In GABAergic neurons, glutamate is then decarboxylated to GABA, which is released during excitation of the neuron. GABA is one of the neurotransmitters that is recycled; a transaminase converts it to succinaldehyde, which is then oxidized to succinate. Succinate enters the TCA cycle.

III. Changes in Amino Acid Metabolism with Dietary and Physiological State

The rate and pattern of amino acid utilization by different tissues change with dietary and physiological state. Two such states, the postprandial period following a high-protein meal and the hypercatabolic state produced by sepsis or surgical trauma, differ from the postabsorptive state with respect to the availability of amino acids and other fuels and the levels of different hormones in the blood. As a result, the pattern of amino acid utilization is somewhat different.

The levels of transthyretin (also known as prealbumin, which binds to vitamin A and thyroid hormones in the blood) and serum albumin in the blood may be used as indicators of the degree of protein malnutrition. In the absence of hepatic disease, decreased levels of these proteins in the blood indicate insufficient availability of amino acids to the liver for synthesis of serum proteins. The levels of transthyretin can be determined by immunological means. The levels of albumin are rapidly determined using a hydrophobic dye-binding assay and determining the amount of colored dye bound to albumin. The dye that is used binds specifically to the hydrophobic pocket of albumin, and not to other proteins in the serum.

A. High-Protein Meal

After the ingestion of a high-protein meal, the gut and the liver use most of the absorbed amino acids (Fig. 40.13). Glutamate and aspartate are used as fuels by the gut, and very little enters the portal vein. The gut also may use some BCAAs. The liver takes up 60% to 70% of the amino acids present in the portal vein. These amino acids, for the most part, are converted to glucose in the gluconeogenic pathway.

FIGURE 40.13 Flux of amino acids after a high-protein meal.; ATP, adenosine triphosphate; BCAAs, branched-chain amino acids; TCA, tricarboxylic acid.

Q In what ways does liver metabolism after a high-protein meal resemble liver metabolism in the fasting state?

After a pure protein meal, the increased levels of dietary amino acids reaching the pancreas stimulate the release of glucagon above fasting levels, thereby increasing amino acid uptake into the liver and stimulating gluconeogenesis. Insulin release is also stimulated, but not nearly to the levels found after a high-carbohydrate meal. In general, the insulin released after a high-protein meal is sufficiently high that the uptake of BCAAs into skeletal muscle and net protein synthesis is stimulated, but gluconeogenesis in the liver is not inhibited. The higher the carbohydrate content of the meal, the higher is the insulin/glucagon ratio and the greater the shift of amino acids away from gluconeogenesis into biosynthetic pathways in the liver such as the synthesis of plasma proteins.

B High-protein, low-carbohydrate diets are based on the premise that ingesting high-protein, low-carbohydrate meals will keep circulating insulin levels low so that energy storage is not induced, and glucagon release will point the insulin/glucagon ratio to energy mobilization, particularly fatty acid release from the adipocyte and oxidation by the tissues. The lack of energy storage, coupled with the loss of fat, leads to weight loss.

Most of the amino acid nitrogen entering the peripheral circulation after a high-protein meal or a mixed meal is present as BCAAs. Because the liver has low levels of transaminases for these amino acids, it cannot oxidize them to a significant extent, and they enter the systemic circulation. The BCAAs are slowly taken up by

skeletal muscle and other tissues. These peripheral nonhepatic tissues use the amino acids derived from the diet principally for net protein synthesis.

B. Hypercatabolic States

Surgery, trauma, burns, and septic stress are examples of hypercatabolic states characterized by increased fuel utilization and a negative nitrogen balance. The mobilization of body protein, fat, and carbohydrate stores serves to maintain normal tissue function in the presence of a limited dietary intake, as well as to support the energy and amino acid requirements for the immune response and wound healing. The negative nitrogen balance that occurs in these hypercatabolic states results from accelerated protein turnover and an increased rate of net protein degradation, primarily in skeletal muscle.

The degree of the body's hypercatabolic response depends on the severity and duration of the trauma or stress. After an uncomplicated surgical procedure in an otherwise healthy patient, the net negative nitrogen balance may be limited to about 1 week. The mild nitrogen losses are usually reversed by dietary protein supplementation as the patient recovers. With more severe traumatic injury or septic stress, the body may catabolize body protein and adipose tissue lipids for a prolonged period, and the negative nitrogen balance may not be corrected for weeks.

Both of these dietary states are characterized by an elevation of glucagon. Glucagon stimulates amino acid transport into the liver, stimulates gluconeogenesis through decreasing levels of fructose 2,6-bisphosphate, and induces the synthesis of enzymes in the urea cycle, the gluconeogenic pathway, and the pathways for degradation of some of the amino acids.

The catabolic state of sepsis (acute, generalized, febrile infection) is one of enhanced mobilization of fuels and amino acids to provide the energy and precursors required by cells of the immune system, host defense mechanisms, and wound healing. The amino acids must provide the substrates for new protein synthesis and cell division. Glucose synthesis and release are enhanced to provide fuel for these cells, and the patient may become mildly hyperglycemic.

Katherine B.'s severe negative nitrogen balance was caused by both her malnourished state and her intra-abdominal infection complicated by sepsis. The systemic and diverse responses the body makes to insults such as an acute febrile illness are termed the acute-phase response. An early event in this response is the stimulation of phagocytic activity (see Fig. 40.14). Stimulated macrophages release cytokines, which are regulatory proteins that stimulate the release of cortisol, insulin, and growth hormone. Cytokines also directly mediate the acute-phase response of the liver and skeletal muscle to sepsis.

FIGURE 40.14 Cytokines and hormones mediate amino acid flux during sepsis. Bacterial products act on macrophages to stimulate the release of cytokines and on the brain to stimulate the sympathoadrenal response. The result is a stimulation of the release of the insulin counterregulatory hormones, epinephrine, glucagon, and glucocorticoids. The glucocorticoid cortisol may be the principal mediator of net muscle protein degradation during sepsis. Hepatic protein synthesis, particularly that of acute-phase proteins, is stimulated by both cortisol and cytokines. Amino acid metabolism in the gut is also probably affected by glucocorticoids and cytokines. Because of the release of the counterregulatory hormones, muscle and other tissues become resistant to insulin action, as indicated by the bar on the figure. ACTH, adrenocorticotropic hormone; CRF, corticotropin-releasing factor; IL-1, interleukin-1; IL-6, interleukin-6; TNF, tumor necrosis factor (Adapted from Fischer JE, Hasselgren PO. Cytokines and glucocorticoids in the regulation of the “hepato-skeletal muscle axis” in sepsis. *Am J Surg*. 1991;161(2):266–271. © 1991 Elsevier, with permission.)

In these hypercatabolic states, skeletal muscle protein synthesis decreases and protein degradation increases. Oxidation of BCAAs is increased and glutamine production enhanced. Amino acid uptake is diminished. Cortisol is the major hormonal mediator of these responses, although certain cytokines may also have direct effects on skeletal muscle metabolism. As occurs during fasting and metabolic acidosis, increased levels of cortisol stimulate ubiquitin-mediated proteolysis, induce the synthesis of glutamine synthetase, and enhance release of amino acids and glutamine from the muscle cells.

The amino acids released from skeletal muscle during periods of hypercatabolic stress are used in a prioritized manner, with the cellular components of the immune system receiving top priority. For example, the uptake of amino acids by the liver for the synthesis of acute-phase proteins, which are part of the immune system, is greatly increased. Conversely, during the early phase of the acute response, the synthesis of other plasma proteins (e.g., albumin) is decreased. The increased availability of amino acids and the increased cortisol levels also stimulate gluconeogenesis, thereby providing fuel for the glucose-dependent cells of the immune system (e.g., lymphocytes). An increase of urea synthesis accompanies the acceleration of amino acid degradation.

The increased efflux of glutamine from skeletal muscle during sepsis serves several functions (see Fig. 40.1). It provides the rapidly dividing cells of the immune system with an energy source. Glutamine is available

as a nitrogen donor for purine synthesis, for NAD⁺ synthesis (to convert nicotinic acid to nicotinamide), and for other biosynthetic functions that are essential to growth and division of the cells. Increased production of metabolic acids may accompany stress such as sepsis, so there is increased utilization of glutamine by the kidney.

Under the influence of elevated levels of glucocorticoids, epinephrine, and glucagon, fatty acids are mobilized from adipose tissue to provide alternate fuels for other tissues and spare glucose. Under these conditions, fatty acids are the major energy source for skeletal muscle, and glucose uptake is decreased. These changes may lead to a mild hyperglycemia.

CLINICAL COMMENTS

Katherine B. The clinician can determine whether a patient such as **Katherine B.** is mounting an acute-phase response to some insult, however subtle, by determining whether several unique acute-phase proteins are being secreted by the liver. One such protein is C-reactive protein, so named because of its ability to interact with the C-polysaccharide of pneumococci. It is presently the most commonly used acute-phase protein used to show signs of an acute-phase response. Another, serum amyloid A protein, a precursor of the amyloid fibril found in secondary amyloidosis, is also elevated in patients undergoing the acute-phase response as compared with healthy individuals, although measurement of serum amyloid A protein is not used in clinical testing. Other proteins normally found in the blood of healthy individuals are present in increased concentrations in patients undergoing an acute-phase response. These include haptoglobin, certain protease inhibitors, complement components, ceruloplasmin, and fibrinogen. The elevated concentration of these proteins in the blood increases the erythrocyte sedimentation rate (ESR), another laboratory measure used to show the presence of an acute-phase response.

To determine the ESR, the patient's blood is placed vertically in a small-bore glass tube. The speed with which the red blood cells sediment toward the bottom of the tube depends on what percentage of the red blood cells clump together and thereby become denser. The degree of clumping is directly correlated with the presence of one or more of the acute-phase proteins listed previously. These proteins interfere with what is known as the zeta-potential of the red blood cells, which normally prevents the red blood cells from clumping. Because many different proteins can individually alter the zeta-potential, the ESR is a nonspecific test for the presence of acute inflammation.

The weight loss often noted in septic patients is caused primarily by a loss of appetite resulting from the effect of certain cytokines on the medullary appetite center. Other causes include increased energy expenditure due to fever and enhanced muscle proteolysis.

BIOCHEMICAL COMMENTS

Amino acid metabolism in trauma and sepsis. After a catabolic insult such as injury, trauma, infection, or cancer, the interorgan flow of glutamine and fuels is altered dramatically. Teleologically, the changes in metabolism that occur give first priority to cells that are part of the immune system. Evidence suggests that the changes in glutamine and fuel metabolism are mediated by the insulin counterregulatory hormones, such as cortisol and epinephrine, and several different cytokines (see Chapter 10 for a review of cytokines). Cytokines appear to play a more important role than hormones during sepsis, although they exert their effects, in part, through hormones (Fig. 40.14). Although cytokines can be released from a variety of cells, macrophages are the principal source during trauma and sepsis.

Hypercatabolic states may be accompanied by varying degrees of insulin resistance caused, in part, by the release of counterregulatory hormones into the blood. Thus, patients with diabetes mellitus may require higher levels of exogenous insulin during sepsis.

Two cytokines that are important in sepsis are interleukin-1 (IL-1) and tumor necrosis factor (TNF). IL-1 and TNF affect amino acid metabolism both through regulation of the release of glucocorticoids and through direct effects on tissues. Although cytokines are generally considered to be paracrine, with their effects being exerted over cells in the immediate vicinity, TNF and IL-1 increase in the blood during sepsis. Other cytokines, such as IL-6, also may be involved.

During sepsis, TNF, IL-1, and possibly other cytokines, bacterial products, or mediators act on the brain to stimulate the release of glucocorticoids from the adrenal cortex (a process mediated by adrenocorticotropic hormone [ACTH]), epinephrine from the adrenal medulla, and both insulin and glucagon from the pancreas. Although insulin is elevated during sepsis, the tissues exhibit an insulin resistance that is similar to that of the noninsulin-dependent diabetes mellitus patient, possibly resulting from the elevated levels of the insulin counterregulatory hormones (glucocorticoids, epinephrine, and glucagon). Changes in the rate of acute-phase protein synthesis are mediated, at least in part, by the effects of TNF, IL-1, and IL-6 on the synthesis of groups of proteins in the liver.

The molecular mechanism whereby sepsis/trauma leads to reduced muscle protein synthesis involves, in part, mTOR (mammalian target of rapamycin; see Chapter 34, Figure 34.9). Sepsis reduces translational efficiency, primarily at the translation initiation step. Initiation is regulated by, and requires, specific eukaryotic initiation factors (eIFs, see Chapter 14). eIF4E is a multifactor complex required to assemble the charged initiator tRNA^{met}—40S small ribosomal subunit complex onto the capped mRNA. The activity of eIF4E is regulated by the eIF4E binding protein, 4E-BP1. When eIF4E is bound to 4E-BP1 translation initiation is reduced. mTOR, when active, will phosphorylate 4E-BP1, causing the binding protein to dissociate from the eIF4E complex, thereby stimulating translation initiation. Sepsis, and release of TNF- α , lead to the inactivation of mTOR, and reduced phosphorylation of 4E-BP1, resulting in a decrease in translation. The reduced translation, coupled with enhanced protein turnover, allows the muscle to export amino acids for use by other tissues.

Interestingly, after consumption of a high-protein meal under normal conditions the elevation of amino acids in the blood, particularly leucine, leads to the activation of mTOR, with a concomitant activation of protein synthesis. Under “normal” conditions, the cytokine release observed during sepsis/trauma does not occur, and the branched-chain amino acids can activate, through a complicated pathway, mTOR.

KEY CONCEPTS

- ◆ The body maintains a large free amino acid pool in the blood, even during fasting, allowing tissues continuous access to these building blocks.
- ◆ Amino acids are used for gluconeogenesis by the liver, as a fuel source for the gut, and as neurotransmitter precursors in the nervous system. They are also required by all organs for protein synthesis.
- ◆ During an overnight fast, and during hypercatabolic states, degradation of labile protein (primarily from skeletal muscle) is the major source of free amino acids.
- ◆ The liver is the major site for urea synthesis. Nitrogen from other tissues travels to the liver in the form of glutamine and alanine.
- ◆ Branched-chain amino acids are oxidized primarily in the skeletal muscle.
- ◆ Glutamine in the blood serves a number of roles:
 - ◆ The kidney utilizes the ammonium ion carried by glutamine for excretion in the urine, to act as a buffer against acidotic conditions.
 - ◆ The kidney and the gut utilize glutamine as a fuel source.
 - ◆ All tissues utilize glutamine for protein synthesis.
- ◆ The body can enter a catabolic state, characterized by negative nitrogen balance, under the following conditions:
 - ◆ Sepsis (the presence of various pathogenic organisms, or their toxins, in the blood or tissues)
 - ◆ Trauma
 - ◆ Injury
 - ◆ Burns
- ◆ The negative nitrogen balance results from increased net protein degradation in skeletal muscle, brought about by release of glucocorticoids. The released amino acids are used for protein synthesis and cell division in cells involved in the immune response and wound healing.
- ◆ Diseases discussed in this chapter are summarized in Table 40.3.

TABLE 40.3 Diseases Discussed in Chapter 40

DISEASE OR	ENVIRONMENTAL
------------	---------------

DISORDER	OF GENETIC	COMMENTS
Catabolic state	Environmental	The body adapts to a catabolic state by degrading proteins to enhance survival. This change in metabolism is initiated through the stress response, as mediated by cortisol, epinephrine, and norepinephrine, among other signaling molecules.
Hyperammonemia	Both	Hyperammonemia can result from mutations in urea cycle enzymes, or due to end-stage liver disease as caused by a variety of conditions (one of which is chronic alcohol use disorder).

REVIEW QUESTIONS—CHAPTER 40

1. Which one of the profiles indicated below would occur within 2 hours after eating a meal that was very high in protein and low in carbohydrates?

	Blood Glucagon Levels	Liver Gluconeogenesis	BCAA Oxidation in Muscle
A	↓	↓	↑
B	↑	↓	↑
C	↓	↑	↑
D	↑	↑	↑
E	↓	↓	↓
F	↑	↓	↓
G	↓	↑	↓
H	↑	↑	↓

2. The gut uses glutamine as an energy source, but it can also secrete citrulline, synthesized from the carbons of glutamine. Which one of the following compounds is an obligatory intermediate in this conversion (consider only the carbon atoms of glutamine while answering this question)?
- Aspartate
 - Succinyl CoA
 - Glutamate
 - Serine
 - Fumarate
3. The signal that indicates to muscle that protein degradation needs to be initiated is which one of the following?
- Insulin
 - Glucagon
 - Epinephrine
 - Cortisol
 - Glucose
4. The skeletal muscles convert BCAA carbons to glutamine for export to the rest of the body. An obligatory intermediate, which carries carbons originally from the BCAAs, in the conversion of BCAAs to glutamine,

is which one of the following?

- A. Urea
 - B. Pyruvate
 - C. Lactate
 - D. Isocitrate
 - E. Phosphoenolpyruvate
5. An individual in sepsis will display which one of the following metabolic patterns?

	Nitrogen Balance	Gluconeogenesis	Fatty Acid Oxidation
A	Positive	↑	↓
B	Negative	↑	↑
C	Positive	↑	↓
D	Negative	↑	↓
E	Positive	↓	↑
F	Negative	↓	↓

6. Ammonia toxicity in the nervous system results, in part, from inhibition of which one of the following enzymes?
- A. Glutaminase
 - B. Glutamate- α -ketoglutarate transaminase
 - C. Glutamine synthetase
 - D. CPS-1
 - E. Ornithine transcarbamoylase
7. The purine nucleotide cycle, which releases fumarate, is found primarily in which one of the following tissues?
- A. Liver
 - B. Red blood cells
 - C. Brain
 - D. Gut
 - E. Kidney
8. Which of the following occurs **primarily** in the liver? Choose the one best answer.

	Alanine Uptake	Urea Synthesis	Amino Acid Degradation	Gluconeogenesis from Amino Acid Precursors	Branched-chain Amino Acid Oxidation
A	No	Yes	No	No	No
B	Yes	Yes	Yes	Yes	Yes
C	No	No	Yes	No	No
D	Yes	Yes	No	Yes	Yes
E	No	No	No	Yes	Yes
F	Yes	Yes	Yes	Yes	No

9. The amino acid pool allows for constant substrates to be available for numerous bodily uses. Which statement below best describes this amino acid pool?
- Approximately 80% of the body's total protein is in the amino acid pool
 - Dietary proteins constitute most of the amino acid pool
 - The concentration of free amino acids is as rigidly controlled as blood glucose levels
 - The synthesis of new protein is the major use of amino acids in the amino acid pool
 - Changes in the rate of protein synthesis and degradation occur within seconds to minutes
10. Which hormone(s) and action(s) are paired correctly regarding protein metabolism/catabolism? Choose the one best answer.
- Insulin stimulates uptake of amino acids into the liver
 - Glucocorticoid induces ubiquitin synthesis
 - Insulin induces ubiquitin-dependent proteolysis
 - Glucocorticoid and insulin induce gluconeogenesis
 - Glucagon suppresses alanine transport to the liver
1. An intern was performing their first colonoscopy under the guidance of an attending GI physician, and during the procedure accidentally perforated the bowel. Inspection of the perforation indicated a small tear that the attending physician did not think warranted a surgical repair. However, the intern was asked what else should be done, and the best answer would be which one of the following?
- Treat the patient with cortisol
 - Alter the patient's diet to a high-protein low-carbohydrate diet
 - Have the patient inject slow-acting insulin for the next week
 - Have the patient take nonsteroidal anti-inflammatory drugs to prevent a fever
 - Have the patient take a course of antibiotics
2. A 25-year-old graphics artist, who minored in biochemistry, developed a severe bronchial infection as a result of catching COVID-19. The patient supplemented their treatment with 3 g of glutamine daily. The artist had read that glutamine supplementation can reduce the severity of infections, and this might be the case because glutamine participates in which of the following pathways? Choose the one best answer.

	Provide Fuel for the Immune System	Provide Nitrogen for Purine and Pyrimidine Biosynthesis	Supply the TCA Cycle With an Intermediate	Stimulate Significant Insulin Release
A	Yes	Yes	Yes	Yes
B	No	Yes	No	Yes
C	Yes	Yes	Yes	No
D	No	No	No	No
E	Yes	No	Yes	No
F	No	No	No	Yes

3. A 3-day-old newborn male was difficult to awake after a nap. Upon going to the emergency department, the parents indicated that the child had been born at home, and after 1 day the child seemed to be very tired all of the time. Blood work indicated hyperammonemia, and a urinalysis indicated orotic aciduria. The child will display neurologic manifestations of this disorder due to increased activity of which one of the following enzymes?
- Glutaminase
 - Glutamine synthetase
 - Carbamoyl phosphate synthetase I
 - Carbamoyl phosphate synthetase II
 - Glutamate decarboxylase
4. A 27-year-old firefighter was trapped in a burning building, and thanks to his colleagues he was rescued and brought to the emergency department. The firefighter, despite the protective clothing, had burns over 30% of his body. During the firefighter's recovery which of the following would be occurring?

	Display a Negative Nitrogen Balance	Liver Protein Proteolysis	Cortisol Release	Hypo-albuminemia
A	No	Yes	No	No
B	Yes	Yes	Yes	No
C	No	Yes	No	Yes
D	Yes	No	Yes	Yes
E	No	No	No	Yes
F	Yes	No	Yes	No

5. Insulin counterregulatory hormones (such as cortisol, epinephrine and glucagon) can blunt insulin's response to a high-protein low-carbohydrate meal. An example of a differential response to insulin is which one of the following?
- Stimulation of amino acid transport in muscle, coupled with liver gluconeogenesis
 - Stimulation of amino acid transport in liver, coupled with increased glycogen synthesis
 - Stimulation of adipocyte triglyceride synthesis, coupled with protein degradation in the muscle
 - Stimulation of muscle branched-chain amino acid degradation, coupled with increased liver gluconeogenesis
 - Stimulation of amino acid transport in muscle, coupled with decreased liver urea synthesis

ANSWERS TO REVIEW QUESTIONS

- The answer is D.** High levels of amino acids in the blood stimulate the pancreas to release glucagon (thus, A, C, E, and G are incorrect). Insulin is also released, but the glucagon/insulin ratio is such that the liver still utilizes the carbons of amino acids to synthesize glucose (thus, A, E, and F are incorrect). However, the insulin levels are high enough to stimulate BCAA uptake into the muscle for oxidation (thus, E, F, G, and H are incorrect).
- The answer is C.** The pathway followed is glutamine to glutamate, to glutamate semialdehyde, to ornithine, and then, after condensation with carbamoyl phosphate, to citrulline. Aspartate, succinyl CoA, serine, and fumarate are not part of this pathway.
- The answer is D.** Cortisol is released during fasting and times of stress and signals muscle cells to initiate ubiquitin-mediated protein degradation. The other hormones listed do not have this effect on muscle protein metabolism. Insulin stimulates protein synthesis; glucagon has no effect on muscle because muscle has no glucagon receptors. Epinephrine initiates glycogen degradation but not protein degradation, and glucose is not a signaling molecule for muscle as it can be for the pancreas.
- The answer is D.** Glutamine is derived from glutamate, which is formed from α -ketoglutarate. Only isoleucine and valine can give rise to glutamine because leucine is strictly ketogenic. These amino acids give rise to succinyl CoA, which goes around the TCA cycle to form citrate (after condensing with acetyl CoA), which then forms isocitrate (the correct answer), and the isocitrate is converted to α -ketoglutarate. Urea, pyruvate, phosphoenolpyruvate, and lactate are not required intermediates in the conversion of BCAA carbons to glutamine carbons.
- The answer is B.** An individual in sepsis will be catabolic; protein degradation exceeds protein intake

(leading to negative nitrogen balance; thus, A, C, and E are incorrect). The liver is synthesizing glucose from amino acid precursors to raise blood glucose levels for the immune cells and the nervous system (thus, gluconeogenesis is active, and E and F must be incorrect). Fatty acid release and oxidation have also been stimulated to provide an energy source for the liver and skeletal muscle (indicating that C, D, and F are incorrect).

6. **The answer is A.** Elevated levels of ammonia in the nervous system inhibit the production of more ammonia by both glutaminase and glutamate dehydrogenase. This leads to high glutamine levels, and low glutamate levels (since the glutamate has been converted to glutamine due to the high ammonia levels). The high glutamine leads to an osmotic imbalance across the astrocyte membrane, leading to brain edema (swelling), and also leads to the opening of the mitochondrial permeability transition pore. The opening of this pore will lead to cell death. The low glutamate levels also interfere with glutamate acting as a neurotransmitter, as well as the synthesis of GABA, and brain signaling goes awry. CPS-1 and ornithine transcarbamoylase are not present in cells of the nervous system. High ammonia promotes the synthesis of glutamine and does not affect transaminase activity.
7. **The answer is C.** The purine nucleotide cycle is found in the brain and skeletal muscle but is absent in the liver and other tissues. It responds to the rapid use of ATP during exercise, which generates AMP. The AMP is deaminated to form IMP, which then reacts with aspartate (with the release of fumarate) to regenerate AMP. The fumarate can be used anaplerotically to allow the TCA cycle to operate more rapidly.
8. **The answer is F.** The liver is the major site of amino acid metabolism and degradation, urea synthesis (from the major nitrogen carriers alanine and glutamine released from muscle), and gluconeogenesis from amino acid substrates, but branched-chain amino acids are oxidized primarily in skeletal muscle and not in the liver.
9. **The answer is D.** The major use of the amino acid pool is to produce new proteins. 300 to 600 g of new proteins are produced daily with only about 100 g originating from the diet. The rest are derived from the turnover of existing proteins, the majority of which are found in skeletal muscle (about 80% of body's total protein is in skeletal muscle). The concentration of free amino acids is not as tightly controlled as blood glucose levels since changes in protein synthesis and degradation occur over a time span of hours, not minutes. Since the amino acid pool consists of free amino acids, the amino acids within proteins do not count as an amino acid pool.
10. **The answer is B.** Glucocorticoids induce ubiquitin synthesis and increase ubiquitin-dependent proteolysis to provide substrates for liver gluconeogenesis. Alanine transport into the liver is particularly enhanced by glucagon (again, to bring in carbons for gluconeogenesis). Glucagon and glucocorticoid stimulate amino acid uptake into the liver, gluconeogenesis, and ureagenesis. Insulin has the opposite effects of glucagon and glucocorticoids, which are considered insulin counterregulatory hormones. Insulin does not stimulate amino acid uptake into the liver (but it does in the muscle).
11. **The answer is E.** The concern with a bowel perforation is the escape of bacteria from the colon into the peritoneal space. This would lead to an infection and the possibility of sepsis. To prevent this from occurring a course of antibiotics should be ordered to destroy any bacteria which may have escaped the colon. A response to sepsis would be cortisol release, but if the antibiotic is successful in killing the bacteria a septic response would not be necessary. As with cortisol treatment, a switch to a high-protein diet would aid if the patient had sepsis, as cortisol release results in an increase in the free amino acid pool to provide energy for immune cells and carbons for gluconeogenesis. Insulin treatment would not aid in preventing septicemia. Fever reduction would only be required if the patient became septic and developed a fever.
12. **The answer is C.** Glutamine is a preferred fuel for the immune system (along with intestinal epithelial cells), as well as a nitrogen donor for both purine and pyrimidine biosynthesis (thereby facilitating DNA replication and differentiation). Glutamine, through deamination and transamination, generates α -ketoglutarate, a TCA cycle intermediate. While amino acids can induce a mild insulin response, it is not as significant as a carbohydrate-induced stimulation of insulin response.
13. **The answer is B.** The child has an ornithine transcarbamoylase deficiency, leading to the hyperammonemia and orotic aciduria. The high ammonia in the blood enters the brain and is added to α -ketoglutarate to form glutamate (glutamate dehydrogenase), and then to glutamate to form glutamine (glutamine synthetase). The reduced levels of glutamate in the brain lead to reduced levels of the neurotransmitters glutamate and γ -aminobutyric acid (GABA, produced from glutamate by glutamate decarboxylase), leading to nervous system dysfunction. Glutaminase activity is actually reduced due to

the high ammonia levels. Carbamoyl phosphate synthetase II does not use ammonia as a substrate, and an increase in CPS-1 or 2 activity will not lead to neuronal dysfunction. Glutamate decarboxylase is needed to synthesize the neurotransmitter GABA, and its activity is reduced due to the low levels of glutamate under these conditions.

14. **The answer is D.** The firefighter is recovering from trauma and is in negative nitrogen balance as skeletal muscle protein is degraded to provide amino acid substrates for wound repair. Liver proteins are not being degraded, but instead liver protein synthesis is reduced (leading to hypoalbuminemia) such that amino acids can be directed to other tissues for protein and DNA synthesis. Cortisol release has also occurred as a result of the trauma to the firefighter.
15. **The answer is A.** A high-protein low-carbohydrate diet leads to a low level of insulin release which is sufficient to stimulate amino acid transport into muscle, but not sufficient to block liver gluconeogenesis (differential organ sensitivity to insulin). Under such dietary conditions, the liver is still degrading glycogen, and not synthesizing it. The insulin levels are not sufficient to stimulate adipocyte triglyceride synthesis. Insulin does not stimulate muscle branched-chain amino acid degradation (insulin will stimulate amino acid transport into muscle but does not activate the degradation pathway for these amino acids). Liver urea synthesis will increase due to the increased protein turnover in muscle and increased amino acid metabolism due to the high levels of amino acids in the diet.

SECTION VII

Tissue Metabolism

Although many of the pathways described previously are present in all tissues of the body, many tissues also carry out specialized functions and contain unique biochemical pathways. This section describes a number of such tissues and, in some cases, how the tissues interact with the rest of the body to coordinate their functions. Previous chapters have focused primarily on insulin and glucagon as the major mediators for regulating metabolic pathways; however, a large number of other hormones also regulate the storage and utilization of metabolic fuels (see Chapter 41). These hormones primarily counteract the effects of insulin and are called insulin counterregulatory hormones. They include growth hormone; thyroid hormone; glucocorticoids, such as cortisol; small peptides, such as the somatostatins; and small molecules, such as the catecholamines. Growth hormone works, in part, by inducing the synthesis of the insulin-like growth factors. These hormones can exert their effects rapidly (through covalent modification of selected enzymes) or long-term (through alterations in the rate of synthesis of selected enzymes). The interplay of these hormones with insulin and glucagon is discussed, as are the synthesis, secretion, and conditions leading to secretion of each hormone.

The proteins and cells in the blood form their own tissue system (see Chapter 42). All blood cells are derived from a common precursor, the stem cell, in the bone marrow. Different cytokine signals trigger differentiation of a particular blood cell lineage. For example, when oxygen supply to the tissues is decreased, the kidney responds by releasing erythropoietin. This hormone specifically stimulates the production of red blood cells.

Red blood cells have limited metabolic functions, owing to their lack of internal organelles. Their main function is to deliver oxygen to the tissues through the binding of oxygen to hemoglobin. When the number of red blood cells is decreased, that, by definition, represents anemia. This can be attributable to many causes, including nutritional deficiencies or mutations (hereditary anemias). The morphology of the red blood cell can sometimes aid in distinguishing the various types of anemia.

Red blood cell metabolism is geared toward preserving the ability of these cells to transport oxygen, as well as to regulate oxygen binding to hemoglobin. Glycolysis provides energy and NADH to protect the oxidation state of the heme-bound iron. The hexose monophosphate shunt pathway generates NADPH to protect red blood cell membranes from oxidation. Heme synthesis, which uses succinyl coenzyme A (succinyl CoA) and glycine for all of the carbon and nitrogen atoms in the structure, occurs in the precursors of red blood cells. Inherited defects in heme synthesis lead to a class of diseases known as the porphyrias. Because red blood cells normally pass through the very narrow capillaries, their membranes must be easily deformable. This deformability is, in part, attributable to the complex cytoskeletal structure that surrounds the erythrocyte. Mutations in these structural proteins can lead to less deformable cells, which are more easily lysed as they circulate in the bloodstream. This, in turn, can result in hemolytic anemia.

Among other functions, the hematologic system is responsible for hemostasis as well as for maintaining a constant blood volume (see Chapter 43). A tear in the wall of a vessel can lead to blood loss, which, when extensive, can be fatal. Repairing vessel damage, whether internal or external, is accomplished by a complicated series of zymogen activations of circulating blood proteins resulting in the formation of a fibrin clot (the coagulation cascade). Platelets play a critical role in hemostasis not only through their release of procoagulants but through their ability to form aggregates within the thrombus (clot) as well. Clots function as a plug, allowing defects or rents in vessel walls to repair and thereby preventing further blood loss. Conversely, inappropriate or accelerated clot formation in the lumen of vessels that supply blood to vital organs or tissues can cause an intraluminal obstruction to flow that may lead to an acute cerebral or myocardial infarction. Because clotting must be tightly controlled, intricate mechanisms exist that regulate this important hematological function.

The liver is an altruistic organ that provides multiple services for other tissues (see Chapter 44). It supplies glucose and ketone bodies to the rest of the body when fuel stores are limited. It disposes of ammonia as urea when amino acid degradation occurs. It is the site of detoxification of xenobiotics, and it synthesizes many of

the proteins found in the blood. The liver synthesizes triacylglycerols and cholesterol and distributes them to other tissues in the form of very-low-density lipoprotein (VLDL). The liver also synthesizes bile acids for fat digestion in the intestine. The liver recycles cholesterol and triglyceride through its uptake of intermediate-density lipoprotein (IDL), chylomicron and VLDL remnants, and low-density lipoprotein (LDL) particles. Because of its protective nature and its strategic location between the gut and the systemic circulation, the liver has “first crack” at all compounds that enter the blood through the enterohepatic circulation. Thus, xenobiotic compounds can be detoxified as they enter the liver, before they have a chance to reach other tissues.

Muscle cells contain unique pathways that allow them to store energy as creatine phosphate and to regulate closely their use of fatty acids as an energy source (see Chapter 45). The adenosine monophosphate (AMP)-activated protein kinase is an important regulator of muscle energy metabolism. Muscle is composed of different types of contractile fibers that derive their energy from different sources. For example, the slow-twitch type I fibers use oxidative energy pathways, whereas the type II fast-twitch fibers use the glycolytic pathway for their energy requirements.

The nervous system consists of various cell types that are functionally interconnected so as to allow efficient signal transmission throughout the system (see Chapter 46). The cells of the central nervous system are protected from potentially toxic compounds by the blood–brain barrier, which restricts entry of potentially toxic compounds into the nervous system (ammonia, however, is a notable exception). The brain cells communicate with each other and with other organs through the synthesis of neurotransmitters and neuropeptides. Many of the neurotransmitters are derived from amino acids, most of which are synthesized within the nerve cells. Because the pathways of amino acid and neurotransmitter biosynthesis require cofactors (such as pyridoxal phosphate, thiamine pyrophosphate, and vitamin B₁₂), deficiencies of these cofactors can lead to neuropathies (dysfunction of specific neurons in the nervous system).

Because of the restrictions imposed by the blood–brain barrier, the brain also must synthesize its own lipids. An adequate supply of lipids is vital to the central nervous system because lipids are constituents of the myelin sheath that surrounds the neurons and allows them to conduct impulses normally. The neurodegenerative disorders, such as multiple sclerosis, are a consequence of varying degrees of demyelination of the neurons.

Connective tissue, which consists primarily of fibroblasts, produces extracellular matrix materials that surround cells and tissues, determining their appropriate position within the organ (see Chapter 47). These materials include structural proteins (collagen and elastin), adhesive proteins (fibronectin), and glycosaminoglycans (heparan sulfate, chondroitin sulfate). The unique structures of the proteins and carbohydrates in the extracellular matrix allow tissues and organs to carry out their many functions. Loss of these supportive and barrier functions of connective tissue sometimes leads to significant clinical consequences, such as those that result from the microvascular alterations that lead to blindness, or renal failure, or peripheral neuropathies in patients with diabetes mellitus.

Actions of Hormones That Regulate Fuel Metabolism

Many hormones affect fuel metabolism, including those that regulate appetite as well as those that influence absorption, transport, and oxidation of foodstuffs. The major hormones that influence nutrient metabolism and their actions on muscle, liver, and adipose tissue are listed in Table 41.1.

TABLE 41.1 Major Hormones That Regulate Fuel Metabolism

HORMONES	MUSCLE			LIVER						ADIPOSE TISSUE	
	GLUCOSE UPTAKE	GLUCOSE UTILIZATION	PROTEIN SYNTHESIS	GLUCOSE OUTPUT	KETO-GENESIS	GLUCONEO-GENESIS	GLYCOGE-NOLYSIS	GLYCO-GENESIS	PROTEIN SYNTHESIS	FAT SYN-THESIS	TISSUE LIPOLYSIS
<i>Anabolic hormones</i>											
Insulin	↑↑	↑↑	↑↑	↓↓	↓↓	↓↓	↓↓	↑	↑	↑↑	↓↓
<i>Counterregulatory hormones^a</i>											
Glucagon	–	–	–	↑↑	↑	↑	↑↑	↓	–	–	↑ (at large doses)

Somatostatin ^c	–	–	–	–	–	–	–	–	–	–	–

↑↑, pronounced increased effect; ↑, moderate increased effect; ↓, moderate decreased effect; –, no effect.

^aHormones with actions that are generally opposed to those of insulin.

^bPermissive: allowing and enhancing the response by other hormones.

^cSomatostatin's effects on metabolism are indirect via suppression of secretion of insulin, glucagon, growth hormone, and thyroid hormone and by effects on gastric acid secretion, gastric emptying time, and pancreatic exocrine secretion (see text).

Insulin is the major **anabolic hormone**. It promotes the **storage** of **nutrients** as **glycogen** in liver and muscle, and as **triacylglycerols** in adipose tissue. It also stimulates the **synthesis** of **proteins** in tissues such as muscle. At the same time, insulin acts to inhibit fuel mobilization.

Glucagon is the major **counterregulatory** hormone. The term “counterregulatory” means that its actions are generally opposed to those of insulin (**contrainsular**). The major action of glucagon is to **mobilize fuel reserves** by stimulating **glycogenolysis** and **gluconeogenesis**. These actions ensure that glucose will be available to glucose-dependent tissues between meals.

Epinephrine, **norepinephrine**, **cortisol**, **somatostatin**, and **growth hormone** also have contrainsular activity. **Thyroid hormone** also must be classified as an insulin counterregulatory hormone because it **increases** the rate of **fuel consumption** and also increases the sensitivity of the target cells to other insulin counterregulatory hormones.

Insulin and the counterregulatory hormones exert two types of metabolic regulation (see Chapter 19). The first type of control occurs within minutes to hours of the hormone–receptor interaction and usually results from changes in the catalytic activity or kinetics of key pre-existing enzymes, caused by phosphorylation or dephosphorylation of these enzymes. The second type of control involves regulation of the **synthesis of key enzymes** by mechanisms that stimulate or inhibit transcription and translation of messenger RNA (mRNA). These processes are slow and require hours to days.

THE WAITING ROOM

Otto S., now a third-year medical student, was assigned to do a history and physical examination on a newly admitted 47-year-old patient named **Chet S.** had consulted his physician for increasing weakness and fatigue and was found to have a severely elevated serum glucose level. While he was examining the patient, **Otto S.** noted marked redness of **Chet S.**'s facial skin as well as reddish-purple stripes (striae) in the skin of his lower abdomen and thighs. The patient's body fat was unusually distributed in that it appeared to be excessively deposited centrally in his face, neck, upper back, chest, and abdomen, while the distal portions of his arms and legs appeared to be almost devoid of fat. **Chet S.**'s skin appeared thinned and large bruises were present over many areas of his body, for which **Chet S.** had no explanation. The neurological examination showed severe muscle weakness, especially in the proximal arms and legs, where the muscles seemed to have atrophied.

Sam A., a 42-year-old jeweler, noted increasingly severe headaches behind his eyes that were sometimes associated with a "flash of light" in his visual field. At times, his vision seemed blurred, making it difficult to perform some of the intricate work required of a jeweler. He consulted his ophthalmologist, who was impressed with the striking change in **Sam A.**'s facial features that had occurred since he last saw the patient 5 years earlier. The normal skin creases in **Sam A.**'s face had grown much deeper, his skin appeared to be thickened, his nose and lips appeared more bulbous, and his jaw seemed more prominent. The doctor also noted that **Sam A.**'s hands appeared bulky, and his voice had deepened. An eye examination showed that **Sam A.**'s optic nerves appeared slightly atrophied, and there was a loss of the upper outer quadrants of his visual fields.

I. Physiologic Effects of Insulin and Amylin

The effects of insulin on fuel metabolism and substrate flux were considered in many of the earlier chapters of this book, particularly in Chapter 19. Insulin stimulates the storage of glycogen in liver and muscle and the synthesis of fatty acids and triacylglycerols and their storage in adipose tissue. In addition, insulin stimulates the synthesis in various tissues of >50 proteins, some of which contribute to the growth of the organism. In fact, it is difficult to separate the effects of insulin on cell growth from those of a family of proteins known as the somatomedins or the insulin-like growth factors I and II (IGF-I and IGF-II) (see Section III.B.6).

The measurement of hormone levels in blood is best performed using immunological reagents that specifically recognize the hormone being measured. Such techniques are further described in the Biochemical Comments of this chapter.

Finally, insulin has paracrine actions within the pancreatic islet cells. When insulin is released from the β -cells, it suppresses glucagon release from the α -cells.

Pramlintide is an amylin analog that is occasionally used to treat individuals with either type 1 or type 2 diabetes. Pramlintide will bind to amylin receptors and elicit amylin-like responses. It is only used in patients using insulin with meals. It can cause nausea in almost half of the patients taking it, and occasionally vomiting. This can lead to patients discontinuing the use of this drug.

Amylin is a 37 amino acid peptide, which is synthesized in the β -cells of the pancreas and is cosecreted with insulin when blood glucose levels rise. Amylin has been demonstrated to suppress the postprandial glucagon secretion (thereby enhancing the effect of insulin, by keeping the insulin:glucagon ratio high), to slow gastric emptying, which decreases the rate at which food reaches the intestine, and the bloodstream (thereby blunting a large increase in blood nutrient levels immediately after a meal), and to reduce food intake (and thereby body weight). All of amylin's actions are geared toward reducing blood glucose levels, just as insulin does when it is released from the pancreas. Individuals with type 1 diabetes, who experience destruction of the β -cells of the pancreas, lose the ability to secrete both insulin and amylin in response to an increase in blood nutrient levels, and may partially explain why insulin therapy for individuals with type 1 diabetes is often inadequate in preventing the long-term complications of diabetes.

II. Physiologic Effects of Glucagon

Glucagon is one of several counterregulatory (contrainsular) hormones. It is synthesized as part of a large precursor protein called proglucagon. Proglucagon is produced in the α -cells of the islets of Langerhans in the pancreas and in the L-cells of the intestine. It contains a number of peptides linked in tandem: glicentin-related peptide, glucagon, glucagon-related peptide 1 (GLP-1), and glucagon-related peptide 2 (GLP-2). Proteolytic cleavage of proglucagon releases various combinations of its constituent peptides. Glucagon is cleaved from proglucagon in the pancreas and constitutes 30% to 40% of the immunoreactive glucagon in the blood. The remaining immunoreactivity is caused by other cleavage products of proglucagon released from the pancreas and the intestine. Pancreatic glucagon has a plasma half-life of 3 to 6 minutes and is removed mainly by the liver and kidney.

Glucagon promotes glycogenolysis, gluconeogenesis, and ketogenesis by stimulating the generation of cyclic adenosine monophosphate (cAMP) in target cells. The liver is the major target organ for glucagon, in part because the concentrations of this hormone bathing the liver cells in the portal blood are higher than in the peripheral circulation. Levels of glucagon in the portal vein may reach concentrations as high as 500 pg/mL.

Finally, glucagon stimulates insulin release from the β -cells of the pancreas. Whether this is a paracrine effect or an endocrine effect has not been established. The pattern of blood flow in the pancreatic islet cells is believed to bathe the β -cells first and then the α -cells. Therefore, the β -cells may influence α -cell function by a paracrine mechanism, whereas the influence of α -cell hormone on β -cell function is more likely to be endocrine. The glucagon-stimulated insulin release is most likely necessary to maintain blood glucose levels in the physiologic range.

III. Physiologic Effects of Other Counterregulatory Hormones

A. Somatostatin

1. Biochemistry

Preprosomatostatin, a 116-amino acid peptide, is encoded by a gene located on the long arm of chromosome 3. Somatostatin (SS-14), a cyclic peptide with a molecular weight of 1,600 Da, is produced from the 14 amino acids at the C-terminus of this precursor molecule. SS-14 was first isolated from the hypothalamus and named for its ability to inhibit the release of growth hormone (GH, somatotropin) from the anterior pituitary. It also inhibits the release of insulin. In addition to the hypothalamus, somatostatin is also secreted from the D cells (δ -cells) of the pancreatic islets, many areas of the central nervous system outside of the hypothalamus, and gastric and duodenal mucosal cells. SS-14 predominates in the central nervous system (CNS) and is the sole form secreted by the δ -cells of the pancreas. In the gut, however, a longer form of somatostatin is produced (SS-28), which has 14 additional amino acids extending from the C-terminal portion of the precursor, and makes up 70% to 75% of the immunoreactivity (the amount of hormone that reacts with antibodies to SS-14). The prohormone SS-28 is 7 to 10 times more potent in inhibiting the release of GH and insulin than is SS-14.

2. Secretion of Somatostatin

The secretagogues for somatostatin are similar to those that cause secretion of insulin. The metabolites that increase somatostatin release include glucose, arginine, and leucine. The hormones that stimulate somatostatin secretion include glucagon, vasoactive intestinal polypeptide (VIP), and cholecystokinin (CCK). Insulin, however, does not influence somatostatin secretion directly.

3. Physiologic Effects of Somatostatin

Five somatostatin receptors have been identified and characterized, all of which are members of the G protein-coupled receptor superfamily. Four of the five receptors do not distinguish between SS-14 and SS-28. Somatostatin binds to its plasma membrane receptors on target cells. These “activated” receptors interact with a variety of intracellular signaling pathways, depending on the cell type expressing the receptor, and which somatostatin receptor is being expressed. These pathways include inactivation of adenylate cyclase (via an inhibitory G-protein), regulation of phosphotyrosine phosphatases and MAP kinases, and alterations of intracellular ion concentrations (calcium and potassium). The inactivation of adenylate cyclases reduces the production of cAMP, and protein kinase A is not activated. This inhibitory effect suppresses the secretion of GH and thyroid-stimulating hormone (TSH) from the anterior pituitary gland as well as the secretion of insulin

and glucagon from the pancreatic islets. If one were to summarize the action of somatostatin in one phrase, it would be “somatostatin inhibits the secretion of many other hormones.” As such, it acts to regulate the effects of those other hormones. In addition to these effects on hormones that regulate fuel metabolism, somatostatin also reduces nutrient absorption from the gut by prolonging gastric emptying time (through a decrease in the secretion of gastrin, which reduces gastric acid secretion), by diminishing pancreatic exocrine secretions (i.e., digestive enzymes, bicarbonate, and water), and by decreasing visceral blood flow. Thus, somatostatin exerts a broad, albeit indirect, influence on nutrient absorption and, therefore, on the utilization of fuels.

Tolbutamide, a first-generation sulfonylurea drug that is now rarely used, increases insulin secretion and also increases the secretion of pancreatic somatostatin.

In addition to its effects on normal GH secretion, somatostatin also suppresses the pathological increase in GH that occurs in acromegaly (caused by a GH-secreting pituitary tumor), diabetes mellitus, and carcinoid tumors (tumors that secrete serotonin). Somatostatin also suppresses the basal secretion of TSH (thyroid-stimulating hormone), TRH (thyrotropin-releasing hormone), insulin, and glucagon. The hormone also has a suppressive effect on a wide variety of nonendocrine secretions.

The major limitation in the clinical use of native somatostatin is its short half-life of <3 minutes in the circulation. Analogs of native somatostatin, however, have been developed that are resistant to degradation and, therefore, have a longer half-life. One such analog is octreotide, an octapeptide variant of somatostatin with a half-life of approximately 110 minutes.

Somatostatin and its synthetic analogs are used clinically to treat a variety of secretory neoplasms such as GH-secreting tumors of the pituitary. Such tumors can cause gigantism if GH is secreted in excess before the closure of the growth centers of the ends of long bones or acromegaly if excess GH is chronically secreted after the closure of these centers (as in **Sam A.**).

B. Growth Hormone

1. Biochemistry

Growth hormone (GH) is a polypeptide that, as its name implies, stimulates growth. Many of its effects are mediated by insulin-like growth factors (IGFs, also known as somatomedins) that are produced by cells in response to the binding of GH to its cell membrane receptors (see Section III.B.6). However, GH also has direct effects on fuel metabolism.

A magnetic resonance imaging (MRI) scan of **Sam A.**'s brain showed a macroadenoma (a tumor >10 mm in diameter) in the pituitary gland, with superior extension that compressed the optic nerve as it crossed above the sella turcica, causing his visual problems. The skeletal and visceral changes noted by the ophthalmologist are characteristic of acromegalic patients with chronically elevated serum levels of GH and IGF-I. Therapy for acromegaly caused by a GH-secreting tumor of the anterior pituitary gland includes surgery if the mass is amenable or if not amendable to surgery, lifelong medical therapy. Medical therapy includes a somatostatin analog, such as octreotide, or a GH-receptor antagonist, such as pegvisomant can be used. A dopamine agonist that inhibits the secretion of GH, such as cabergoline can also be used when there are only mild elevations of IGF-1 and GH. Another therapeutic option is stereotactic radiation therapy if the others are not successful. If the excessive secretion of GH is controlled successfully, some of the visceral or soft tissue changes of acromegaly may slowly subside to varying degrees. The skeletal changes, however, cannot be reversed.

Human GH is a water-soluble 22-kDa polypeptide with a plasma half-life of 20 to 50 minutes. It is composed of a single chain of 191 amino acids having two intramolecular disulfide bonds (Fig. 41.1). The gene for GH is located on chromosome 17. It is secreted by the somatotroph cells (the cells that synthesize and release GH) in the lateral areas of the anterior pituitary. GH is structurally related to human prolactin and to human chorionic somatomammotropin (hCS) from the placenta, a polypeptide that stimulates growth of the developing fetus. Yet the hCS peptide has only 0.1% of the growth-inducing potency of GH. GH is the most abundant trophic hormone in the anterior pituitary, being present in concentrations of 5 to 15 mg/g of tissue. The other anterior pituitary hormones are present in quantities of micrograms per gram of tissue.

Human growth hormone

FIGURE 41.1 Structure of human growth hormone. (Republished with permission of McGraw Hill LLC from Murray RK, Granner DK, Mayes PA, et al. *Harper's Biochemistry*. 23rd ed. Appleton & Lange; 1993:502; permission conveyed through Copyright Clearance Center, Inc.)

The actions of GH can be classified as those that occur as a consequence of the hormone's direct effect on target cells and those that occur indirectly through the ability of GH to generate other factors, particularly IGF-I.

The IGF-I-independent actions of GH are exerted primarily in hepatocytes. GH administration is followed by an early increase in the synthesis of 8 to 10 proteins, among which are IGF-I, α_2 -macroglobulin, and the serine protease inhibitors Spi 2.1 and Spi 2.3. Expression of the gene for ornithine decarboxylase, an enzyme that is active in polyamine synthesis (and, therefore, in the regulation of cell proliferation), is also significantly increased by GH.

The ophthalmologist ordered insulin-like growth factor I (IGF-I) and a morning fasting serum GH level on **Sam A.** The GH level was elevated at 56 ng/mL (normal, 0 to 5 ng/mL).

Sam A. was given an oral dose of 75 g glucose syrup. This dose would suppress serum GH levels to <1 ng/mL in normal subjects, but not in patients with acromegaly who have an autonomously secreting pituitary tumor making GH. Because **Sam A.**'s serum GH level was 41 ng/mL after the oral glucose load, a diagnosis of acromegaly was made. The patient was referred to an endocrinologist for further evaluation.

Muscle and adipocyte cell membranes contain GH receptors that mediate direct, rapid metabolic effects on glucose and amino acid transport as well as on lipolysis. These receptors use associated cytoplasmic tyrosine kinases for signal transduction (such as the Janus kinases; see Chapter 10, Section XII.B). STAT (signal

transducer and activator of transcription) transcription factors are activated, and, depending on the tissue, the MAP kinase pathway, or the AKT pathway is also activated. For example, in adipose tissue, GH has acute insulin-like effects followed by increased lipolysis, inhibition of lipoprotein lipase, stimulation of hormone-sensitive lipase, decreased glucose transport, and decreased lipogenesis. In muscle, GH causes increased amino acid transport, increased nitrogen retention, increased fat-free (lean) tissue, and increased energy expenditure. GH also has growth-promoting effects. GH receptors are present on a variety of tissues in which GH increases IGF-I gene expression. The subsequent rise in IGF-I levels contributes to cell multiplication and differentiation by autocrine or paracrine mechanisms. These, in turn, lead to skeletal, muscular, and visceral growth. These actions are accompanied by a direct anabolic influence of GH on protein metabolism with a diversion of amino acids from oxidation to protein synthesis and a shift to a positive nitrogen balance.

2. Control of Secretion of Growth Hormone

Although the regulation of GH secretion is complex, the major influence is hormonal (Fig. 41.2). The pulsatile pattern of GH secretion reflects the interplay of two hypothalamic regulatory peptides. Release is stimulated by growth hormone–releasing hormone (GHRH, also called somatotropin). The structure of GHRH was identified in 1982 (Fig. 41.3). It exists as both a 40- and a 44-amino acid peptide encoded on chromosome 20 and produced exclusively in cells of the arcuate nucleus. Its C-terminal leucine residue is amidated. Full biological activity of this releasing hormone resides in the first 29 amino acids of the *N*-terminal portion of the molecule. GHRH interacts with specific receptors on the plasma membranes of the somatotrophs. The intracellular signaling mechanisms that result in GH synthesis and release appear to be multiple, as cAMP and calcium–calmodulin both stimulate GH release.

FIGURE 41.2 Control of growth hormone secretion. Various factors stimulate the release of growth hormone–releasing hormone (GHRH) from the hypothalamus. The hypothalamus also releases somatostatin in response to other stimuli. GHRH stimulates and somatostatin inhibits the release of growth hormone from the somatotrophs of the anterior pituitary. Growth hormone causes the release of insulin-like growth factor-1 (IGF-I) from liver and other tissues. IGF-I inhibits GHRH release and stimulates somatostatin release.

**Growth hormone–
releasing hormone (GHRH)**

**Growth hormone release–
inhibiting hormone
(GHRH) (Somatostatin)**

FIGURE 41.3 Structures of growth hormone–releasing hormone (GHRH) and growth hormone release–inhibiting hormone (GHRH, the same as somatostatin). GHRH has an amide at the C-terminal (in *box*).

GH stimulates IGF-I gene expression not only in the liver but in a number of extrahepatic tissues as well. In acromegalics, rising levels of IGF-I cause a gradual generalized increase in skeletal, muscular, and visceral growth. As a consequence, a diffuse increase occurs in the bulk of all tissues (“megaly” means enlargement) especially in the “acral” (most peripheral) tissues of the body, such as the face, the hands, and the feet, hence the term “acromegaly.”

Sam A.'s coarse facial features and bulky hands are typical of patients with acromegaly.

Conversely, GH secretion is suppressed by growth hormone release–inhibiting hormone (GHRH, the same as somatostatin, which has already been discussed). In addition, IGF-I, produced primarily in the liver in response to the action of GH on hepatocytes, feeds back negatively on the somatotrophs to limit GH secretion. Other physiologic factors (e.g., exercise and sleep) and many pathologic factors also control its release (Table e-41.1) .

In addition, GH release is modulated by plasma levels of all of the metabolic fuels, including proteins, fats, and carbohydrates. A rising level of glucose in the blood normally suppresses GH release, whereas hypoglycemia increases GH secretion in normal subjects. Amino acids, such as arginine, stimulate release of GH when their concentrations rise in the blood. Rising levels of fatty acids may blunt the GH response to arginine or a rapidly dropping blood glucose level. However, prolonged fasting, in which fatty acids are mobilized in an effort to spare protein, is associated with a rise in GH secretion. Some of the physiologic, pharmacologic, and pathologic influences on GH secretion are given in Table e-41.1 . These modulators of GH secretion provide the basis for clinical suppression and stimulation tests in patients suspected of having excessive or deficient GH secretion.

3. Effects of Growth Hormone on Energy Metabolism

GH affects the uptake and oxidation of fuels in adipose tissue, muscle, and liver and indirectly influences energy metabolism through its actions on the islet cells of the pancreas. In summary, GH increases the availability of fatty acids, which are oxidized for energy. This and other effects of GH spare glucose and protein; that is, GH indirectly decreases the oxidation of glucose and amino acids (Fig. 41.4).

FIGURE 41.4 Anabolic effects of growth hormone on various tissues. GHRH, growth hormone–releasing hormone; IGF-I, insulin-like growth factor-1.

4. Effects of Growth Hormone on Adipose Tissue

GH increases the sensitivity of the adipocyte to the lipolytic action of the catecholamines and decreases its sensitivity to the lipogenic action of insulin. These actions lead to the release of free fatty acids and glycerol into the blood to be metabolized by the liver. GH also decreases esterification of fatty acids, thereby reducing triacylglycerol synthesis within the fat cell. Recent evidence suggests that GH may impair glucose uptake by both fat and muscle cells by a postreceptor inhibition of insulin action. As a result of the metabolic effects of GH, the clinical course of acromegaly (increased GH secretion) may be complicated by impaired glucose tolerance or even overt diabetes mellitus.

5. Effects of Growth Hormone on Muscle

The lipolytic effects of GH increase free fatty acid levels in the blood that bathes muscle. These fatty acids are used preferentially as fuel, indirectly suppressing glucose uptake by muscle cells. Through the effects on glucose uptake, the rate of glycolysis is proportionately reduced.

GH increases the transport of amino acids into muscle cells, providing substrate for protein synthesis. Through a separate mechanism, GH increases the synthesis of DNA and RNA. The positive effect on nitrogen balance is reinforced by the protein-sparing effect of GH-induced lipolysis that makes fatty acids available to muscle as an alternative fuel source.

6. Effects of Growth Hormone on the Liver

When plasma insulin levels are low, as in the fasting state, GH enhances fatty acid oxidation to acetyl CoA. This effect, in concert with the increased flow of fatty acids from adipose tissue, enhances ketogenesis. The increased amount of glycerol reaching the liver as a consequence of enhanced lipolysis acts as a substrate for gluconeogenesis.

While **Sam A.** was trying to decide which of the major alternatives for the treatment of his growth hormone (GH)-secreting pituitary tumor to choose, he noted progressive fatigue and the onset of increasing urinary frequency associated with a marked increase in thirst. In addition, he had lost 4 lb over the course of the last 6 weeks in spite of a good appetite. His physician suspected that **Sam A.** had developed diabetes mellitus, perhaps related to the chronic hypersecretion of GH. This suspicion was confirmed when **Sam A.**'s serum glucose level, drawn before breakfast, was reported to be 236 mg/dL.

Hepatic glycogen synthesis is also stimulated by GH in part because of the increased gluconeogenesis in the liver. Finally, glucose metabolism is suppressed by GH at several steps in the glycolytic pathway.

A major effect of GH on liver is to stimulate production and release of IGFs. The IGFs are also known as somatomedins. The two somatomedins in humans share structural homologies with proinsulin, and both have substantial insulin-like growth activity—hence the designations insulin-like growth factor I (human IGF-I, or somatomedin-C) and insulin-like growth factor II (human IGF-II, or somatomedin A). IGF-I is a single-chain basic peptide that has 70 amino acids, and IGF-II is slightly acidic, with 67 amino acids. These two peptides are identical to insulin in half of their residues. In addition, they contain a structural domain that is homologous to the C-peptide of proinsulin.

A broad spectrum of normal cells respond to high doses of insulin by increasing thymidine uptake and initiating cell propagation. In most instances, IGF-I causes the same response as insulin in these cells but at significantly lower, more physiologic concentrations. Thus, the IGFs are more potent than insulin in their growth-promoting actions.

Evidence suggests that the IGFs exert their effects through either an endocrine or a paracrine/autocrine mechanism. IGF-I appears to stimulate cell propagation and growth by binding to specific IGF-I receptors on the plasma membrane of target cells, rather than binding to GH receptors (Fig. 41.5).

FIGURE 41.5 Production and action of insulin-like growth factor (IGF). The hypothalamus produces growth hormone–releasing hormone (GHRH), which stimulates somatotrophs in the anterior pituitary to release growth hormone (GH). Growth hormone release–inhibiting hormone (GHRH) inhibits GH release. GH binds to cell surface receptors and stimulates IGF production and release by liver and other tissues. IGF binds to cell surface receptors and stimulates the phosphorylation of proteins that lead to cell division and growth.

Like insulin, the intracellular portion of the plasma membrane receptor for IGF-I (but not IGF-II) has intrinsic tyrosine kinase activity. The fact that the receptors for insulin and a number of other growth factors have intrinsic tyrosine kinase activity indicates that tyrosine phosphorylation initiates the process of cellular replication and growth. Subsequently, a chain of kinases is activated, which include a number of proto-oncogene products (see Chapters 10 and 17).

High levels of circulating IGF-1 have been linked to the development of breast, prostate, colon, and lung cancer. Additionally, experimental modulation of IGF-1 receptor activity can alter the growth of different types of tumor cells. Current research is aimed at targeting the interaction of IGF-1 and its receptor to reduce tumor cell proliferation. Clinical trials utilizing monoclonal antibodies to the IGF-1 receptor, however, have been disappointing and further work is needed.

Most cells of the body have mRNA for IGF, but the liver has the greatest concentration of these messages, followed by kidney and heart. The synthesis of IGF-I is regulated, for the most part, by GH, whereas hepatic production of IGF-II is independent of GH levels in the blood.

C. Catecholamines (Epinephrine, Norepinephrine, Dopamine)

The catecholamines belong to a family of bioamines and are secretory products of the sympathoadrenal system. They are required for the body to adapt to a great variety of acute and chronic stresses. Epinephrine (80% to 85% of stored catecholamines) is synthesized primarily in the cells of the adrenal medulla, whereas norepinephrine (15% to 20% of stored catecholamines) is synthesized and stored not only in the adrenal medulla but also in various areas of the central nervous system (CNS) and in the nerve endings of the adrenergic nervous system. Dopamine, another catecholamine, acts primarily as a neurotransmitter and has little effect on fuel metabolism.

In patients suspected of having a neoplasm of the adrenal medulla that is secreting excessive quantities of epinephrine or norepinephrine (a pheochromocytoma), either the catecholamines themselves (epinephrine, norepinephrine, and dopamine) or their metabolites (the metanephrines and vanillylmandelic acid, VMA) may be measured in a 24-hour urine collection, or the level of catecholamines in the blood may be measured. A patient who has consistently elevated levels in the blood or urine should be considered to have a pheochromocytoma, particularly if the patient has signs and symptoms of catecholamine excess, such as excessive sweating, palpitations, tremulousness, and hypertension.

The first total chemical synthesis of epinephrine was accomplished by Stolz et al. in 1904. In 1950, Sutherland was the first to demonstrate that epinephrine (and glucagon) induces glycogenolysis. This marked the beginning of our understanding of the molecular mechanisms through which hormones act.

1. Synthesis of the Catecholamines

Tyrosine is the precursor of the catecholamines. The pathway for the biosynthesis of these molecules is described in Chapter 46.

2. Secretion of the Catecholamines

Secretion of epinephrine and norepinephrine from the adrenal medulla is stimulated by a variety of stresses, including pain, hemorrhage, exercise, hypoglycemia, and hypoxia. Release is mediated by stress-induced transmission of nerve impulses emanating from adrenergic nuclei in the hypothalamus. These impulses stimulate the release of the neurotransmitter acetylcholine from preganglionic neurons that innervate the adrenomedullary cells. Acetylcholine depolarizes the plasma membranes of these cells, allowing the rapid entry of extracellular calcium (Ca^{2+}) into the cytosol. Ca^{2+} stimulates the synthesis and release of epinephrine and norepinephrine from the chromaffin granules into the extracellular space by exocytosis.

3. Physiological Effects of Epinephrine and Norepinephrine

The catecholamines act through two major types of receptors on the plasma membrane of target cells, the α -

adrenergic and the β -adrenergic receptors (see Chapter 19, Section IV.C).

A relatively rare form of secondary hypertension (high blood pressure) is caused by a catecholamine-secreting neoplasm of the adrenal medulla, known as a pheochromocytoma. Patients with this kind of tumor periodically secrete large amounts of epinephrine and norepinephrine into the bloodstream. Symptoms related to this secretion include a sudden and often severe increase in blood pressure, heart palpitations, a throbbing headache, and inappropriate and diffuse sweating. In addition, chronic hypersecretion of these catecholamines may lead to impaired glucose tolerance or even overt diabetes mellitus. Describe the actions of these hormones that lead to the significant rise in glucose levels.

The actions of epinephrine and norepinephrine in the liver, the adipocyte, the skeletal muscle cell, and the α - and β -cells of the pancreas directly influence fuel metabolism (Fig. 41.6). These catecholamines are counterregulatory hormones that have metabolic effects directed toward mobilization of fuels from their storage sites for oxidation by cells to meet the increased energy requirements of acute and chronic stress. They simultaneously suppress insulin secretion, which ensures that fuel fluxes will continue in the direction of fuel utilization rather than storage as long as the stressful stimulus persists.

FIGURE 41.6 Effects of epinephrine on fuel metabolism and pancreatic endocrine function. Epinephrine (Epi) stimulates glycogen breakdown in muscle and liver, gluconeogenesis in liver, and lipolysis in adipose tissue. Epinephrine further reinforces these effects because it increases the secretion of glucagon, a hormone that shares many of the same effects as epinephrine. Epi also inhibits insulin release while stimulating glucagon release from the pancreas. FA, fatty acid; TG, triglyceride.

In addition, norepinephrine works as a neurotransmitter and affects the sympathetic nervous system in the heart, lungs, blood vessels, bladder, gut, and other organs. These effects of catecholamines on the heart and blood vessels increase cardiac output and systemic blood pressure, hemodynamic changes that facilitate the delivery of blood-borne fuels to metabolically active tissues.

Epinephrine has a short half-life in the blood and to be effective pharmacologically it must be administered parenterally. It may be used clinically to support the beating of the heart, to dilate inflamed bronchial muscles, and even to decrease bleeding from organs during surgery.

The catecholamines are counterregulatory hormones that mobilize fuels from their storage sites for oxidation in target cells to meet the increased energy requirements that occur during acute or chronic stress, or, in this case, the release of catecholamines by a tumor in the adrenal medulla. These actions provide the liver, for example, with increased levels of substrate needed for gluconeogenesis. Although in normal individuals most of the glucose generated through this mechanism is oxidized, blood glucose levels rise in the process. In addition, the catecholamines suppress insulin secretion to ensure that fuels will continue to flow in the direction of utilization rather than storage under these circumstances. Hence, blood glucose levels may rise in patients who have a pheochromocytoma.

4. Metabolism and Inactivation of Catecholamines

Catecholamines have a relatively low affinity for both α - and β -receptors. After binding, the catecholamine disassociates from its receptor quickly, causing the duration of the biological response to be brief. The free hormone is degraded in several ways, as outlined in Chapter 46.

D. Glucocorticoids

1. Biochemistry

Cortisol (hydrocortisone) is the major physiological glucocorticoid (GC) in humans, although corticosterone also has some glucocorticoid activity. Glucocorticoids, such as cortisol, were named for their ability to raise blood glucose levels. These steroids are among the “counterregulatory” hormones that protect the body from insulin-induced hypoglycemia. The biosynthesis of steroid hormones and their basic mechanism of action has been described in Chapters 15 and 32.

2. Secretion of Glucocorticoids

The synthesis and secretion of cortisol are controlled by a cascade of neural and endocrine signals linked in tandem in the cerebrocortical–hypothalamic–pituitary–adrenocortical axis. Cerebrocortical signals to the midbrain are initiated in the cerebral cortex by “stressful” signals such as pain, hypoglycemia, hemorrhage, and exercise (Fig. 41.7). These nonspecific “stresses” elicit the production of monoamines in the cell bodies of neurons of the midbrain. Those that stimulate the synthesis and release of corticotropin-releasing hormone (CRH) are acetylcholine and serotonin. These neurotransmitters then induce the production of CRH by neurons originating in the paraventricular nucleus. These neurons discharge CRH into the hypothalamico-hypophyseal portal blood. CRH is delivered through these portal vessels to specific receptors on the cell membrane of the adrenocorticotrophic hormone (ACTH)-secreting cells of the anterior pituitary gland (corticotrophs). This hormone–receptor interaction causes ACTH to be released into the general circulation, eventually to interact with specific receptors for ACTH on the plasma membranes of cells in the zona fasciculata and zona reticularis of the adrenal cortex. The major trophic influence of ACTH on cortisol synthesis is at the level of the conversion of cholesterol to pregnenolone, from which the adrenal steroid hormones are derived (see Chapter 32 for the biosynthesis of the steroid hormones).

FIGURE 41.7 Regulation of cortisol secretion. Various factors act on the hypothalamus to stimulate the release of corticotrophin-releasing hormone (CRH). CRH stimulates the release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary, which stimulates the release of cortisol from the adrenal cortex. Cortisol inhibits the release of CRH and ACTH via negative feedback loops.

 When **Otto S.** was writing his list of differential diagnoses to explain the clinical presentation of **Chet S.**, he suddenly thought of a relatively rare endocrine disorder that could explain all of the presenting signs and symptoms. He made a provisional diagnosis of excessive secretion of cortisol causing Cushing syndrome, most likely secondary to an excess secretion of ACTH (Cushing disease) or by a primary increase of cortisol production by an adrenocortical tumor.

Otto S. suggested that plasma cortisol and ACTH levels be measured in the evening. These studies showed that **Chet S.**'s morning plasma ACTH and cortisol levels were both significantly above the reference range. Therefore, **Otto S.** concluded that **Chet S.** probably had a tumor that was producing ACTH autonomously (i.e., not subject to normal feedback inhibition by cortisol). The high plasma levels of ACTH were stimulating the adrenal cortex to produce excessive amounts of cortisol. Additional laboratory and imaging studies indicated that the hypercortisolemia was caused by a benign ACTH-secreting adenoma of the anterior pituitary gland (Cushing disease).

Cortisol is secreted from the adrenal cortex in response to ACTH. The concentration of free (unbound) cortisol that bathes the CRH-producing cells of the hypothalamus and the ACTH-producing cells of the anterior pituitary acts as a negative feedback signal that has a regulatory influence on the release of CRH and ACTH (see Fig. 41.7). High cortisol levels in the blood suppress CRH and ACTH secretion, and low cortisol levels stimulate secretion. In severe stress, however, the negative feedback signal on ACTH secretion exerted by high cortisol levels in the blood is overridden by the stress-induced activity of the higher portions of the axis (see Fig. 41.7).

The effects of glucocorticoids on fuel metabolism in liver, skeletal muscle, and adipose tissue are outlined in Table 41.1 and in Figure 41.8. Their effects on other tissues are diverse and, in many instances, essential for life. Some of the nonmetabolic actions of GCs are listed in Table e-41.2. 

TABLE 42.2 Normal Hemoglobin Levels in Blood (g/dL)

ADULT	
Males	13.5–17.5
Females	11.5–15.5
CHILDREN	
Newborns	15.0–21.0
3–12 month	9.5–12.5
1 year to puberty	11.0–13.5

FIGURE 41.8 Effects of glucocorticoids (GC) on fuel metabolism. Glucocorticoids stimulate lipolysis in adipose tissue and the release of amino acids from muscle protein. In liver, glucocorticoids stimulate gluconeogenesis and the synthesis of glycogen. The breakdown of liver glycogen is stimulated by epinephrine. AA, amino acid; Epi, epinephrine; PEPCK, phosphoenolpyruvate carboxykinase; TG, triglyceride.

3. Effects of Glucocorticoids

Glucocorticoids have diverse actions that affect most tissues of the body. At first glance, some of these effects may appear to be contradictory (such as inhibition of glucose uptake by certain tissues), but taken together they promote survival in times of stress.

Otto S. was now able to explain the mechanism for most of **Chet S.**'s signs and symptoms. For example, **Otto S.** knew the metabolic explanation for the patient's hyperglycemia. Some of **Chet S.**'s muscle wasting and weakness were caused by the catabolic effect of hypercortisol on protein stores, such as those in skeletal muscle, to provide amino acids as precursors for gluconeogenesis. This catabolic action also resulted in the degradation of elastin, a major supportive protein of the skin, as well as an increased fragility of the walls of the capillaries of the cutaneous tissues. These changes resulted in the easy bruisability and the torn subcutaneous tissues of the lower abdomen, which resulted in red striae or stripes. The plethora (redness) of **Chet S.**'s facial skin was also caused in part by the thinning of the skin as well as by a cortisol-induced increase in the bone marrow production of red blood cells, which enhanced the "redness" of the subcutaneous tissues.

In many tissues, GCs inhibit DNA, RNA, and protein synthesis and stimulate the degradation of these macromolecules. In response to chronic stress, GCs act to make fuels available, so that when the acute alarm sounds and epinephrine is released, the organism can fight or flee. When GCs are elevated, glucose uptake by the cells of many tissues is inhibited, lipolysis occurs in peripheral adipose tissue, and proteolysis occurs in skin, lymphoid cells, and muscle. The fatty acids that are released are oxidized by the liver for energy, and the glycerol and amino acids serve in the liver as substrates for the production of glucose, which is converted to glycogen and stored. The alarm signal of epinephrine stimulates liver glycogen breakdown, making glucose available as fuel to combat the acute stress.

The mechanism by which GCs exert these effects involves binding of the steroid to intracellular receptors,

interaction of the steroid–receptor complex with GC response elements on DNA, transcription of genes, and synthesis of specific proteins (see Chapter 15, Section III.C.2). In some cases, the specific proteins responsible for the GC effect are known (e.g., the induction of phosphoenolpyruvate carboxykinase that stimulates gluconeogenesis). In other cases, the proteins responsible for the GC effect have not yet been identified.

E. Thyroid Hormone

1. Biochemistry

The secretory products of the thyroid acinar cells are tetraiodothyronine (thyroxine, T_4) and triiodothyronine (T_3). Their structures are shown in Figure 41.9. The basic steps in the synthesis of T_3 and T_4 in these cells involve the transport or trapping of iodide from the blood into the thyroid acinar cell against an electrochemical gradient; the oxidation of iodide to form an iodinating species; the iodination of tyrosyl residues on the protein, thyroglobulin, to form iodotyrosines; and the coupling of residues of mono-iodo- and diiodotyrosine in thyroglobulin to form residues of T_3 and T_4 (Fig. 41.10). Proteolytic cleavage of thyroglobulin releases free T_3 and T_4 . The steps in thyroid hormone synthesis are stimulated by thyroid-stimulating hormone (TSH), a glycoprotein produced by the anterior pituitary. Approximately 35% of T_4 is deiodinated at the 5'-position to form T_3 , and 41% is deiodinated at the 5-position to form the inactive “reverse” T_3 . Further deiodination or oxidative deamination leads to formation of compounds that have no biological activity.

FIGURE 41.9 Thyroid hormones, T_3 and T_4 .

FIGURE 41.10 Synthesis of the thyroid hormones (triiodothyronine [T₃] and tetraiodothyronine [T₄]). The protein thyroglobulin (Tgb) is synthesized in thyroid follicular cells and secreted into the colloid. Iodination and coupling of tyrosine residues in Tgb produce T₃ and T₄ residues, which are released from Tgb by pinocytosis (endocytosis) and lysosomal action. The coupling of a monoiodotyrosine with a diiodotyrosine (DIT) to form T₃ is not depicted here. NIS, sodium iodide symporter; PD, pendrin; RER, rough endoplasmic reticulum.

Q If **Chet S.**'s problem had been caused by a neoplasm of the adrenal cortex, what would his levels of blood ACTH and cortisol have been?

Iodide transport from the blood into the thyroid acinar cell is accomplished through an energy-requiring, iodide-trapping mechanism that requires symport with sodium. The sodium iodide symporter (NIS, encoded by the SLC5A5 gene) is driven by the electrochemical gradient across the membrane that is established by the Na⁺, K⁺-ATPase. For each iodide anion transported across the membrane, two sodium ions are cotransported to facilitate and drive the translocation of the ions. Loss of NIS activity leads to a congenital iodide transport defect.

A If **Chet S.**'s problem had resulted from primary hypersecretion of cortisol by a neoplasm of the adrenal cortex, his blood cortisol levels would have been elevated. The cortisol would have acted on the CRH-producing cells of the hypothalamus and the ACTH-secreting cells of the anterior pituitary by a negative feedback mechanism to decrease ACTH levels in the blood.

Because his cortisol and ACTH levels were both high, **Chet S.**'s tumor was most likely in the pituitary gland or possibly in neoplastic extrapituitary tissue that was secreting ACTH "ectopically." ("Ectopic" means that the tumor or neoplasm is producing and secreting a substance that is not ordinarily made or secreted by the tissue from which the tumor developed.) **Chet S.**'s tumor was in the anterior pituitary, not in an extrapituitary ACTH-producing site.

The rate of iodide transport is influenced by the absolute concentration of iodide within the thyroid cell. An internal autoregulatory mechanism decreases transport of iodide into the cell when the intracellular iodide concentration exceeds a certain threshold and increases transport when intracellular iodide falls below this threshold level. The iodide-concentrating or trapping process in the plasma membrane of thyroid acinar cells creates iodide levels within the thyroid cell that are several hundredfold greater than those in the blood, depending on the current size of the total body iodide pool and the present need for new hormone synthesis.

The oxidation of intracellular iodide is catalyzed by thyroid peroxidase (located at the apical border of the thyroid acinar cell) in what may be a two-electron oxidation step forming I^+ (iodonium ion). Iodonium ion may react with a tyrosine residue in the protein thyroglobulin to form a tyrosine quinoid and then a 3'-monoiodotyrosine (MIT) residue. It has been suggested that a second iodide is added to the ring by similar mechanisms to form a 3,5-diiodotyrosine (DIT) residue. Because iodide is added to these organic compounds, iodination is also referred to as the "organification of iodide."

Once iodide anion enters the thyroid follicular cell, it must be transported across the apical membrane to react with thyroid peroxidase and thyroglobulin. The apical iodide transporter is pendrin (encoded by the SLC26A4 gene), and mutations in pendrin lead to Pendred syndrome. Children with this syndrome display a total loss of hearing, goiter (swelling of the thyroid gland), and metabolic defects in iodide organification.

The biosynthesis of thyroid hormone proceeds with the coupling of an MIT and a DIT residue to form a triiodothyronine (T_3) residue or of two DIT residues to form a tetraiodothyronine (T_4) residue. T_3 and T_4 are stored in the thyroid follicle as amino acid residues in thyroglobulin. Under most circumstances, the T_4/T_3 ratio in thyroglobulin is approximately 13:1. Normally, the thyroid gland secretes 80 to 100 μg of T_4 and approximately 5 μg of T_3 per day. The additional 22 to 25 μg of T_3 "produced" daily is the result of the deiodination of the 5'-carbon of T_4 in peripheral tissues. T_3 is believed to be the predominant biologically active form of thyroid hormone in the body. The thyroid gland is unique in that it has the capacity to store large amounts of hormone as amino acid residues in thyroglobulin within its colloid space. This storage accounts for the low overall turnover rate of T_3 and T_4 in the body.

The "central" deposition of fat in patients, such as **Chet S.**, with Cushing disease or syndrome is not readily explained because GCs actually cause lipolysis in adipose tissue. The increased appetite caused by an excess of GC and the lipogenic effects of the hyperinsulinemia that accompanies the GC-induced chronic increase in blood glucose levels have been suggested as possible causes. Why the fat is deposited centrally under these circumstances, however, is not understood. This central deposition leads to the development of a large fat pad at the center of the upper back ("buffalo hump"), to accumulation of fat in the cheeks and jowls ("moon facies") and neck area, as well as a marked increase in abdominal fat. Simultaneously, there is a loss of adipose and muscle tissue below the elbows and knees, exaggerating the appearance of "central obesity" in Cushing disease or syndrome.

The plasma half-life of T_4 is approximately 7 days, and that of T_3 is 1 to 1.5 days. These relatively long plasma half-lives result from binding of T_3 and T_4 to several transport proteins in the blood. Of these transport proteins, thyroid-binding globulin (TBG) has the highest affinity for these hormones and carries approximately 70% of bound T_3 and T_4 . Only 0.03% of total T_4 and 0.3% of total T_3 in the blood are in the unbound state. This free fraction of hormone has biological activity because it is the only form that is capable of diffusing across target cell membranes to interact with intracellular receptors. The transport proteins, therefore, serve as a large reservoir of hormone that can release additional free hormone as the metabolic need arises.

The thyroid hormones are degraded in liver, kidney, muscle, and other tissues by deiodination, which produces compounds with no biological activity.

2. Secretion of Thyroid Hormone

The release of T_3 and T_4 from thyroglobulin is controlled by thyroid-stimulating hormone (TSH) from the anterior pituitary. TSH stimulates the endocytosis of thyroglobulin to form endocytic vesicles within the thyroid acinar cells (see Fig. 41.10). Lysosomes fuse with these vesicles, and lysosomal proteases hydrolyze

thyroglobulin, releasing free T_4 and T_3 into the blood in a 10:1 ratio. In various tissues, T_4 is deiodinated, forming T_3 , which is the active form of the hormone.

TSH is synthesized in the thyrotropic cells of the anterior pituitary. Its secretion is regulated primarily by a balance between the stimulatory action of hypothalamic thyrotropin-releasing hormone (TRH) and the inhibitory (negative feedback) influence of thyroid hormone (primarily T_3) at levels above a critical threshold in the blood bathing the pituitary thyrotrophs. TSH secretion occurs in a circadian pattern, a surge beginning late in the afternoon and peaking before the onset of sleep. In addition, TSH is secreted in a pulsatile fashion, with intervals of 2 to 6 hours between peaks.

In areas of the world in which the soil is deficient in iodine, hypothyroidism is common. The thyroid gland enlarges (forms a goiter) in an attempt to produce more thyroid hormone. In the United States, table salt (NaCl) enriched with iodide (iodized salt) is used to prevent hypothyroidism caused by iodine deficiency.

TSH stimulates all phases of thyroid hormone synthesis by the thyroid gland, including iodide trapping from the plasma, organification of iodide, coupling of monoiodotyrosine and diiodotyrosine, endocytosis of thyroglobulin, and proteolysis of thyroglobulin to release T_3 and T_4 (see Fig. 41.10). In addition, the vascularity of the thyroid gland increases as TSH stimulates hypertrophy and hyperplasia of the thyroid acinar cells.

The predominant mechanism of action of TSH is mediated by binding of TSH to its G protein-coupled receptor on the plasma membrane of the thyroid acinar cell, leading to an increase in the concentration of cytosolic cAMP (through G_α) and calcium (through G_α). The increase in calcium is brought about by activation of phospholipase C, eventually leading to the activation of the MAP kinase pathway.

The large protein thyroglobulin, which contains T_3 and T_4 in peptide linkage, is stored extracellularly in the colloid that fills the central space of each thyroid follicle. Each of the biochemical reactions that leads to the release and eventual secretion of T_3 and T_4 , such as those that lead to their formation in thyroglobulins, is TSH-dependent. Rising levels of serum TSH stimulate the endocytosis of stored thyroglobulin into the thyroid acinar cell. Lysosomal enzymes then cleave T_3 and T_4 from thyroglobulin. T_3 and T_4 are secreted into the bloodstream in response to rising levels of TSH.

As the free T_3 level in the blood bathing the thyrotrophs of the anterior pituitary gland rises, the feedback loop is closed. Secretion of TSH is inhibited until the free T_3 levels in the systemic circulation fall just below a critical level, which once again signals the release of TSH. This feedback mechanism ensures an uninterrupted supply of biologically active free T_3 in the blood (Fig. 41.11). High levels of T_3 also inhibit the release of TRH from the hypothalamus.

FIGURE 41.11 Feedback regulation of thyroid hormone levels. Thyrotropin-releasing hormone (TRH) from the hypothalamus stimulates the release of thyroid-stimulating hormone (TSH) from the anterior pituitary, which stimulates the release of triiodothyronine (T_3) and tetraiodothyronine (T_4) from the thyroid. T_4 is converted to T_3 in the liver and other cells. T_3 inhibits the release of TSH from the anterior pituitary and of TRH from the hypothalamus.

3. Physiologic Effects of Thyroid Hormone

Only those physiological actions of thyroid hormone that influence fuel metabolism are considered here. It is important to stress the term “physiologic,” because the effects of supraphysiological concentrations of thyroid hormone on fuel metabolism may not be simple extensions of their physiological effects. For example, when T_3 is present in excess, it has severe catabolic effects that increase the flow of amino acids from muscle into the blood and eventually to the liver. In general, the following comments apply to the effects of thyroid hormone on energy metabolism in individuals who have normal thyroid hormone levels in their blood.

a. Effects of Thyroid Hormone on the Liver

Several of the actions of thyroid hormone affect carbohydrate and lipid metabolism in the liver. Thyroid hormone increases glycolysis and cholesterol synthesis and increases the conversion of cholesterol to bile salts. Through its action of increasing the sensitivity of the hepatocyte to the gluconeogenic and glycogenolytic actions of epinephrine, T_3 indirectly increases hepatic glucose production (permissive or facilitatory action). Because of its ability to sensitize the adipocyte to the lipolytic action of epinephrine, T_3 increases the flow of fatty acids to the liver and thereby indirectly increases hepatic triacylglycerol synthesis. The concurrent increase in the flow of glycerol to the liver (as a result of increased lipolysis) further enhances hepatic gluconeogenesis.

b. Effects of Thyroid Hormone on the Adipocyte

T_3 has an amplifying or facilitatory effect on the lipolytic action of epinephrine on fat cells. Yet thyroid hormone has a bipolar effect on lipid storage because it increases the availability of glucose to the fat cells, which serves as a precursor for fatty acid and glycerol 3-phosphate synthesis. The major determinant of the rate of lipogenesis, however, is not T_3 , but rather the amount of glucose and insulin available to the adipocyte for triacylglycerol synthesis.

c. Effects of Thyroid Hormone on Muscle

In physiological concentrations, T_3 increases glucose uptake by muscle cells. It also stimulates protein synthesis, and, therefore, growth of muscle, through its stimulatory actions on gene expression.

In physiologic concentrations, thyroid hormone sensitizes the muscle cell to the glycogenolytic actions of epinephrine. Glycolysis in muscle is increased by this action of T_3 .

d. Effects of Thyroid Hormone on the Pancreas

Thyroid hormone increases the sensitivity of the β -cells of the pancreas to those stimuli that normally promote insulin release and is required for optimal insulin secretion.

4. Calorigenic Effects of Thyroid Hormone

The oxidation of fuels converts approximately 25% of the potential energy present in the foods ingested by humans to adenosine triphosphate (ATP). This relative inefficiency of the human “engine” leads to the production of heat as a consequence of fuel utilization. This inefficiency, in part, allows homeothermic animals to maintain a constant body temperature in spite of rapidly changing environmental conditions. The acute response to cold exposure is shivering, which is probably secondary to increased activity of the sympathetic nervous system in response to this “stressful” stimulus.

A patient presents with the following clinical and laboratory profile: the serum free and total T_3 and T_4 and the serum TSH levels are elevated, but the patient has symptoms of mild hypothyroidism, including a diffuse, palpable goiter. What single abnormality in the pituitary–thyroid–thyroid hormone target cell axis would explain all of these findings?

Thyroid hormone participates in this acute response by sensitizing the sympathetic nervous system to the

stimulatory effect of cold exposure. The ability of T_3 to increase heat production is related to its effects on the pathways of fuel oxidation, which both generate ATP and release energy as heat. The effects of T_3 on the sympathetic nervous system increase the release of norepinephrine. Norepinephrine stimulates the uncoupling protein thermogenin in brown adipose tissue (BAT), resulting in increased heat production from the uncoupling of oxidative phosphorylation (see Chapter 24). Very little residual brown fat persists in normal adult human beings, however.

 A generalized (i.e., involving all of the target cells for thyroid hormone in the body), but incomplete resistance of cells to the actions of thyroid hormone could explain the profile of the patient. In Refetoff disorder, a mutation in the portion of the gene that encodes the ligand-binding domain of the β -subunit of the thyroid hormone–receptor protein (expressed in all thyroid hormone–responsive cells) causes a relative resistance to the suppressive action of thyroid hormone on the secretion of TSH by the thyrotrophs of the anterior pituitary gland. Therefore, the gland releases more TSH than normal into the blood. The elevated level of TSH causes an enlargement of the thyroid gland (goiter) as well as an increase in the secretion of thyroid hormone into the blood. As a result, the serum levels of both T_3 and T_4 rise in the blood. The increase in the secretion of thyroid hormone may or may not be adequate to fully compensate for the relative resistance of the peripheral tissues to thyroid hormone. If the compensatory increase in the secretion of thyroid hormone is inadequate, the patient may develop the signs and symptoms of hypothyroidism.

Norepinephrine also increases the permeability of BAT and skeletal muscle to sodium. Because an increase of intracellular Na^+ is potentially toxic to cells, Na^+ , K^+ -ATPase is stimulated to transport Na^+ out of the cell in exchange for K^+ . The increased hydrolysis of ATP by Na^+ , K^+ -ATPase stimulates the oxidation of fuels and the regeneration of more ATP and heat from oxidative phosphorylation. Over a longer time course, thyroid hormone also increases the level of Na^+ , K^+ -ATPase, and many of the enzymes of fuel oxidation. Because even at normal room temperature ATP utilization by Na^+ , K^+ -ATPase accounts for 20% or more of our basal metabolic rate (BMR), changes in its activity can cause relatively large increases in heat production.

Thyroid hormone also may increase heat production by stimulating ATP utilization in substrate cycling (in which reversible ATP-consuming conversions of substrate to product and back to substrate use fuels and, therefore, produce heat; also known as a futile cycle).

F. Gastrointestinal-Derived Hormones That Affect Fuel Metabolism

In addition to insulin and the counterregulatory hormones discussed so far, a variety of peptides synthesized in the endocrine cells of the pancreatic islets, or the cells of the enteric nervous system, or the endocrine cells of the stomach, small bowel and large bowel, as well as certain cells of the central and peripheral nervous system, influence fuel metabolism directly. Some of these peptides and their tissues of origin, their actions on fuel metabolism, and the factors that stimulate (or suppress) their secretion are listed in Table 41.2. In addition to these peptides, others, such as gastrin, motilin, pancreatic polypeptide (PP), peptide YY (PYY), and secretin may also influence fuel metabolism but by indirect effects on the synthesis or secretion of insulin or the counterregulatory hormones (Table e-41.3) . For example, gastrin induces gastric acid secretion, which ultimately affects nutrient absorption and metabolism. Motilin, secreted by enteroendocrine M-cells of the proximal small bowel, stimulates gastric and pancreatic enzyme secretion, which, in turn, influences nutrient digestion. Pancreatic polypeptide (PP) from the pancreatic islets reduces gastric emptying and slows upper intestinal motility. Peptide YY from the α -cells in the mature pancreatic islets inhibits gastric acid secretion. Finally, secretin, produced by the enteroendocrine S-cells in the proximal small bowel, regulates pancreatic enzyme secretion and inhibits gastrin release and secretion of gastric acid. Although these “gut” hormones do not influence fuel metabolism directly, they have a significant impact on how ingested nutrients are digested and prepared for absorption. If digestion or absorption of fuels is altered through a disturbance in the delicate interplay among all of the peptides, fuel metabolism will be altered as well.

TABLE 41.2 Gastrointestinal-Derived Hormones That Affect Fuel Metabolism Directly

HORMONE	PRIMARY CELL/TISSUE OF ORIGIN	ACTIONS	SECRETORY STIMULI (AND INHIBITORS)
Amylin	Pancreatic β -cell, endocrine cells of stomach and small intestine	1. Inhibits arginine-stimulated and postprandial glucagon secretion 2. Inhibits insulin secretion	Cosecreted with insulin in response to oral nutrients

Calcitonin gene-related peptide (CGRP)	Enteric neurons and enteroendocrine cells of the rectum	Inhibits insulin secretion	Oral glucose intake and gastric acid secretion
Galanin	Nervous system, pituitary, neurons of gut, pancreas, thyroid, and adrenal gland	Inhibits secretion of insulin, somatostatin, enteroglucagon, pancreatic polypeptide, and others	Intestinal distension
Gastric inhibitory polypeptide/glucose-dependent insulinotropic polypeptide (GIP)	Neuroendocrine K-cells of duodenum and proximal jejunum	1. Increases insulin release via an “incretin” effect 2. Regulates glucose and lipid metabolism	Oral nutrient ingestion, especially long-chain fatty acids
Gastrin-releasing peptide (GRP)	Enteric nervous system and pancreas	Stimulates release of cholecystokinin; GIP, gastrin, glucagon, GLP-1, GLP-2, and somatostatin	
Ghrelin	Central nervous system, stomach, small intestine, and colon	Stimulates growth hormone release	Fasting
Glucagon	Pancreatic α -cell, central nervous system	Primary counterregulatory hormone that restores glucose levels in hypoglycemic state (increases glycogenolysis and gluconeogenesis as well as protein-lipid flux in liver and muscle)	Neural and humoral factors released in response to hypoglycemia
Glucagon-like peptide-1 (GLP-1)	Enteroendocrine L-cells in ileum, colon, and central nervous system	1. Enhances glucose disposal after meals by inhibiting glucagon secretion and stimulating insulin secretion 2. Acts through second messengers in β -cells to increase sensitivity of these cells to glucose (an incretin)	1. Oral nutrient ingestion 2. Vagus nerve 3. GRP and GIP 4. Somatostatin inhibits secretion
Glucagon-like peptide-2 (GLP-2)	Same as for GLP-1	Stimulates intestinal hexose transport	Same as GLP-1
Neuropeptide Y	Central and peripheral nervous system, pancreatic islet cells	Inhibits glucose-stimulated insulin secretion	Oral nutrient ingestion and activation of sympathetic nervous system
Neurotensin (NT)	Small intestine N-cells (especially ileum), enteric nervous system, adrenal gland, pancreas	In brain, modulates dopamine neurotransmission and anterior pituitary secretions	1. Luminal lipid nutrients 2. GRP 3. Somatostatin inhibits secretion
Pituitary adenylate cyclase-activating peptide (PACAP)	Brain, lung, and enteric nervous system	Stimulates insulin and catecholamine release	Activation of central nervous system
Somatostatin	Central nervous system, pancreatic δ -cells, and enteroendocrine δ -cells	1. Inhibits secretion of insulin, glucagon and PP (islets), and gastrin, secretin, GLP-1, and GLP-2 (in gut) 2. Reduces carbohydrate absorption from gut lumen	1. Luminal nutrients 2. GLP-1 3. GIP 4. PACAP 5. VIP 6. β -Adrenergic stimulation
Vasoactive intestinal peptide (VIP)	Widely expressed in the central and peripheral nervous systems	May regulate release of insulin and pancreatic glucagon	1. Mechanical stimulation of gut 2. Activation of central and peripheral nervous systems

TABLE 41.3 Actions of GLP-1 and GIP Relevant to Glucose Control

	GLP-1	GIP
Pancreas		
Stimulates glucose-dependent insulin release	+	+
Increase insulin biosynthesis	+	+
Inhibits glucagon secretion	+	–
Stimulates somatostatin secretion	+	+
Induces β -cell proliferation	+	+
Inhibits β -cell apoptosis	+	+
Gastrointestinal tract		
Inhibits gastric emptying	+	–
Inhibits gastric acid secretion	+	+
Central nervous system		
Inhibits food and water intake	+	–
Promotes satiety and weight loss	+	–
Cardiovascular system		
Improves cardiovascular function after ischemia	+	–
Adipose tissue		
Insulin-like lipogenic actions	–	+
Lipid storage	–	+

In hypothyroid patients, insulin release may be suboptimal, although glucose intolerance on this basis alone is uncommon.

In hyperthyroidism, the degradation and the clearance of insulin are increased. These effects, plus the increased demand for insulin caused by the changes in glucose metabolism, may lead to varying degrees of glucose intolerance in these patients (a condition called metathyroid diabetes mellitus). A patient with uncomplicated hyperthyroidism, however, rarely develops significant diabetes mellitus.

Ghrelin, a hormone identified as a growth hormone secretagogue, has recently been linked to appetite stimulation. The mechanism whereby this occurs is through the activation of the AMP-activated protein kinase in the hypothalamus. The activation of this kinase leads to the release of neuropeptide Y, which increases appetite. Research geared toward interrupting the ghrelin/ghrelin receptor signaling system is increasing to develop new antiobesity agents.

Several of these gastrointestinal peptides, such as glucagon-like peptide-1 (GLP-1) and gastric inhibitory polypeptide/glucose-dependent insulinotropic polypeptide (GIP), do not act as direct insulin secretagogues when blood glucose levels are normal but do so after a meal large enough to cause an increase in the blood glucose concentration. The release of these peptides may explain why the modest postprandial increase in serum glucose that is seen in normal subjects has a relatively robust stimulatory effect on insulin release, whereas a similar glucose concentration in vitro elicits a significantly smaller increase in insulin secretion. Likewise, this effect (certain factors potentiating insulin release), known as the “incretin effect,” could account for the greater β -cell response seen after an oral glucose load as opposed to that seen after the administration of glucose intravenously. This phenomenon is estimated to account for approximately 50% to 70% of the total insulin secreted after oral glucose administration. It is clear, then, that the gastrointestinal tract plays a critical role in peripheral energy homeostasis through its ability to influence the digestion, absorption, and assimilation of ingested nutrients. Importantly, the incretin hormones also regulate the amount of nutrients ingested, through their central action as satiety signals.

In Table 41.3, the actions of GLP-1 and GIP on key target organs that are important for the control of glucose homeostasis are given. Both GLP-1 and GIP enhance the synthesis and release of insulin as well as exerting a positive influence on the survival of pancreatic islet cells. In addition, GLP-1 contributes to the regulation of glucose homeostasis by inhibiting the secretion of glucagon from the α -cells of the pancreas as well as by slowing the rate of gastric emptying. GIP, but not GLP-1, interacts with GIP receptors on adipocytes, an interaction that is coupled to energy storage. Figure 41.12 summarizes the key effects of GLP-1 and GIP on energy metabolism.

FIGURE 41.12 Actions of selected peptides on vital tissues involved in glucose homeostasis. Both glucagon-like peptide 1 (GLP-1) and gastric inhibitory polypeptide/glucose-dependent insulinotropic polypeptide (GIP) increase insulin secretion and β -cell survival. GLP-1 has additional actions related to glucose metabolism. In contrast, gastrin and cholecystokinin (CCK) do not acutely regulate plasma glucose levels but appear to increase β -cell proliferation.

As the biological effects of the incretins were being discovered, it was hypothesized that agents that would increase the levels of the incretins, or increase their half-life in circulation, may provide an effective means of treating type 2 diabetes by increasing insulin secretion from the pancreas. The half-lives of GIP and GLP-1 in the circulation are on the order of 2.5 minutes. The protease DPP-4 (dipeptidyl protease 4), found on the surface of kidneys, intestine, liver, and many other tissues, is responsible for inactivating GIP and GLP-1. To increase the efficacy of the incretins, synthetic incretin mimetics with longer half-lives were developed, along with drugs which inhibit DPP-4, thereby increasing the serum half-lives of GIP and GLP-1. These types of medications are used for the treatment of type 2 diabetes mellitus. The first are potent GLP-1 receptor agonists. Exenatide or exenatide (Byetta) isolated from the venom of a lizard, *Heloderma suspectum*, was the first drug approved for such treatment. This agonist of the GLP-1 receptor must be administered subcutaneously, but because of its relative resistance to enzymatic cleavage by DPP4 (unlike native GLP-1, which is rapidly cleaved by this enzyme), its biological half-life in the plasma allows it to be administered only twice daily. DPP-4 cleaves GLP-1 after amino acid 2 (alanine) and breaks the alanine-glutamate peptide bond at that position. Exenatide has a glycine-glutamate sequence at amino acids 2 and 3, rendering this peptide more resistant to DPP-4 action than GLP-1. A second GLP-1 receptor agonist is liraglutide, which is a modified version of GLP-1. Liraglutide has a substitution at position 34 of the peptide, of an arginine for a lysine (K34R), along with the addition of a palmitate at position K26 (covalently linked to the lysine side chain). Addition of the fatty acid to the peptide allows liraglutide to bind to albumin in the circulation, protecting it from DPP-4, and allowing just a single daily dosing.

 It has long been noted that when an obese individual with type 2 diabetes mellitus undergoes a gastric bypass procedure their type 2 diabetes is resolved very shortly after surgery, and before there is significant weight loss. This effect has been linked to a rapid and sustained increase in both amylin and GLP-1, which is greater than in individuals who have not had the procedure done. The incretin effect of GLP-1 leads to insulin and amylin release, and a reduction of high blood glucose levels in the patient.

The second class of agents (first marketed in October 2006 as sitagliptin [Januvia]) are orally administered inhibitors of DPP-4. Through this action, sitagliptin slows the rate of catalytic cleavage of GIP and of GLP-1 by DPP-4 and, therefore, prolongs their half-lives in the blood, allowing sitagliptin to be administered just twice daily. The contrasting actions of GLP-1 receptor agonists and the DPP-4 inhibitors are listed in Table 41.4.

Since the introduction of sitagliptin other DPP-4 inhibitors have been introduced including alogliptin, linagliptin, and saxagliptin. All have been approved by the FDA for use in the United States, and some are bundled in combinations with other drugs to treat type 2 diabetes. Vildagliptin is available in other countries, but not the United States.

TABLE 41.4 Similarities and Differences in GLP-1 Receptor Agonists and DPP-4 Inhibitors

CHARACTERISTIC	GLP-1 RECEPTOR AGONISTS	DPP-4 INHIBITORS
Administration	Injection	Oral
GLP-1 concentrations	Pharmacological	Physiological
Increased insulin secretion	Yes	Yes
Reduced glucagon secretion	Yes	Yes
Activation of portal glucose sensor	No	Yes
Gastric emptying inhibited	Yes	No
Weight loss	Yes	No
Loss of appetite, nausea	Yes	No
Proliferation of β -cells	Yes	Yes
Potential immunogenicity	Yes	No

Early estimates of their glucose-lowering efficacy in patients with type 2 diabetes mellitus suggest that the drugs which boost incretin action lower the blood hemoglobin A₁C level to approximately the same extent as do the other currently available oral antidiabetic agents (see the “Biochemical Comments” in Chapter 32) such as the sulfonylureas, metformin, and the thiazolidinediones (e.g., rosiglitazone [Avandia] and pioglitazone [Actos]).

G. Neural Factors That Control Secretion of Insulin and Counterregulatory Hormones

Although a full treatment is beyond the scope of this text, the gastrointestinal neuroendocrine system is described briefly here with regard to its effects on fuel metabolism. The pancreatic islet cells are innervated by both the adrenergic and the cholinergic limbs of the autonomic nervous system. Although stimulation of both the sympathetic and the parasympathetic systems increases glucagon secretion, insulin secretion is increased by vagus nerve fibers and suppressed by sympathetic fibers via the α -adrenoreceptors. Evidence also suggests that the sympathetic nervous system regulates pancreatic β -cell function indirectly, through stimulation or suppression of the secretion of somatostatin, β_2 -adrenergic receptor number, and the neuropeptides, neuropeptide Y, and galanin.

To establish the diagnosis of a secretory tumor of an endocrine gland, one must first demonstrate that basal serum levels of the hormone in question are regularly elevated. More important, one must show that the hypersecretion of the hormone (and hence its elevated level in the peripheral blood) cannot be adequately inhibited by “maneuvers” that are known to suppress secretion from a normally functioning gland (i.e., one must show that the hypersecretion is “autonomous”).

To ensure that both the basal and the postsuppression levels of the specific hormone to be tested will reflect the true secretory rate of the suspected endocrine tumor, all of the known factors that can stimulate the synthesis of the hormone must be eliminated. For GH, for example, the secretagogues (stimulants to secretion) include nutritional factors; the patient’s level of activity, consciousness, and stress; and certain drugs. GH secretion is stimulated by a high-protein meal or by a low level of fatty acids or of glucose in the blood. Vigorous exercise, stage III-IV sleep, psychological and physical stress, and levodopa, clonidine, and estrogens also increase GH release.

The suppression test used to demonstrate the autonomous hypersecretion of GH involves giving the patient an oral glucose load and measuring GH levels subsequently. A sudden rise in blood glucose suppresses serum GH to 1 ng/mL or less in normal subjects, but not in patients with active acromegaly.

If one attempts to demonstrate autonomous hypersecretion of GH in a patient suspected of having acromegaly, therefore, before drawing the blood for both the basal (preglucose load) serum GH level and the postglucose load serum GH level, one must be certain that the patient has not eaten for 6 to 8 hours, has not done vigorous exercise for at least 4 hours, remains fully awake during the entire testing period (in a nonstressed state to the extent possible), and has not taken any drugs known to increase GH secretion for at least 1 week.

Under these carefully controlled circumstances, if both the basal and postsuppression serum levels of the suspect hormone are elevated, one can conclude that autonomous hypersecretion is probably present. At this point, localization procedures (such as an MRI of the pituitary gland in an acromegalic suspect) are performed to further confirm the diagnosis.

A tightly controlled interaction between the hormonal and neural factors that control nutrient metabolism is necessary to maintain normal fuel and hence energy homeostasis. 

CLINICAL COMMENTS

Chet S. One of the functions of cortisol is to prepare the body to deal with periods of stress. In response to cortisol, the body resorts its fuel stores so that they can rapidly be made available for the “fight or flight” response to the alarm signal sounded by epinephrine. Cortisol causes gluconeogenic substrates to move from peripheral tissues to the liver, where they are converted to glucose and stored as glycogen. The release of epinephrine stimulates the breakdown of glycogen, increasing the supply of glucose to the blood. Thus, fuel becomes available for muscle to fight or flee.

Cushing syndrome is a prolonged, inappropriate, and increased level of cortisol. The most common cause is Cushing disease, the cause of **Chet S.**'s current problems. This results from prolonged hypersecretion of ACTH from a benign pituitary tumor. ACTH stimulates the adrenal cortex to produce cortisol, and blood levels of this steroid hormone rise.

Other nonpituitary causes of Cushing syndrome include a primary tumor of the adrenal cortex secreting excessive amounts of cortisol directly into the bloodstream. This disorder also can result from the release of ACTH from secretory nonendocrine, nonpituitary neoplasms (“ectopic” ACTH syndrome). Cushing syndrome is often caused by excessive doses of synthetic GCs used to treat a variety of disorders because of their potent anti-inflammatory effects (iatrogenic Cushing syndrome).

Sam A. The diabetogenic potential of chronically elevated GH levels in the blood is manifest by the significant incidence of diabetes mellitus (10% to 15%) and impaired glucose tolerance (50%) in patients with acromegaly, such as **Sam A.** Under normal circumstances, however, physiological concentrations of GH (as well as of cortisol and thyroid hormone) have a facilitatory or permissive effect on the quantity of insulin released in response to hyperglycemia and other insulin secretagogues. This “proinsular” effect is probably intended to act as a “brake” to dampen any potentially excessive “contra-insular” effects that increments in GH and the other counterregulatory hormones exert.

BIOCHEMICAL COMMENTS

Radioimmunoassays. Most hormones are present in body fluids in picomolar to nanomolar amounts, requiring highly sensitive assays to determine their concentration in the blood or urine. Radioimmunoassays (RIAs), developed in the 1960s, use an antibody, generated in animals, against a specific antigen (the hormone to be measured). Determining the concentration of the hormone in the sample involves incubating the plasma or urine sample with the antibody and then quantifying the level of antigen–antibody complex formed during the incubation by one of several techniques.

The classic RIA uses very high-affinity antibodies, which have been fixed (immobilized) on the inner surface of a test tube, a Teflon bead, or a magnetized particle. A standard curve is prepared, using a set amount of the antibody and various known concentrations of the unlabeled hormone to be measured. In addition to a known concentration of the unlabeled hormone, each tube contains the same small, carefully measured amount of radiolabeled hormone. The labeled hormone and the unlabeled hormone compete for binding to the antibody. The higher the amount of unlabeled hormone in the sample, the less radiolabeled hormone is bound. A standard curve is plotted (Fig. 41.13). The sample from the patient’s blood or urine, containing the unlabeled hormone to be measured, is incubated with the immobilized antibody in the presence of the same small, carefully measured amount of radiolabeled hormone. The amount of radiolabeled hormone bound to the antibody is determined, and the standard curve is used to quantitate the amount of unlabeled hormone in the patient sample.

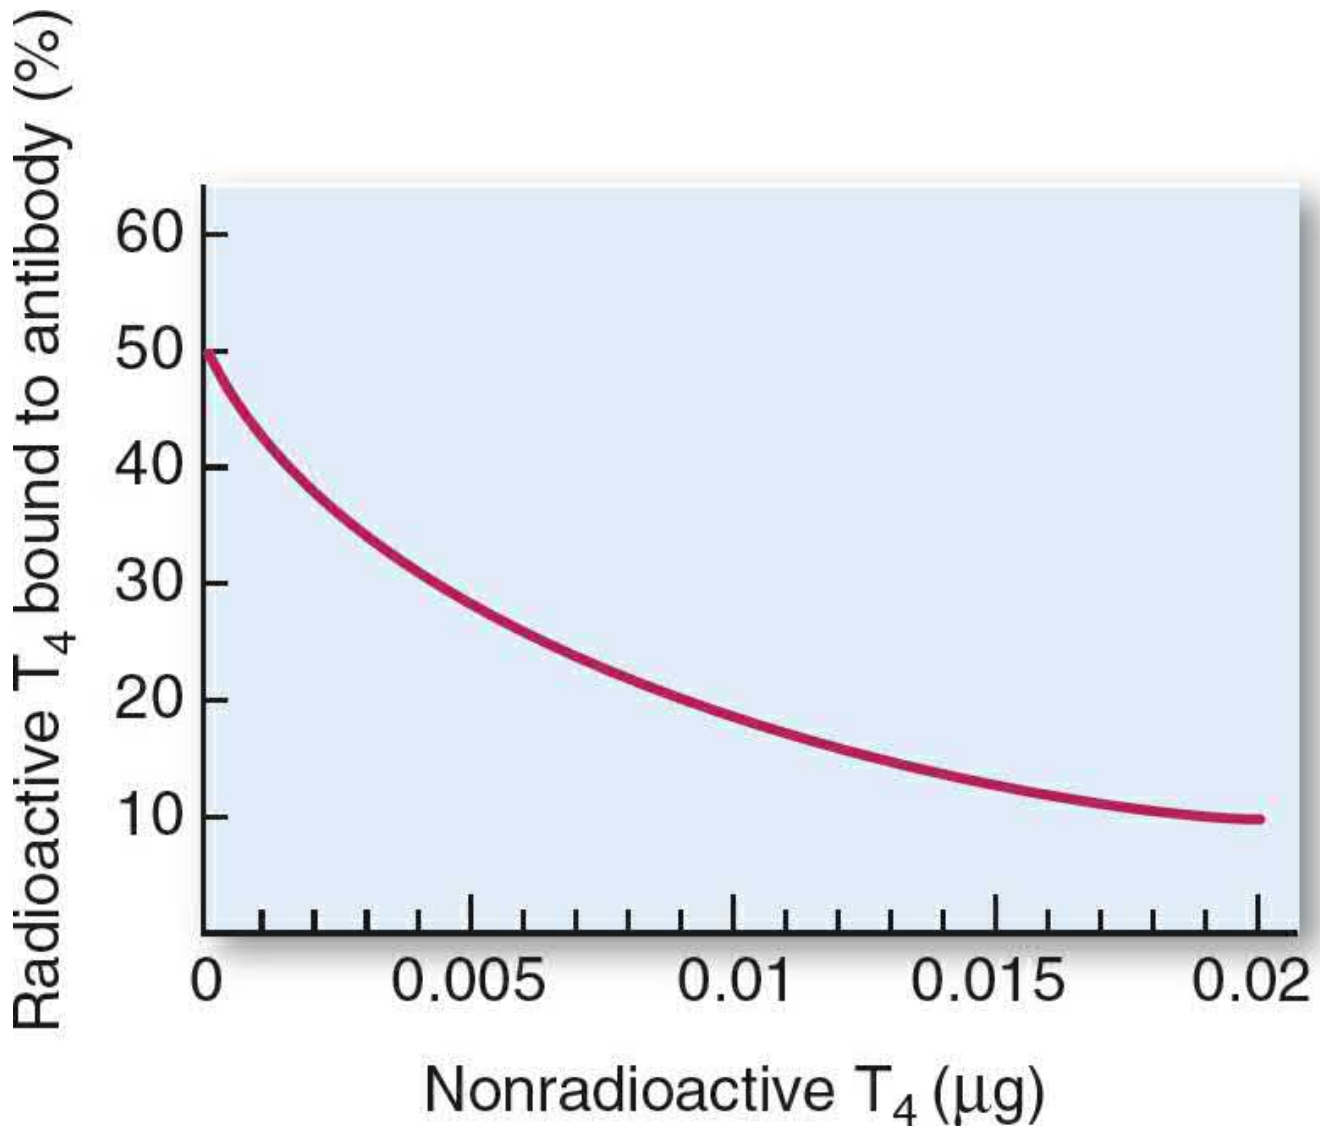

FIGURE 41.13 Standard curve for a radioimmunoassay. A constant amount of radioactive tetraiodothyronine (T_4) is added to a series of tubes, each of which contains a different amount of nonradioactive T_4 . The amount of radioactive hormone that binds to an antibody that is specific for the hormone is measured and plotted against the nonradioactive hormone concentration. When more nonradioactive T_4 is present in the tube, less radioactive T_4 binds to the antibody. To reduce the use of radioactivity in laboratory settings the assay has been adapted to the use of fluorescent-labeled antibodies and antigens to determine thyroid hormone levels in a biological sample.

The same principle is used in immunoradiometric assays (IRMAs), but with this technique the antibody, rather than the antigen to be measured, is radiolabeled.

The sensitivity of RIAs can be enhanced using a “sandwich technique.” This method uses two different monoclonal antibodies (antibodies generated by a single clone of plasma cells rather than multiple clones), each of which recognizes a different specific portion of the hormone’s structure. The first antibody, attached to a solid support matrix such as a plastic culture dish, binds the hormone to be assayed. After exposure of the patient sample to this first antibody, the excess plasma is washed away, and the second antibody (which is radiolabeled) is then incubated with the first antibody–hormone complex. The amount of binding of the second (labeled) antibody to the first complex is proportional to the concentration of the hormone in the sample.

The sandwich technique can be improved even further if the second antibody is attached to an enzyme, such as alkaline phosphatase. The enzyme rapidly converts an added colorless substrate into a colored product, or a nonfluorescent substrate into a highly fluorescent product. These changes can be quantitated if the degree of change in color or fluorescence is proportional to the amount of hormone present in the patient sample. Less than a nanogram (10^{-9} g) of a protein can be measured by such an enzyme-linked immunosorbent assay (ELISA).

KEY CONCEPTS

- ◆ Insulin is the major anabolic hormone of the body.
- ◆ Hormones that counteract the action of insulin are known as counterregulatory (contra-insular) hormones.
- ◆ Glucagon is the major counterregulatory hormone.
- ◆ Other contra-insular hormones are
 - ◆ Epinephrine
 - ◆ Norepinephrine
 - ◆ Cortisol
 - ◆ Somatostatin
 - ◆ GH
 - ◆ Thyroid hormone
- ◆ Somatostatin inhibits insulin secretion, as well as the secretion of a large number of other hormones.
- ◆ Growth hormone (GH) exhibits a wide variety of effects.
 - ◆ GH increases lipolysis in adipose tissue, which increases the availability of fatty acids for oxidation, thereby reducing the oxidation of glucose and amino acids.
 - ◆ GH increases amino acid uptake into muscle cells, thereby increasing muscle protein synthesis.
 - ◆ GH stimulates gluconeogenesis (from amino acid substrates) and glycogen production in the liver.
- ◆ The catecholamines have metabolic effects directed toward mobilization of fuels from their storage sites for oxidation by cells, while simultaneously suppressing insulin secretion.
- ◆ Cortisol (a glucocorticoid) promotes survival in times of stress, primarily via alteration of gene expression.
 - ◆ ATP-requiring processes, such as DNA, RNA, and protein synthesis, are inhibited.
 - ◆ Fuels are made available.
 - ◆ Fat-cell lipolysis is stimulated.
 - ◆ Muscle proteolysis is stimulated.
 - ◆ Glucose uptake by many tissues is inhibited, to provide the nervous system with the glucose.
 - ◆ The liver utilizes the carbons of the amino acids for gluconeogenesis and glycogen storage.
- ◆ Thyroid hormone secretion is regulated by thyroid-stimulating hormone (TSH) and thyrotropin-releasing hormone (TRH).
- ◆ Thyroid hormone effects in the liver include:
 - ◆ Increases in glycolysis and cholesterol synthesis
 - ◆ Increase in the synthesis of bile salts
 - ◆ Increase in triglyceride synthesis
- ◆ Thyroid hormone effects on fat cells include:
 - ◆ Increased lipolysis
 - ◆ Increased glycerol release to the liver
- ◆ Thyroid hormone also stimulates heat production via a variety of mechanisms.
- ◆ The intestine and stomach (the gut) also secrete a variety of factors that affect fuel metabolism by working with (or against) the other hormones already described.
- ◆ The incretins glucagon-like peptide-1 (GLP-1) and GIP are synthesized in specialized cells of the gastrointestinal tract.
- ◆ GLP-1 and GIP influence nutrient homeostasis by increasing insulin release from the pancreatic β -cells in a glucose-dependent manner.
- ◆ Incretin action facilitates the uptake of glucose by muscle tissue and by the liver while simultaneously suppressing glucagon secretion by the α -cells of the pancreas.
- ◆ The incretins also increase the levels of cAMP in the islets leading to expansion of β -cell mass and resistance to β -cell apoptosis.
- ◆ Diseases discussed in this chapter are summarized in Table 41.5.

TABLE 41.5 Diseases Discussed in Chapter 41

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Hypercortisolemia	Both	Excessive cortisol secretion, leading to inappropriate catabolic responses.
Acromegaly	Environmental	Excessive secretion of growth hormone, most

		often due to GH-secreting neoplasms of the pituitary.
Cushing disease	Environmental	A pituitary adenoma leading to excessive secretion of ACTH, which leads to excessive cortisol secretion.
Cushing syndrome	Environmental or genetic (MEN; multiple endocrine neoplasia I)	Exposure to high levels of cortisol for prolonged periods of time, with its subsequent effects.
Hypothyroidism	Environmental or genetic	Reduced secretion of thyroid hormone, weight gain.

REVIEW QUESTIONS—CHAPTER 41

- As a third-year medical student, you examine your first patient. You find that he is 52 years old, has a round face, acne, and a large hump of fat on the back of his neck. He complains that he is too weak to mow his lawn. His fasting blood glucose level is 170 mg/dL (reference range, 70 to 100 mg/dL). His plasma cortisol levels are 62 $\mu\text{g/mL}$ (reference range, 3 to 31 $\mu\text{g/mL}$). His plasma ACTH levels are 0 pg/mL (reference range, 10 to 60 pg/mL). Based on the information given, if the patient's problem is attributable to a single cause, the most likely diagnosis is which one of the following?
 - Noninsulin-dependent diabetes mellitus
 - Insulin-dependent diabetes mellitus
 - A secretory tumor of the anterior pituitary
 - A secretory tumor of the posterior pituitary
 - A secretory tumor of the adrenal cortex
- A woman was scheduled for a growth hormone–suppression test. If each of the following events occurred the morning of the test, which one of the events would be most likely to cause a decrease in GH levels?
 - She ate four large doughnuts for breakfast.
 - She was on estrogen replacement therapy and took her tablets after breakfast.
 - While unlocking her car, she was chased by the neighbor's vicious dog.
 - She fell asleep at the start of the test and slept soundly until it was completed 1.5 hours later.
 - She forgot to eat breakfast before the test.
- A dietary deficiency of iodine will lead to which one of the following?
 - A direct effect on the synthesis of thyroglobulin on ribosomes
 - An increased secretion of thyroid-stimulatory hormone (TSH)
 - Decreased production of thyrotropin-releasing hormone (TRH)
 - Increased heat production
 - Weight loss
- A woman whose thyroid gland was surgically removed was treated with 0.10 mg of thyroxine daily (tablet form). After 3 months of treatment, serial serum TSH levels ranged between 10 and 15 MIU/mL (reference range, 0.3 to 5.0 MIU/mL). She complained of fatigue, weight gain, and hoarseness. Her dose of thyroid hormone should be adjusted in which direction?
 - Increased
 - Decreased
 - Remain the same
- Which one of the insulin counterregulatory hormones stimulates both amino acid release from the muscle and glycogenesis?
 - Glucagon
 - Epinephrine
 - Cortisol
 - GH
 - Thyroid hormone
- Which of the following are hormones that would antagonize the actions of insulin (insulin counterregulatory hormones)? Choose the one best answer.
 - Glucagon
 - Epinephrine
 - Cortisol
 - GH
 - Thyroid hormone

	Erythro- poietin	Epineph- rine	Norepi- nephrine	Soma- tostatin	Growth Hormone
A	Yes	No	No	No	Yes
B	Yes	Yes	Yes	Yes	No
C	Yes	No	No	No	Yes
D	No	Yes	Yes	Yes	Yes
E	No	No	Yes	No	No
F	No	Yes	Yes	Yes	No

7. A patient has been diagnosed with acromegaly due to a growth hormone (GH) secreting tumor in the anterior pituitary. The patient is prescribed an analog of somatostatin to suppress GH secretion from the tumor to treat the condition. This treatment will also lead to the suppression of which one of the following hormones?
 - A. Epinephrine
 - B. Norepinephrine
 - C. Glucocorticoid
 - D. Thyroid hormone
 - E. Erythropoietin
8. A patient had a recent history of headaches, sweating, and rapid heart palpitations. The physician ordered a 24-hour urine test that indicated greatly elevated levels of vanillylmandelic acid (VMA). This finding strongly suggests that the patient has which type of tumor?
 - A. Prolactinoma
 - B. Growth hormone-secreting tumor
 - C. Insulinoma
 - D. Glucagonoma
 - E. Pheochromocytoma
9. A new patient to your practice has been diagnosed with type 2 diabetes. Your treatment plan includes prescribing a drug that would be beneficial in lowering postprandial serum glucose levels. A class of such a drug is which one of the following?
 - A. Drugs that decrease levels of gastric inhibitory peptide (GIP)
 - B. Drugs that decrease levels of glucagon-like peptide 1 (GLP-1)
 - C. Drugs that increase levels of somatostatin
 - D. Drugs that decrease levels of dipeptidyl-peptidase 4 (DPP-4)
 - E. Drugs that increase the levels of glucagon
10. When viewing the adrenal gland from external covering (capsule) through the cortex into the medulla, which one of the following is the correct order of hormone synthesis?
 - A. Epinephrine, cortisol, DHEA, aldosterone
 - B. Aldosterone, cortisol, DHEA, epinephrine
 - C. Cortisol, DHEA, epinephrine, aldosterone
 - D. Aldosterone, DHEA, cortisol, epinephrine
 - E. DHEA, aldosterone, epinephrine, cortisol
11. GH release results in cellular proliferation due to the liver responding to GH by synthesizing which one of the following?
 - A. Somatostatin
 - B. Somatomedin
 - C. GLP-1
 - D. GIP

- E. Insulin
- Insulin release is significantly greater after ingesting a well-balanced meal (carbohydrates, lipids, and proteins) than when an equivalent amount of glucose is introduced intravenously. This is due to the actions of which one of the following tissues?
 - Hypothalamus
 - Liver
 - Pancreas
 - Stomach
 - Intestine
 - A similarity between active thyroid hormones and the incretins is which one of the following?
 - Both require active mineral transport to synthesize the hormone
 - Both are synthesized in the thyroid colloid
 - Insulin stimulates the synthesis of both sets of hormones
 - The active hormones are proteolytic peptides derived from a larger precursor
 - Somatostatin induces the synthesis of both sets of proteins
 - Two friends, A and B, both in their mid-forties, were discussing their doctor's advice on how to manage their diabetes. Both ate a well-balanced diet, and each took an appropriate multivitamin tablet daily. Both were taking insulin injections at various times during the day, but one of them (A) was also taking a drug which helped boost insulin levels after eating. Friend B was not prescribed that medication and asked to borrow some of A's medicine. It turns out that taking the other drug had no effect on B's insulin levels after eating. This was most likely due to which one of the following?
 - B has type 1 diabetes, while A has type 2 diabetes
 - A has type 1 diabetes, while B has type 2 diabetes
 - B has a defective DPP-4 enzyme
 - B has a zinc deficiency
 - B could not produce incretins
 - Bafilomycin is a member of the macrolide family of antibiotics, and while bafilomycin has antifungal and antiparasitic activity it also has a wide number of undesirable side effects in humans so is only used with caution. One effect of bafilomycin is to inhibit the lysosomal proton pump, leading to alkalinization of the lysosomes. This drug would have the greatest effect on the synthesis of which one of the following hormones?
 - Cortisol
 - GLP-1
 - Insulin
 - Thyroid hormone
 - Growth hormone

ANSWERS TO REVIEW QUESTIONS

- The answer is E.** A tumor of the adrenal cortex is secreting excessive amounts of cortisol into the blood, which adversely affects glucose tolerance, suppresses pituitary secretion of ACTH, and, through chronic hypercortisolemia, causes the physical changes described in this patient. Uncomplicated noninsulin-dependent and insulin-dependent diabetes mellitus can be eliminated as possible diagnoses because they are not associated with elevated plasma cortisol levels and low plasma ACTH levels. In this patient, hyperglycemia resulted from the diabetogenic effects of chronic hypercortisolemia. An ACTH-secreting tumor of the anterior pituitary gland would cause hypercortisolemia, which, in turn, could adversely affect glucose tolerance, but in this case, the plasma ACTH levels would have been high rather than 0 pg/mL. The posterior pituitary gland secretes oxytocin and vasopressin, neither of which influences blood glucose, cortisol, or ACTH levels.
- The answer is A.** High blood glucose levels cause a decrease in GH levels in the blood. This fact serves as the basis for the glucose suppression test for GH. Answers B, C, and D all would cause GH levels to increase, while answer E would have no effect on the test.
- The answer is B.** When iodine is deficient in the diet, the thyroid does not make normal amounts of T₃ and T₄. Consequently, there is less feedback inhibition of TSH production and release; hence, an

increased secretion of TSH would be observed. There is no direct effect on thyroglobulin synthesis (thus, A is incorrect). TRH is released by the hypothalamus to release TSH from the pituitary; a lack of thyroid hormone would increase production of TRH, not decrease it (thus, C is incorrect). An overproduction of thyroid hormone leads to increased heat production and weight loss; lack of thyroid hormone does not lead to these symptoms (thus, D and E are incorrect).

4. **The answer is A.** The woman is experiencing hypothyroidism; TSH is elevated in an attempt to secrete more thyroid hormone, as the existing dose is too low to suppress TSH release.
5. **The answer is C.** Glucagon, epinephrine, and norepinephrine decrease glycogenesis (the synthesis of glycogen). Growth and thyroid hormones have no effect on glycogenesis. The only counterregulatory hormone to increase glycogenesis is cortisol, which is preparing the body for future needs by storing amino acid carbons (obtained from protein degradation in the muscle) as glycogen in the liver.
6. **The answer is D.** Counterregulatory hormones oppose the actions of insulin. Glucagon is the major counterregulatory hormone, but epinephrine, norepinephrine, cortisol, somatostatin, GH, and thyroid hormone are all classified as counterregulatory hormones as all affect fuel metabolism in a manner opposite that of insulin's action on fuel metabolism. Erythropoietin stimulates bone marrow production of red blood cells and does not oppose the actions of insulin.
7. **The answer is D.** Somatostatin leads to the inactivation of adenylate cyclase, thereby reducing cAMP levels. This reduces the secretion of GH, thyroid-stimulating hormone (TSH), insulin, glucagon, serotonin, and thyrotropin-releasing hormone (TRH). The reduction of TRH and TSH would reduce thyroid hormone production. Somatostatin will not reduce the secretion of glucocorticoids, catecholamines (such as epinephrine and norepinephrine), and erythropoietin.
8. **The answer is E.** A pheochromocytoma is a catecholamine-producing tumor of the adrenal glands that overproduces and secretes epinephrine and other catecholamines. VMA and the metanephrines are the degradation products from these hormones. Since the levels of the degradation products are elevated the tumor is secreting catecholamines, which also explains the symptoms. None of the other listed tumors will produce VMA as a degradation product.
9. **The answer is D.** GIP and GLP-1 accentuate insulin release after a meal large enough to cause an increase in blood glucose concentration (so they should be increased as a treatment for diabetes). Both GIP and GLP-1 have a very short half-life due to inactivation by DPP-4. Reducing the levels of DPP-4 would allow more GLP-1 and GIP to stimulate insulin release and to lower postprandial blood glucose levels. Somatostatin and glucagon are counterregulatory hormones and would antagonize the effects of insulin.
10. **The answer is B.** The outermost layer of the adrenal cortex produces mineralocorticoids (aldosterone). The intermediate layer produces glucocorticoids (cortisol). The innermost layer of the cortex produces adrenal androgens (DHEA). The adrenal medulla (inside the cortex) produces catecholamines such as epinephrine.
11. **The answer is B.** GH binding to its receptor on the liver cell surface induces the synthesis of the somatomedin's (insulin-like growth factors, IGF-1 and IGF-2). The IGF's are secreted from the liver and bind to receptors on other tissues, promoting cellular proliferation. Somatostatin is produced by the D cells of the pancreas and reduces the secretion of both insulin and glucagon from the pancreas, as well as blocking the actions of other hormones. Glucagon-like peptide 1 (GLP-1) and GIP are produced by the small intestine in response to food ingestion and work in concert to stimulate insulin release from the pancreas. Insulin synthesis and release in the pancreas is not affected by GH.
12. **The answer is E.** The presence of fat in the small intestine (in particular, long-chain unsaturated fatty acids) results in the secretion of GLP-1 and GIP, the incretins, which work in concert with elevated carbohydrate levels to stimulate insulin release from the pancreas. Taking intravenous glucose would bypass this mechanism of stimulating insulin release and would result in a less robust insulin response to the meal. The incretins are not produced by the hypothalamus, liver, pancreas, or stomach.
13. **The answer is D.** Thyroid hormones (T3 and T4) are derived from the larger protein, iodinated thyroglobulin, whereas GLP-1 and GIP are also derived from larger proteins through proteolytic cleavage. Thyroid hormone requires iodine to be synthesized, but neither GLP-1 nor GIP require minerals for their synthesis. The incretins are synthesized in the intestine, not the thyroid colloid. Insulin does not affect the synthesis of either set of hormones. Somatostatin usually represses hormone synthesis and does not induce the synthesis of both sets of proteins.
14. **The answer is A.** Friend A most likely has type 2 diabetes and is supplementing the insulin shots with possibly a DPP-4 inhibitor, which will extend the half-life of the incretins in circulation, which would

boost insulin production by the pancreas to supplement the insulin obtained from the injection. Another possible drug being taken by friend A is an incretin mimetic, which has a longer half-life in circulation than the naturally occurring incretins. Friend B, who most likely has type 1 diabetes, is unable to produce insulin (the β -cells of the pancreas have been destroyed via an autoimmune reaction), so taking drugs which increase the effectiveness of incretins cannot lead to increased levels of insulin in circulation. An individual with type 1 diabetes can still produce incretins in response to eating and would have functional DPP-4 activity. Since the friends are taking multivitamin pills it is unlikely either would have a zinc deficiency.

15. **The answer is D.** While GLP-1, insulin, and GH are all derived from a larger propeptide, the cleavage of the propeptide occurs in the cytoplasm and not the lysosome. The maturation of thyroid hormone, however, requires lysosomal proteases, which will not function if the pH of the lysosomes is >5 . Cortisol, derived from cholesterol, is not a polypeptide hormone.

The Biochemistry of Erythrocytes and Other Blood Cells

The cells of the blood are classified as **erythrocytes**, **leukocytes**, or **thrombocytes**. The erythrocytes (**red cells**) carry oxygen to the tissues and are the most numerous cells in the blood. The leukocytes (**white cells**) are involved in defense against infection, and the thrombocytes (**platelets**) function in blood clotting. All of the cells in the blood can be generated from hematopoietic stem cells in the bone marrow on demand. For example, in response to infection, leukocytes secrete **cytokines** called **interleukins** that stimulate the production of additional leukocytes to fight the infection. Decreased supply of oxygen to the tissues signals the kidney to release **erythropoietin**, a hormone that stimulates the production of red cells.

The red cell has limited metabolic function, owing to its lack of internal organelles. **Glycolysis** is the main energy-generating pathway, with lactate production regenerating NAD^+ for glycolysis to continue. The NADH produced in glycolysis is also used to reduce the ferric form of hemoglobin, **methemoglobin**, to the normal ferrous state. Glycolysis also leads to a side pathway in which **2,3-bisphosphoglycerate** is produced, which is a major allosteric effector for oxygen binding to hemoglobin (see Chapter 7). The **hexose monophosphate shunt** pathway generates **NADPH** to protect red cell membrane lipids and proteins from oxidation, through regeneration of reduced glutathione. **Heme synthesis** occurs in the precursors of red cells and is a complex pathway that originates from succinyl coenzyme A (succinyl CoA) and glycine. Mutations in any of the steps of heme synthesis lead to a group of diseases known collectively as **porphyrias**.

The red cell membrane must be highly deformable to allow it to travel throughout the capillary system in the body. This is because of a complex **cytoskeletal** structure that consists of the major proteins spectrin, ankyrin, and **band 3 protein**. Mutations in these proteins lead to improper formation of the membrane cytoskeleton, ultimately resulting in malformed red cells, **spherocytes**, in the circulation. Spherocytes have a shortened lifespan, leading to loss of blood cells.

When the body does not have sufficient red cells, the patient is said to be **anemic**. Anemia can result from many causes. **Nutritional deficiencies** of iron, folate, or **vitamin B12** prevent the formation of adequate numbers of red cells. **Mutations** in the genes that encode red cell metabolic **enzymes**, **membrane structural proteins**, and **globins** cause **hereditary anemias**. The appearance of red cells on a blood smear frequently provides clues to the cause of an anemia. Because the mutations that give rise to hereditary anemias also provide some protection against malaria, hereditary anemias are some of the most common genetic diseases known.

In humans, globin gene expression is altered during development, a process known as **hemoglobin switching**. The switch between the expression of one gene to another is regulated by transcription factor binding to the promoter regions of these genes. Current research is attempting to reactivate fetal hemoglobin genes to combat sickle cell disease and thalassemia.

THE WAITING ROOM

Lisa N., who has β^+ -thalassemia, complains of pain in her lower spine (see Chapters 13 and 14). A quantitative computed tomogram (CT) of the vertebral bodies of the lumbar spine shows evidence of an area of early spinal cord compression in the upper lumbar region. She is suffering from severe anemia, resulting in stimulation of production of red blood cell precursors (the erythroid mass) from the stem cells in her bone marrow. This expansion of marrow volume causes osteoporosis leading to compression

fractures in the lumbar spine area, which, in turn, causes pain. In addition to treatment of the osteoporosis, a program of regular blood transfusions is considered to reduce the marrow volume and maintain the oxygen-carrying capacity of circulating red blood cells. The results of special studies related to the genetic defect underlying her thalassemia are pending, although preliminary studies have shown that she has elevated levels of fetal hemoglobin, which, in part, moderates the manifestations of her disease. **Lisa N.**'s parents have returned to the clinic to discuss the results of these tests.

Edward R. is a 21-year-old college student who complains of feeling tired all the time. Two years previously he had had gallstones removed, which consisted mostly of bilirubin. His spleen is palpable, and jaundice (icterus) is evidenced by yellowing of the whites of his eyes. His hemoglobin is low (8 g/dL; reference value, 13.5 to 17.5 g/dL). A blood smear showed dark, rounded, abnormally small red cells called spherocytes as well as an increase in the number of circulating immature red blood cells known as reticulocytes.

I. Cells of the Blood

The blood, together with the bone marrow, makes up the organ system that makes a significant contribution to achieving homeostasis, the maintenance of the normal composition of the body's internal environment. Blood can be considered a liquid tissue consisting of water, proteins, and specialized cells. The most abundant cells in the blood are the erythrocytes or red blood cells, which transport oxygen to the tissues and contribute to buffering of the blood through the binding of protons by hemoglobin (see the material in Chapter 4, Section IV.B, and Chapter 7, Section VII). Red blood cells lose all internal organelles during the process of differentiation. The white blood cells (leukocytes) are nucleated cells present in blood that function in the defense against infection. The platelets (thrombocytes), which contain cytoplasmic organelles but no nucleus, are involved in the control of bleeding by contributing to normal thrombus (clot) formation within the lumen of the blood vessel. The average concentration of these cells in the blood of normal individuals is presented in Table 42.1.

TABLE 42.1 Normal Values of Blood Cell Concentrations in Adults

CELL TYPE	MEAN (CELLS/MM ³)
Erythrocytes	5.2 × 10 ⁶ (men); 4.6 × 10 ⁶ (women)
Neutrophils	4,300
Lymphocytes	2,700
Monocytes	500
Eosinophils	230
Basophils	40
Platelets	1.5 × 10 ⁵ –4.0 × 10 ⁵

A. Classification and Functions of Leukocytes and Thrombocytes

The leukocytes can be classified either as polymorphonuclear leukocytes (granulocytes) or mononuclear leukocytes, depending on the morphology of the nucleus in these cells. The mononuclear leukocyte has a rounded nucleus, whereas the polymorphonuclear leukocytes have a multilobed nucleus.

1. The Granulocytes

The granulocytes, so named because of the presence of secretory granules visible on staining, are the neutrophils, eosinophils, and basophils. When these cells are activated in response to chemical stimuli, the vesicle membranes fuse with the cell plasma membrane, resulting in the release of the granule contents (degranulation). The granules contain many cell-signaling molecules that mediate inflammatory processes. The granulocytes, in addition to displaying segmented nuclei (are polymorphonuclear), can be distinguished from each other by their staining properties (caused by different granular contents) in standard hematological blood smears: Neutrophils stain pink, eosinophils stain red, and basophils stain blue.

Neutrophils are phagocytic cells that migrate rapidly to areas of infection or tissue damage. As part of the response to acute infection, neutrophils engulf foreign bodies and destroy them, in part, by initiating the respiratory burst (see Chapter 25). The respiratory burst creates oxygen radicals that rapidly destroy the foreign material found at the site of infection.

A primary function of eosinophils is to protect against parasites such as worms and to remove fibrin during inflammation. The eosinophilic granules are lysosomes containing hydrolytic enzymes and cationic proteins, which are toxic to parasitic worms. Increased eosinophils are also present in asthma and allergic responses, autoimmune diseases, and some cancers. Elucidating the function of eosinophils is currently an active area of research.

Basophils, the least abundant of the leukocytes, participate in hypersensitivity reactions, such as allergic responses. Histamine, produced by the decarboxylation of histidine, is stored in the secretory granules of basophils. Release of histamine during basophil activation stimulates smooth muscle cell contraction and increases vascular permeability. The granules also contain enzymes such as proteases, β -glucuronidase, and lysophospholipase. These enzymes degrade microbial structures and assist in the remodeling of damaged tissue.

2. Mononuclear Leukocytes

The mononuclear leukocytes consist of various classes of lymphocytes and the monocytes. Lymphocytes are small, round cells that were originally identified in lymph fluid. These cells have a high ratio of nuclear volume to cytoplasmic volume and are the primary antigen (foreign body)-recognizing cells. There are three major types of lymphocytes: T cells, B cells, and NK cells. The precursors of T cells (thymus-derived lymphocytes) are produced in the bone marrow and then migrate to the thymus, where they mature before being released to the circulation. Several subclasses of T cells exist. These subclasses are identified by different surface membrane proteins, the presence of which correlate with the function of the subclass. Lymphocytes that mature in the bone marrow are the B cells, which secrete antibodies in response to antigen binding. The third class of lymphocytes is the natural killer cells (NK cells), which target virally infected and malignant cells for destruction.

Circulatory monocytes are the precursors of tissue macrophages. Macrophages (“large eaters”) are phagocytic cells that enter inflammatory sites and consume microorganisms and necrotic host cell debris left behind by granulocyte attack of the foreign material. Macrophages in the spleen play an important role in maintaining the oxygen-delivering capabilities of the blood by removing damaged red blood cells that have a reduced oxygen-carrying capacity.

3. The Thrombocytes

Platelets are heavily granulated disk-like cells that aid in intravascular clotting. Like the erythrocyte, platelets lack a nucleus. Their function is discussed in the following chapter. Platelets arise by budding of the cytoplasm of megakaryocytes, multinucleated cells that reside in the bone marrow.

B. Anemia

The major function of erythrocytes is to deliver oxygen to the tissues. To do this, a sufficient concentration of hemoglobin in the red blood cells is necessary for efficient oxygen delivery to occur. When the hemoglobin concentration falls below normal values (Table 42.2), the patient is classified as anemic. Anemias can be categorized based on red cell size and hemoglobin concentration. Red cells can be of normal size (normocytic), small (microcytic), or large (macrocytic). Cells containing a normal hemoglobin concentration are termed normochromic; those with decreased concentration are hypochromic. This classification system provides important diagnostic tools (Table 42.3) that enable one to properly classify, diagnose, and treat the anemia.

TABLE 42.3 Classification of the Anemias on the Basis of Red Cell Morphology

RED CELL MORPHOLOGY	FUNCTIONAL DEFICIT	POSSIBLE CAUSES
Microcytic, hypochromic	Impaired hemoglobin synthesis	Iron deficiency, mutation leading to thalassemia, lead poisoning
Macrocytic, normochromic	Impaired DNA synthesis	Vitamin B ₁₂ or folic acid deficiency, erythroleukemia
Normocytic, normochromic	Red cell loss	Acute bleeding, sickle cell disease, red cell metabolic defects, red cell membrane defects

A complete blood count (CBC) is ordered when a physician suspects a problem in the cellular composition of a patient's blood. The cells within the collected blood are counted and typed using an automated analyzer, based on flow cytometry (counting cells one at a time as they flow through a detector). As each cell flows through the machine, a laser shines light at the cell, which leads to predictable light scattering and absorbance depending on the cell type. Based on the light scattering and absorption pattern, the machine keeps track of the results of each cell that flows through the machine, leading to a very accurate count of each cell type present in the sample. The data from this analysis will include the total number of red cells per liter, the amount of hemoglobin in the red cells (in grams per liter), the hematocrit (the fraction of whole blood that consists of red blood cells), the MCV, the total number of white blood cells, as well as a count of the different types of white blood cells (neutrophils, lymphocytes, monocytes, eosinophils, and basophils).

An inherited deficiency in erythrocyte pyruvate kinase leads to hemolytic anemia (an anemia caused by the destruction of red blood cells; hemoglobin values typically drop to 4 to 10 g/dL in this condition, with normal values being 13.5 to 17.5 in males, or 11.5 to 15.5 in females). Because the amount of ATP formed from glycolysis can be decreased by 50%, red blood cell ion transporters cannot function effectively. The red blood cells tend to gain Ca^{2+} and lose K^+ and water. The water loss increases the intracellular hemoglobin concentration. With the increase in intracellular hemoglobin concentration, the internal viscosity of the cell is increased to the point that the cell becomes rigid and, therefore, more susceptible to damage by shear forces in the circulation. Once they are damaged, the red blood cells are removed from circulation, leading to the anemia. However, the effects of the anemia are frequently moderated by the twofold to threefold elevation in 2,3-BPG concentration that results from the blockage of the conversion of phosphoenolpyruvate to pyruvate. Because 2,3-BPG binding to hemoglobin decreases the affinity of hemoglobin for oxygen, the red blood cells that remain in circulation are highly efficient in releasing their bound oxygen to the tissues.

Other measurements used to classify the type of anemia present include the mean corpuscular volume (MCV) and the mean corpuscular hemoglobin concentration (MCHC). The MCV is the average volume of the red blood cell, expressed in femtoliters (10^{-15} L). Normal MCV values range from 80 to 100 fL. The MCHC is the average concentration of hemoglobin in each individual erythrocyte, expressed in grams per liter. The normal range is 32 to 37 g/L; a value of <32 g/L indicates hypochromic cells. Thus, microcytic, hypochromic red blood cells have an MCV of <80 and an MCHC of <32 . Macrocytic, normochromic cells have an MCV of >100 , with an MCHC between 32 and 37.

II. Erythrocyte Metabolism

A. The Mature Erythrocyte

To understand how the erythrocyte can carry out its major function a discussion of erythrocyte metabolism is required. Mature erythrocytes contain no intracellular organelles, so the metabolic enzymes of the red blood cell are limited to those found in the cytoplasm. In addition to hemoglobin, the cytosol of the red blood cell contains enzymes necessary for the prevention and repair of damage done by reactive oxygen species (see Chapter 25) and the generation of energy (Fig. 42.1). Erythrocytes can only generate adenosine triphosphate (ATP) by glycolysis (see Chapter 22). The ATP is used for ion transport across the cell membrane (primarily Na^+ , K^+ , and Ca^{++}), the phosphorylation of membrane proteins, and the priming reactions of glycolysis. Erythrocyte glycolysis also uses the Rapoport–Luebering shunt to generate 2,3-bisphosphoglycerate (2,3-BPG). Red cells contain 4 to 5 mM 2,3-BPG, compared with trace amounts in other cells. The trace amounts of 2,3-BPG found in cells other than erythrocytes are required for the phosphoglycerate mutase reaction of glycolysis, in which 3-phosphoglycerate is isomerized to 2-phosphoglycerate. As the 2,3-BPG is regenerated during each reaction cycle, it is required in only catalytic amounts. As has been discussed in more detail in Chapter 7, 2,3-BPG is a modulator of oxygen binding to hemoglobin that stabilizes the deoxy form of hemoglobin, thereby facilitating the release of oxygen to the tissues.

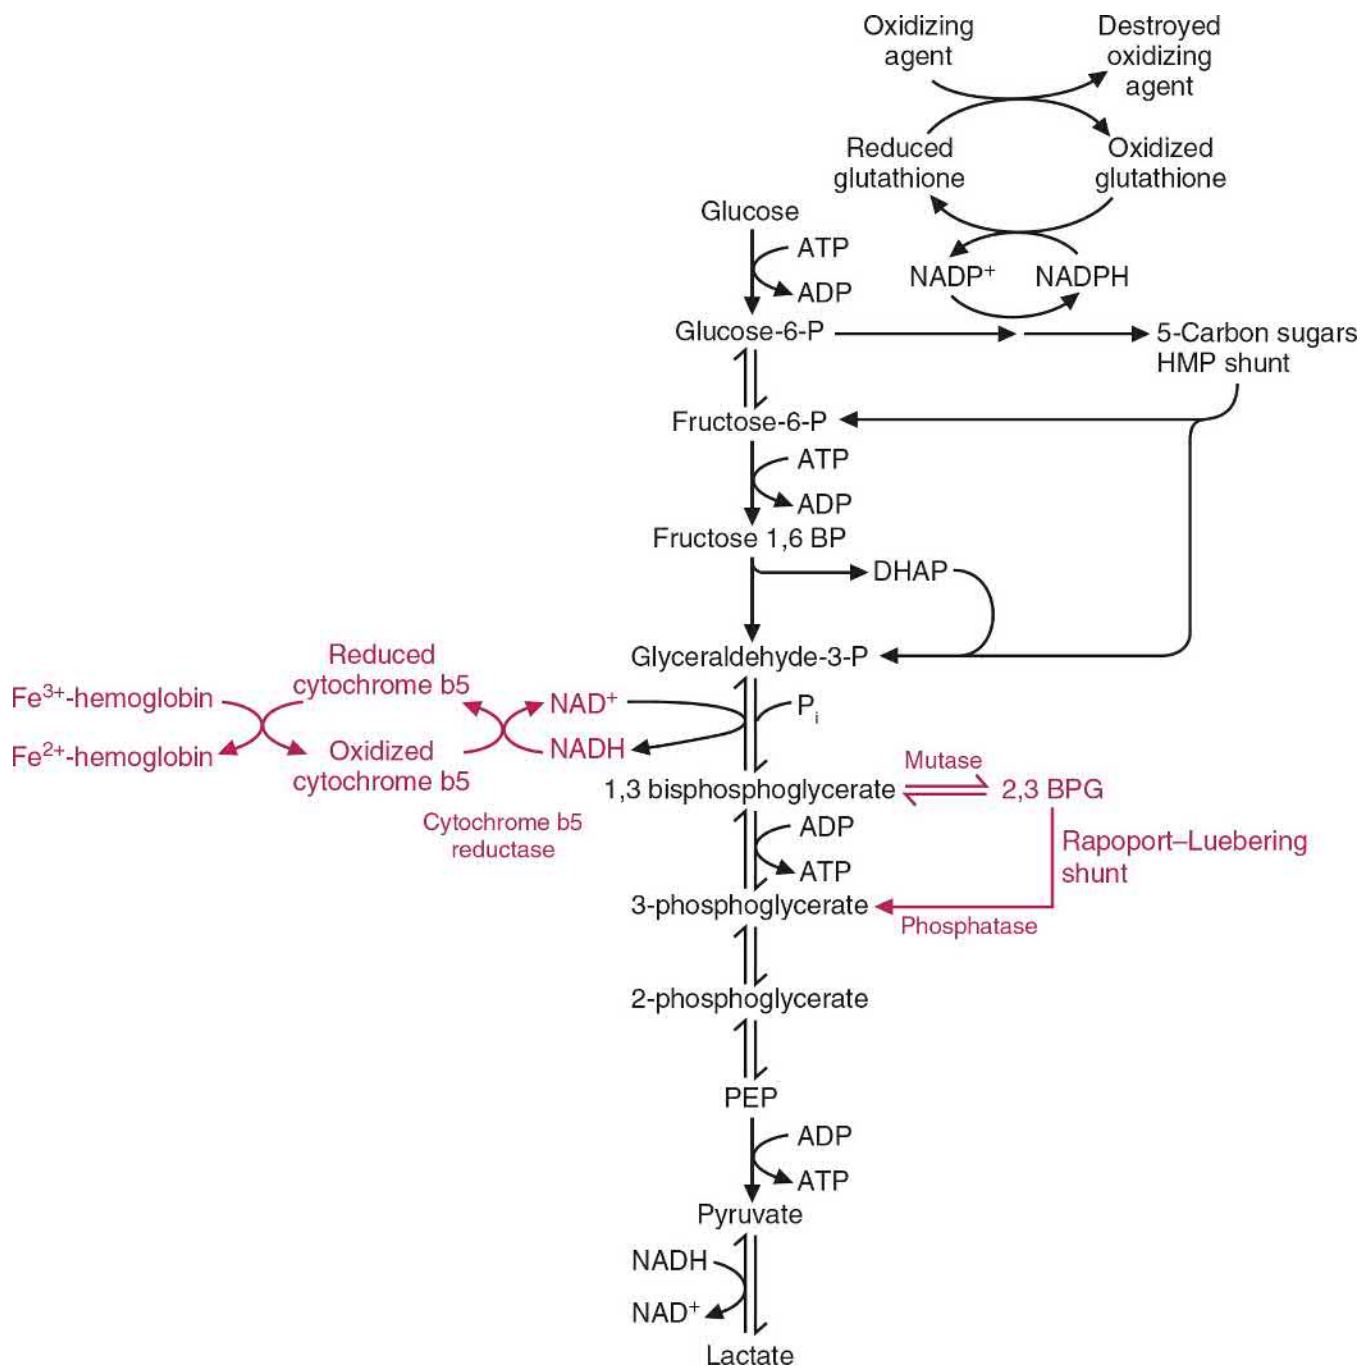

FIGURE 42.1 Overview of erythrocyte metabolism. Glycolysis is the major pathway, with branches for the hexose monophosphate (HMP) shunt (for protection against oxidizing agents) and the Rapoport–Luebering shunt (which generates 2,3-bisphosphoglycerate [2,3-BPG], which moderates oxygen binding to hemoglobin). The reduced nicotinamide adenine dinucleotide (NADH) generated from glycolysis can be used to reduce methemoglobin (Fe^{3+}) to normal hemoglobin (Fe^{2+}), or to convert pyruvate to lactate, so that NAD^+ can be regenerated and used for glycolysis. Pathways that are unique to the erythrocyte are indicated in red. ADP, adenosine diphosphate; ATP, adenosine triphosphate; DHAP, dihydroxyacetone phosphate; Fructose 1,6-BP, fructose 1,6-bisphosphate; Fructose 6-P, fructose 6-phosphate; Glucose 6-P, glucose 6-phosphate; Glyceraldehyde 3-P, glyceraldehyde 3-phosphate; P_i , inorganic phosphate; PEP, phosphoenolpyruvate.

Congenital methemoglobinemia, the presence of excess methemoglobin, is found in people with an enzymatic deficiency in cytochrome b_5 reductase or in people who have inherited hemoglobin M. In hemoglobin M, a single amino acid substitution in the heme-binding pocket stabilizes the ferric (Fe^{3+}) oxygen. Individuals with congenital methemoglobinemia appear cyanotic but have few clinical problems. Methemoglobinemia can be acquired by ingestion of certain oxidants such as nitrites, quinones, aniline, and sulfonamides. Acquired methemoglobinemia can be treated by the administration of reducing agents, such as ascorbic acid or methylene blue.

To bind oxygen, the iron of hemoglobin must be in the ferrous (+2) state. Reactive oxygen species can

oxidize the iron to the ferric (+3) state, producing methemoglobin. Some of the NADH produced by glycolysis is used to regenerate hemoglobin from methemoglobin by the NADH-cytochrome b_5 methemoglobin reductase system. Cytochrome b_5 reduces the Fe^{3+} of methemoglobin. The oxidized cytochrome b_5 is then reduced by a flavin-containing enzyme, cytochrome b_5 reductase (also called methemoglobin reductase), using NADH as the reducing agent.

Approximately 5% to 10% of the glucose metabolized by red blood cells is used to generate NADPH by way of the hexose monophosphate shunt. The NADPH is used to maintain glutathione in the reduced state. The glutathione cycle is the red blood cell's chief defense against damage to proteins and lipids by reactive oxygen species (see Chapter 25).

The enzyme that catalyzes the first step of the hexose monophosphate shunt is glucose 6-phosphate dehydrogenase (G6PD). The lifetime of the red blood cell correlates with G6PD activity. Lacking ribosomes, the red blood cell cannot synthesize new G6PD protein. Consequently, as the G6PD activity decreases, oxidative damage accumulates, leading to lysis of the erythrocyte. When red blood cell lysis (hemolysis) substantially exceeds the normal rate of red blood cell production, the number of erythrocytes in the blood drops below normal values, leading to hemolytic anemia.

G6PD deficiency is the most common enzyme deficiency in humans, probably, in part, because individuals with G6PD deficiency have resistance to malaria. The resistance to malaria counterbalances the deleterious effects of the deficiency. G6PD-deficient red cells have a shorter life span and are more likely to lyse under conditions of oxidative stress. When soldiers during the Korean War were given the antimalarial drug primaquine prophylactically, approximately 10% of the soldiers of African ancestry developed spontaneous anemia. Because the gene for **G6PD** is found on the X chromosome, these men had only one copy of a variant **G6PD** gene.

B. The Erythrocyte Precursor Cells and Heme Synthesis

1. Heme Structure

Heme consists of a porphyrin ring coordinated with an atom of iron (Fig. 42.2). Four pyrrole rings are joined by methenyl bridges ($=CH-$) to form the porphyrin ring (see Fig. 7.12). Eight side chains serve as substituents on the porphyrin ring, two on each pyrrole. These side chains may be acetate (A), propionate (P), methyl (M), or vinyl (V) groups. In heme, the order of these groups is M V M V M P P M. This order, in which the position of the methyl group is reversed on the fourth ring, is characteristic of the porphyrins of the type III series, the most abundant in nature.

FIGURE 42.2 Structure of heme. The side chains can be abbreviated as MVMVMPPM. M, methyl (-CH₃); P, propionate (-CH₂-CH₂-COO⁻); V, vinyl (-CH=CH₂).

Heme is the most common porphyrin found in the body. It is complexed with proteins to form hemoglobin, myoglobin, and the cytochromes (see Chapters 7 and 24), including cytochrome P450 (see Chapter 25).

All known **G6PD** variant genes contain small in-frame deletions or missense mutations. The corresponding proteins, therefore, have decreased stability or lowered activity, leading to a reduced half-life or life span for the red cell. No mutations have been found that result in complete absence of G6PD. Based on studies with knockout mice, those mutations would be expected to result in embryonic lethality.

2. Synthesis of Heme

Heme is synthesized from glycine and succinyl CoA (Fig. 42.3), which condense in the initial reaction to form δ -aminolevulinic acid (δ -ALA) (Fig. 42.4). The enzyme that catalyzes this reaction, δ -ALA synthase, requires the participation of pyridoxal phosphate, as the reaction is an amino acid decarboxylation reaction (glycine is decarboxylated; see Chapter 37).

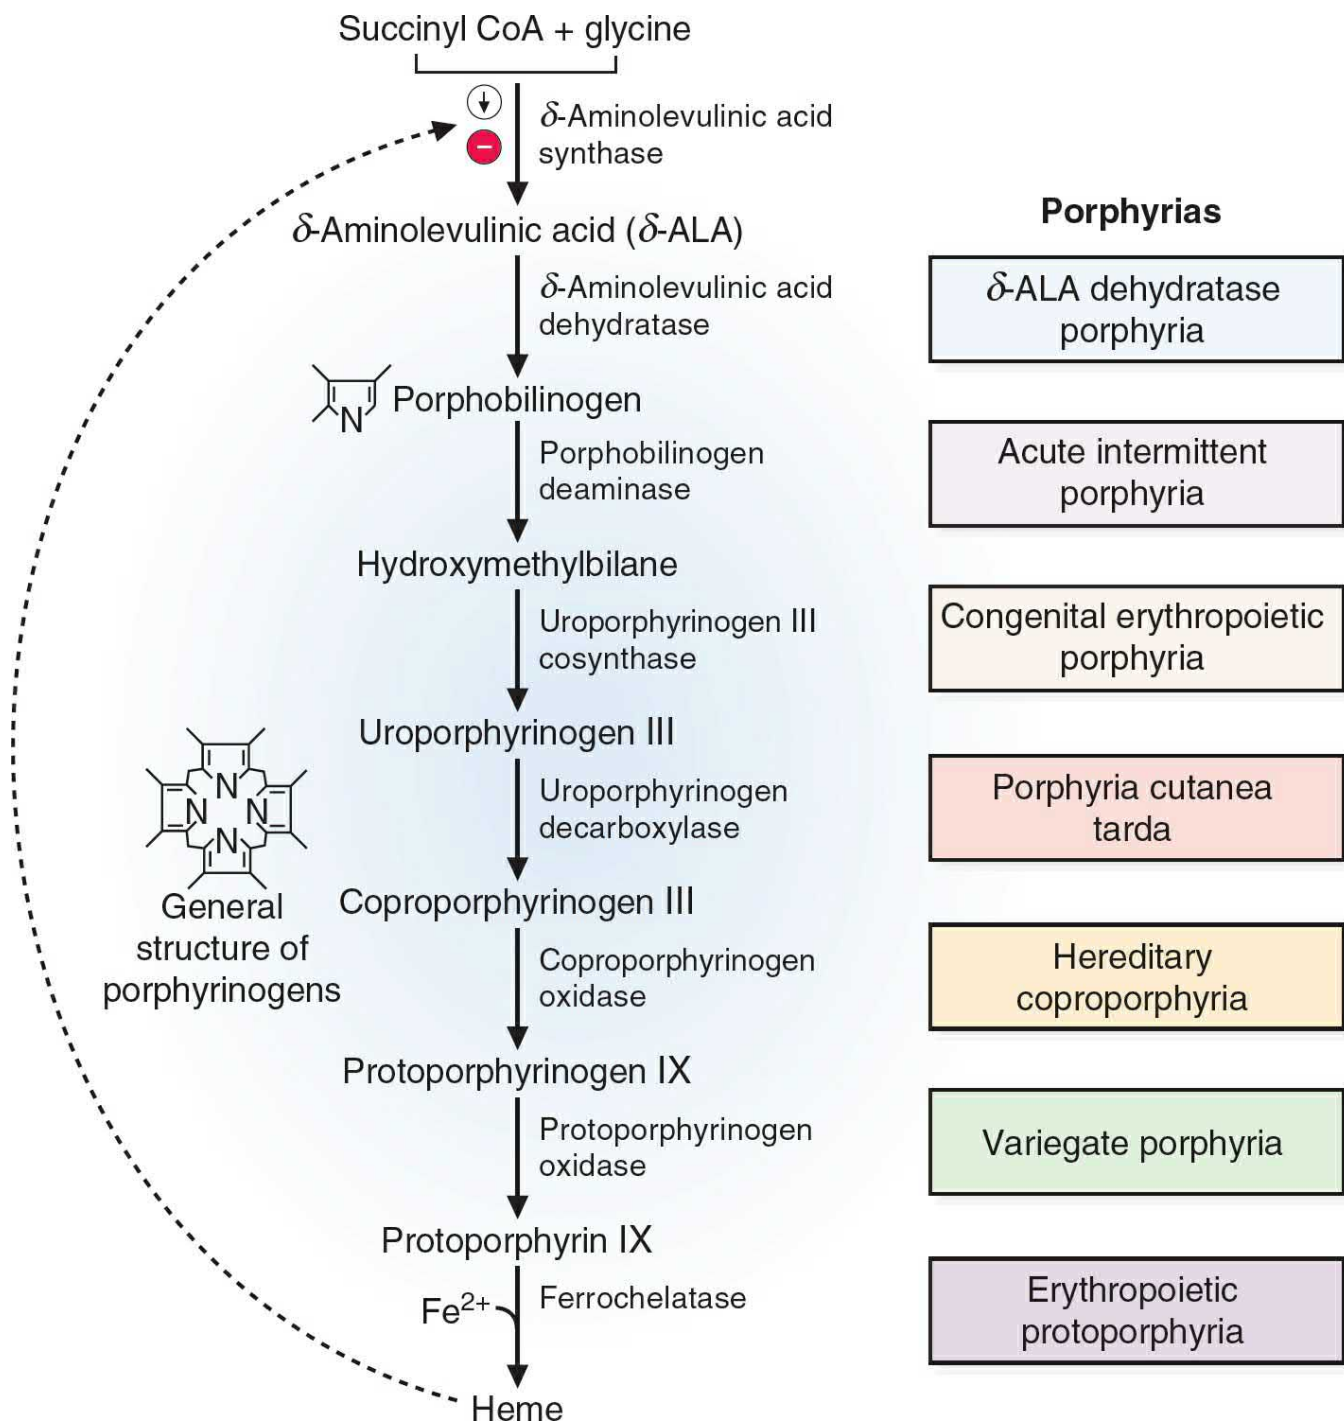

FIGURE 42.3 Synthesis of heme. To produce one molecule of heme, eight molecules each of glycine and succinyl coenzyme A (succinyl CoA) are required. A series of porphyrinogens are generated in sequence. Finally, iron is added to produce heme. Heme regulates its own production by repressing the synthesis of δ -aminolevulinic acid (δ -ALA) synthase (\downarrow) and by directly inhibiting the activity of this enzyme ($-$). Deficiencies of enzymes in the pathway result in a series of diseases known as porphyrias (listed on the right, beside the deficient enzyme).

Pyridoxine (vitamin B₆) deficiencies are often associated with a microcytic, hypochromic anemia. Why would a B₆ deficiency result in small (microcytic), pale (hypochromic) red blood cells?

The next reaction of heme synthesis is catalyzed by δ -ALA dehydratase, in which two molecules of δ -ALA condense to form the pyrrole, porphobilinogen (Fig. 42.5). Four of these pyrrole rings condense to form a linear chain and then a series of porphyrinogens. The side chains of these porphyrinogens initially contain acetate (A) and propionate (P) groups. The acetyl groups are decarboxylated to form methyl groups. Then the first two propionyl side chains are decarboxylated and oxidized to vinyl groups, forming a protoporphyrinogen. The methylene bridges are subsequently oxidized to form protoporphyrin IX (see Fig. 42.3). Heme is red and is responsible for the color of red blood cells and of muscles that contain a large number of mitochondria.

2 δ -ALA

Porphobilinogen
(a pyrrole)

FIGURE 42.5 Two molecules of δ -aminolevulinic acid (δ -ALA) condense to form porphobilinogen.

 δ -ALA dehydratase, which contains zinc, and ferrochelatase are inactivated by lead. Thus, in lead poisoning, δ -ALA and protoporphyrin IX accumulate, and the production of heme is decreased. Anemia results from a lack of hemoglobin, and energy production decreases because of the lack of cytochromes for the electron transport chain.

In the final step of the pathway, iron (as Fe^{2+}) is incorporated into protoporphyrin IX in a reaction catalyzed by ferrochelatase (also known as heme synthase).

3. Source of Iron

Iron, which is obtained from the diet, has a US Recommended Dietary Allowance (RDA) of 10 mg for men and postmenopausal women and 15 mg for premenopausal women. The average daily US diet contains 10 to 50 mg of iron. However, only 10% to 15% is normally absorbed, and iron deficiencies are fairly common. The iron in meats is in the form of heme, which is readily absorbed. The nonheme iron in plants is not as readily absorbed, in part because plants often contain oxalates, phytates, tannins, and other phenolic compounds that chelate or form insoluble precipitates with iron, preventing its absorption. Conversely, vitamin C (ascorbic acid) increases the uptake of nonheme iron from the digestive tract. The uptake of iron is also increased in times of need by mechanisms that are not yet understood. Iron is absorbed in the ferrous (Fe^{2+}) state (Fig. 42.6) but is oxidized to the ferric state by a ferroxidase known as ceruloplasmin (a copper-containing enzyme) for transport through the body.

FIGURE 42.6 Iron metabolism. Iron is absorbed from the diet, transported in the blood by transferrin, stored in ferritin, and used for the synthesis of cytochromes, iron-containing enzymes, hemoglobin, and myoglobin. It is lost from the body with bleeding and sloughed-off cells, sweat, urine, and feces. Hemosiderin is the protein in which excess iron is stored. Small amounts of ferritin enter the blood and can be used to measure the adequacy of iron stores. RBC, red blood cells; RE, reticuloendothelial.

 In a B₆ deficiency, the rate of heme production is slow because the first reaction in heme synthesis requires pyridoxal phosphate (see Fig. 42.4). Thus, less heme is synthesized, causing red blood cells to be small and pale. Iron stores are usually elevated.

 Porphyrins are a group of rare inherited disorders resulting from deficiencies of enzymes in the pathway for heme biosynthesis (see Fig. 42.3). Intermediates of the pathway accumulate and may have toxic effects on the nervous system that cause neuropsychiatric symptoms. When porphyrinogens accumulate, they may be converted by light to porphyrins, which react with molecular oxygen to form oxygen radicals. These radicals may cause severe damage to the skin. Thus, individuals with excessive production of porphyrins are photosensitive. The scarring and increased growth of facial hair seen in some porphyrias may have contributed to the rise of the werewolf legends.

Because free iron is toxic, it is usually found in the body bound to proteins (see Fig. 42.6). Iron is carried in the blood (as Fe³⁺) by the protein apotransferrin, with which it forms a complex known as transferrin. Transferrin is usually only one-third saturated with iron. The total iron-binding capacity of blood, due mainly to its content of transferrin, is approximately 300 µg/dL. Transferrin, with bound iron, binds to the transferrin receptor on the cell surface and the complex is internalized into the cell. The internalized membrane develops into an endosome, with a slightly acidic pH. The iron is reduced by a membrane-bound oxidoreductase and the ferrous iron is transported out of the endosome into the cytoplasm via the divalent metal ion transporter 1 (DMT-1). Once in the cytoplasm, the iron is shunted to necessary enzymes, or can be oxidized and bind to ferritin for long-term storage.

 An inherited mutation in SLC11A2 (the gene encoding DMT-1) leads to an iron-deficiency anemia, as indicated by a refractory hypochromic microcytic anemia. The iron is trapped in endosomal vesicles and cannot be released to bind to ferritin or used in other necessary biosynthetic reactions. This leads to reduced heme synthesis, reduced globin synthesis, and anemia.

Storage of iron occurs in most cells but especially those of the liver, spleen, and bone marrow. In these cells, the storage protein, apoferritin, forms a complex with iron (Fe³⁺) known as ferritin. Normally, ferritin is present in the blood in small amounts. The level increases, however, as iron stores increase. Therefore, the amount of ferritin in the blood is the most sensitive indicator of the amount of iron in the body's stores.

Iron can be drawn from ferritin stores, transported in the blood as transferrin, and taken up via receptor-mediated endocytosis by cells that require iron (e.g., by reticulocytes that are synthesizing hemoglobin). When excess iron is absorbed from the diet, it is stored as hemosiderin, a form of ferritin complexed with additional iron that cannot be readily mobilized.

 The iron lost by adult men (~1 mg/day) by desquamation of the skin and in bile, feces, urine, and sweat is replaced by iron absorbed from the diet. Men are not as likely to suffer from iron deficiencies as premenopausal adult women, who also lose iron during menstruation and who must supply iron to meet the needs of a growing fetus during pregnancy. If a man eating a Western diet has iron-deficiency anemia, his physician should suspect bleeding from the gastrointestinal tract as a result of ulcers or colon cancer.

4. Regulation of Heme Synthesis

Heme regulates its own synthesis by mechanisms that affect the first enzyme in the pathway, δ-ALA synthase (see Fig. 42.3). Heme represses the synthesis of this enzyme and also directly inhibits the activity of the enzyme (an allosteric modifier). Thus, heme is synthesized when heme levels fall. As heme levels rise, the rate of heme synthesis decreases.

Heme also regulates the synthesis of hemoglobin by stimulating the synthesis of the protein globin. Heme maintains the ribosomal initiation complex for globin synthesis in an active state (see Chapter 15).

 Drugs, such as phenobarbital, induce enzymes of the drug-metabolizing systems of the endoplasmic reticulum that contain cytochrome P450. Because heme is used for synthesis of cytochrome P450, free heme levels fall and δ-ALA synthase is induced to increase the rate of heme synthesis.

5. Degradation of Heme

Heme is degraded to form bilirubin, which is conjugated with glucuronic acid and excreted in the bile (Fig. 42.7). Although heme from cytochromes and myoglobin also undergoes conversion to bilirubin, the major source of this bile pigment is hemoglobin. After red blood cells reach the end of their lifespan (~120 days), they

are phagocytosed by cells of the reticuloendothelial system. Globin is cleaved to its constituent amino acids, and iron is returned to the body's iron stores. Heme is oxidized and cleaved to produce carbon monoxide and biliverdin (Fig. 42.8). Biliverdin is reduced to bilirubin, which is transported to the liver complexed with serum albumin.

FIGURE 42.7 Overview of heme degradation. Heme is degraded to bilirubin, carried in the blood by albumin, conjugated to form the diglucuronide in the liver, and excreted in the bile. The iron is returned to the body's iron stores. RBC, red blood cells; RES, reticuloendothelial system.

Heme

Biliverdin IX α

Bilirubin IX α

FIGURE 42.8 Conversion of heme to bilirubin. A methylene bridge in heme is cleaved, releasing carbon monoxide (CO) and iron. Then the center methylene bridge is reduced. NADP, nicotinamide adenine dinucleotide phosphate.

In the liver, bilirubin is converted to a more water-soluble compound by reacting with UDP-glucuronate to form bilirubin monoglucuronide, which is converted to the diglucuronide (see Fig. 27.12). This conjugated form of bilirubin is excreted into the bile.

In the intestine, bacteria deconjugate bilirubin diglucuronide and convert the bilirubin to urobilinogen (see Fig. 42.7). Some urobilinogen is absorbed into the blood and excreted in the urine. However, most of the urobilinogen is oxidized to urobilin, such as stercobilin, and excreted in the feces. These pigments give feces their brown color.

III. The Red Blood Cell Membrane

Under the microscope, the red blood cell appears to be a red disc with a pale central area (biconcave disc) (Fig. 42.9). The biconcave disc shape (as opposed to a spherical shape) serves to facilitate gas exchange across the cell membrane. The membrane proteins that maintain the shape of the red blood cell also allow the red blood cell to traverse the capillaries with very small luminal diameters to deliver oxygen to the tissues. The interior diameters of many capillaries are smaller than the approximately 7.5- μm diameter of the red cell. Furthermore, in passing through the kidney, red blood cells traverse hypertonic areas that are up to six times the normal isotonicity, and back again, causing the red cell to shrink and expand during its travels. The spleen is the organ responsible for determining the viability of the red blood cells. Erythrocytes pass through the spleen 120 times per day. The elliptical passageways through the spleen are approximately 3 μm in diameter, and normal red cells traverse them in approximately 30 seconds. Thus, to survive in the circulation, the red cell must be highly deformable. Damaged red cells that are no longer deformable become trapped in the passages in the spleen, where they are destroyed by macrophages. The reason for the erythrocyte's deformability lies in its shape and in the organization of the proteins that make up the red blood cell membrane.

A

B

FIGURE 42.9 The shape of the red blood cell. **A.** Wright-stained cells, displaying the pale staining in the center. **B.** Scanning electron micrograph, showing the biconcave disc structure of the cells. The stacks of erythrocytes in this preparation (collected from a blood tube) are not unusual. (Reprinted with permission from Cohen BJ, Wood DL. *Memmler's the Human Body in Health and Disease*. 9th ed. Lippincott Williams & Wilkins, 2000:230. [Panel A]; and The Centers for Disease Control and Prevention. Public Health Image Library/Janice Haney Carr, ID 7315, 2005. [Panel B].)

In an iron deficiency, what characteristics will be evident in the blood?

The surface area of the red cell is approximately $140 \mu\text{m}^2$, which is greater than the surface of a sphere needed to enclose the contents of the red cell ($98 \mu\text{m}^2$). The presence of this extra membrane and the cytoskeleton that supports it allows the red cell to be stretched and deformed by mechanical stresses as the cell passes through narrow vascular beds. On the cytoplasmic side of the membrane, proteins form a two-dimensional lattice that gives the red cell its flexibility (Fig. 42.10). The major proteins are spectrin, actin, band 4.1, band 4.2, and ankyrin. Spectrin, the major protein, is a heterodimer composed of α - and β -subunits wound around each other. The dimers self-associate at the heads. At the opposite end of the spectrin dimers, actin and band 4.1 bind near to each other. Multiple spectrins can bind to each actin filament, resulting in a branched membrane cytoskeleton.

A

B

FIGURE 42.10 A generalized view of the erythrocyte cytoskeleton. **A.** The major protein, spectrin, is linked to the plasma membrane either through interactions with ankyrin and band 3, or with actin, band 4.1, and glycophorin. Other proteins in this complex, not shown, are tropomyosin and adducin. **B.** A view from inside the cell, looking up at the cytoskeleton. This view displays the cross-linking of the spectrin dimers to actin and band 3 anchor sites.

Defects in erythrocyte cytoskeletal proteins lead to hemolytic anemia. Shear stresses in the circulation result in the loss of pieces of the red cell membrane. As the membrane is lost, the red blood cell becomes more spherical and loses its deformability. As these cells become more spherical, they are more likely to lyse in response to mechanical stresses in the circulation, or to be trapped and destroyed in the spleen.

The spectrin cytoskeleton is connected to the membrane lipid bilayer by ankyrin, which interacts with β -spectrin and the integral membrane protein, band 3. Band 4.2 helps to stabilize this connection. Band 4.1 anchors the spectrin skeleton with the membrane by binding the integral membrane protein glycophorin C and the actin complex, which has bound multiple spectrin dimers.

When the red blood cell is subjected to mechanical stress, the spectrin network rearranges. Some spectrin molecules become uncoiled and extended; others become compressed, thereby changing the shape of the cell, but not its surface area.

The mature erythrocyte cannot synthesize new membrane proteins or lipids. However, membrane lipids can be freely exchanged with circulating lipoprotein lipids. The glutathione system protects the proteins and lipids from oxidative damage.

The unusual names for some erythrocyte membrane proteins, such as band 4.1, arose through analysis of red blood cell membranes by polyacrylamide gel electrophoresis. The stained bands observed in the gel were numbered according to molecular weight (band 1, band 2, etc.), and as functions were assigned to the proteins, more common names were assigned to the proteins (e.g., spectrin is actually band 1).

Iron deficiency will result in a microcytic, hypochromic anemia. Red blood cells will be small and pale. In contrast to a vitamin B₆ deficiency, which also results in a microcytic, hypochromic anemia, iron stores are low in an iron-deficiency anemia.

IV. Hematopoiesis

The various types of cells (lineages) that make up the blood are constantly being produced in the bone marrow. All cell lineages are descended from hematopoietic stem cells, cells that are renewable throughout the life of the host. The population of hematopoietic stem cells is quite small. Estimates vary between 1 and 10 per 10⁵ bone marrow cells. In the presence of the appropriate signals, hematopoietic stem cells proliferate, differentiate, and mature into any of the types of cells that make up the blood (Fig. 42.11).

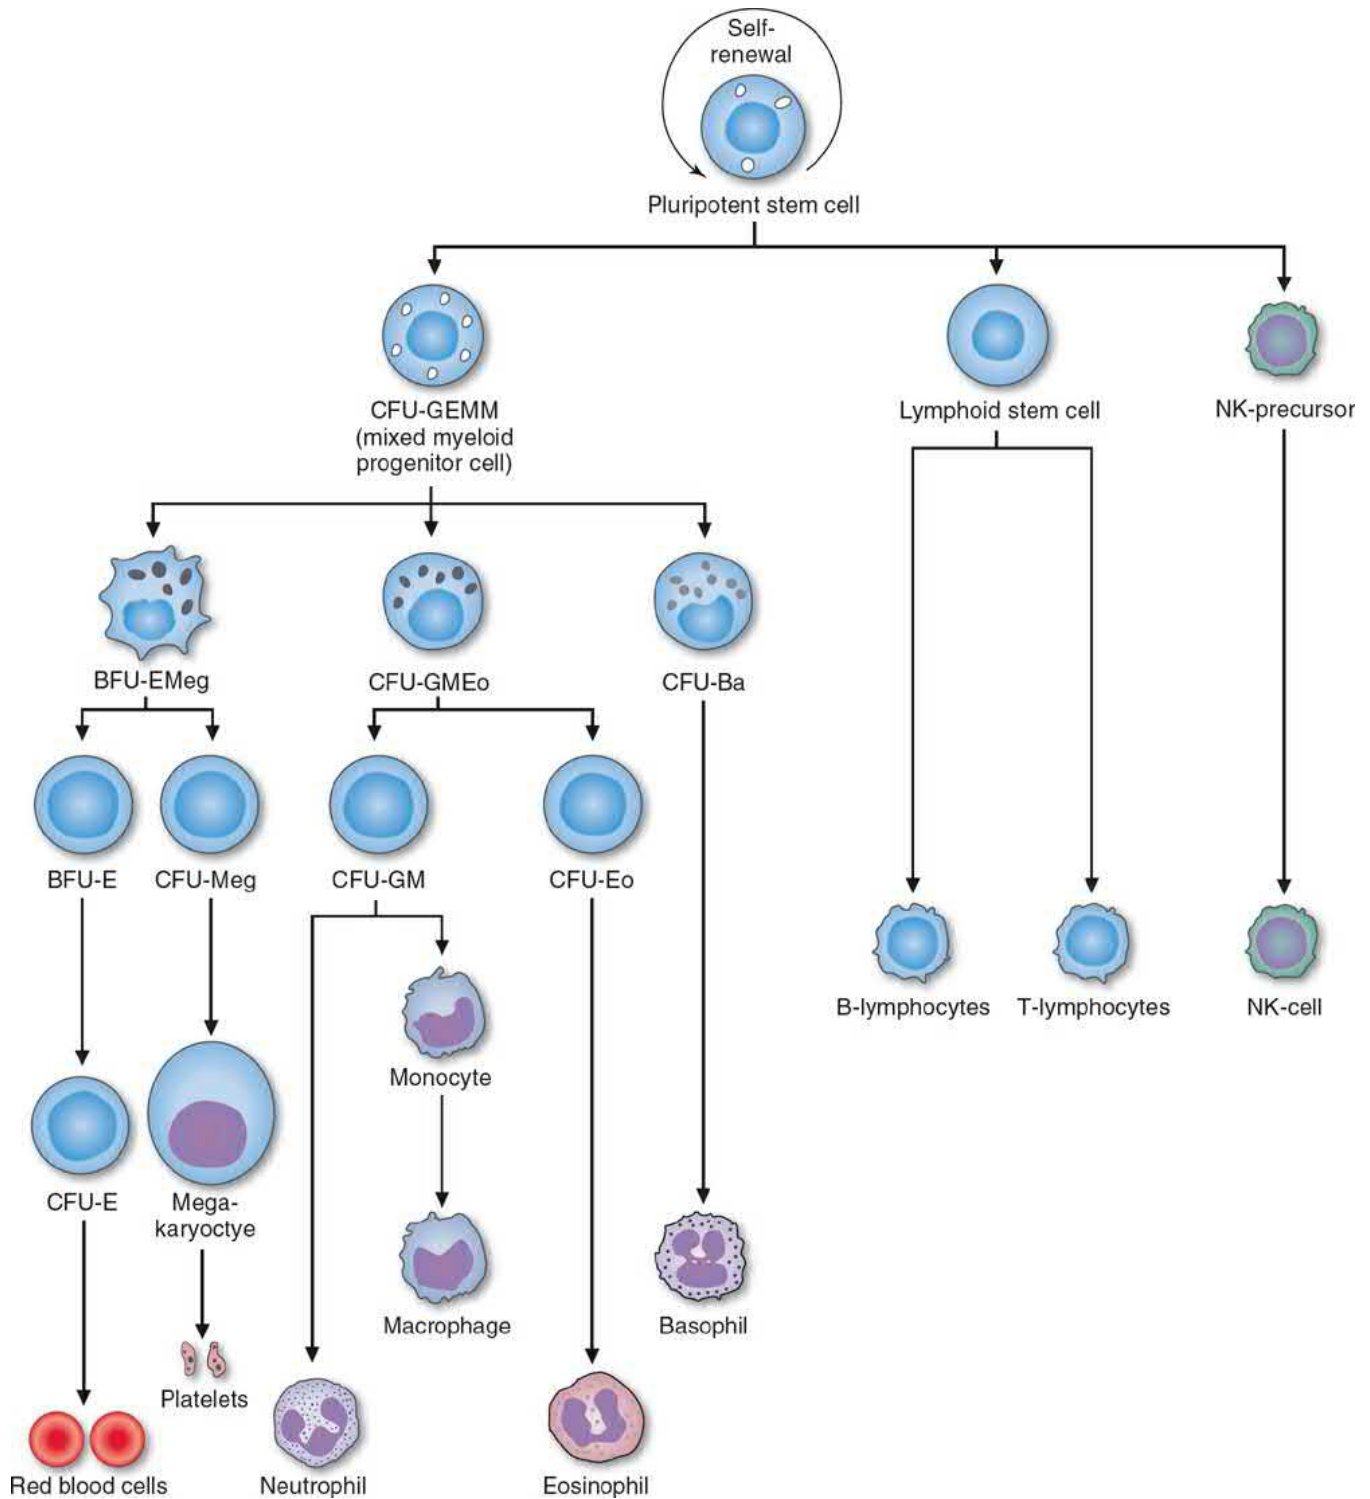

FIGURE 42.11 The hematopoietic tree. All blood cells arise from the self-renewing pluripotent stem cell. Different cytokines are required at each step for these events to occur. BFU, burst-forming unit; CFU, colony-forming unit.

 Populations of hematopoietic cells enriched with stem cells can be isolated by fluorescence-activated cell sorting, based on the expression of specific cell-surface markers. Increasing the population of stem cells in cells used for a bone marrow transplantation increases the chances of success of the transplantation.

Hematopoietic differentiation is hierarchical. The number of fates a developing blood cell may adopt becomes progressively restricted. Hematopoietic progenitors are designated colony-forming unit–lineage or colony-forming unit–erythroid (CFU-E). Progenitors that form very large colonies are termed burst-forming units.

A. Cytokines and Hematopoiesis

Developing progenitor cells in the marrow grow in proximity with marrow stromal cells. These include fibroblasts, endothelial cells, adipocytes, and macrophages. The stromal cells form an extracellular matrix and secrete growth factors that regulate hematopoietic development.

Leukemias, malignancies of the blood, arise when a differentiating hematopoietic cell does not complete its developmental program but remains in an immature, proliferative state. Leukemias have been found in every hematopoietic lineage.

The hematopoietic growth factors have multiple effects. An individual growth factor may stimulate proliferation, differentiation, and maturation of the progenitor cells and also may prevent apoptosis. These factors also may activate various functions within the mature cell. Some hematopoietic growth factors act on multiple lineages, whereas others have more limited targets.

Most hematopoietic growth factors are recognized by receptors belonging to the cytokine receptor superfamily. Binding of ligand to receptor results in receptor aggregation, which induces phosphorylation of Janus kinases (JAKs). The JAKs are a family of cytoplasmic tyrosine kinases that are active when phosphorylated (see Chapter 10, Section XII.B, and Fig. 10.16). The activated JAKs then phosphorylate the cytokine receptor. Phosphorylation of the receptor creates docking regions where additional signal transduction molecules bind, including members of the signal transducer and activator of transcription (STAT) family of transcription factors. The JAKs phosphorylate the STATs, which dimerize and translocate to the nucleus, where they activate target genes. Additional signal transduction proteins bind to the phosphorylated cytokine receptor, leading to activation of the Ras/Raf/MAP kinase pathways. Other pathways are also activated, some of which lead to an inhibition of apoptosis (see Chapter 17).

In X-linked severe combined immunodeficiency disease (SCID), the most common form of SCID, circulating mature T lymphocytes are not formed, and therefore B-lymphocytes are not active. The affected gene encodes the γ -chain of the interleukin 2 receptor. Mutant receptors are unable to activate JAK3, and the cells are unresponsive to the cytokines that stimulate growth and differentiation. Recall also that adenosine deaminase deficiency (see Chapter 39), which is not X-linked, also leads to a form of SCID, but for different reasons.

The response to cytokine binding is usually transient because the cell contains multiple negative regulators of cytokine signaling. The family of suppressor of cytokine signaling (SOCS) proteins is induced by cytokine binding. One member of the family binds to the phosphorylated receptor and prevents the docking of signal transduction proteins. Other SOCS proteins bind to JAKs and inhibit them. Whether SOCS inhibition of JAKs is a consequence of steric inhibition or whether SOCS recruit phosphatases that then dephosphorylate the JAKs (Fig. 42.12) is uncertain.

FIGURE 42.12 Cytokine signaling through the JAK (Janus kinase)/STAT (signal transducer and activator of transcription) pathway. (1) Cytokine binding to receptors initiates dimerization and activation of the JAK kinase, which phosphorylates the receptor on tyrosine residues. (2) STAT proteins bind to the activated receptors and are themselves phosphorylated. (3) Phosphorylated STAT proteins dimerize, travel to the nucleus, and initiate gene transcription. (4) One family of proteins whose synthesis is stimulated by STATs is the SOCS (suppressor of cytokine signaling) family, which inhibits further activation of STAT proteins (5) by a variety of mechanisms. GF, growth factor.

SHP-1 is a tyrosine phosphatase found primarily in hematopoietic cells that is necessary for proper development of myeloid and lymphoid lineages. Its function is to dephosphorylate JAK2, thereby inactivating it.

 Families have been identified whose members have a mutant erythropoietin (Epo) receptor that is unable to bind SHP-1. Erythropoietin is the hematopoietic cytokine that stimulates production of red blood cells. Individuals with the mutant Epo receptor have a higher than normal percentage of red blood cells in the circulation because the mutant Epo receptor cannot be deactivated by SHP-1. Erythropoietin causes sustained activation of JAK2 and STAT 5 in these cases.

STATs are also inactivated. The **protein inhibitors of activated STAT (PIAS)** family of proteins bind to phosphorylated STATs and prevent their dimerization or promote the dissociation of STAT dimers. STATs also may be inactivated by dephosphorylation, although the specific phosphatases have not yet been identified, or by targeting activated STATs for proteolytic degradation.

B. Erythropoiesis

The production of red cells is regulated by the demands of oxygen delivery to the tissues. In response to reduced tissue oxygenation, the kidney releases the hormone erythropoietin, which stimulates the multiplication and maturation of erythroid progenitors. The progression along the erythroid pathway begins with the stem cell and passes through the mixed myeloid progenitor cell (CFU-GEMM, colony-forming unit–granulocyte, erythroid, monocyte, megakaryocyte), burst-forming unit–erythroid (BFU-E), colony-forming unit–erythroid (CFU-E), and to the first recognizable red cell precursor, the normoblast. Each normoblast undergoes four more cycles of cell division. During these four cycles, the nucleus becomes smaller and more condensed. After the last division, the nucleus is extruded. The red cell at this state is called a reticulocyte. Reticulocytes still retain ribosomes and mRNA and are capable of synthesizing hemoglobin. They are released from the bone marrow and circulate for 1 to 2 days. Reticulocytes mature in the spleen, where the ribosomes and mRNA are lost (Fig. 42.13).

FIGURE 42.13 Erythropoietin stimulation of erythrocyte maturation. BFU, burst-forming unit; CFU, colony-forming unit; CFU-GEMM, colony-forming unit–granulocyte, erythroid, monocyte, megakaryocyte.

 Perturbed JAK/STAT signaling is associated with development of lymphoid and myeloid leukemias, severe congenital neutropenia (a condition in which levels of circulating neutrophils are severely reduced), and Fanconi anemia, which is characterized by bone marrow failure and increased susceptibility to malignancy.

 A complication of sickle cell disease is an increased formation of gallstones. A sickle cell crisis accompanied by the intravascular destruction of red blood cells (hemolysis) experienced by patients with sickle cell disease, such as **Will S.**, increases the amount of unconjugated bilirubin that is transported to the liver. If the concentration of this unconjugated bilirubin exceeds the capacity of the hepatocytes to conjugate it to the more soluble diglucuronide through interaction with hepatic UDP-glucuronate, both the total and the unconjugated bilirubin levels in the blood increase. More unconjugated bilirubin is then secreted by the liver into the bile. The increase in unconjugated bilirubin (which is not very water-soluble) results in its precipitation within the gallbladder lumen, leading to the formation of pigmented (calcium bilirubinate) gallstones.

C. Nutritional Anemias

Each person produces approximately 10^{12} red blood cells per day. Because so many cells must be produced, nutritional deficiencies in iron, vitamin B₁₂, and folate prevent adequate red blood cell formation. The physical appearance of the cells in the case of a nutritional anemia frequently provides a clue as to the nature of the deficiency.

In the case of iron deficiency, the cells are smaller and paler than normal. The lack of iron results in decreased heme synthesis, which in turn affects globin synthesis. Maturing red cells following their normal developmental program divide until their hemoglobin has reached the appropriate concentration. Iron (and hemoglobin)-deficient developing red blood cells continue dividing past their normal stopping point, resulting in small (microcytic) red cells. The cells are also pale, because of the lack of hemoglobin, compared with normal cells (thus, a pale, microcytic anemia results).

Deficiencies of folate or vitamin B₁₂ can cause megaloblastic anemia, in which the cells are larger than normal. Folate and B₁₂ are required for DNA synthesis (see Chapters 38 and 39). When these vitamins are deficient, DNA replication and nuclear division do not keep pace with the maturation of the cytoplasm. Consequently, the nucleus is extruded before the requisite number of cell divisions has taken place, and the cell volume is greater than it should be, and fewer blood cells are produced.

V. Hemoglobinopathies, Hereditary Persistence of Fetal Hemoglobin, and Hemoglobin Switching

A. Hemoglobinopathies: Disorders in the Structure or Amount of the Globin Chains

More than 700 different mutant hemoglobins have been discovered. Most arise from a single base substitution, resulting in a single amino acid replacement. Many have been discovered during population screenings and are not clinically significant. However, in patients with hemoglobin S (HbS, sickle cell anemia), the most common hemoglobin mutation, the amino acid substitution has a devastating effect in the homozygote (see **Will S.** in Chapter 6). Another common hemoglobin variant, HbC, results from a glu-to-lys replacement in the same position as the HbS mutation. This mutation has two effects. It promotes water loss from the cell by activating the K^+ transporter by an unknown mechanism, resulting in a higher than normal concentration of hemoglobin within the cell. The amino acid replacement also substantially lowers the hemoglobin solubility in the homozygote, resulting in a tendency of the mutant hemoglobin to precipitate within the red cell, although, unlike sickle cells, the cell does not become deformed. Homozygotes for the HbC mutation have a mild hemolytic anemia. Heterozygous individuals are clinically unaffected.

HbC is found in high frequency in West Africa, in regions with a high frequency of HbS. Consequently, compound heterozygotes for HbS and HbC are not uncommon both in some African regions and among African Americans. HbS/HbC individuals have significantly more hematopathology than individuals with sickle cell trait (HbA/HbS). Polymerization of deoxygenated HbS is dependent on the HbS concentration within the cell. The presence of HbC in the compound heterozygote increases the HbS concentration by stimulating K^+ and water efflux from the cell. Because the HbC globin tends to precipitate, the proportion of HbS tends to be higher in HbS/HbC cells than in the cells of individuals with sickle cell trait (HbS/HbA). The way in which multiple mutations ameliorate or exacerbate hematological diseases has provided insights into the molecular mechanisms of hemoglobin function and developmental regulation.

B. Thalassemias

For optimum function, the hemoglobin α - and β -globin chains must have the proper structure and be synthesized in a 1:1 ratio. A large excess of one subunit over the other results in the class of diseases called thalassemias. These anemias are clinically very heterogeneous, as they can arise by multiple mechanisms. Like sickle cell anemia, the thalassemia mutations provide resistance to malaria in the heterozygous state.

There are two ways in which an individual might have two α -globin genes deleted. In one case, one copy of chromosome 16 might have both α -globin genes deleted, whereas the other copy had two functional α -globin genes. In the second case, both chromosomes might have lost one of their two copies of the α -globin gene. The former possibility is more common among Asians, the latter among Africans.

Hemoglobin single amino acid replacement mutation that gives rise to a globin subunit of decreased stability is one mechanism by which thalassemia arises. More common, however, are mutations that result in decreased synthesis of one subunit. The α -thalassemias usually arise from complete gene deletions. Two copies of the α -globin gene are found on each chromosome 16, for a total of 4 α -globin genes per precursor cell. If one copy of the gene is deleted, the size and hemoglobin concentration of the individual red blood cells is minimally reduced. If two copies are deleted, the red blood cells are of decreased size (microcytic) and reduced hemoglobin concentration (hypochromic). However, the individual is usually not anemic. The loss of three α -globin genes causes a moderately severe microcytic hypochromic anemia (hemoglobin, 7 to 10 g/dL) with splenomegaly (enlarged spleen). The absence of four α -globin genes (hydrops fetalis) is usually fatal in utero.

As discussed in Chapter 14, β -thalassemia is a very heterogeneous genetic disease. Insufficient β -globin synthesis can result from deletions, promoter mutations, and splice-junction mutations. Heterozygotes for β^+ (some globin chain synthesis) or β^0 (no globin chain synthesis) are generally asymptomatic, though they typically have microcytic, hypochromic red blood cells and may have mild anemia. β^+/β^+ homozygotes have anemia of variable severity, β^+/β^0 compound heterozygotes tend to be more severely affected, and β^0/β^0 homozygotes have severe disease. In general, diseases of β -chain deficiency are more severe than diseases of α -chain deficiency. Excess β -chains form a homotetramer, hemoglobin H (HbH), which is ineffective for delivering oxygen to the tissues because of its high oxygen affinity. As red blood cells age, HbH precipitates in the cells, forming inclusion bodies. Red blood cells with inclusion bodies have shortened lifespans, because they are more likely to be trapped and destroyed in the spleen. Excess α -chains are unable to form a stable

tetramer. However, excess α -chains precipitate in erythrocytes at every developmental stage. The α -chain precipitation in erythroid precursors results in their widespread destruction, a process called ineffective erythropoiesis. The precipitated α -chains also damage red blood cell membranes through the heme-facilitated lipid oxidation by reactive oxygen species. Both lipids and proteins, particularly band 4.1, are damaged.

The difference in amino acid composition between the β -chains of HbA and the γ -chains of HbF results in structural changes that cause HbF to have a lower affinity for 2,3-BPG than adult hemoglobin (HbA) and thus a greater affinity for oxygen. Therefore, the oxygen released from the mother's hemoglobin (HbA) is readily bound by HbF in the fetus. Thus, the transfer of oxygen from the mother to the fetus is facilitated by the structural difference between the hemoglobin molecule of the mother and that of the fetus.

C. Hereditary Persistence of Fetal Hemoglobin

Fetal hemoglobin (HbF), the predominant hemoglobin of the fetal period, consists of two α -chains and two γ -chains, whereas adult Hb consists of two α - and two β -chains. The process that regulates the conversion of HbF to HbA is called hemoglobin switching. Hb switching is not 100%; most individuals continue to produce a small amount of HbF throughout life. However, some people, who are clinically normal, produce abnormally high levels (up to 100%) of fetal hemoglobin (hemoglobin F) in place of HbA. Patients with hemoglobinopathies such as β thalassemia or sickle cell anemia frequently have less severe illnesses if their levels of fetal hemoglobin are elevated. One goal of much research on hemoglobin switching is to discover a way to reactivate transcription of the γ -globin genes to compensate for defective β -globin synthesis. Individuals who express fetal hemoglobin past birth have hereditary persistence of fetal hemoglobin (HPFH).

1. Nondeletion Forms of HPFH

The nondeletion forms of HPFH are those that derive from point mutations in the $A\gamma$ and $G\gamma$ promoters. When these mutations are found with sickle cell or β -thalassemia mutations, they have an ameliorating effect on the disease, because of the increased production of γ chains. As discussed in biochemical comments, these mutations cluster in the -115 and -200 regions of the gene, where specific transcription factor inhibitors of γ -gene expression bind.

2. Deletion Forms of HPFH

In deletion HPFH, both the entire δ and β genes have been deleted from one copy of chromosome 11 and only HbF can be produced. In some individuals, the fetal globins remain activated after birth, and enough HbF is produced that the individual is clinically normal. Other individuals with similar deletions that remove the entire δ and β genes do not produce enough fetal hemoglobin to compensate for the deletion and are considered to have $\delta^0\beta^0$ -thalassemia. The difference between these two outcomes is believed to be the site at which the deletions end within the β -globin gene cluster. In deletion HPFH, powerful enhancer sequences 3' of the β -globin gene are resituated because of the deletion so that they activate the γ promoters. In individuals with $\delta^0\beta^0$ -thalassemia, the enhancer sequences have not been relocated so that they can interact with the γ promoters.

D. Hemoglobin Switching: A Developmental Process Controlled by Transcription Factors

In humans, embryonic megakaryoblasts (the embryonic red blood cell is large and is termed a "blast" because it retains its nucleus) are first produced in the yolk sac approximately 15 days after fertilization. After 6 weeks, the site of erythropoiesis shifts to the liver. The liver, and to a lesser extent the spleen, are the major sites of fetal erythropoiesis. In the last few weeks before birth, the bone marrow begins producing red blood cells. By 8 to 10 weeks after birth, the bone marrow is the sole site of erythrocyte production. The composition of the hemoglobin also changes with development, because both the α -globin locus and the β -globin locus have multiple genes that are differentially expressed during development (Fig. 42.14).

FIGURE 42.14 Globin gene clusters and expression during development. **A.** The globin gene clusters with the α -genes on chromosome 16 and the β -genes on chromosome 11. The gene designations are indicated below the lines in the figure. **B.** The switching of globin chain synthesis during development. HbF, fetal hemoglobin; LCR, locus control region.

E. Structure and Transcriptional Regulation of the α - and β -Globin Gene Loci

The α -globin locus on chromosome 16 contains the embryonic ζ (zeta) gene and two copies of the α -gene, α_2 and α_1 . The β -globin locus on chromosome 11 contains the embryonic ε -gene; two copies of the fetal β -globin gene, G_γ and A_γ (which differ by one amino acid); and two adult genes, δ and β . The order of the genes along the chromosome parallels the order of expression of the genes during development (see Fig. 42.14). The embryonic hemoglobins are $\zeta_2\varepsilon_2$ (Gower 1), $\zeta_2\gamma_2$ (Portland), and $\alpha_2\varepsilon_2$ (Gower 2). Fetal hemoglobin is predominantly $\alpha_2G_\gamma_2$. The major adult species is $\alpha_2\beta_2$ (hemoglobin A); the minor adult species is $\alpha_2\delta_2$

(hemoglobin A₂). The fetal hemoglobin found in adult cells is $\alpha_2\text{A}\gamma_2$. The timing of hemoglobin switching is controlled by a developmental clock that is not significantly altered by environmental conditions and is related to changes in expression of specific transcription factors. Premature newborns convert from HbF to HbA on schedule with their gestational ages.

CLINICAL COMMENTS

Edward R.'s red blood cells are deficient in spectrin. This deficiency impairs the ability of his erythrocytes to maintain the redundant surface area necessary to maintain deformability. Mechanical stresses in the circulation cause progressive loss of pieces of membrane. As membrane components are lost, his red blood cells become spherical and unable to deform. His spleen is enlarged because of the large number of red blood cells that have become trapped within it. His erythrocytes are lysed by mechanical stresses in the circulation and by macrophages in the spleen. Consequently, this hemolytic process results in anemia. His gallstones were the result of the large amounts of bilirubin that were produced and stored in the gallbladder as a result of the hemolysis. The abnormally rounded red cells seen on a blood smear are characteristic of hereditary spherocytosis.

Mutations in the genes for ankyrin, β -spectrin, or band 3 account for three-quarters of the cases of hereditary spherocytosis, whereas mutations in the genes for α -spectrin or band 4.2 account for the remainder. The result of defective synthesis of any of the membrane cytoskeletal proteins results in improper formation of the membrane cytoskeleton. Excess membrane proteins are catabolized, resulting in a net deficiency of spectrin. **Edward R.** underwent a splenectomy. Because the spleen was the major site of destruction of his red blood cells, his anemia improved significantly after surgery. He was discharged with the recommendation to take a folate supplement daily. It was explained to **Edward R.** that because the spleen plays a major role in protection against certain bacterial agents, he would require immunizations against pneumococcus, meningococcus, and *Haemophilus influenzae* type b.

Lisa N. was found to be a compound heterozygote for mutations in the β -globin gene. On one gene, a mutation in position 6 of intron 1 converted a T to a C. The presence of this mutation, for unknown reasons, raises HbF production. The other β -globin gene had a mutation in position 110 of exon 1 (a C-to-T mutation). Both β -globin chains have reduced activity, but combined with the increased expression of HbF, the result is a β^+ -thalassemia.

BIOCHEMICAL COMMENTS

Control of Hemoglobin Switching. How is hemoglobin switching controlled? Although there are still many unanswered questions, some of the molecular mechanisms have been identified. The α -globin locus covers ~ 100 kb (kilobases). The major regulatory element, HS40, is a nuclease-sensitive region of DNA that lies 5' of the ζ -gene (see Fig. 42.14). HS40 acts as an erythroid-specific enhancer that interacts with the upstream regulatory regions of the ζ - and α -genes and stimulates their transcription. The region immediately 5' of the ζ -gene contains the regulatory sequences responsible for silencing ζ -gene transcription. However, the exact sequences and transcription factors responsible for this silencing have not yet been identified. Even after silencing, low levels of ζ -gene transcripts are still produced after the embryonic period; however, they are not translated. This is because both the ζ -globin and α -globin transcripts have regions that bind to a messenger ribonucleoprotein (mRNP) stability-determining complex. Binding to this complex prevents the mRNA from being degraded. The α -globin messenger RNA has a much higher affinity for the mRNP than the ζ -globin message, which leads to the ζ -globin message being rapidly degraded.

The β -globin locus covers ~ 100 kb. From 5 to 25 kb upstream of the ϵ -gene is the locus control region (LCR), containing five DNase hypersensitive sites. The LCR is necessary for the function of the β -globin locus. It maintains the chromatin of the entire locus in an active configuration and acts as an enhancer and entry point for the factors that transcribe the genes of the β -globin locus. One model of the control of hemoglobin switching postulates that proteins bound at the promoters of the ϵ -, γ -, and β -globin genes compete to interact with the enhancers of the LCR.

Each gene in the β -globin locus has individual regulatory elements—a promoter, silencers, or enhancers that control its developmental regulation. The promoters that control the γ - and β -globin genes have been

intensively studied because of their clinical relevance.

The ϵ -globin gene, like the ζ -globin gene, has silencers in the 5'-regulatory region. Binding of proteins to these regions turns off the ϵ -gene (*HBE1* gene).

The proximal region of the γ -globin gene promoter (*HBG2* gene) has multiple transcription factor-binding sites (Fig. 42.15). Many HPFH mutations map to these transcription factor-binding sites, either by destroying a site or by creating a new one, but the exact mechanisms are still not understood. Two sites (out of many) that appear to be significant in the control of hemoglobin switching are the stage-selector protein-binding (SSP) site and the CAAT box region. When the SSP complex (consisting of the transcription factors CP2 and NFE4) is bound to the promoter, the γ -globin gene has a competitive advantage over the β -globin promoter for interaction with the LCR. A second transcription factor, Sp1, also binds at the SSP-binding site, where it may act as a repressor, and competition between these two protein complexes for the SSP-binding site helps to determine the activity of the γ -globin gene. A similar mechanism appears to be operating at the CAAT box. CP1, thought to be a transcription activator, binds at the CAAT box. CAAT displacement protein (CDP) is a repressor that binds at the CAAT site and displaces CP1. Part of the mechanism of hemoglobin switching appears to be the binding of repressors at the ϵ -globin and γ -globin upstream regulatory regions.

A.

B.

Chromosome 11

FIGURE 42.15 **A.** The γ -globin gene promoter, indicating some of the transcription factor–binding sites associated with hereditary persistence of fetal hemoglobin. **B.** The β -globin gene locus. When BCL11A or ZBTB7A is expressed, the interaction between the LCR and the γ -gene promoter is blocked, turning off γ -gene expression. NURD is a chromatin remodeling complex containing histone deacetylase activity.

The β -globin gene also has binding sites for multiple transcription factors in its regulatory regions. Mutations that affect binding of transcription factors can produce thalassemia by reducing the activity of the β -globin promoter. There is also an enhancer 3' of the poly-A signal that seems to be required for stage-specific activation of the β -globin promoter.

Further insights into the control of hemoglobin switching indicate that the transcription factors BCL11A and ZBTB7A are strong repressors of γ -globin gene expression. BCL11A interacts with a variety of other transcription factors (GATA-1, FOG1, and the NURD repressor complex [nucleosome remodeling and histone deacetylase]) to repress γ -globin expression through binding in the -115 region of the γ -gene promoter. ZBTB7A binds in the -200 region of the promoter. This appears to be due to BCL11A and ZBTB7A interfering with LCR interactions with the γ -globin gene promoter. Experiments that reduce, or eliminate,

BCL11A or ZBTB7A expression lead to an increase in γ -globin synthesis. BCL11A expression is regulated by the transcription factor KLF1, which is essential for β -globin expression. KLF1 increases BCL11A expression, which blocks γ -globin gene expression, while KLF1 stimulates β -globin gene expression. These recent results suggest that drugs that interfere with KLF1 action would enhance and activate *fetal globin* gene expression in individuals with either β -thalassemia or sickle cell disease (see Fig. 42.15B). Current studies are also aimed at developing drugs that block BCL11A and ZBTB7A from binding to the **HBG2** gene promoter, which could have similar results in leading to increased HbF levels.

KEY CONCEPTS

- ◆ The blood contains a wide variety of distinct cell types, each of whose function is necessary for maintaining the body's internal environment.
- ◆ Erythrocytes transport oxygen throughout the body and return carbon dioxide back to the lung.
 - ◆ Erythrocytes lack nuclei and carry out limited metabolic reactions.
 - ◆ Glycolysis provides energy and NADH.
 - ◆ The NADH maintains the iron in hemoglobin in the ferrous state.
 - ◆ The HMP shunt provides NADPH to regenerate reduced glutathione to protect the membrane from oxidative damage.
 - ◆ 1,3-bisphosphoglycerate is converted to 2,3-bisphosphoglycerate as a by-product of glycolysis to regulate oxygen binding to hemoglobin.
 - ◆ Heme synthesis occurs in the erythrocyte precursor, utilizing succinyl CoA and glycine. Inherited defects in heme synthesis lead to porphyrias.
 - ◆ Iron, a critical part of heme, is carried throughout the body on protein carriers, because free iron is toxic.
 - ◆ The erythrocyte membrane is flexible as a result of its unique cytoskeletal structure, which allows erythrocytes to deform to travel through narrow capillaries.
- ◆ Hematopoiesis is the generation of the unique blood cell types from a single precursor stem cell in the bone marrow.
- ◆ Polymorphonuclear leukocytes consist of a variety of cell types that release chemical signals when activated (granulocytes), phagocytose foreign bodies (neutrophils), destroy parasites (eosinophils), and are involved in the allergic response (basophils).
- ◆ Mononuclear leukocytes include the lymphocytes (necessary for the immune response) and monocytes (which develop into macrophages, which engulf debris left behind after granulocytes attack foreign material).
- ◆ A wide variety of mutations can lead to alterations in hemoglobin function (hemoglobinopathies):
 - ◆ Sickle cell anemia
 - ◆ Thalassemias
 - ◆ HPFH (hemoglobin switching and its regulation)
- ◆ Diseases discussed in this chapter are summarized in Table 42.4.

TABLE 42.4 Diseases Discussed in Chapter 42

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Thalassemias	Genetic	Unbalanced synthesis of α and β chains of hemoglobin, leading to anemia
Pyruvate kinase deficiency	Genetic	Red cell hemolysis, leading to fewer red cells. An increase in 2,3 BPG levels often masks the effects of the anemia.
Congenital methemoglobinemia	Genetic	Oxidation of the iron in heme to the ferric state, which will not bind oxygen, although many individuals with this disorder are asymptomatic.
Glucose 6-phosphate dehydrogenase deficiency	Genetic	Affects red blood cell membrane stability through an inability to protect membrane proteins and lipids against oxidation
Porphyrias	Genetic	Inherited defects in almost any step of heme synthesis leading to a series of diseases with different symptoms and outcomes

Iron deficiency	Both	Reduced iron leads to reduced heme synthesis, and reduced oxygen delivery to the tissues.
X-linked severe combined immunodeficiency syndrome	Genetic	Loss of a cytokine receptor subunit, leading to a complete loss of B and T cell maturation and proliferation, and no functional immune system
Defective erythropoietin receptor	Genetic	Red blood cell formation is reduced under conditions in which red blood cell production should be increased (such as reduced oxygen delivery to the tissues).
Hemoglobin C	Genetic	A point mutation in hemoglobin leading to a lysine for a glutamic acid at position 6 of the β -chain (E6K), leading to hemolytic anemia in the homozygous state
Hereditary persistence of fetal hemoglobin	Genetic	Mutations in promoter and enhancer regions leading to misexpression of the globin γ gene, and constant expression of the gene
Spherocytosis	Genetic	Mutations in any of a number of red blood cell membrane proteins (such as Spectrin), leading to instability of the red cells, destruction of the red blood cells, and an anemia

REVIEW QUESTIONS—CHAPTER 42

- A compensatory mechanism to allow adequate oxygen delivery to the tissues at high altitudes, where oxygen concentrations are low, is which one of the following?
 - An increase in 2,3-bisphosphoglycerate synthesis by the red cell
 - A decrease in 2,3-bisphosphoglycerate synthesis by the red cell
 - An increase in hemoglobin synthesis by the red cell
 - A decrease in hemoglobin synthesis by the red cell
 - Decreasing the blood pH
- A 2-year-old boy of normal weight and height is brought to a clinic because of excessive fatigue. Blood work indicates anemia, with microcytic hypochromic red cells. The boy lives in a 100-year-old apartment building and has been caught ingesting paint chips. His parents indicate that the child eats a healthy diet and takes a Flintstones vitamin supplement every day. His anemia is most likely attributable to a deficiency in which one of the following?
 - Iron
 - Vitamin B₁₂
 - Folate
 - Heme
 - Vitamin B₆
- Drugs are being developed that will induce the transcription of certain globin genes, which are normally silent in patients affected with sickle cell disease. A good target gene for such therapy in this disease would be which one of the following?
 - The **HBA1** gene
 - The **HBA2** gene
 - The **HBG2** gene
 - The **HBB** gene
 - The **HBZ** gene
- A mature blood cell that lacks a nucleus is which one of the following?
 - Lymphocyte
 - Basophil
 - Eosinophil
 - Platelet
 - Neutrophil
- A family has two children, one with a mild case of thalassemia, and a second with a severe case of thalassemia, requiring frequent blood transfusions as part of the treatment plan. One parent is of Mediterranean descent; the other is of Asian descent. Neither parent exhibits clinical signs of thalassemia. Both children express 20% of the expected level of β -globin; the more severely affected child expresses

normal levels of α -globin, whereas the less severely affected child expresses only 50% of the normal levels of α -globin. Why is the child who has a deficiency in α -globin expression less severely affected?

- A. Thalassemia is caused by a mutation in the α -gene, and the more severely affected child expresses more of it.
 - B. The less severely affected child must be synthesizing the ζ -gene to make up for the deficiency in α -chain synthesis.
 - C. The more severely affected child also has HPFH.
 - D. The more severely affected child produces more inactive globin tetramers than the less severely affected child.
 - E. Thalassemia is caused by an iron deficiency, and when the child is synthesizing normal levels of α -globin there is insufficient iron to populate all of the heme molecules synthesized.
6. An individual displays an anemic condition, and upon molecular analysis is shown to be a compound heterozygote for HbS/HbC. The symptoms exhibited by the patient are more severe than those exhibited by patients with sickle cell trait (HbA/HbS) due primarily to which one of the following?
- A. Increased concentration of HbC molecules in the patient's red blood cells.
 - B. Increased volume of the patient's red blood cells.
 - C. Increased concentration of HbS in the patient's red blood cells.
 - D. Alterations in the patient's red blood cell morphology.
 - E. Precipitation of HbS molecules within the patient's red blood cells.
7. A young boy has been observed to have bluish fingertips and toes. Blood work indicates a mild anemia, and molecular analysis indicates the child has an inherited erythrocyte pyruvate kinase deficiency. This enzyme mutation leads to an increase in the 2,3 bisphosphoglycerate levels in the erythrocyte, which helps to ameliorate the effects of the mutation. The increase in 2,3 bisphosphoglycerate levels occurs due to which one of the following?
- A. The lack of pyruvate kinase leads to an increase in 1,3 bisphosphoglycerate levels, which is used to form 2,3 bisphosphoglycerate by the Rapoport–Luebering shunt pathway.
 - B. The increase in PEP levels leads to the phosphorylation of 3-phosphoglycerate, forming 2,3 bisphosphoglycerate.
 - C. The increase in PEP levels leads to the phosphorylation of 2-phosphoglycerate, forming 2,3 bisphosphoglycerate.
 - D. The increase in PEP levels leads to an increase in 3-phosphoglycerate, which is phosphorylated by ATP to produce 2,3 bisphosphoglycerate.
 - E. The lack of pyruvate kinase activity leads to an increase of glyceraldehyde 3-phosphate, which is oxidized by an isozyme of glyceraldehyde 3-phosphate dehydrogenase to form 2,3 bisphosphoglycerate.
8. A young boy was recently diagnosed with anemia, and further analysis demonstrated he had hereditary spherocytosis. This disease leads to anemia through which one of the following mechanisms?
- A. Lack of NADPH to protect cell membrane lipids and proteins from oxidation
 - B. Nutritional deficiency of iron, folate, or B₁₂
 - C. Inability to reduce ferric hemoglobin to the normal ferrous state
 - D. Improper formation of the red blood cell membrane cytoskeleton
 - E. A mutation in heme synthesis
9. A patient is a strict vegetarian, and, as such, is concerned about getting sufficient iron in his diet. Which suggestion below could increase his dietary iron absorption?
- A. Never peel potatoes when preparing a potato dish
 - B. Squeeze fresh lemon juice on spinach salad
 - C. Reassure him that iron in plants is readily absorbed
 - D. Meat is the only dietary source of iron
 - E. Taking a vitamin with B₁₂ would help iron absorption
10. The pluripotent stem cell of the bone marrow produces all blood cells through different lineages via induction of different differentiation pathways. Which one of the following is produced from the same cell line as red blood cells?
- A. NK cells
 - B. B lymphocytes
 - C. T lymphocytes
 - D. Basophils
 - E. Platelets

1. A family has recently moved from New Jersey (elevation ~10 ft above sea level) to Keystone, Colorado (elevation ~9,200 ft above sea level). The family members initially had trouble breathing at this altitude. An adaptation to the increased altitude would include which one of the following?
 - A. A decrease in red blood cell 2,3 bisphosphoglycerate levels
 - B. A decrease in proton concentration in the red blood cell
 - C. Increased transcription of a cytokine in the kidney
 - D. Reduced synthesis of heme in the marrow
 - E. Increased production of bilirubin
2. HPFH may occur due to mutations in which region of the hemoglobin genes?
 - A. Promoter region of the *HBA1* gene
 - B. Promoter region of the *HBZ* gene
 - C. Promoter region of the *HBE1* gene
 - D. Promoter region of the *HBG1* gene
 - E. Promoter region of the *HBB* gene
3. NADH produced in the red blood cell can be utilized for which of the following? Choose the one best answer.

	Produce Lactate	Produce 6-phosphogluconate	Produce 2,3-bisphosphoglycerate	Reduce Methemoglobin
A	Yes	No	No	No
B	Yes	Yes	No	No
C	Yes	No	No	Yes
D	No	Yes	Yes	Yes
E	No	No	Yes	No
F	No	Yes	Yes	Yes

4. HbS and HbC are both variants derived from mutations in the *HBB* gene. Both variants have a different amino acid at the sixth position of the β chain of hemoglobin and yield a different phenotype in individuals with the mutation. Which explanation below best explains how an amino acid substitution at the same position in the primary structure of the protein can lead to different symptoms in individuals who express the mutation?
 - A. One substitution is E6V; the other is E6D
 - B. One substitution is E6K; the other is E6D
 - C. One disorder is due to the introduction of a hydrophobic residue, the other to an aromatic residue
 - D. One disorder is due to the introduction of a basic residue, the other a hydrophobic residue
 - E. Both HbC and HbS are due to E6V, but the mutated protein can fold into two stable conformations, each conformation unique for a different disease
5. Which of the following deficiencies or disorders would lead to a microcytic anemia? Choose the one best answer.

	Vitamin B ₆	β-thalassemia	Glucose 6-phosphate Dehydrogenase Deficiency	Iron Deficiency
A	Yes	Yes	No	Yes
B	Yes	No	No	No
C	Yes	Yes	No	No
D	No	No	Yes	No
E	No	Yes	Yes	Yes
F	No	No	Yes	Yes

ANSWERS TO REVIEW QUESTIONS

- The answer is A.** Increased 2,3-bisphosphoglycerate in the red cell will favor the deoxy conformation of hemoglobin and thus allow more oxygen to be released in the tissues. This is useful because the hemoglobin is not as saturated at high altitudes as at low elevations, because of the lower concentration of oxygen at high altitudes. Answers C and D are incorrect because the red cells do not synthesize proteins. Answer E is incorrect because reducing the blood pH will not aid in oxygen delivery; the Bohr effect works best when tissue pH is lower than blood pH, to stabilize the deoxy form of hemoglobin. If the pH of both the blood and the tissue are the same, the Bohr effect will not be able to occur.
- The answer is D.** The boy is suffering from lead poisoning, which interrupts heme synthesis at the ALA dehydratase and ferrochelatase steps. Without heme, the oxygen-carrying capability of blood is reduced, and the flow of electrons through the electron transfer chain is reduced because of the lack of functional cytochromes. Together, these lead to an inability to generate energy and fatigue results. Answer A is incorrect because although an iron deficiency would lead to the same symptoms, this would not be expected in the patient because of his daily vitamin uptake. Lead ingestion will not lead to an iron loss. Answers B and C are incorrect because vitamin B₁₂ and folate deficiencies will lead to macrocytic anemia, due to disruption of DNA synthesis. Answer E is incorrect because the ingestion of paint chips is unlikely to lead to a vitamin B₆ deficiency in a child, particularly one who is taking daily vitamins.
- The answer is C.** Turning on a gene that would provide a functional alternative to the β-gene would enable the defective β-protein to be bypassed. Only the γ-chain can do this, but it is normally only found in fetal hemoglobin. The δ-chain is also a β-replacement globin, but it was not listed as a potential answer. Answer D is incorrect because it is the β-chain that is mutated, and it is already being expressed. Unlike the α-gene, of which there are two copies per chromosome, there is only one copy of the β-gene per chromosome. The other genes listed (answers A, B, and E) are α-chain replacements, and expression of these genes will not alleviate the problem inherent in the β-gene.
- The answer is D.** The only two types of blood cells that lack nuclei are the mature red blood cell and the platelet. Platelets arise from membrane budding from megakaryocytes and are essentially membrane sacs containing the cytoplasmic contents of their precursor cell. All of the other cell types listed contain a nucleus.
- The answer is D.** Thalassemias results from an imbalance in the synthesis of α- and β-chains. Excessive synthesis of α-chains results in their precipitation in developing red cells, which often kills the developing cell. The more severely affected child has an α/β ratio of 5 to 1, whereas the less severely affected child

has a ratio of 2.5 to 1. When β -chains are in excess, they form stable tetramers that bind but do not release oxygen, thus reducing the red cell's ability to deliver oxygen. Thus, this difference in chain ratio makes an important difference in the functioning of the red cell.

6. **The answer is C.** Hemoglobin C forms an insoluble tetramer that precipitates in red blood cells. Because of this, the concentration of HbS is increased in the red blood cells, leading to enhanced sickling as compared to someone who has a mixture of HbS and HbA molecules. The enhanced sickling is not directly due to the precipitation of the HbC molecules, nor to an increased volume of the red blood cell (an increased volume would reduce the concentration of HbS, which would reduce sickling). The HbS molecules will form rods under low-oxygen conditions, but they do not precipitate in the cell, as do the HbC molecules. Alterations in red blood cell morphology are a result of the sickling, not a cause of the sickling.
7. **The answer is A.** When pyruvate kinase activity is reduced PEP will accumulate. PEP is in equilibrium with 2-phosphoglycerate, which is in equilibrium with 3-phosphoglycerate (3-PG). As 3-PG accumulates the phosphoglycerate kinase reaction will be inhibited, increasing the levels of 1,3 bisphosphoglycerate. As 1,3 bisphosphoglycerate levels accumulate some of it will be shunted to produce 2,3 bisphosphoglycerate via 1,3 bisphosphoglycerate mutase. The increase in 2,3 bisphosphoglycerate levels will then impact the release of oxygen to the tissues from hemoglobin. PEP is not used as a phosphate donor in phosphorylation reactions in the generation of higher levels of 2,3 bisphosphoglycerate. ATP is used in the conversion of 3-phosphoglycerate to 1,3 bisphosphoglycerate but not to form 2,3 bisphosphoglycerate. The oxidation of glyceraldehyde 3-phosphate (G3P) does not generate 2,3 bisphosphoglycerate; there is no isozyme of glyceraldehyde 3-phosphate dehydrogenase which will produce 2,3 bisphosphoglycerate from G3P.
8. **The answer is D.** Mutations in spectrin, ankyrin, and band 3 proteins lead to improper formation of the red blood cell membrane cytoskeleton, resulting in malformed red blood cells (spherocytes), which have a shortened life span, thus leading to anemia. Mutations in heme synthesis lead to porphyrias. Lack of NADPH (such as in glucose 6-phosphate dehydrogenase deficiency) leads to anemia via cell membrane oxidation and lysis. Oxidation of the heme iron to the ferric state results in reduced oxygen binding to hemoglobin. Nutritional deficiencies of iron, folate, or B₁₂ would lead to a megaloblastic anemia (folate and B₁₂ deficiencies) or a microcytic anemia (iron deficiency).
9. **The answer is B.** Meats, green leafy vegetables, and fortified cereals and grains are all sources of dietary iron, whereas potatoes are not. Plant nonheme iron is not readily absorbed from the diet, but the presence of Vitamin C (citrus fruits) increases the uptake of nonheme iron from the digestive tract. Vitamin B₁₂ is not involved in iron absorption.
10. **The answer is E.** Both platelets and red blood cells are derived from the BFU-EMeg lineage. Basophils are derived from the CFU-Ba lineage, B and T lymphocytes from the lymphoid stem cell lineage, and NK cells from NK-precursor.
11. **The answer is C.** The family was having trouble breathing due to the reduced oxygen levels at high altitude as compared to lower altitude. The body can adapt to the lower oxygen levels by increasing red blood cell 2,3 bisphosphoglycerate levels (which would stabilize the deoxy form of hemoglobin and enhance oxygen removal in the tissues from oxyhemoglobin) or by increasing the number of red blood cells in the circulation. When the kidney senses a reduced oxygen concentration in the blood hypoxia-inducible factor 1 is activated. HIF-1 is a transcription factor that stimulates the synthesis of erythropoietin, which is released from the kidneys and stimulates red blood cell production in the bone marrow. A reduced proton concentration favors the oxygenated form of hemoglobin (the opposite of the Bohr effect) and would not aid in delivering oxygen to the tissues. Reduced synthesis of heme would lead to a microcytic anemia and would not help deliver oxygen to tissues. Bilirubin is a degradation product of heme, and if there were to be an increased production of bilirubin then heme levels would be dropping, and oxygen would not be delivered to the tissues efficiently.
12. **The answer is D.** The *HBG1* gene encodes the A- γ protein, one of the components of fetal hemoglobin. A mutation in the promoter of the *HBG1* gene may lead to overexpression of the gene, and an inability to turn off the gene as programmed during development. This would lead to the expression of γ -globin at the expense of β -globin, and the persistence of fetal hemoglobin through life. The *HBA1* gene encodes the α protein; the *HBZ* gene encodes the ζ globin gene; the *HBHE1* gene encodes the epsilon protein, and the *HBB* gene encodes the *hemoglobin* β gene. Mutations in the promoter regions of those other genes would not lead to overexpression of the γ chain, nor HPFH.

13. **The answer is C.** NADH is produced in red blood cells via the glyceraldehyde 3-phosphate dehydrogenase step of glycolysis. As red blood cells lack mitochondria the NADH can be converted back into NAD^+ , in order for glycolysis to continue, by either lactate dehydrogenase (producing lactate) or by converting oxidized hemoglobin (methemoglobin) to reduced, or ferrous, hemoglobin, the form that can bind oxygen. 6-phosphogluconate is formed in the HMP shunt pathway, and the required cofactor is NADP^+ , not NADH. The production of 2,3 bisphosphoglycerate utilizes phosphoglycerate mutase, and converts 1,3 bisphosphoglycerate to 2,3 bisphosphoglycerate, and does not require an oxidation or reduction reaction.
14. **The answer is D.** HbS is due to an E6V mutation, while HbC is due to an E6K mutation. The substitution of a hydrophobic valine for a charged glutamate sidechain in HbS allows deoxyhemoglobin to polymerize through hydrophobic interactions, leading to the formation of rod-like polymers which distort the shape of the red blood cell. In HbC the substitution is a lysine (positively charged molecule) for the glutamate at position 6 (a negatively charged sidechain). This substitution reduces the solubility of hemoglobin, but not to a great extent, such that heterozygotes are mostly asymptomatic. The mutation in HbC does not lead to polymerization of the hemoglobin molecule.
15. **The answer is A.** Iron deficiency and a vitamin B_6 deficiency lead to reduced heme synthesis, and if heme is limiting the red blood cells will be smaller than normal, in an effort to maintain an appropriate concentration of heme within the cell. A β -thalassemia, which reduces the production of β -globin, leads to a reduction in functional hemoglobin levels (as excess α -globin chains will precipitate as α_4 tetramers in the cell), and a microcytic anemia will result. A deficiency of glucose 6-phosphate dehydrogenase activity, in the presence of oxidizing agents, leads to a hemolytic anemia, but not a microcytic anemia.

Blood Plasma Proteins, Coagulation, and Fibrinolysis

The blood is the body's main transport system. Although the transport and delivery of oxygen to the cells of the tissues is carried out by specialized cells, other vital components such as nutrients, metabolites, electrolytes, and hormones are all carried in the noncellular fraction of the blood, the **plasma**. Some components, such as glucose, are dissolved in the plasma; others, for example, lipids and steroid hormones, are bound to carrier proteins for transport. The **osmotic pressure** exerted by the plasma proteins regulates the distribution of water between the blood and the tissues. Plasma proteins in conjunction with platelets maintain the integrity of the circulatory system through the process of clotting.

Blood normally circulates through endothelium-lined blood vessels. When a blood vessel is severed, a **blood clot** (called a **thrombus**, which is formed by the process of **thrombosis**) forms as part of **hemostasis**, the physiological response that stops bleeding. Blood clots also form to repair damage to the endothelial lining, in which components of the **subendothelial layer** become accessible to plasma proteins.

In hemostasis and thrombosis, a primary hemostatic plug, consisting of **aggregated platelets** and a **fibrin clot**, forms at the site of injury. Platelets are attached to the subendothelial layer of the vessel principally through the protein **von Willebrand factor** and are activated to bind fibrinogen. **Fibrinogen** binds the platelets to each other to form a platelet aggregate. The platelet aggregate is rapidly covered with layers of **fibrin**, which are formed from fibrinogen by the proteolytic enzyme **thrombin**.

Injury to the endothelium and exposure of **tissue factor** on the **subendothelial layer** to plasma proteins also activate the blood coagulation cascade, which ultimately activates thrombin and **factor XIII**. Factor XIII **cross-links** strands of polymerized fibrin monomers to form a stable clot (the **secondary hemostatic plug**). The blood coagulation cascade consists of a series of enzymes (such as **factor X**), which are inactive until they are proteolytically cleaved by the preceding enzyme in the cascade. Other proteins (**factor V** and **factor VIII**) serve as binding proteins, which assemble factor complexes at the site of injury. Ca^{2+} and **γ -carboxyglutamate** residues in the proteins (formed by a vitamin K–dependent process in the liver) attach the factor complexes to **phospholipids** exposed on platelet membranes. Consequently, thrombus formation is rapidly accelerated and localized to the site of injury.

Regulatory mechanisms within the blood coagulation cascade and **antifibrinolytic mechanisms** prevent random coagulation within blood vessels that might obstruct blood flow. Impairments in these mechanisms lead to thrombosis.

There are two basic assays for measuring the activity of factor VIII in a blood sample. The first is a functional (clotting) assay; the second is a coupled (to factor X activation) enzyme system leading to the cleavage of a chromogenic substrate, generating a colored product.

For the functional assay, a sample of the patient's plasma is added to a factor VIII-deficient sample of plasma (which can be obtained commercially), and the time to generate clot formation is determined. Although clot formation is the end product of this assay, one is measuring the eventual activation of factor II to IIa, which allows clot formation to initiate.

In the automated, chromogenic assay, a sample of the unknown is mixed with purified factor IXa, Ca^{2+} , phospholipid vesicles, the chromogenic substrate, and purified factor X. If the unknown sample contains factor VIII, the factors VIII and IXa will synergize and activate factor X to Xa. The factor Xa will cleave the chromogenic substrate, forming a colored product, whose concentration can be determined spectrophotometrically. Comparison to a standard curve of factor VIII addition enables an accurate estimate of the level of active factor VIII in the sample.

THE WAITING ROOM

Peter K., a 6-month-old male infant, was brought to his pediatrician's office with a painful, expanding mass in his right upper thigh that was first noted just hours after he fell down three uncarpeted steps in his home. The child appeared to be in severe distress.

A radiograph showed no fractures, but a soft tissue swelling, consistent with a hematoma (bleeding into the tissues), was noted. **Peter K.**'s mother related that soon after he began to crawl, his knees occasionally became swollen and seemed painful.

The pediatrician suspected a disorder of coagulation. A screening coagulation profile suggested a possible deficiency of factor VIII, a protein involved in the formation of blood clots. **Peter K.**'s plasma factor VIII level was found to be only 3% of the average level found in normal subjects. A diagnosis of hemophilia A was made.

I. Plasma Proteins Maintain Proper Distribution of Water between Blood and Tissues

When cells are removed from the blood, the remaining plasma is composed of water, nutrients, metabolites, hormones, electrolytes, and proteins. Plasma has essentially the same electrolyte composition as other extracellular fluids and constitutes approximately 25% of the body's total extracellular fluid. The plasma proteins serve a number of functions, including maintaining the proper distribution of water between the blood and the tissues, transporting nutrients, metabolites, and hormones throughout the body, defending against infection, and maintaining the integrity of the circulation through clotting. Many diseases alter the amounts of plasma proteins produced and hence their concentration in the blood. These changes can be determined by electrophoresis of plasma proteins over the course of a disease.

In cases of severe protein malnutrition (kwashiorkor), the concentration of the plasma proteins decreases, as a result of which the osmotic pressure of the blood decreases. As a result, fluid is not drawn back to the blood and instead accumulates in the interstitial space (edema). The distended bellies of famine victims are the result of fluid accumulation in the extravascular tissues because of the severely decreased concentration of plasma proteins, particularly albumin. Albumin synthesis decreases fairly early under conditions of protein malnutrition.

A. Body Fluid Maintenance between Tissues and Blood

As the arterial blood enters the capillaries, fluid moves from the intravascular space into the interstitial space (that surrounding the capillaries) due to Starling's forces. The hydrostatic pressure in the arteriolar end of the capillaries (~37 mm Hg) exceeds the sum of the tissue pressure (~1 mm Hg) and the osmotic pressure of the plasma proteins (~25 mm Hg). Thus, water tends to leave the capillaries and enter extravascular spaces. At the venous end of the capillaries, the hydrostatic pressure falls to approximately 17 mm Hg while the osmotic pressure and the tissue pressure remain constant, resulting in movement of fluid back from the extravascular (interstitial) spaces and into the blood. Thus, most of the force bringing water back from the tissues into the plasma is the osmotic pressure mediated by the presence of proteins in the plasma.

In spite of the importance of albumin in the maintenance of osmotic pressure in the blood, individuals who lack albumin (analbuminemia) have only moderate edema. Apparently, the concentration of other plasma proteins is increased to compensate for the lack of albumin. The frequency of analbuminemia is <1 per million individuals.

B. The Major Serum Protein, Albumin

As indicated in Table 43.1, the liver produces a number of transport or binding proteins and secretes them into the blood. The major protein synthesized is albumin, which constitutes approximately 60% of the total plasma protein, but because of its relatively small size (69 kDa), it is thought to contribute 70% to 80% of the total osmotic pressure of the plasma. Albumin is a carrier of free fatty acids, calcium, zinc, steroid hormones, copper, and bilirubin. Many drugs also bind to albumin, which may have important pharmacologic implications. For example, when a drug binds to albumin, such binding will likely lower the effective concentration of that drug and may lengthen its lifetime in the circulation. Drug dosimetry may need to be

recalculated if a patient's plasma protein concentration is abnormal.

TABLE 43.1 Specific Plasma-Binding Proteins Synthesized in the Liver

Albumin	Binds free fatty acids, calcium, zinc, steroid hormones, copper, bilirubin
Ceruloplasmin	Binds copper; appears to be more important as a copper storage pool than as a transport protein; integrates iron and copper homeostasis
Corticosteroid-binding globulin	Binds cortisol
Haptoglobin	Binds extracorporeal heme
Lipoproteins	Transport cholesterol and fatty acids
Retinol-binding protein	Binds vitamin A
Sex hormone-binding globulin	Binds estradiol and testosterone
Transferrin	Transports iron
Transthyretin	Binds thyroxine (T ₄); also forms a complex with retinol-binding protein

II. The Plasma Contains Proteins That Aid in Immune Defense

Two different sets of proteins aid in the immune response, the immunoglobulins, and the complement proteins. The immunoglobulins are secreted by a subset of differentiated B lymphocytes termed plasma cells and bind antigens at binding sites formed by the hypervariable regions of the proteins (see Chapter 7). Once the antibody-antigen complex is formed, it must be cleared from the circulation. The complement system participates in this function. The complement system consisting of approximately 20 proteins becomes activated in either of two ways. The first is interaction with antigen-antibody complexes, and the second, specific for bacterial infections, is through interaction of bacterial cell polysaccharides with complement protein C3b. Activation of the complement system by either trigger results in a proteolytic activation cascade of the proteins of the complement system, resulting in the release of biologically active peptides or polypeptide fragments. These peptides mediate the inflammatory response, attract phagocytic cells to the area, initiate degranulation of granulocytes, and promote clearance of antigen-antibody complexes.

α_1 -Antiproteinase (AAP), also known as α_1 -antitrypsin, is the main serine protease inhibitor of human plasma.

Individuals with a point mutation in exon 5 of the AAP gene, which results in a single amino acid substitution in the protein, have diminished secretion of AAP from the liver. These individuals are at increased risk for developing emphysema. When neutrophils degranulate in the lungs as part of the body's defense against microorganisms, insufficient levels of AAP are present to neutralize the elastase and other proteases released. The excess proteolytic activity damages lung tissue, leading to loss of alveolar elasticity and the development of emphysema.

Methionine 358 of AAP is necessary for AAP binding to the proteases. Oxidation of this methionine destroys AAP's protease-binding capacity. Chemicals within cigarette smoke lead to the oxidation of Met-358, thereby increasing the risk for emphysema through the inactivation of AAP.

Protease inhibitors in plasma serve to carefully control the inflammatory response. Activated neutrophils release lysosomal proteases from their granules that can attack elastin, the various types of collagen, and other extracellular matrix proteins. The plasma proteins α_1 -antiproteinase (α_1 -antitrypsin) and α_2 -macroglobulin limit proteolytic damage by forming noncovalent complexes with the proteases, thereby inactivating them. However, the product of neutrophil myeloperoxidase, HOCl, inactivates the protease inhibitors, thereby ensuring that the proteases are active at the site of infection.

III. Plasma Proteins Maintain the Integrity of the Circulatory System

Blood is lost from the circulation when the endothelial lining of the blood vessels is damaged, and the vessel wall is partly or wholly severed. When this occurs, the subendothelial cell layer is exposed, consisting of the basement membrane of the endothelial cells and smooth muscle cells. In response to the damage, a barrier (the hemostatic plug, a fibrin clot), initiated by platelet binding to the damaged area, is formed at the site of injury. Regulatory mechanisms limit clot formation to the site of injury and control its size and stability. As the vessel heals, the clot is degraded (fibrinolysis). Plasma proteins are required for these processes to occur.

Idiopathic thrombocytopenic purpura (ITP) is an autoimmune disease in which antibodies to platelet glycoproteins are

produced. Antibody binding to platelets results in their clearance by the spleen. An early symptom of the disorder is the appearance of small red spots on the skin (petechial hemorrhages) caused by blood leakage from capillaries. Minor damage to vascular endothelial cells is constantly being caused by mechanical forces related to blood flow. In patients with ITP, few platelets are available to repair the damage.

A. Formation of the Hemostatic Plug

1. The Platelet

Platelets are nonnucleated cells in the blood whose major role is to form mechanical plugs at the site of vessel injury and to secrete regulators of the clotting process and vascular repair. In the absence of platelets, leakage of blood from rents in small vessels is common. Platelets are derived from megakaryocytes in the bone marrow. Megakaryocytes differentiate from the hematopoietic stem cell. As the megakaryocyte matures, it undergoes synchronous nuclear replication without cellular division, to form a cell with a multilobed nucleus and enlarged cytoplasm. At approximately the eight-nucleus stage, the cytoplasm becomes granular, and the platelets are budded off the cytoplasm. A single megakaryocyte gives rise to approximately 4,000 platelets.

In the nonactivated platelet (a platelet that is not involved in forming a clot), the plasma membrane invaginates extensively into the interior of the cell, forming an open membrane (canalicular) system. Because the plasma membrane contains receptors and phospholipids that accelerate the clotting process, the canalicular structure substantially increases the membrane surface area that is potentially available for clotting reactions. The platelet interior contains microfilaments and an extensive actin/myosin system. Platelet activation in response to endothelial injury causes Ca^{2+} -dependent changes in the contractile elements, which, in turn, substantially change the architecture of the plasma membrane. Long pseudopodia are generated, increasing the surface area of the membrane as clot formation is initiated.

Platelets contain three types of granules. The first is electron-dense granules, which contain calcium, adenosine diphosphate (ADP), adenosine triphosphate (ATP), and serotonin. The second type of granule is the α -granule, which contains a heparin antagonist (heparin interferes with blood clotting; see “Biochemical Comments”), platelet-derived growth factor, β -thromboglobulin, fibrinogen, von Willebrand factor (vWF), and other clotting factors. The third type of granule is the lysosomal granule, which contains hydrolytic enzymes. During activation, the contents of these granules, which modulate platelet aggregation and clotting, are secreted.

2. Platelet Activation

Three fundamental mechanisms are involved in platelet function during blood coagulation: adhesion, aggregation, and secretion. Adhesion sets off a series of reactions termed platelet activation, which leads to platelet aggregation and secretion of platelet granule contents.

Von Willebrand factor is a large multimeric glycoprotein with a subunit molecular weight of 220,000 Da. Its size in the circulation ranges between 500 and 20,000 kDa, and its role in circulation is to stabilize factor VIII and protect it from degradation. The HMW forms are concentrated in the endothelium of blood vessels and are released in response to stress hormones and endothelial damage. HMW vWF released by the endothelium is cleaved by a specific metalloprotease in the serum, reducing the size of the circulating vWF. Large vWF multimers are more effective at forming complexes with platelets than are small vWF multimers.

vWF deficiency is the most common cause of inherited bleeding disorders. Both platelet adherence and the clotting cascade are affected because levels of factor VIII are low. In the absence of vWF, factor VIII is rapidly cleared from the system. The vWF gene is large, covering approximately 180 kb, and contains 52 exons. Multiple mutations are known, with varying clinical presentations.

The adhesion step refers primarily to the platelet-subendothelial interaction that occurs when platelets initially adhere to the sites of blood vessel injury (Fig. 43.1). Blood vessel injury exposes collagen, subendothelial matrix-bound vWF, and other matrix components. vWF is a protein synthesized in endothelial cells and megakaryocytes, and it is located in the subendothelial matrix, in specific platelet granules, and in the circulation bound to factor VIII. The platelet cell membrane contains glycoproteins (GPs) that bind to collagen and to vWF, causing the platelet to adhere to the subendothelium. Binding to collagen by GPIa (integrin $\alpha_2\beta_1$) causes the platelet to change its shape from a flat disk to a spherical cell. The latter extrudes long pseudopods, which promote platelet/platelet interactions. Binding of subendothelial vWF by GPIb causes changes in the platelet membrane that expose GPIIb/IIIa (integrin $\alpha_{IIb}\beta_3$)-binding sites to fibrinogen and vWF.

FIGURE 43.1 Adhesion of platelets to the subendothelial cell layer. (1) GPIa initially binds to the exposed collagen, which results in changes in the three-dimensional configuration of the complex, allowing GPIb to bind to von Willebrand factor (Vwf) (2). (3) This second binding event exposes the GPIIb/GPIIIa complex, which also can bind to vWF and fibrinogen.

 Mutations in GPIb cause a bleeding disorder known as Bernard–Soulier syndrome. Platelet aggregation is affected because of the inability of GPIb to adhere to subendothelial vWF.

 Thrombotic thrombocytopenic purpura (TTP) is a disease characterized by the formation in the circulation of microclots (microthrombi) consisting of aggregated platelets. The microthrombi collect in the microvasculature and damage red blood cells, resulting in hemolytic anemia. They also damage vascular endothelium, exposing collagen and releasing HMW vWF, promoting more platelet aggregation. The subsequent depletion of platelets renders the patient susceptible to internal hemorrhage. Mortality in untreated TTP can approach 90%.

Familial TTP, which is a less common cause of TTP, is associated with mutations in the vWF-specific metalloprotease, although not all individuals with defective protease develop TTP. Sporadic cases of TTP are associated with the development of an antibody to the metalloprotease.

The initial adherence of platelets sets off a series of reactions (platelet activation) that results in more platelets being recruited and aggregated at the site of injury. After initial adherence, some of the platelets release the contents of their dense granules and their α -granules, with ADP release being of particular importance because ADP is a potent platelet activator. ADP released from the platelets and from damaged red blood cells binds to a receptor on the platelet membrane, which leads to the further unmasking of GPIIb/IIIa-binding sites. Aggregation of platelets cannot take place without ADP stimulation because ADP induces swelling of the activated platelets, promoting platelet/platelet contact, and adherence.

Fibrinogen is a protein that circulates in the blood and is also found in platelet granules. It consists of two triple helices held together with disulfide bonds (Fig. 43.2). Binding of fibrinogen to activated platelets is necessary for aggregation, providing, in part, the mechanism by which platelets adhere to one another. Cleavage of fibrinogen by thrombin (a protease that is activated by the coagulation cascade) produces fibrin monomers that polymerize and, together with platelets, form a “soft clot.” Thrombin itself is a potent activator of platelets, through binding to a specific receptor on the platelet surface.

A N-Terminal regions of α, β -chains of two triple helices held together with disulfide bonds

B

FIGURE 43.2 Cleavage of fibrinogen results in clot formation. **A.** Fibrinogen, the precursor protein of fibrin, is formed from two triple helices joined together at their *N*-terminal ends. The α,β -peptides are held together by disulfide bonds, and the γ -peptides are joined to each other by disulfide bonds. The terminal α,β -peptide regions, shown in red, contain negatively charged glutamate and aspartate residues that repel each other and prevent aggregation. **B.** Thrombin, a serine protease, cleaves the terminal portions of fibrinogen that contain negative charges. The fibrin monomers can then aggregate and form a “soft” clot. The soft clot is subsequently cross-linked by another enzyme.

B. The Blood Coagulation Cascade

Thrombus (clot) formation is enhanced by thrombin activation, which is mediated by the complex interaction that constitutes the blood coagulation cascade. This cascade (Fig. 43.3) consists primarily of proteins that serve as enzymes or cofactors, which function to accelerate thrombin formation and localize it at the site of injury. These proteins are listed in Table 43.2. All of these proteins are present in the plasma as proproteins (zymogens). These precursor proteins are activated by cleavage of the polypeptide chain at one or more sites. The key to successful and appropriate thrombus formation is the regulation of the proteases that activate these zymogens.

TABLE 43.2 Proteins of Blood Coagulation		
FACTOR	DESCRIPTIVE NAME	FUNCTION/ACTIVE FORM
<i>Coagulation Factors</i>		
I	Fibrinogen	Fibrin
II	Prothrombin	Serine protease
III	Tissue factor	Receptor and cofactor
IV	Ca ²⁺	Cofactor
V	Proaccelerin, labile factor	Cofactor
VII	Proconvertin	Serine protease
VIII	Antihemophilia factor A	Cofactor
IX	Antihemophilia factor B, Christmas factor	Serine protease
X	Stuart–Prower factor	Serine protease
XI	Plasma thromboplastin antecedent	Serine protease
XIII	Fibrin-stabilizing factor	Ca ²⁺ -dependent transglutaminase
<i>Regulatory Proteins</i>		
Thrombomodulin	Endothelial cell receptor binds thrombin	
Proteins C and S	Activated by thrombomodulin-bound thrombin; is a serine protease cofactor; binds activated protein C	

FIGURE 43.3 The blood coagulation cascade. Activation of clot formation occurs through interlocking pathways, termed the intrinsic and extrinsic pathways. The intrinsic pathway is activated when factor XI is converted to factor XI_a by thrombin. The extrinsic pathway (external damage, such as a cut) is activated by tissue factor. The reactions designated by “PL, Ca” are occurring through cofactors bound to phospholipids (PL) on the platelet and blood vessel endothelial cell surface in a Ca²⁺-coordination complex. Factors XI_a, IX_a, VII_a, X_a, and thrombin are serine proteases. Note the positive feedback regulation of thrombin on the activation of proteases earlier in the cascade sequence (indicated by the *dashed lines*).

The proenzymes (factors VII, XI, IX, X, and prothrombin) are serine proteases that, when activated by cleavage, cleave the next proenzyme in the cascade. Because of the sequential activation, great acceleration and amplification of the response are achieved. That cleavage and activation have occurred are indicated by the addition of an “a” to the name of the proenzyme (e.g., factor IX is cleaved to form the active factor IX_a).

The cofactor proteins (tissue factor, factors V and VIII) serve as binding sites for other factors. Tissue factor is not related structurally to the other blood coagulation cofactors and is an integral membrane protein that does not require cleavage for active function. Factors V and VIII serve as procofactors, which, when activated by cleavage, function as binding sites for other factors.

Two additional proteins that are considered part of the blood coagulation cascade, protein S and protein C, are regulatory proteins. Only protein C is regulated by proteolytic cleavage, and when it is activated, it is itself a serine protease.

Additionally, in response to collagen and thrombin, platelets release vasoconstrictors. Serotonin is released from the dense granules of the platelets, and the synthesis of thromboxane A₂ is stimulated. This reduces blood flow to the damaged area. Platelet-derived growth factor, which stimulates proliferation of vascular cells, is also released into the environment surrounding the damage.

The utilization of an active-site serine to cleave a peptide bond is common to a variety of enzymes referred to as serine proteases. Serine proteases are essential for activating the formation of a blood clot from fibrin. Fibrin and many of the other proteins involved in blood coagulation are present in the blood as inactive precursors or zymogens, which must be activated by proteolytic cleavage. Thrombin, the serine protease that converts fibrinogen to fibrin, has the same aspartate–histidine–serine catalytic triad found in chymotrypsin and trypsin.

Thrombin is activated by proteolytic cleavage of its precursor protein, prothrombin. The sequence of proteolytic cleavages leading to thrombin activation requires factor VIII, the blood clotting protein that is deficient in **Peter K**.

C. The Process of Blood Coagulation

Activation of the blood coagulation cascade is triggered by the reaction of plasma proteins with the subendothelium at the same time that platelets are adhering to the subendothelial layer. Historically, two different pathways were discovered, one dependent on external stimuli (such as blunt trauma, which initiates the extrinsic pathway) and one using internal stimuli (the intrinsic pathway). As our understanding of blood clotting has expanded, it has become obvious that these distinctions are no longer correct, because there is overlap between the pathways, but the terms have persisted in the description of the pathways.

In the case of external trauma, damaged tissues present tissue factor to the blood at the injured site, thereby triggering the extrinsic phase of blood coagulation. Circulating factor VII binds to tissue factor, which autocatalyzes its own activation to factor VIIa. Factor VIIa then activates factor X (to Xa) in the extrinsic pathway and factor IX (to IXa) in the intrinsic pathway. Factor IXa, as part of the intrinsic pathway, also activates factor X. Therefore, activation of both the extrinsic and intrinsic pathways results in the conversion of factor X to factor Xa. All of these conversions require access to membranes and calcium; the platelet membrane, which had adhered to the damaged site, is used as a scaffold for the activation reactions to occur. The γ -carboxylated clotting proteins are chelated to membrane surfaces via electrostatic interactions with calcium and negatively charged phospholipids of the platelet membrane. The protein cofactors VIIIa and Va serve as sites for assembling enzyme–cofactor complexes on the platelet surface, thereby accelerating and localizing the reaction. The result is thrombin formation, which augments its own formation by converting factors V, VIII, and XI into activated cofactors and stimulating platelet degranulation. The initial activation of prothrombin is slow because the activator cofactors, VIIIa and Va, are present only in small amounts. However, once a small amount of thrombin is activated, it accelerates its own production by cleaving factors V and VIII to their active forms. Note that these factors are in the intrinsic pathway. The intrinsic pathway is thought to sustain the coagulation response initiated by the extrinsic pathway. The major substrate of thrombin is fibrinogen, which is hydrolyzed to form fibrin monomers that undergo spontaneous polymerization to form the fibrin clot. This is considered a “soft” clot because the fibrin monomers are not cross-linked. Cross-linking requires factor XIIIa, which is activated by thrombin cleavage of factor XIII.

1. Cross-Linking of Fibrin

Factor XIIIa catalyzes a transamidation reaction between glutamine and lysine side chains on adjacent fibrin monomers. The covalent cross-linking takes place in three dimensions, creating a strong network of fibers that is resistant to mechanical and proteolytic damage. This network of fibrin fibers traps the aggregated platelets and other cells, forming the clot that plugs the vent in the vascular wall (Fig. 43.4). Factor XIIIa is the only enzyme in the blood coagulation cascade that is not a serine protease.

FIGURE 43.4 The transamidation reaction catalyzed by factor XIII_a, transglutaminase. This reaction cross-links fibrin monomers, allowing “hard” clots to form.

2. Factor Complexes

In several of the essential steps in the blood coagulation cascade, the activated protease is bound in a complex attached to the surfaces of the platelets that have aggregated at the site of injury. Factors VII, IX, X, and

prothrombin contain a domain in which one or more glutamate residues are carboxylated to γ -carboxyglutamate in a reaction that requires vitamin K (Fig. 43.5). Prothrombin and factor X both contain 10 or more γ -carboxyglutamate residues that bind Ca^{2+} . The Ca^{2+} forms a coordination complex with the negatively charged platelet membrane phospholipids and the γ -carboxyglutamates, thereby localizing the complex assembly and thrombin formation to the platelet surface.

FIGURE 43.5 **A.** Structures of vitamin K derivatives. Phylloquinone is found in green leaves, and intestinal bacteria synthesize menaquinone. Humans convert menadione to a vitamin K active form. **B:** Vitamin K–dependent formation of γ -carboxyglutamate residues. Thrombin, factors VII, IX, and X are bound to their phospholipid activation sites on cell membranes by Ca^{2+} . The vitamin K–dependent carboxylase, which adds the extra carboxyl group, uses a reduced form of vitamin K (KH_2) as the electron donor and converts vitamin K to an epoxide. Vitamin K epoxide is reduced, in two steps, back to its active form by the enzymes vitamin K epoxide reductase and vitamin K reductase.

 Warfarin (Coumadin) is a slow- and long-acting blood anticoagulant with a structure resembling that of vitamin K. The structural similarity allows the compound to compete with vitamin K and prevent γ -carboxylation of glutamate residues in factors II, VII, IX, X, and proteins C and S. The noncarboxylated blood clotting protein precursors increase in both the blood and plasma, but they are unable to promote blood coagulation because they cannot bind calcium and thus cannot bind to their phospholipid membrane sites of activation.

Cofactor Va contains a binding site for both factor Xa and prothrombin, the zymogen substrate of factor Xa. Upon binding to the factor Va–platelet complex, prothrombin undergoes a conformational change, rendering it more susceptible to enzymatic cleavage. Binding of factor Xa to the factor Va–prothrombin–platelet complex allows the prothrombin-to-thrombin conversion. Complex assembly accelerates the rate of this conversion 10,000- to 15,000-fold as compared with noncomplex formation.

Factor VIIIa forms a similar type of complex on the surface of activated platelets but binds factor IXa and its zymogen substrate, factor X. Tissue factor works slightly differently because it is an integral membrane protein. However, once it is exposed by injury, it also binds factor VIIa and initiates complex formation.

Complex assembly has two physiologically important consequences. First, it enhances the rate of thrombin formation by as much as several hundred thousand-fold, enabling the clot to form rapidly enough to preserve hemostasis. Second, such explosive thrombin formation is localized to the site of vascular injury at which the negatively charged phospholipids are exposed. From our knowledge of the location of such phospholipids in cellular and subcellular organelle membranes, these surface-binding sites are only exposed at an injury site in which cell rupture exposes the internal membrane surface (recall that certain phospholipids face only the cytoplasm; if these lipids are now exposed to the environment, substantial cell damage must have occurred).

3. Vitamin K Requirement for Blood Coagulation

The formation of the γ -carboxyglutamate residues on blood coagulation factors takes place in the hepatocyte before release of the protein. Within the hepatocyte, vitamin K (which is present in the quinone form) is reduced to form vitamin KH_2 by a microsomal quinone reductase (see Fig. 43.5). Vitamin KH_2 is a cofactor for carboxylases that add a carboxyl group to the appropriate glutamate residues in the proenzyme to form the carboxylated proenzyme (e.g., prothrombin). In the same reaction, vitamin K is converted to vitamin K epoxide. To recover active vitamin KH_2 , vitamin K is first reduced to the quinone form by vitamin K epoxide reductase, and then to the active hydroquinone form.

Warfarin is a commonly used rat poison and thus is occasionally encountered in emergency departments in cases of accidental poisoning. It is effective as a rat poison because it takes many hours to develop pathological symptoms, which allows one poisoned trap to kill more than one rat.

D. Regulation through Feedback Amplification and Inhibition

Once the formation of the clot (thrombus) begins, clot formation is accelerated in an almost explosive manner by a number of processes that are collectively termed feedback amplification.

1. The Role of Thrombin in Regulation

Thrombin has both a prothrombotic regulatory role (feedback amplification) and an antithrombotic regulatory role (feedback inhibition). The prothrombotic action is initiated when thrombin stimulates its own formation by activating factors V, VIII, and XI, thereby accelerating the rate of clot formation (see Fig. 43.3). Thrombin also promotes clot formation by activating platelet aggregation, stimulating the release of factor VIII from vWF, and cleaving factor XIII to factor XIIIa.

Antithrombotic effects of thrombin result from its binding to an endothelial cell receptor called thrombomodulin (Fig. 43.6). Thrombomodulin abolishes the clotting function of thrombin and allows thrombin to activate protein C, which has anticoagulant effects.

FIGURE 43.6 Antithrombotic effects of thrombin. Thrombin, bound to thrombomodulin on the endothelial cell surface, activates protein C. Activated protein C, in complex with protein S, binds to the platelet membrane, and the activated complex destroys factors V_a and VIII_a, thereby inhibiting the coagulation cascade. PL, phospholipids.

Deficiency in the amount or functionality of protein C or protein S increases the risk for venous thromboembolism. Individuals who are homozygous for these mutations do not survive the neonatal period unless they are given enzyme replacement therapy.

2. Proteins S and C

Protein C and its cofactor protein S serve to suppress the activity of the coagulation cascade. After activation, protein C forms a complex with protein S. Protein S anchors the activated protein C complex (APC) to the clot through Ca²⁺/γ-carboxyglutamate binding to platelet phospholipids. The APC destroys the active blood coagulation cofactors factor VIIIa and Va by proteolytic cleavage, decreasing the production of thrombin. The APC also stimulates endothelial cells to increase secretion of the prostaglandin PGI₂, which reduces platelet aggregation.

In European populations, a point mutation in the factor V gene (factor V Leiden) causes the replacement of an Arg with a Gln in the preferred site for cleavage by activated protein C, rendering factor Va Leiden resistant to APC. Heterozygous individuals have a 6-fold to 8-fold increased risk of deep vein thromboses, and homozygous individuals have a 30- to 140-fold increased risk. The factor V Leiden mutation does not appear to be associated with increased risk for arterial thrombosis, such as myocardial infarction, except in young women who smoke.

Genetic studies suggest that the factor V Leiden mutation arose after the separation of the European, Asian, and African populations. The frequency of this variant indicates that it conferred some selective advantage at one time. In the developed world, inherited APC resistance is the most prevalent risk factor for familial thrombotic disease.

3. Serpins

Many proteases of the blood coagulation enzyme system are serine proteases. Because uncontrolled proteolytic activity would be destructive, modulating mechanisms control and limit intravascular proteolysis. The serpins (**serine protease inhibitors**) are a group of naturally occurring inhibitory proteins that are present in the plasma at high concentration (~10% of the plasma proteins are serpins). At least eight major inhibitors have been found that share a common mechanism of action and inhibit proteases involved in coagulation and clot dissolution (fibrinolysis). Each inhibitor possesses a reactive site that appears to be an ideal substrate for a specific serine protease and thus acts as a trap for that protease. The bound serine protease attacks a peptide bond located at a critical amino acid residue within the serpin and forms a tight enzyme–inhibitor complex.

The activity of thrombin is controlled by the serpin antithrombin III (ATIII). Regulation of blood coagulation at the level of thrombin is critical because this enzyme affects the pathways of both coagulation and fibrinolysis (see Section III.F). One molecule of ATIII irreversibly inactivates one molecule of thrombin through reaction of an arginine residue in ATIII with the active-site serine residue of thrombin. ATIII–thrombin complex formation is markedly enhanced in the presence of heparin. Heparin is a glycosaminoglycan (see Chapter 47) found in the secretory granules of mast cells and in the loose connective tissue around small vascular beds. Heparin binds to lysyl residues on ATIII and dramatically accelerates its rate of binding to thrombin. This is because of an allosteric alteration in ATIII such that the position of the critical arginine residue of ATIII is more readily available for interaction with thrombin. The formation of the ATIII–thrombin complex releases the heparin molecule so that it can be reused and, therefore, the function of heparin is catalytic. Thrombin that is attached to a surface, for example, to thrombomodulin on the endothelial cell membrane, is no longer participating in clot formation and is not readily attacked by ATIII or the ATIII–heparin complex. The ATIII–heparin complex can also inactivate the serine protease factors XIa, IXa, and Xa but has no effect on factor VIIa or activated protein C.

E. Thromboresistance of Vascular Endothelium

Endothelial cells of blood vessels provide a selectively permeable barrier between the circulating blood and the tissues. The normal endothelial cell lining neither activates coagulation nor supports platelet adhesion; thus, it is called a nonthrombogenic surface. The thromboresistance of normal vascular endothelium is contributed to by several properties. Endothelial cells are highly negatively charged, a feature that may repel the negatively charged platelets. Endothelial cells synthesize prostaglandin I₂ (PGI₂) and nitric oxide, vasodilators and powerful inhibitors of platelet aggregation. PGI₂ synthesis is stimulated by thrombin, epinephrine, and local vascular injury. Endothelial cells also synthesize two cofactors that each inhibit the action of thrombin, thrombomodulin, and heparan sulfate. Heparan sulfate is a glycosaminoglycan similar to heparin that potentiates antithrombin III but not as efficiently. The inactivation of thrombin is accelerated by heparan sulfate present on the endothelial cell surface. Thus, the intact endothelium has the capability of modifying thrombin action and inhibiting platelet aggregation.

F. Fibrinolysis

After successful formation of a hemostatic plug, further propagation of the clot must be prevented. This is accomplished in part by switching off blood coagulation and in part by turning on fibrinolysis. Fibrinolysis involves the degradation of fibrin in a clot by plasmin, a serine protease that is formed from its zymogen, plasminogen. Plasminogen is a circulating serum protein that has a high affinity for fibrin, promoting the incorporation of plasminogen in the developing clot. The activity of plasminogen is mediated by proteins known as plasminogen activators. The conversion of plasminogen to plasmin by plasminogen activators can occur both in the liquid phase of the blood and at the clot surface; however, the latter process is by far more efficient. Activated protein C (APC), in addition to turning off the blood coagulation cascade, also stimulates the release of plasminogen activator from tissues (t-PA, tissue plasminogen activator) and simultaneously inactivates an inhibitor of plasminogen activator, PAI-1.

Plasminogen activator release can lead to plasmin formation in the circulation. However, the circulating plasmin is rapidly inactivated by binding with α_2 -antiplasmin, a circulating protease inhibitor. Clot-bound plasmin is not readily inactivated by α_2 -antiplasmin. Thus, plasminogen binding to fibrin facilitates its activation to plasmin, protects it from blood serpins, and localizes it on the fibrin substrate for subsequent efficient proteolytic attack. This mechanism allows for dissolution of fibrin in pathological thrombi or

oversized hemostatic plugs, and at the same time prevents degradation of fibrinogen in the circulating blood.

Two endogenous plasminogen activators are most important; both are synthesized in a variety of cells. Tissue plasminogen activator (t-PA) is produced chiefly by the vascular endothelial cells, has a high binding affinity for fibrin, and plays a major role in fibrinolysis. Single-chain urokinase (u-PA) is synthesized in most cells and tissues and has a moderate affinity for fibrin. Streptokinase, the bacterial exogenous plasminogen activator from β -hemolytic streptococci, is not an enzyme but an allosteric modifier of human plasminogen that allows an autocatalytic reaction such that plasmin is formed. In vivo, physical stress, hypoxia, and large numbers of low-molecular-weight organic compounds promote increased synthesis and release of t-PA and u-PA from tissues into the blood. The balance between release of plasminogen activators, the availability of fibrin, and inhibitors of the activators and plasmin determines regulation of the fibrinolytic response, as indicated in Figure 43.7.

FIGURE 43.7 Regulation of plasmin activation. Plasminogen can be activated by either t-PA or u-PA (+). PAI-1 blocks t-PA action (-). Streptokinase binding to plasminogen allows autocatalysis to form plasmin. Circulating α_2 -antiplasmin blocks (-) the activity of any soluble plasmin that may be in the blood.

 Both streptokinase and t-PA have been approved for the treatment of myocardial infarction but have been used less frequently since cardiac catheterization has become more accessible. If cardiac catheterization is available, this procedure will be used to treat a myocardial infarction. t-PA can also be used to dissolve clots in an acute CVA (cerebral vascular accident or stroke) or a massive PE (lung clot). Due to the availability of newer drugs streptokinase is rarely used at this time.

G. Regulation of Fibrinolysis

Antiactivators regulate interaction of plasminogen in blood with plasminogen activators in a dynamic

equilibrium. Even if minute amounts of plasmin are generated (e.g., after stress-induced release of vascular plasminogen activator), the enzyme is probably inactivated by antiplasmin. Upon activation of the blood coagulation system, a fibrin clot is formed, which not only strongly binds t-PA and plasminogen from blood but also accelerates the rate of plasmin activation. The clot-bound plasmin is protected from inhibitors while attached to fibrin. The enzyme is inactivated by α_2 -antiplasmin and α_2 -macroglobulin after proteolytic dissolution of fibrin and its liberation into the liquid phase of blood. Thus, the fibrin network catalyzes both initiation and regulation of fibrinolysis.

CLINICAL COMMENTS

Peter K. has hemophilia A, the most frequently encountered serious disorder of blood coagulation in humans, occurring in 1 in every 5,000 males. The disease is transmitted with an X-linked pattern of inheritance.

The most common manifestations of hemophilia A are those caused by bleeding into soft tissues (hematomas) such as muscle or into body spaces such as the peritoneal cavity, joint spaces, or the lumen of the gastrointestinal tract. When bleeding occurs repeatedly into joints (hemarthrosis), the joint may eventually become deformed and immobile.

In the past, bleeding episodes have been managed primarily by administration of factor VIII, sometimes referred to as antihemophilia cofactor. Unfortunately, the concentration of factor VIII in plasma is quite low (0.3 nM, compared with 8,800 nM for fibrinogen), requiring that it be prepared from multiple human donors. Before donor screening and virus-inactivation procedures during preparation essentially eliminated transmission with blood transfusions, a large percent of hemophiliac patients treated with factor VIII during the 1980s in Western Europe or North America became infected with HIV (human immunodeficiency virus) and hepatitis C. Recombinant factor VIII is now available for clinical use and mitigates the threat of HIV/hepatitis C transmission in these patients.

Another X-linked bleeding disorder is hemophilia B, which is caused by mutations in the gene for factor IX. Lack of factor IX activity leads to an inability to convert prothrombin to thrombin, and impaired clotting.

BIOCHEMICAL COMMENTS

Drugs That Alter Blood Coagulation: Inhibitors. A number of drugs have been developed that inhibit the blood coagulation cascade. Such drugs are useful in cases in which patients develop spontaneous thrombi, which, if left untreated, would result in a fatal pulmonary embolism. There are a number of major classes of such drugs: the heparins, vitamin K antagonists, specific inhibitors of thrombin, and P2Y₁₂ inhibitors.

Heparin binds to and activates ATIII, which leads to thrombin inactivation. ATIII also blocks the activity of factors VIIIa, IXa, Xa, and XIa. Heparin can be administered in either of two forms: unfractionated, or high-molecular-weight (HMW) heparin; and fractionated, or low-molecular-weight (LMW) heparin. HMW heparin is a heterogenous mixture of glycosaminoglycans, with an average chain length of 43 monosaccharides with an average molecular weight of 15 kDa (the range is 3 to 30 kDa). LMW heparins are fragments of HMW heparin, containing fewer than 18 monosaccharides with an average molecular weight of 4 to 5 kDa.

HMW heparin binds to plasma proteins and cell surfaces in addition to its prime target, ATIII. Because different individuals synthesize different levels of plasma proteins, the use of this form of heparin as an anticoagulant requires constant monitoring of the patient to ensure that the correct dosage has been given so that spontaneous thrombi do not develop, but not so much that spontaneous bleeding occurs. LMW heparin has fewer nonspecific interactions than HMW heparin, and its effects are easier to predict on patients, so constant monitoring is not required.

Warfarin inhibits blood clotting by blocking the activity of the vitamin K epoxide reductase multiprotein complex (VKOR). This complex consists of a number of proteins, and mutations in the VKORC1 subunit, which is a small transmembrane protein in the endoplasmic reticulum, leads to two inheritable disorders. One is warfarin resistance, and the other is a rarer disorder, combined deficiency of vitamin K–dependent clotting factors type 2 (VKCFD2). Almost all of the mutations described in VKORC1 lead to resistance to several vitamin K analogs, such that treatment of clotting disorders with those agents are not effective in these patients. Interestingly, there is one specific mutation in VKORC1, which leads to VKCFD2, and that is R98W,

where an arginine residue at position 98 in the protein is changed to a tryptophan residue. This mutation leads to a loss of the VKORC1 protein from the endoplasmic reticulum, as the arginine which has been altered is in an ER-retention domain for the protein. Treatment for individuals with VKCFD2, which is a bleeding disorder, is increased vitamin K in the diet, or as supplements, as the problem is in regenerating active vitamin K.

A major complication of heparin therapy is heparin-induced thrombocytopenia (HIT, excessive blood clotting with a reduction in the number of circulating platelets). This unexpected result of heparin treatment is caused by heparin binding to a platelet protein, platelet factor 4 (PF4), which induces a conformational change in PF4 such that the immune system believes the complex is foreign. Thus, antibodies are developed against the heparin–PF4 complex. When the antibodies bind to the platelets, the platelets become activated, and thrombi develop. Treatment consists of removing the heparin and using a different form of antithrombotic agent.

The classic vitamin K antagonist is warfarin. Warfarin acts by blocking the vitamin K reductase enzymes required to regenerate active vitamin K (see Fig. 43.5). This results in reduced γ -carboxylation of factors II, VII, IX, and X. In the absence of γ -carboxylation, the factors cannot bind calcium nor form the complexes necessary for the coagulation cascade to be initiated. However, warfarin also blocks the activity of proteins S and C, so both blood clotting and the regulation of clotting are impaired by warfarin administration.

Both heparin and warfarin therapy suffer from their lack of specificity, so drugs specific for single steps in the blood coagulation pathway have been sought and identified. Analysis of heparin potentiation of factor Xa binding to ATIII showed that a unique pentasaccharide sequence was required. An appropriate pentasaccharide, named fondaparinux, was developed that would specifically enhance ATIII interactions with factor Xa. Fondaparinux stimulates the binding of ATIII to factor Xa by 300-fold and is specific for factor Xa inhibition. Fondaparinux does not affect thrombin or platelet activity, and it is not an activating agent of platelets. Because fondaparinux does not bind to PF4, HIT is not a complication with this therapy.

Direct thrombin inhibitors are based on the hirudin molecules, which were initially discovered in leeches and other blood-sucking organisms. These organisms would not be able to feed if the blood clotted at the site of the puncture wound, so the organisms secrete thrombin inhibitors to prevent clotting from occurring. Hirudin treatment itself is dangerous in that formation of the hirudin-thrombin complex is irreversible and use of the drug requires constant monitoring of the patient. Thus, to overcome this problem, rational drug design based on the hirudin structure was used, and a synthetic 20-amino acid peptide known as bivalirudin was synthesized. This agent has a high binding affinity and specificity for thrombin although its effects on thrombin are transient (not irreversible), making this a safer agent for long-term use. More recently, there have been multiple other direct-acting anticoagulants developed, which inhibit either thrombin or factor Xa. There are now multiple direct oral anticoagulants (DOACs), which inhibit factor Xa and are used commonly to treat clotting disorders.

The P2Y₁₂ receptor inhibitors (examples of which are clopidogrel [Plavix] and ticagrelor [Brilinta]) inhibit platelet aggregation by binding tightly to the ADP receptor on the platelet surface. These drugs are used in patients to prevent strokes and heart attacks in patients who have had a previous stroke or heart attack, as well as in patients with cardiovascular disease who have had stents placed to correct narrowed coronary arteries. The use of the drugs prevents platelet aggregation on the newly placed stent. The P2Y₁₂ receptor is coupled to an inhibitory G protein. ADP is found in the platelet dense granule, and when the platelet encounters an appropriate agent (such as thrombin), the granular contents are released and ADP binds to its receptor, which amplifies the platelet response and contributes to platelet aggregation. Blocking ADP binding to its receptor will prevent efficient platelet aggregation.

Treatment of hemophilia A. Hemophilia A, as indicated previously, is an X-linked disorder in which factor VIII is defective such that the blood coagulation cascade is interrupted, leading to a bleeding disorder. Factor VIII is required to orient factor IXa and factor X appropriately such that factor X can be converted to factor Xa, to convert prothrombin to thrombin. Hemophilia A was originally treated with human factor VIII isolated from donor blood, and now with recombinant factor VIII. Once the techniques of gene cloning and monoclonal antibody production were refined (see Chapter 16) it became possible to create bispecific antibodies, in which the classical IgG molecule (see Chapter 7) was engineered to contain one arm of the bivalent antibody which specifically recognized factor IXa, while the other arm was engineered to recognize factor X (Fig. 43.8). The antibody allows the two factors to interact, leading to the activation of factor X. In 2017 the FDA approved the use of emicizumab (the name for the bispecific antibody) for the treatment of patients with hemophilia A. While the antibody approach has proven to be successful a disadvantage to this approach is the lack of an on/off mechanism, with very low levels of self-regulation as well.

FIGURE 43.8 Activation of factor X using a bispecific antibody, which recognizes factor IXa with one arm and factor X with the other arm. The antibody can take the place of factor VIII in orienting factor IXa and factor X to allow activation of factor X.

KEY CONCEPTS

- ◆ The plasma contains water, nutrients, metabolites, hormones, electrolytes, and proteins.
- ◆ Plasma proteins provide osmotic pressure to maintain fluid balance between the tissues and the blood.
- ◆ The plasma proteins provide transport for many molecules, and also aid in immune defense.
- ◆ The plasma proteins, in association with platelets, maintain the integrity of the circulatory system.
 - ◆ Platelets form mechanical plugs at the site of vessel injury and secrete regulators of the blood clotting process.
 - ◆ Platelets become activated when bound to a site of injury, which leads to more platelet binding and aggregation at the injured site.
 - ◆ Circulating fibrinogen also binds to the activated platelets at sites of injury.
- ◆ Clot formation is carefully regulated such that overclotting (thrombosis) or underclotting (bleeding) does not occur.
 - ◆ The clotting cascade consists of a series of protease activation steps leading to the activation of thrombin, which converts fibrinogen to fibrin.
 - ◆ Thrombin also activates transglutaminase, which cross-links the fibrin and leads to “hard clot” formation.
 - ◆ Proteins S and C regulate the clotting cascade and are activated by thrombin.
 - ◆ To form a clot, protein complexes must adhere to the activated platelets, which occurs via γ -carboxy glutamate binding to calcium and platelet membranes.
 - ◆ Serpins are serine protease inhibitors; the serpin antithrombin III (ATIII) aids in regulating blood coagulation by modulating thrombin activity.
 - ◆ Heparin enhances the interaction of thrombin with ATIII.
 - ◆ Plasmin, the active product of plasminogen, is the only protease that can dissolve fibrin clots.
 - ◆ Hemophilia A is due to a lack of factor VIII, an essential factor required for thrombin activation.
- ◆ Diseases discussed in this chapter are summarized in Table 43.3.

TABLE 43.3 Diseases Discussed in This Chapter

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Factor V Leiden	Genetic	Factor V is altered such that it cannot be inactivated by activated protein C, leading to hypercoagulation, and deep vein thrombosis (excessive clotting).
Hemophilia B	Genetic	Lack of factor IX in the blood clotting cascade such that clots cannot be formed.
Hemophilia A	Genetic	Lack of factor VIII in blood clotting cascade, leading to a bleeding disorder (reduced clot formation).
α_1 -antitrypsin deficiency	Genetic	Lack of α_1 -antitrypsin leads to elastase destruction of lung tissue, progressing to emphysema and chronic obstructive pulmonary disease (COPD).
Kwashiorkor	Environmental	Protein deficiency in a calorie-sufficient diet leads to a reduction in circulating blood proteins, resulting in edema.
Thrombocytopenic purpura (TPP)	Both	Formation of microscopic thrombi which lead to hemolysis, and organ failure, if untreated. The idiopathic type may be due to autoimmune destruction of platelets. Mutations in the cell surface protease ADAMTS13 lead to an inability to cleave vWF from the cell surface, giving rise to an inherited form of the disease.
vWF deficiency	Both	A defect in von Willebrand factor, a necessary factor for initiation of the blood clotting cascade. In its absence, clotting will not occur, and bleeding disorders will result.
Bernard–Soulier syndrome	Genetic	Lack of glycoprotein 1b, the receptor for von Willebrand factor. Leads to lack of function of vWF, and a bleeding disorder as the coagulation cascade cannot be fully initiated.

REVIEW QUESTIONS—CHAPTER 43

- The edema observed in patients with noncalorie protein malnutrition is due to which of the following?
 - Loss of muscle mass
 - Ingestion of excess carbohydrates
 - Increased fluid uptake
 - Reduced protein synthesis in the liver
 - Increased production of ketone bodies
- A recent surgery patient receiving warfarin therapy was found to be bleeding internally. The clotting process is impaired in this patient primarily because of which one of the following?
 - Inability of the liver to synthesize clotting factors
 - Specific inhibition of factor XIII activation
 - Inability to form clotting factor complexes on membranes
 - Reduction of plasma calcium levels
 - Enhancement of protein C activity
- An inactivating mutation in which one of the following proenzymes would be expected to lead to thrombosis, uncontrolled blood clotting?
 - Factor XIII
 - Prothrombin
 - Protein C
 - Factor VIII
 - Tissue factor
- Classical hemophilia A results in an inability to directly activate which one of the following factors?
 - Factor II
 - Factor IX
 - Factor X
 - Protein S
 - Protein C

5. Hemophilia B results in an inability to directly activate which one of the following factors?
 - A. Factor II
 - B. Factor IX
 - C. Factor X
 - D. Protein S
 - E. Protein C
6. An infant is born with a severe bleeding disorder. It is quickly determined via analysis of blood components that the patient has greatly decreased levels of circulating vWF. The bleeding disorder most likely results from which one of the following as a primary cause?
 - A. Inability to activate factor II.
 - B. Inability of platelets to bind to blood vessel walls.
 - C. Inability to activate factor IX.
 - D. Inability to activate protein C.
 - E. Inability of platelets to bind fibrinogen.
7. An individual has a family history of factor V Leiden. Factor V Leiden leads to an increased risk of deep vein thrombosis due to which one of the following?
 - A. The activated form of factor V Leiden is resistant to protein C cleavage.
 - B. Factor V Leiden does not need to be cleaved to be activated.
 - C. Factor V Leiden enhances factor XIIIa formation.
 - D. Factor V Leiden has a reduced need for phospholipids and calcium to activate other factors.
 - E. Factor V Leiden directly converts fibrinogen to fibrin.
8. An individual accidentally ingested rat poison that interfered with vitamin K action. The activity of which one of the following clotting factors is vitamin K dependent?
 - A. Factor II
 - B. Factor III
 - C. Factor V
 - D. Factor VIII
 - E. Factor XIII
9. A patient had a stroke (a cerebrovascular accident, CVA) caused by a clot in the carotid circulation and received "clot busters" intravenously as emergency treatment. Which "clot buster" below is not normally found in the human body?
 - A. APC (activated protein C)
 - B. PAI-1 (plasminogen activator inhibitor 1)
 - C. t-PA (tissue plasminogen activator)
 - D. Streptokinase
 - E. uPA (Urokinase)
10. A patient had a deep venous thrombosis (DVT) complicated by a pulmonary embolus (PE) and was placed on an anticoagulant as prevention of future clots. He decided to adopt a healthier lifestyle and changed his diet from primarily meat and potatoes to strict vegetarian. This change in diet could affect the efficiency of which one of his following medications?
 - A. Unfractionated heparin
 - B. LMW heparin
 - C. Warfarin
 - D. Fondaparinux
 - E. Direct thrombin inhibitor
11. A 32-year-old male had fatigue for the past 6 months, had developed a cough over the last 2 months, was wheezing while breathing, and indicated being frequently out of breath upon mild exertion. The patient also indicated he smoked 10 to 15 cigarettes a day, and that he did not know of any genetic disorders in his parents as they both died when he was young. Upon physical exam, the physician noted a slight yellowing of the eyes. Blood work was ordered, which would most likely indicate which one of the following?
 - A. Increased blood glucose levels while fasting
 - B. Increased vitamin K levels
 - C. Increased plasminogen levels
 - D. Decreased vitamin B₁₂ levels
 - E. Decreased iron levels
 - F. Decreased levels of α -1 antitrypsin

2. A patient with celiac spruce has been trying to treat their condition via dietary means after mistakenly eating something containing gluten but has recently noticed that they bruise very easily, have blood spots under their fingernails, and have developed tar-colored stools, indicating bleeding in the colon. The patient most likely has developed a reduced ability to catalyze which one of the following reactions?
 - A. Hydroxylation of proline residues
 - B. Calcium transport across membranes
 - C. γ -Glutamate carboxylation
 - D. Carbon-carbon bond breakage
 - E. Pyruvate to acetyl CoA
3. The liver plays a key role in hemostasis due to which one of the following?
 - A. It is the initial site of vitamin K absorption from the diet
 - B. It is the site of synthesis of many clotting factors
 - C. It is the site of tissue factor disposition
 - D. It is where new red blood cells are synthesized
 - E. It is the tissue which synthesizes tissue plasminogen activator
4. The coagulation cascade rapidly allows clot formation to occur at sites of blood vessel injury, an important component for the enhancement of factor II activation is which one of the following?
 - A. Protein C
 - B. Protein S
 - C. Factor IX
 - D. Tissue factor
 - E. Factor XI
5. Patients who are prescribed warfarin have a problem in their blood clotting cascade that allows clots to form when not needed. The use of warfarin as an anticoagulant differs from the use of heparin as an anticoagulant in which one of the following ways?
 - A. Warfarin blocks intestinal vitamin K absorption, while heparin blocks liver vitamin K absorption
 - B. Warfarin blocks the γ -glutamate carboxylation of clotting factors, while heparin accelerates the γ -glutamate carboxylation of clotting factors
 - C. Warfarin blocks liver synthesis of factor II, while heparin activates an inhibitor of vitamin K cycling
 - D. Warfarin blocks vitamin K cycling, while heparin activates an inhibitor of factor IIa
 - E. Warfarin activates protein C, while heparin inhibits protein S

ANSWERS TO REVIEW QUESTIONS

1. **The answer is D.** Under conditions of reduced protein ingestion, essential amino acids are scarce and the liver reduces protein synthesis, including circulating plasma proteins. The reduction of protein in the plasma results in a lower osmotic pressure, so excess fluid in the extravascular spaces cannot return to the blood, and remains outside of the circulation, collecting in tissues.
2. **The answer is C.** Warfarin inhibits the reduction of vitamin K epoxide, so active vitamin K levels decrease. The reduction in active vitamin K levels reduces the γ -carboxylation of clotting factors. In the absence of γ -carboxylation, the clotting factors cannot bind to calcium to form membrane-associated complexes with other clotting factors. Warfarin has no effect on the liver's ability to synthesize the clotting factor (the synthesized factor is not modified), nor does warfarin specifically inhibit the activation of factor XIII. The inhibition is more global than just attacking one step in the coagulation cascade. Plasma calcium levels are not altered by warfarin, and protein C activity is actually decreased in the presence of warfarin because protein C is one of the proteins that is γ -carboxylated in a vitamin K-dependent reaction.
3. **The answer is C.** Activated protein C turns off the clotting cascade; in the absence of protein C, regulation of clotting is impaired, and clots can develop when not required. Mutations in any of the other answers listed would lead to excessive bleeding, as an essential component of the clotting cascade would be inactivated.
4. **The answer is C.** Classical hemophilia is absence of factor VIII, which is a necessary cofactor for the activation of factor X by factor IXa. Factor II is directly activated by factor Xa, and factor IX is directly activated by factor XIa. Proteins C and S are directly activated by thrombin, factor IIa.
5. **The answer is B.** Hemophilia B is an inactivating mutation in factor IX, such that factor IXa cannot be

formed. Factor XIa is formed, but its substrate, factor IX, is defective, and a nonactive protein results.

6. **The answer is B.** GPIb on the platelet membrane binds to vWF exposed on the subendothelial cell layer. In this patient, vWF levels are reduced, and the initial platelet adhesion event is disturbed. Inability of platelets to adhere to the sites of injury leads to blockage of platelet aggregation, fibrinogen deposition, and clot formation. Due to this problem, most clotting factors will not be activated, but the inability to activate these factors is not the primary cause of the disorder.
7. **The answer is A.** Factor V Leiden still needs to be converted to factor Va to be active, but once active, it is not inactivated by activated protein C. Continued Va activity leads to dysregulation of the clotting cascade, and the potential for thrombi formation when none is required. Va aids in factor II activation, not factor XIII activation, and factor V Leiden does not have an altered phospholipid or calcium requirement for complex formation. Factor V Leiden also cannot convert fibrinogen to fibrin, which is the function of thrombin (factor IIa).
8. **The answer is A.** Factors VII, IX, X, and prothrombin (factor II) contain a domain in which glutamate residues are carboxylated to γ -carboxyglutamate in a reaction that requires vitamin K (vitamin K dependent). The carboxylation is required to allow the factors to bind to positive charges on the forming clot surface, many times aided by the presence of calcium. Factors III, V, VIII, and XIII are not carboxylated in a vitamin K-dependent reaction.
9. **The answer is D.** Streptokinase is produced by β -hemolytic streptococci but has the ability to activate plasminogen to plasmin. All the other proteins listed are produced in the human body. PAI-1 is an inhibitor of plasminogen activator promoting clot retention instead of “clot busting.” Urokinase activates plasminogen to plasmin, as does t-PA. Protein C is a normal component of the body, and when activated works with protein S to inhibit the clotting cascade.
10. **The answer is C.** Warfarin acts as a vitamin K antagonist. Green leafy vegetables are high in vitamin K and are a staple in vegetarian diets. The increased vitamin K in the patient’s diet, and subsequently in his circulation, would greatly reduce warfarin’s action and could put the patient at risk for further clots. Both types of heparin bind to and activate antithrombin III (ATIII) which, when activated, directly inhibits thrombin. Direct thrombin inhibitors bind to thrombin directly to inhibit clotting. Fondaparinux enhances ATIII interaction with factor Xa, inhibiting Xa and blocking the clotting cascade. The mechanism of action of the heparins, fondaparinux, and direct thrombin inhibitors would not be influenced by a vegetarian diet and an increase in vitamin K levels.
11. **The answer is F.** The patient is exhibiting the signs of α -1 antitrypsin deficiency, due to a single nucleotide change in the α -1 antitrypsin gene which leads to the protein not being secreted from the liver. In addition to the lung problems exhibited by the patient, he is also beginning to develop liver disease, as indicated by the mild jaundice (yellow in the eyes). As α -1 antitrypsin deficiency is an autosomal recessive disorder the early death of his parents did not allow one to determine if either parent exhibited symptoms of the disorder. His disorder is exacerbated by his smoking habit, as components of cigarette smoke inactivate α -1 antitrypsin, so what little enzyme which leaves the liver is most likely inactivated once it reaches the lungs. Reduction in vitamin B₁₂ or iron levels would not lead to emphysema-like symptoms, nor would elevation of blood glucose (diabetes) or elevated vitamin K (toxicity of vitamin K is usually only seen in infants). Plasminogen levels would not be elevated in an individual who is in the initial stages of liver disease.
12. **The answer is C.** The patient with celiac sprue has a lipid malabsorption problem when their intestinal tract is inflamed. This includes the fat-soluble vitamins, such as vitamin K. The patient is becoming vitamin K deficient, as vitamin K is required for the γ -glutamate carboxylation reactions. In the absence of such reactions, the blood clotting cascade cannot function, as the required factors cannot congregate on the platelet surface to initiate clot formation. This leads to a bleeding disorder, as indicated by the easy bruising, blood under the fingernails, and blood in the stool. Lack of proline hydroxylation (vitamin C deficiency) would lead to collagen disorders but not to a bleeding problem. Calcium transport would be affected by a vitamin D deficiency, leading to bone weakening (rickets), but not to a bleeding disorder. Thiamin is required for many reactions in which carbon-carbon bonds are broken, but thiamin is not required for blood clotting. An inability to convert pyruvate to acetyl CoA (a defective pyruvate dehydrogenase complex) does not lead to a bleeding disorder, although neuronal and muscular symptoms would occur.
13. **The answer is B.** The liver hepatocyte is the site of production of many clotting factors, including fibrinogen, prothrombin, factors V, VII, IX, XI, and XIII, as well as proteins C and S. Factor VIII is produced by liver sinusoidal cells, along with vWF. Vitamin K absorption occurs in the intestine, and

tissue factor is found in the vascular smooth muscle cell layer, as well as the central nervous system, lungs, and placenta. In the adult, red blood cells are produced in the bone marrow. Tissue plasminogen activator is produced by the endothelial cells lining the blood vessels, and not the liver.

14. **The answer is E.** Once factor II has been activated by factor X (with help from factor V), it will activate factors XIII (transglutaminase), V, VIII, and XI. Factors V and VIII are accessory factors, but the activation of factor XI will accelerate the activation of more factor II through the clotting cascade reactions. Factor II also activates protein C, but activated protein C, in combination with protein S, acts as a brake on the clotting cascade, and reduces further activation of factor II. Factors XI and III (tissue factor) are not activated by factor II.
15. **The answer is D.** Warfarin inhibits the vitamin K epoxide reductase and interferes with the cycling and regeneration of vitamin K, leading to a reduced ability to γ -glutamate carboxylate the clotting factors, and an impaired ability to clot. Heparin works by binding to antithrombin III, thereby enhancing the inhibitor's affinity for thrombin (factor IIa) and blocking the coagulation cascade. Heparin does not interfere with vitamin K action, and warfarin does not activate protein C, or affect the synthesis of factor II.

Liver Metabolism

The liver is strategically interposed between the general circulation and the digestive tract. It receives 20% to 25% of the volume of blood leaving the heart each minute (the cardiac output) through the portal vein (which delivers absorbed nutrients and other substances from the gastrointestinal tract to the liver) and through the hepatic artery (which delivers blood from the general circulation back to the liver). Potentially toxic agents absorbed from the gut or delivered to the liver by the hepatic artery must pass through this **metabolically active organ** before they can reach the other organs of the body. The liver's relatively large size (~3% of total body weight) allows extended residence time in the liver for nutrients to be properly metabolized as well as for potentially harmful substances to be detoxified and prepared for excretion into the urine or feces. Among other functions, therefore, the liver, along with the kidney and gut, is an **excretory organ**, equipped with a broad spectrum of detoxifying mechanisms. It can, for example, carry out **metabolic conversion pathways** and utilize **secretory systems** that allow the excretion of potentially toxic compounds. Concurrently, the liver contains highly specific and selective **transport mechanisms** for essential nutrients that are required not only to sustain its own energy but to provide physiologically important substrates for the systemic needs of the organism. In addition to the myriad of transport processes within the sinusoidal and canalicular plasma membrane sheets (see below), intracellular hepatocytic transport systems exist in organelles such as **endosomes**, **mitochondria**, **lysosomes**, as well as the **nucleus**. The sequential transport steps carried out by these organelles include (1) **uptake**, (2) **intracellular binding and sequestration**, (3) **metabolism**, (4) **sinusoidal secretion**, and (5) **biliary excretion**. The rate of hepatobiliary transport is determined, in part, by the rate of activity of each of these steps. The overall transport rate is also determined by such factors as hepatic blood flow, plasma protein binding, and the rate of canalicular reabsorption. The various aspects of the major metabolic processes performed by the liver have been discussed in greater detail elsewhere in this text. These previous sources will be referred to as the broad spectrum of the liver's contributions to overall health and disease is described.

THE WAITING ROOM

Jean T.'s family difficulties continued, and, in spite of a period of sobriety that lasted 6 months, she eventually started drinking increasing amounts of gin again in an effort to deal with her many anxieties. Her appetite for food declined slowly as well. She gradually withdrew from much of the social support system that her doctors and friends had attempted to build during her efforts for rehabilitation. Upper mid-abdominal pain became almost constant, and she noted increasing girth and distention of her abdomen. Early one morning, she was awakened with pain in her upper abdomen. She vomited dark-brown "coffee ground" material followed by copious amounts of bright red blood. She called a friend, who rushed her to the hospital emergency department.

Amy B., a 23-year-old missionary, was brought to the hospital emergency department complaining of the abrupt onset of fever, chills, and severe pain in the right upper quadrant of her abdomen. The pain was constant and radiated to her right shoulder top. She vomited undigested food twice in the hour before arriving at the emergency department. This did not relieve her pain.

Her medical history indicated that, while serving as a missionary in western Belize, Central America, 2 months earlier, she had several days of mild but persistent diarrhea. A friend of **Amy B.**'s there, a medical missionary, had given her an unidentified medication for 7 days. **Amy B.**'s diarrhea slowly resolved, and she

felt well again until her current abdominal symptoms began.

On physical examination, she appeared toxic and had a temperature of 101°F. She was sweating profusely. Her inferior anterior liver margin was palpable three fingerbreadths below the right rib cage, suggestive of an enlarged liver. The liver edge was rounded and tender. Gentle fist percussion of the lower posterior right rib cage caused severe pain. Routine laboratory studies were ordered, and a computed tomogram (CT) of the upper abdomen was scheduled to be done immediately.

I. Liver Anatomy

The human liver consists of two lobes, each containing multiple lobules and sinusoids. The liver receives 75% of its blood supply from the portal vein, which carries blood returning to the heart from the small intestine, stomach, pancreas, and spleen. The remaining 25% of the liver's blood supply is arterial, carried to the liver by the hepatic artery.

Blood from both the portal vein and hepatic artery empty into a common conduit, mixing their contents as they enter the liver sinusoids (Fig. 44.1). The sinusoids are expandable vascular channels that run through the hepatic lobules. They are lined with endothelial cells that have been described as "leaky" because, as blood flows through the sinusoids, the contents of the plasma have relatively free access to the hepatocytes, which are located on the other side of the endothelial cells.

Liver lobule

FIGURE 44.1 Schematic view of liver anatomy.

The liver is also an exocrine organ, secreting bile into the biliary drainage system. The hepatocytes secrete bile into the bile canaliculus, whose contents flow parallel to that in the sinusoids but in the opposite direction. The canaliculi empty into the bile ducts. The lumina of the bile ducts then fuse, forming the common bile duct. The common duct then releases bile into the duodenum. Some of the liver's effluent is stored in the gallbladder and discharged into the duodenum postprandially to aid in digestion.

The entire liver surface is covered by a capsule of connective tissue that branches and extends throughout the liver. This capsule provides support for the blood vessels, lymphatic vessels, and bile ducts that permeate the liver. In addition, this connective tissue sheet subdivides the liver lobes into smaller lobules.

II. Liver Cell Types

The primary cell type of the liver is the hepatocyte. Hepatocytes, also known as hepatic parenchymal cells,

form the liver lobules. Eighty percent of the liver volume is composed of hepatocytes, but only 60% of the total number of cells in the liver are hepatocytes. The other 40% of the cells are nonparenchymal cells and constitute the lining cells of the walls of the sinusoids. The lining cells comprise the endothelial cells, Kupffer cells, and hepatic stellate cells. In addition, intrahepatic lymphocytes, which include pit cells (liver-specific natural killer cells), are also present in the sinusoidal lining.

The reports of **Amy B.**'s initial laboratory studies showed an elevation in her serum hepatic transaminases, her serum alkaline phosphatases, as well as her serum total bilirubin level.

A. Hepatocytes

The hepatocyte is the cell that carries out the many functions of the liver. Almost all pathways of metabolism are represented in the hepatocyte and these pathways are controlled through the actions of hormones that bind to receptors located on the plasma membrane of their cells. Although hepatocytes are normally quiescent cells with low turnover and a long life span, they can be stimulated to grow if damage occurs to other cells in the liver. The liver mass has a relatively constant relationship to the total body mass of adult individuals. Deviation from the normal or optimal ratio (caused, e.g., by a partial hepatectomy or significant hepatic cell death or injury) is rapidly corrected by hepatic growth caused by a proportional increase in hepatocyte replication.

B. Endothelial Cells

The sinusoidal endothelial cells constitute the lining cells of the sinusoid. Unlike endothelial cells in other body tissues, these cells contain fenestrations with a mean diameter of 100 nm. They do not, therefore, form a tight basement membrane barrier between themselves and the hepatocytes. In this way, they allow for free diffusion of small molecules to the hepatocytes but not of particles the size of chylomicrons (chylomicron remnants, however, which are smaller than chylomicrons, do have free passage to the hepatocyte). The endothelial cells are capable of endocytosing many ligands and also may secrete cytokines when appropriately stimulated. Because of their positioning, lack of tight junctions, and the absence of a tight basement membrane, the liver endothelial cells do not present a significant barrier to the movement of the contents of the sinusoids into hepatocytes. Their fenestrations or pores further promote the free passage of blood components through this membrane into the liver parenchymal cells.

C. Kupffer Cells

Kupffer cells are located within the sinusoidal lining. They contain almost one quarter of all the lysosomes of the liver. The Kupffer cells are tissue macrophages with both endocytotic and phagocytic capacity. They phagocytose many substances such as denatured albumin, bacteria, and immune complexes. They protect the liver from gut-derived particulate materials and bacterial products. On stimulation by immunomodulators, these cells secrete potent mediators of the inflammatory response and play a role in liver immune defense through the release of cytokines that lead to the inactivation of substances considered foreign to the organism. The Kupffer cells also remove damaged erythrocytes from the circulation.

D. Hepatic Stellate Cells

The stellate cells are also called perisinusoidal or Ito cells. There are approximately 5 to 20 of these cells per 100 hepatocytes. The stellate cells are lipid-filled cells and serve as the primary storage site for vitamin A. They also control the turnover of hepatic connective tissue and extracellular matrix and regulate the contractility of the sinusoids. When cirrhosis of the liver is present, the stellate cells are stimulated by various signals to increase their synthesis of extracellular matrix material. This, in turn, diffusely infiltrates the liver, eventually interfering with the function of the hepatocytes.

The CT scan of **Amy B.**'s upper abdomen showed an elevated right hemidiaphragm as well as several cystic masses in her liver, the largest of which was located in the superior portion of the right lobe. Her clinical history as well as her history of possible exposure to various parasites while working in a part of Belize, Central America, that is known to have substandard sanitation, prompted her physicians to order a titer of serum antibodies against the parasite *Entamoeba histolytica*, in addition to measuring serum antibodies against other invasive parasites.

E. Pit Cells

The hepatic pit cells, also known as liver-associated lymphocytes, are natural killer cells, which are a defense mechanism against the invasion of the liver by potentially toxic agents, such as tumor cells or viruses.

III. Major Functions of the Liver

A. The Liver Is a Central Receiving and Recycling Center for the Body

The liver can carry out a multitude of biochemical reactions. This is necessary because of its role in constantly monitoring, recycling, modifying, and distributing all of the various compounds absorbed from the digestive tract and delivered to the liver. If any portion of an ingested compound is potentially useful to that organism, the liver retrieves this portion and converts it to a substrate that can be used by hepatic and nonhepatic cells. At the same time, the liver removes many of the toxic compounds that are ingested or produced in the body and targets them for excretion in the urine or in the bile.

As mentioned previously, the liver receives nutrient-rich blood from the enteric circulation through the portal vein; thus, all of the compounds that enter the blood from the digestive tract pass through the liver on their way to other tissues. The enterohepatic circulation allows the liver to first access the nutrients to fulfill specific functions (such as the synthesis of blood coagulation proteins, heme, purines, and pyrimidines) and then to access the ingested toxic compounds (such as ethanol) and potentially harmful metabolic products (such as NH_4^+ produced from bacterial metabolism in the gut).

In addition to the blood supply from the portal vein, the liver receives oxygen-rich blood through the hepatic artery; this arterial blood mixes with the blood from the portal vein in the sinusoids. This unusual mixing process gives the liver access to various metabolites ingested and produced in the periphery and secreted into the peripheral circulation, such as glucose, individual amino acids, certain proteins, iron–transferrin complexes, and waste metabolites as well as potential toxins produced during substrate metabolism. As mentioned, fenestrations in the endothelial cells, combined with gaps between the cells, the lack of a basement membrane between the endothelial cells and the hepatocytes, and low portal blood pressure (which results in slow blood flow) contribute to the efficient exchange of compounds between sinusoidal blood and the hepatocyte and clearance of unwanted compounds from the blood. Thus, large molecules targeted for processing, such as serum proteins and chylomicron remnants, can be removed by hepatocytes, degraded, and their components recycled. Similarly, newly synthesized molecules, such as very-low-density lipoprotein (VLDL) and serum proteins, can be easily secreted into the blood. In addition, the liver can convert all of the amino acids found in proteins into glucose, fatty acids, or ketone bodies. The secretion of VLDL by the liver not only delivers excess calories to adipose tissue for storage of fatty acids in triacylglycerol, but it also delivers phospholipids and cholesterol to tissues that are in need of these compounds for the synthesis of cell walls as well as other functions. The secretion of glycoproteins by the liver is accomplished through the liver's gluconeogenic capacity and its access to a variety of dietary sugars to form the oligosaccharide chains, as well as its access to dietary amino acids with which it synthesizes proteins. Thus, the liver has the capacity to carry out a large number of biosynthetic reactions. It has the biochemical wherewithal to synthesize a myriad of compounds from a broad spectrum of precursors. At the same time, the liver metabolizes compounds into biochemically useful products. Alternatively, it has the ability to degrade and excrete those compounds presented to it that cannot be further used by the body.

 A knowledge of functional characteristics of liver cells has been used to design agents to determine the normalcy of specific biochemical pathways of the hepatocytes. These “tailor-made” pharmaceuticals can be designed to be taken up by one or more of the transport mechanisms available to the liver. For example, receptor-related endocytic processes can be used as targets to probe specific receptor-mediated transport functions of the liver cells. The asialoglycoprotein receptor, also known as the hepatic-binding protein, has been used in this approach. The substrate $^{99}\text{Tc}^m$ -galactosyl-neoglycoalbumin (NGA) was developed as a specific ligand for selective uptake via this hepatic receptor. The timing and extent of the assimilation of this probe into the hepatocytes, as determined by imaging the liver at precise intervals after the administration of this isotope, yield an estimate of hepatic blood flow as well as the transport capacity of this particular hepatic transporter protein.

Each of the liver cells described contains specialized transport and uptake mechanisms for enzymes, infectious agents, drugs, and other xenobiotics that specifically target these substances to certain liver cell types. These are accomplished by linking these agents covalently by way of biodegradable bonds to their

specific carriers. The latter then determines the particular fate of the drug by using specific cell recognition, uptake, transport, and biodegradation pathways.

B. Inactivation and Detoxification of Xenobiotic Compounds and Metabolites

Xenobiotics are compounds that have no nutrient value (cannot be used by the body for energy requirements) and are potentially toxic. They are present as natural components of foods or they may be introduced into foods as additives or through processing. Pharmacological and recreational drugs are also xenobiotic compounds. The liver is the principal site in the body for the degradation of these compounds. Because many of these substances are lipophilic, they are oxidized, hydroxylated, or hydrolyzed by enzymes in phase I reactions. Phase I reactions introduce or expose hydroxyl groups or other reactive sites that can be used for conjugation reactions (the phase II reactions). The conjugation reactions add a negatively charged group such as glycine, sulfate, or glucuronic acid to the molecule. Many xenobiotic compounds are transformed through several different pathways. A general scheme of inactivation is shown in Figure 44.2.

FIGURE 44.2 General scheme of xenobiotic detoxification. The toxic compound RH has been converted to a sulfated derivative suitable for excretion. RH, a general xenobiotic.

Antibody titers against *Entamoeba histolytica* by the use of an enzyme immunoassay were strongly reactive in **Amy B.**'s blood. A diagnosis of **amoebiasis** was made. Her physicians started a nitroimidazole amebicide (metronidazole) orally in a dose of 750 mg every 8 hours for 10 days. By the third day of treatment, **Amy B.** began to feel noticeably better. Her physicians told her that they expected a full clinical response in 95% of patients with amoebic liver abscesses treated in this way, although her multiple hepatic abscesses adversely affected her prognosis to a degree. After her response to oral therapy for the liver abscess, she was also treated with a "luminal agent" (a drug that acts primarily in the lumen of the intestine) to clear the organism from her intestine.

The conjugation and inactivation pathways are similar to those used by the liver to inactivate many of its own metabolic waste products. These pathways are intimately related to the biosynthetic cascades that exist in the liver. The liver can synthesize the precursors that are required for conjugation and inactivation reactions from other compounds. For example, sulfation is used by the liver to clear steroid hormones from circulation. The sulfate used for this purpose can be obtained from the degradation of cysteine or methionine.

The liver, kidney, and intestine are the major sites in the body for the biotransformation of xenobiotic compounds. Many xenobiotic compounds contain aromatic rings (such as benzopyrene in tobacco smoke) or heterocyclic ring structures (such as the nitrogen-containing rings of nicotine or pyridoxine) that we are unable to degrade or recycle into useful components. These structures are hydrophobic, causing the molecules to be retained in adipose tissue unless they are sequestered by the liver, kidney, or intestine for biotransformation reactions. Sometimes, however, the phase I and II reactions backfire, and harmless hydrophobic molecules are converted to toxins or potent chemical carcinogens.

1. Cytochrome P450 and Xenobiotic Metabolism

The toxification/detoxification of xenobiotics is accomplished through the activity of a group of enzymes with a broad spectrum of biological activity. Some examples of enzymes involved in xenobiotic transformation are described in Table 44.1. Of the wide variety of enzymes that are involved in xenobiotic metabolism, only the cytochrome P450–dependent mono-oxygenase system is discussed here (see Chapter 33). The cytochrome P450–dependent mono-oxygenase enzymes are determinants in oxidative, peroxidative, and reductive degradation of exogenous (chemicals, carcinogens, pollutants, etc.) and endogenous (steroids, prostaglandins,

retinoids, etc.) substances. The key enzymatic constituents of this system are the flavoprotein NADPH-cytochrome P450 oxidoreductase and cytochrome P450 (see Fig. 33.5). The latter is the terminal electron acceptor and substrate-binding site of the microsomal mixed-function oxidase complex, a very versatile catalytic system. The system got its name in 1962 when Omura and Sato found a pigment with unique spectral characteristics derived from liver microsomes of rabbits. When reduced and complexed with carbon monoxide, it exhibited a spectral absorbance maximum at 450 nm.

TABLE 44.1 Examples of Enzymes Used in Biotransformation of Xenobiotic Compounds

Reductase
Sulfotransferase
UDP-glucosyltransferase
UDP-glucuronosyltransferase

The major role of the cytochrome P450 enzymes (see Chapter 33) is to oxidize substrates and introduce oxygen to the structure. Similar reactions can be carried out by other flavin mono-oxygenases that do not contain cytochrome P450.

The human cytochrome P450 enzyme family contains 57 functional genes, which produce proteins with at least 40% sequence homology. These isozymes have different but overlapping specificities. The human enzymes are generally divided into nine major subfamilies, and each of these is further subdivided. For example, in the naming of the principal enzyme involved in the oxidation of ethanol to acetaldehyde, CYP2E1, the CYP denotes the cytochrome P450 family, the 2 denotes the subfamily, the E denotes ethanol, and the 1 denotes the specific isozyme.

The CYP3A4 isoform accounts for 30% to 40% of CYP450 enzymes in the liver and 70% of cytochrome enzymes in gut wall enterocytes. It metabolizes the greatest number of drugs in humans. Specific drugs are substrates for CYP3A4. The concomitant ingestion of two CYP3A4 substrates could potentially induce competition for the binding site, which, in turn, could alter the blood levels of these two agents. The drug with the highest affinity for the enzyme will be preferentially metabolized, whereas the metabolism (and degradation) of the other drug will be reduced. The latter drug's concentration in the blood will then rise.

Moreover, many substances or drugs impair or inhibit the activity of the CYP3A4 enzyme, thereby impairing the body's ability to metabolize a drug. Some of the lipid-lowering agents known as the statins (HMG-CoA reductase inhibitors) require CYP3A4 for degradation. Appropriate drug treatment and dosing take into account the normal degradative pathway of the drug. However, a component of grapefruit juice is a potent inhibitor of CYP3A4-mediated drug metabolism. Evidence suggests that if certain statins are regularly taken with grapefruit juice, their level in the blood may increase as much as 15-fold. This marked increase in plasma concentration could increase the muscle and liver toxicity of the statin in question because side effects of the statins appear to be dose-related.

The cytochrome P450 isozymes all have certain features in common:

1. They all contain cytochrome P450, oxidize the substrate, and reduce oxygen.
2. They all have a flavin-containing reductase subunit that uses NADPH, and not NADH, as a substrate.
3. They are all found in the smooth endoplasmic reticulum and are referred to as microsomal enzymes (e.g., CYP2E1 is also referred to as the microsomal ethanol-oxidizing system, MEOS).
4. They are all bound to the lipid portion of the membrane, probably to phosphatidylcholine.
5. They are all inducible by the presence of their own best substrate and somewhat less inducible by the substrates for other P450 isozymes.
6. They all generate a reactive free-radical compound as an intermediate in the reaction.

2. Examples of Cytochrome P450 Detoxification Reactions

a. Vinyl Chloride

The detoxification of vinyl chloride provides an example of effective detoxification by a P450 isozyme (ethanol detoxification was discussed in Chapter 33). Vinyl chloride is used in the synthesis of plastics and can cause angiosarcoma in the liver of exposed workers. It is activated in a phase I reaction to a reactive epoxide by a hepatic P450 isozyme (CYP2E1), which can react with guanine in DNA or other cellular molecules. However, it also can be converted to chloroacetaldehyde, conjugated with reduced glutathione, and excreted in a series of phase II reactions (Fig. 44.3).

FIGURE 44.3 Detoxification of vinyl chloride.

b. Aflatoxin B₁

Aflatoxin B₁ is an example of a compound that is made more toxic by a cytochrome P450 reaction (CYP2A1). Current research suggests that ingested aflatoxin B₁ in contaminated food (it is produced by a fungus [*Aspergillus flavus*] that grows on peanuts that may have been stored in damp conditions) is directly involved in hepatocarcinogenesis in humans by introducing a G → T mutation into the *p53* gene. Aflatoxin is metabolically activated to its 8,9-epoxide by two different isozymes of cytochrome P450. The epoxide modifies DNA by forming covalent adducts with guanine residues. In addition, the epoxide can combine with lysine residues in proteins and thus is also a hepatotoxin.

c. Acetaminophen

Acetaminophen (Tylenol) is an example of a xenobiotic that is metabolized by the liver for safe excretion; however, it can be toxic if ingested in high doses. The pathways for acetaminophen metabolism are shown in Figure 44.4. As shown in the figure, acetaminophen can be glucuronylated or sulfated for safe excretion by the kidney. However, a cytochrome P450 enzyme produces the toxic intermediate *N*-acetyl-*p*-benzoquinoneimine (NAPQI), which can be excreted safely in the urine after conjugation with glutathione.

FIGURE 44.4 Pathways of acetaminophen detoxification. *N*-Acetyl cysteine stimulates the production of glutathione, thereby reducing the levels of NAPQI, which can damage cellular proteins. Ethanol upregulates CYP2E1 activity (the microsomal ethanol-oxidizing system [MEOS]). GSH, reduced glutathione; UDP, uridine diphosphate.

NAPQI is a dangerous and unstable metabolite that can damage cellular proteins and lead to the death of the hepatocyte. Under normal conditions, when acetaminophen is taken in the correct therapeutic amounts, <10% of the drug forms NAPQI, an amount that can be readily handled by the glutathione detoxifying system (phase II reactions). However, when taken in doses that are potentially toxic, the sulfotransferase and glucuronyl transferase systems are overwhelmed, and more acetaminophen is metabolized through the NAPQI route. When this occurs, the levels of glutathione in the hepatocyte are insufficient to detoxify NAPQI, and hepatocyte death can result.

The enzyme that produces NAPQI, CYP2E1, is induced by alcohol (see Chapter 33, MEOS). Thus, individuals who chronically abuse alcohol have increased sensitivity to acetaminophen toxicity, because a higher percentage of acetaminophen metabolism is directed toward NAPQI, compared with an individual with low levels of CYP2E1. Therefore, even recommended therapeutic doses of acetaminophen can be toxic to these individuals.

Effective treatment for acetaminophen poisoning or overdose involves the use of *N*-acetyl cysteine. This compound supplies cysteine as a precursor for increased glutathione production, which, in turn, enhances the phase II reactions, which reduces the levels of the toxic intermediate.

C. Regulation of Blood Glucose Levels

One of the primary functions of the liver is to maintain blood glucose concentrations within the normal range. The manner in which the liver accomplishes this has been the subject of previous chapters (Chapters 19, 28, and 34). In brief, the pancreas monitors blood glucose levels and secretes insulin when blood glucose levels rise and glucagon when such levels decrease. These hormones initiate regulatory cascades that affect liver glycogenolysis, glycogen synthesis, glycolysis, and gluconeogenesis. In addition, sustained physiological increases in growth hormone, cortisol, and catecholamine secretion help to sustain normal blood glucose levels

during fasting (see Chapter 41).

When blood glucose levels drop, glycolysis and glycogen synthesis are inhibited, and gluconeogenesis and glycogenolysis are activated. Concurrently, fatty acid oxidation is activated to provide energy for glucose synthesis. During an overnight fast, blood glucose levels are maintained primarily by glycogenolysis and, if gluconeogenesis is required, the energy (six ATP molecules are required to produce one molecule of glucose from two molecules of lactate) is obtained by fatty acid oxidation. On insulin release, the opposing pathways are activated such that excess fuels can be stored either as glycogen or fatty acids. The pathways are regulated by the activation or inhibition of two key kinases, the cyclic adenosine monophosphate (cAMP)-dependent protein kinase and the AMP-activated protein kinase (see Fig. 34.8 for a review of these pathways). Recall that the liver can export glucose because it is one of the only two tissues that express glucose 6-phosphatase.

D. Synthesis and Export of Cholesterol and Triacylglycerol

When food supplies are plentiful, hormonal activation leads to fatty acid, triacylglycerol, and cholesterol synthesis. High dietary intake and intestinal absorption of cholesterol compensatorily reduces the rate of hepatic cholesterol synthesis, in which case the liver acts as a recycling depot for sending excess dietary cholesterol to the peripheral tissue when needed as well as accepting cholesterol from these tissues when required. The pathways of cholesterol metabolism were discussed in Chapter 32.

E. Ammonia and the Urea Cycle

The liver is the primary organ for synthesizing urea and thus is the central depot for the disposition of ammonia in the body. Ammonia groups travel to the liver on glutamine and alanine, and the liver converts these ammonia nitrogens to urea for excretion in the urine. The reactions of the urea cycle were discussed in Chapter 36.

Table e-44.1  lists some of the important nitrogen-containing compounds that are primarily synthesized or metabolized by the liver.

F. Formation of Ketone Bodies

The liver is the only organ that can produce ketone bodies, yet it is one of the few that cannot use these molecules for energy production. Ketone bodies are produced when the rate of glucose synthesis is limited (i.e., substrates for gluconeogenesis are limited) and fatty acid oxidation is occurring rapidly. Ketone bodies can cross the blood-brain barrier and become a major fuel for the nervous system under conditions of starvation. Synthesis and metabolism of ketone bodies have been described in Chapter 30.

G. Nucleotide Biosynthesis

The liver can synthesize and salvage all ribonucleotides and deoxyribonucleotides for other cells to use. Certain cells have lost the capacity to produce nucleotides de novo but can use the salvage pathways to convert free bases to nucleotides. The liver can secrete free bases into the circulation for these cells to use for this purpose. Nucleotide synthesis and degradation are discussed in Chapter 39.

H. Synthesis of Blood Proteins

The liver is the primary site of the synthesis of circulating proteins such as albumin and the clotting factors. When liver protein synthesis is compromised, the protein levels in the blood are reduced. Hypoproteinemia may lead to edema because of a decrease in the protein-mediated osmotic pressure in the blood. This, in turn, causes plasma water to leave the circulation and enter (and expand) the interstitial space, leading to edema.

 Cirrhosis of the liver results in portal hypertension, which, because of increasing back pressure into the esophageal veins, promotes the development of dilated thin-walled esophageal veins (varices). At the same time, the synthesis of blood coagulation proteins by the liver and required vitamin K-dependent reactions are greatly diminished (resulting in a prolonged prothrombin time; which, in turn, increases clotting time). When the esophageal varices rupture, massive bleeding can occur. Much of the protein content of the blood entering the gastrointestinal tract is metabolized by intestinal bacteria, releasing ammonium ion, which enters the portal vein. Because hepatocellular function has been compromised, the urea cycle capacity is inadequate, and the ammonium ion enters the peripheral circulation, thereby contributing to hepatic encephalopathy (brain toxicity due to elevated ammonia levels).

Most circulating plasma proteins are synthesized by the liver. Therefore, the hepatocyte has a well-developed endoplasmic reticulum, Golgi system, and cellular cytoskeleton, all of which function in the synthesis, processing, and secretion of proteins. The most abundant plasma protein produced by the liver is albumin, which represents 55% to 60% of the total plasma protein pool. Albumin serves as a carrier for a large number of hydrophobic compounds, such as fatty acids, steroids, hydrophobic amino acids, vitamins, and pharmacological agents. It is also an important osmotic regulator in the maintenance of normal plasma osmotic pressure. The other proteins synthesized by the liver are, for the most part, glycoproteins. They function in hemostasis, transport, protease inhibition, and ligand binding, and as secretagogues for hormone release. The acute-phase proteins that are part of the immune response and the body's response to many forms of "injury" are also synthesized in the liver.

I. The Synthesis of Glycoproteins and Proteoglycans

The liver, because it is the site of synthesis of most of the blood proteins (including the glycoproteins), has a high requirement for the sugars that go into the oligosaccharide portion of glycoproteins. (The synthesis of glycoproteins is discussed in Chapter 27.) These include mannose, fructose, galactose, and amino sugars.

One of the intriguing aspects of the hepatic biosynthetic pathways that use carbohydrates in the synthesis of these compounds is that the liver is not dependent on either dietary glucose or hepatic glucose to generate the precursor intermediates for these pathways. This is because the liver can generate carbohydrates from dietary amino acids (which enter gluconeogenesis generally as pyruvate or an intermediate of the tricarboxylic acid [TCA] cycle), lactate (generated from anaerobic glycolysis in other tissues), and glycerol (generated by the release of free fatty acids from the adipocyte). Of course, if dietary carbohydrate is available, the liver can use that source as well.

Most of the sugars secreted by the liver are *O*-linked, that is, the carbohydrate is attached to the protein at its anomeric carbon through a glycosidic link to the $-OH$ of a serine or a threonine residue. This is in contrast to the *N*-linked arrangement in which there is an *N*-glycosyl link to the amide nitrogen of an asparagine residue (Fig. 44.5). A particularly important *O*-linked sugar is *N*-acetylneuraminic acid (NANA or sialic acid), a nine-carbon sugar that is synthesized from fructose 6-phosphate and phosphoenolpyruvate (see Fig. 27.15). As circulating proteins age, NANA (sialic acid) residues are lost from the serum proteins. This change signals their removal from circulation and their eventual degradation. An asialoglycoprotein receptor on the liver cell surface binds such proteins, and the receptor–ligand complex is endocytosed and transported to the lysosomes. The amino acids from the degraded protein are then recycled within the liver.

J. The Pentose Phosphate Pathway

The major functions of the pentose phosphate pathway (see Chapter 27) are the generation of NADPH and five-carbon sugars. All cell types, including red blood cells, can carry out this pathway because they need to generate NADPH so that the activity of glutathione reductase, the enzyme that catalyzes the conversion of oxidized glutathione (GSSG) back to reduced glutathione (GSH) can be maintained. Without the activity of this enzyme, the protection against free-radical injury is lost. All cells also need this pathway for the generation of ribose, especially those cells that are dividing rapidly or that have high rates of DNA synthesis.

The liver has a much greater demand for NADPH than do most other organs. It uses NADPH for the biosynthesis of fatty acids (which are needed to produce phospholipids) and cholesterol, and for the synthesis of VLDL and bile salts. It also uses NADPH for other biosynthetic reactions, such as proline synthesis. NADPH is also used by mixed-function oxidases such as cytochrome P450 that are involved in the metabolism of xenobiotics and of a variety of pharmaceuticals. Because the liver participates in so many reactions that are capable of generating free radicals, the liver uses more glutathione and NADPH to maintain glutathione reductase and catalase activity than any other tissue. Consequently, the concentration of glucose 6-phosphate dehydrogenase (the rate-limiting and regulated enzyme in the pentose phosphate pathway) is high in the liver, and the rate of flux through this pathway may be as high as 30% of the rate of flux through glycolysis.

IV. Fuels for the Liver

The reactions used to modify and inactivate dietary toxins and waste metabolites are energy-requiring, as are the reactions used by anabolic (biosynthetic) pathways such as gluconeogenesis and fatty acid synthesis. Thus, the liver has a high-energy requirement and consumes approximately 20% of the total oxygen used by the body. The principal forms in which energy is supplied to these reactions are the high-energy phosphate bonds of adenosine triphosphate (ATP), uridine triphosphate (UTP), and guanosine triphosphate (GTP), reduced NADPH, and acyl coenzyme A (acyl CoA) thioesters. The energy for the formation of these compounds is obtained directly from oxidative metabolism, the TCA cycle, or the electron transport chain and oxidative phosphorylation. After a mixed meal containing carbohydrates, the major fuels used by the liver are glucose, galactose, and fructose. If ethanol is consumed, the liver is the major site of ethanol oxidation, yielding principally acetate and then acetyl CoA. During an overnight fast, fatty acids become the major fuel for the liver. They are oxidized to carbon dioxide or ketone bodies. The liver also can use all of the amino acids as fuels (although its use of branched-chain amino acids (BCAAs) is small compared to the muscles), converting many of them to glucose. The urea cycle disposes of the ammonia that is generated from amino acid oxidation.

A. Carbohydrate Metabolism in the Liver

After a carbohydrate-containing meal, glucose, galactose, and fructose enter the portal circulation and flow to the liver. This organ serves as the major site in the body for the utilization of dietary galactose and fructose. It metabolizes these compounds by converting them to glucose and intermediates of glycolysis. Their fate is essentially the same as that of glucose (Table 44.2).

TABLE 44.2 Major Fates of Carbohydrates in the Liver

Storage as Glycogen
Glycolysis to pyruvate
Followed by oxidation to carbon dioxide in the TCA cycle
Precursors for the synthesis of glycerol 3-phosphate (the backbone of triacylglycerols and other glycolipids), sialic acid, and serine
Entry into the TCA cycle and exit as citrate, followed by conversion to acetyl CoA, malonyl CoA, and entry into fatty acid synthesis and secretion as VLDL
Synthesis of phospholipids and other lipids from triacylglycerols
Conversion to mannose, sialic acid, and other sugars necessary for the synthesis of oligosaccharides for glycoproteins, including those secreted into the blood
Synthesis of acid sugars for proteoglycan synthesis and formation of glucuronides
Oxidation in the pentose phosphate pathway for the formation of NADPH (necessary for biosynthetic reactions such as fatty acid synthesis, glutathione reduction, and other NADPH-utilizing detoxification reactions)

B. Glucose as a Fuel

The entry of glucose into the liver is dependent on a high concentration of glucose in the portal vein after a high-carbohydrate meal. Because the K_m for both the glucose transporter (GLUT2) and glucokinase is so high (~10 mM), glucose enters the liver principally after its concentration rises to 10 to 40 mM in the portal blood and not at the lower 5-mM concentration in the hepatic artery. The increase in insulin secretion that follows a high-carbohydrate meal promotes the conversion of glucose to glycogen. In addition, the rate of glycolysis is increased (PFK-2 kinase activity is active; thus PFK-1 is activated by fructose 2,6-bisphosphate) so that acetyl CoA can be produced for fatty acid synthesis (acetyl CoA carboxylase is activated by citrate; see Chapter 31). Thus, after a high-carbohydrate meal, the liver uses glucose as its major fuel while activating the pathways for glycogen and fatty acid synthesis.

The rate of glucose utilization by the liver is determined, in part, by the level of activity of glucokinase. Glucokinase activity is regulated by a glucokinase regulatory protein (RP), which is located in the nucleus. In the absence of glucose, glucokinase is partially sequestered within the nucleus, bound to RP, in an inactive form. High concentrations of fructose 6-phosphate promote the interaction of glucokinase with RP, whereas high levels of either glucose or fructose 1-phosphate block glucokinase from binding to RP and promote the dissociation of the complex. Thus, as glucose levels rise in the cytoplasm and nucleus (e.g., because of increased blood glucose levels after a meal), there is a significant enhancement of glucose phosphorylation as glucokinase is released from the nucleus, travels to the cytoplasm, and phosphorylates glucose.

Why would you expect fructose 1-phosphate levels to promote the dissociation of glucokinase from RP?

The major regulatory step for liver glycolysis is the PFK-1 step. Even under fasting conditions, the ATP concentration in the liver (~2.5 mM) is sufficiently high to inhibit PFK-1 activity. Thus, liver glycolysis is basically controlled by modulating the levels of fructose 2,6-bisphosphate, the product of the PFK-2 reaction. As fructose 2,6-bisphosphate levels increase (which will occur in the presence of insulin) the rate of glycolysis increases; when glucagon levels increase and protein kinase A is activated so that PFK-2 is phosphorylated and its kinase activity inactive, glycolysis slows down and gluconeogenesis is enhanced (see Chapters 22 and 28).

C. Lipid Metabolism

Long-chain fatty acids are a major fuel for the liver during periods of fasting, when they are released from adipose tissue triacylglycerols and travel to the liver as fatty acids bound to albumin. In the liver, they bind to fatty acid-binding proteins and are then activated on the outer mitochondrial membrane, the peroxisomal membrane, and the smooth endoplasmic reticulum by fatty acyl CoA synthetases. The fatty acyl group is transferred from CoA to carnitine for transport through the inner mitochondrial membrane, where it is reconverted back into fatty acyl CoA and oxidized to acetyl CoA in the β -oxidation spiral (see Chapter 30).

Fructose 1-phosphate is produced from fructose metabolism. The major dietary source of fructose, the ingestion of which would lead to increased fructose 1-phosphate levels, is sucrose. Sucrose is a disaccharide of glucose and fructose. Thus, an elevation of fructose 1-phosphate usually indicates an elevation of glucose levels as well.

The enzymes in the pathways of fatty acid activation and β -oxidation (the synthetases, the carnitine acyltransferases, and the dehydrogenases of β -oxidation) are somewhat specific for the length of the fatty acid carbon chain. The chain-length specificity is divided into enzymes for very-long-chain fatty acids (C20 to ~C12), medium-chain (~C12 to C4), and short-chain (C4 to C2). The major lipids oxidized in the liver as fuels are the long-chain fatty acids (palmitic, stearic, and oleic acids), because these are the lipids that are synthesized in the liver, are the major lipids ingested from meat or dairy sources, and are the major form of fatty acids present in adipose tissue triacylglycerols. The liver, as well as many other tissues, uses fatty acids as fuels when the concentration of the fatty acid-albumin complex is increased in the blood.

MCTs are important components of nutritional supplements used in patients with digestive disorders. They, therefore, can be employed as an easily absorbed source of calories in patients who have a gastrointestinal (GI) disorder that may result in malabsorption of nutrients. These diseases include pancreatic insufficiency, intraluminal bile salt deficiency due to cholestatic liver disease, biliary obstruction, ileal disease or resection, and disease that causes obstruction of intestinal lymphatics. Remember, however, that MCTs do not contain polyunsaturated fatty acids that can be used for the synthesis of eicosanoids (see Chapter 31).

1. Medium-Chain-Length Fatty Acid Oxidation

The liver and certain cells in the kidney are the major sites for the oxidation of medium-chain-length fatty acids. These fatty acids usually enter the diet of infants in maternal milk as medium-chain-length triacylglycerols (MCTs). In the intestine, the MCTs are hydrolyzed by gastric lipase, bile salt-dependent lipases, and pancreatic lipase more readily than long-chain triacylglycerols. In the enterocytes, they are neither reconverted to triacylglycerols nor incorporated into chylomicrons. Instead, they are released directly into the portal circulation (fatty acids of approximately eight-carbon chain lengths or less are water-soluble). In the liver, they diffuse through the inner mitochondrial membrane and are activated to acyl CoA derivatives by medium-chain-length acyl CoA synthetase, a family of similar isozymes present only in the liver and kidney. The medium-chain fatty acyl CoA is then oxidized by the normal route, beginning with medium-chain-length acyl CoA dehydrogenase (MCAD; see Chapter 30).

2. Peroxisomal Oxidation of Very-Long-Chain Fatty Acids

Peroxisomes are present in greater numbers in the liver than in other tissues. Liver peroxisomes contain the enzymes for the oxidation of very-long-chain fatty acids such as C24:0 and phytanic acid, for the cleavage of the cholesterol side chain necessary for the synthesis of bile salts, for a step in the biosynthesis of ether lipids, and for several steps in arachidonic acid metabolism. Peroxisomes also contain catalase and are capable of detoxifying hydrogen peroxide.

Zellweger (cerebrohepato) syndrome occurs in individuals with a rare inherited absence of peroxisomes in all tissues. Patients accumulate C26 to C38 polyenoic acids in brain tissue because of defective peroxisomal oxidation of the very-long-chain fatty acids synthesized in the brain for myelin formation. In the liver, bile acid and ether lipid synthesis are affected, as is the oxidation of very-long-chain fatty acids.

Very-long-chain fatty acids of C20 to C26 or greater are activated to CoA derivatives by very-long-chain acyl CoA synthetase present in the peroxisomal membrane. The very-long-chain acyl CoA derivatives are then oxidized in liver peroxisomes to the eight-carbon octanoyl CoA level. In contrast to mitochondrial β -oxidation, the first enzyme in peroxisomal β -oxidation introduces a double bond and generates hydrogen peroxide instead of FAD(2H). The remainder of the cycle, however, remains the same, releasing NADH and acetyl CoA. Peroxisomal catalase inactivates the hydrogen peroxide, and the acetyl CoA can be used in biosynthetic pathways such as those of cholesterol and dolichol synthesis.

The octanoyl CoA that is the end product of peroxisomal oxidation leaves the peroxisomes and the octanoyl group is transferred through the inner mitochondrial membrane by medium-chain-length acylcarnitine transferase. In the mitochondria, it enters the regular β -oxidation pathway, beginning with MCAD.

3. Peroxisome Proliferator-Activated Receptors

The peroxisome proliferator-activated receptors (PPARs) play an important role in liver metabolism. These receptors obtained their name from the finding that certain agonists were able to induce the proliferation of peroxisomes in the liver. These agonists included hypolipidemic agents, nonsteroidal anti-inflammatory agents, and environmental toxins. The receptors that bind these agents, the PPARs, are members of a nuclear receptor family and, when activated, stimulate new gene transcription. In the liver, the major form of PPAR regulates directly the activity of genes that are involved in fatty acid uptake and β - and ω -oxidation of fatty acids.

The fibrates (e.g., clofibrate) are a class of drugs that bind to PPARs to elicit changes in lipid metabolism. They are prescribed for individuals with very elevated triglyceride levels because they increase the rate of triglyceride oxidation. This, in turn, leads to a reduction in serum triacylglycerol levels. Fibrates, through PPAR α stimulation, also suppress apolipoprotein CIII synthesis and stimulate LPL activity. ApoCIII normally inhibits LPL activity, so by reducing CIII synthesis overall, LPL activity is increased. ApoCIII also blocks apolipoprotein E on IDL particles, causing the IDL particles to accumulate because they cannot be taken up by the apoE receptor in the liver. The suppression of apoCIII levels allows more IDL to be endocytosed, thereby also reducing circulating triacylglycerol levels.

While the roles of the PPARs have been discussed previously (see Section Five of this text), it is worth reviewing them here. There are three major PPAR isoforms, α , δ/β , and γ . The major form found in the liver is the α -form. Fatty acids are an endogenous ligand for PPAR α , such that when the level of fatty acids in the circulation is increased (with a concurrent increase in the fatty acid content of hepatocytes), there is increased gene transcription for those proteins involved in regulating fatty acid metabolism (Table 44.3). Genetically altered mice have been generated that lack PPAR α . These knockout mice exhibit no abnormal phenotype when they are fed a normal diet. When they are fasted, however, or when they are fed a high-fat diet, these mice

develop severe fatty infiltration of the liver. The inability to increase the rate of fatty acid oxidation in this organ leads to excessive fatty acid buildup in the hepatocytes. It also leads to an insufficient energy supply with which to make glucose (leading to hypoglycemia) as well as an inability to produce ketone bodies. In normal fasted mice or mice fed a high-fat diet, fatty acids will eventually stimulate their own oxidation via peroxisome proliferation and by induction of other enzymes needed for their oxidation. The knockout mice cannot make these compensations.

TABLE 44.3 Genes Regulated by Activation of PPAR α

Fatty acid transport proteins (upregulated)
The mitochondrial and peroxisomal enzymes of fatty acid oxidation (upregulated)
Carnitine palmitoyl transferase I (upregulated)
Lipoprotein lipase (upregulated)
Apolipoproteins A1 and A2 (upregulated, leading to increased HDL production)
Apolipoprotein CIII (downregulated)
Acyl coenzyme A synthetase (upregulated)

Reye's syndrome is characterized clinically by vomiting with signs of progressive central nervous system damage. In addition, there are signs of hepatic injury and hypoglycemia. There is mitochondrial dysfunction with decreased activity of hepatic mitochondrial enzymes. Hepatic coma may occur as serum ammonia levels rise. It is associated epidemiologically with the consumption of aspirin by children during a viral illness, but it may occur in the absence of exposure to salicylates. The incidence in the United States has decreased dramatically since the 1980s, when parents were made aware of the dangers of giving aspirin to children to reduce fever. Reye's syndrome is not necessarily confined to children. In patients who die of this disease, the liver at autopsy shows swollen and disrupted mitochondria and extensive accumulation of lipid droplets with fatty vacuolization of cells in both the liver and the renal tubules.

4. Xenobiotics Metabolized as Fatty Acids

The liver uses the pathways of fatty acid metabolism to detoxify very hydrophobic and lipid-soluble xenobiotics that, like fatty acids, either have carboxylic acid groups or can be metabolized to compounds that contain carboxylic acids. Benzoate and salicylate are examples of xenobiotics that are metabolized in this way. Benzoate is naturally present in plant foods and is added to foods such as sodas as a preservative. Its structure is similar to that of salicylic acid (which is derived from the degradation of aspirin). Salicylic acid and benzoate are similar in size to medium-chain-length fatty acids and are activated to an acyl CoA derivative by medium-chain acyl CoA synthetases (Fig. 44.6). The acyl group is then conjugated with glycine, which targets the compound for urinary excretion. The glycine derivatives of salicylate and benzoate are called salicylurate and hippurate, respectively. Salicylurate is the major urinary metabolite of aspirin in humans. Benzoate can be administered to treat hyperammonemia associated with congenital defects because urinary hippurate excretion tends to lower the free ammonia pool. Aspirin cannot be used for this purpose because it is toxic in the large doses required.

FIGURE 44.6 Benzoate and salicylate metabolism. AMP, adenosine monophosphate; ATP, adenosine triphosphate; CoA, coenzyme A; PP_i, pyrophosphate.

5. The Metabolism of Lipids in Liver Disease

Chronic parenchymal liver disease is associated with relatively predictable changes in plasma lipids and lipoproteins. Some of these changes are related to a reduction in the activity of lecithin-cholesterol acyltransferase (LCAT). This plasma enzyme is synthesized and glycosylated in the liver; then enters the blood, where it catalyzes the transfer of a fatty acid from the 2-position of lecithin to the 3 β -OH group of free cholesterol to produce cholesterol ester and lysolecithin. As expected, in severe parenchymal liver disease, in which LCAT activity is decreased, plasma levels of cholesterol ester are reduced and free cholesterol levels are normal or increased.

Plasma triacylglycerols are normally cleared by peripheral lipases (lipoprotein lipase or LPL and hepatic triglyceride lipase or HTGL). Because the activities of both LPL and HTGL are reduced in patients with the hepatocellular disease, a relatively high level of plasma triacylglycerols may be found in both acute and chronic hepatitis, in patients with cirrhosis of the liver and in patients with other diffuse hepatocellular disorders.

With low LCAT activity and the elevated triacylglycerol level described, low-density lipoprotein (LDL) particles have an abnormal composition. They are relatively triacylglycerol-rich and cholesterol ester-poor.

The level of nonesterified fatty acid (NEFA) in blood samples can be determined using enzyme-coupled reactions. The unknown sample is incubated with coenzyme A and acyl CoA synthetase, which adds the coenzyme to the nonesterified fatty acids, creating acyl CoA. The acyl CoA produced is oxidized by acyl CoA oxidase, which generates hydrogen peroxide. The hydrogen peroxide is used as a source of electrons by peroxidase to reduce a chromogenic substrate, which produces a colored reaction product. The concentration of the reaction product is determined spectrophotometrically and is directly proportional to the level of NEFA in the sample.

High-density lipoprotein (HDL) metabolism may be abnormal in chronic liver disease as well. For example, because the conversion of HDL₃ (less antiatherosclerotic) to HDL₂ (more antiatherosclerotic) is catalyzed by LCAT, the reduced activity of LCAT in patients with cirrhosis leads to a decrease in the HDL₂:HDL₃ ratio.

Conversely, the conversion of HDL₂ to HDL₃ requires hepatic lipases. If the activity of this lipase is reduced, one would expect an elevation in the HDL₂:HDL₃ ratio. Because the HDL₂:HDL₃ ratio is usually elevated in cirrhosis, the lipase deficiency appears to be the more dominant of the two mechanisms. These changes may result in an overall increase in serum total HDL levels. How this affects the efficiency of the reverse cholesterol transport mechanism and the predisposition to atherosclerosis is not fully understood.

With regard to triacylglycerol levels in patients with severe parenchymal liver disease, the hepatic production of the triacylglycerol-rich, VLDL particle is impaired. Yet the total level of plasma triacylglycerols remains relatively normal because the LDL particle in such patients is triacylglycerol-rich, for reasons that have not been fully elucidated.

Nonesterified fatty acid (NEFA) levels are elevated in patients with cirrhosis. This change might be expected because basal hepatic glucose output is low in these patients. As a result, more NEFA are presumably required (via increased lipolysis) to meet the fasting energy requirements of peripheral tissues.

D. Amino Acid Metabolism in the Liver

The liver is the principal site of amino acid metabolism in humans. It essentially balances the free amino acid pool in the blood through the metabolism of amino acids supplied by the diet after a protein-containing meal and through the metabolism of amino acids supplied principally by skeletal muscles during an overnight fast. In an adult who is no longer growing linearly, the total protein content of the body on a daily basis is approximately constant, so the net degradation of amino acids (either to other compounds or used for energy) is approximately equal to the amount consumed. The key points concerning hepatic amino acid metabolism are the following:

1. The liver contains all the pathways for catabolism of all of the amino acids (although its metabolism of the BCAAs is low) and can oxidize most of the carbon skeletons to carbon dioxide. A small proportion of the carbon skeletons is converted to ketone bodies. The liver also contains the pathways for converting amino acid carbon skeletons to glucose (gluconeogenesis) that can be released into the blood.
2. Because the liver is the principal site of amino acid catabolism, it also contains the urea cycle, the pathway that converts toxic ammonium ion to nontoxic urea. The urea is then excreted in the urine.
3. After a mixed or high-protein meal, the gut uses dietary aspartate, glutamate, and glutamine as fuel (during fasting, the gut uses glutamine from the blood as a major fuel). Thus, the ingested acidic amino acids do not enter the general circulation. The nitrogen from gut metabolism of these amino acids is passed to the liver as citrulline or ammonium ion via the portal vein.

Unlike **Amy B.**, whose hepatic amoebic disorder was more localized (abscesses), **Jean T.** had a diffuse hepatic disease, known as alcohol-induced cirrhosis (referred to historically as “Laennec’s cirrhosis”). The latter is characterized by diffuse fine scarring, a fairly uniform loss of hepatic cells, and the formation of small regenerative nodules (sometimes referred to as “micronodular cirrhosis”). With continued alcohol intake, fibroblasts and activated stellate cells deposit collagen at the site of persistent injury. This leads to the formation of weblike septa of connective tissue in periportal and pericentral zones. These eventually connect portal triads and central veins. With further exposure to alcohol, the liver shrinks and then becomes nodular and firm as end-stage cirrhosis develops. Unless they are successfully weaned from alcohol, these patients eventually die of liver failure. **Amy B.**, however, can probably look forward to enjoying normal liver function after successful amebicidal therapy without the evidence of residual hepatic scarring.

4. The BCAAs (valine, leucine, and isoleucine) can be used as a fuel by most cell types, including cells of the gut and skeletal muscle. After a high-protein meal, most of the BCAAs are not oxidized by the liver (because of very low activity of the branched-chain amino acid transaminase) and instead enter the peripheral circulation to be used as a fuel by other tissues or for protein synthesis (these amino acids are essential amino acids). The liver does, however, take up whatever amino acids it needs to carry out its own protein synthesis.
5. Most tissues transfer the amino acid nitrogen to the liver to dispose of as urea. They, therefore, produce either alanine (from the pyruvate–glucose–alanine cycle, in skeletal muscle, kidney, and intestinal mucosa) or glutamine (skeletal muscle, lungs, neural tissues) or serine (kidney), which are released into the blood and taken up by the liver.
6. The liver uses amino acids for the synthesis of proteins that it requires as well as for the synthesis of proteins to be used elsewhere. For example, the liver uses the carbon skeletons and nitrogens of amino acids for the synthesis of nitrogen-containing compounds such as heme, purines, and pyrimidines. The amino acid

precursors for these compounds are all nonessential because they can be synthesized in the liver.

E. Amino Acid Metabolism in Liver Disease

The concentration of amino acids in the blood of patients with liver disease is often elevated. This change is, in part, attributable to a significantly increased rate of protein turnover (a general catabolic effect seen in severely ill patients) as well as to impaired amino acid uptake by the diseased liver. It is unlikely that the increased levels are due to the degradation of liver protein and the subsequent release of amino acids from the failing hepatocyte into the blood. This is true because the total protein content of the liver is only approximately 300 g. To account for the elevated amino acid levels in the blood, the entire protein content of the liver would have to be degraded within 6 to 8 hours to account for the increased protein turnover rates found. Because 18 to 20 times more protein is present in skeletal muscle (greater mass), the muscle is probably the major source of the elevated plasma levels of amino acids seen in catabolic states such as cirrhosis of the liver.

In cirrhotic patients, such as **Jean T.**, the fasting blood α -amino nitrogen level is elevated as a result of reduced clearance. Urea synthesis is reduced as well.

The plasma profile of amino acids in cirrhosis characteristically shows an elevation in aromatic amino acids, phenylalanine and tyrosine, and in free tryptophan and methionine. The latter changes may be caused by impaired hepatic utilization of these amino acids as well as by portosystemic shunting. Although the mechanism is not known, a reduction in fasting plasma levels of the BCAAs is also seen in cirrhotic patients. These findings, however, must be interpreted with caution because most of the free amino acid pool in humans is found in the intracellular space. Therefore, changes seen in their plasma concentrations do not necessarily reflect their general metabolic fate. Yet the elevation in aromatic amino acids and the suppression of the level of BCAAs in the blood of cirrhotics have been implicated in the pathogenesis of hepatic encephalopathy.

V. Diseases of the Liver

Diseases of the liver can be clinically and biochemically devastating because no other organ can compensate for the loss of the multitude of functions that the liver normally performs. Alcohol-induced liver disease has been discussed in Chapter 33. A number of diseases can lead to hepatic fibrosis (see “Biochemical Comments”) and cirrhosis. When this occurs to a great enough extent, the liver function becomes inadequate for life. Signs and symptoms of liver disease include elevated levels of the enzymes alanine aminotransferase (ALT) and aspartate aminotransferase (AST) in the plasma (due to hepatocyte injury or death with a consequent release of these enzymes into the blood), jaundice (an accumulation of bilirubin in the blood caused by inefficient bilirubin glucuronidation by the liver; see Chapter 43), increased clotting times (the liver has difficulty producing clotting factors for secretion), edema (reduced albumin synthesis by the liver leads to a reduction in osmotic pressure in the blood), and hepatic encephalopathy (reduced urea cycle activity leading to excessive levels of ammonia and other toxic compounds in the central nervous system).

CLINICAL COMMENTS

Jean T. Patients with cirrhosis of the liver who have no known genetic propensity to glucose intolerance, such as **Jean T.**, tend to have higher blood glucose levels than do normal subjects in both fasting and fed states. The mechanisms that may increase glucose levels in the fasting state include a reduction in the metabolic clearance rate of glucose by 25% to 40% compared with normal subjects. This reduction in glucose clearance results, in part, from increased oxidation of fatty acids and ketone bodies and the consequent decrease in glucose oxidation by peripheral tissues in cirrhosis patients. This is suggested by the discovery that plasma NEFA levels are high in many patients with hepatocellular dysfunction, in part because of decreased hepatic clearance of NEFA and in part because of increased adipose tissue lipolysis. Another possible explanation for the reduction in whole-body glucose utilization in cirrhotic patients relates to the finding that ketone body production is increased in some patients with cirrhosis. This could lead to enhanced utilization of ketone bodies for fuel by the central nervous system in such patients, thereby reducing the need for glucose oxidation by the highly metabolically active brain.

After glucose ingestion (fed state), many patients with liver disease have abnormally elevated blood glucose levels (“hepatogenous diabetes”). Using World Health Organization (WHO) criteria, 60% to 80% of cirrhotic patients have varying degrees of glucose intolerance, and overt diabetes mellitus occurs two to four times as

often in cirrhotics than it does in subjects without liver disease. The proposed mechanisms include a degree of insulin resistance in peripheral tissues; however, as the cirrhotic process progresses, these patients develop a marked impairment of insulin secretion as well. Although the mechanisms are not well understood, this decrease in insulin secretion leads to increased hepatic glucose output (leading to fasting hyperglycemia) and reduced suppression of hepatic glucose output after meals, leading to postprandial hyperglycemia as well. If the patient has an underlying genetic predisposition to diabetes mellitus, the superimposition of the mechanisms outlined above will lead to an earlier and more significant breakdown in glucose tolerance in these specific patients.

After **Amy B.**'s treatment for amoebiasis was concluded she made an uneventful recovery, with no permanent damage to her liver. The metronidazole initially used to treat her inhibited DNA replication in her intestinal parasite by altering the DNA structure. In order to clear the parasite from the intestines, she was given paromomycin. This drug is poorly absorbed in the digestive tract and stays within the intestine and inhibits parasitic protein synthesis by binding to the 16S rRNA, leading to incorrect translation of the genetic code. This results in defective proteins and the death of the parasite.

BIOCHEMICAL COMMENTS

Hepatic Fibrosis. Extensive and progressive fibrosis of the hepatic parenchyma leads to cirrhosis of the liver, a process that has many causes. The development of fibrosis requires the activities of hepatic stellate cells, cytokines, proteases, and protease inhibitors.

A major change that occurs when fibrosis is initiated is that the normally “sparse” or “leaky” basement membrane between the endothelial cell and the hepatocyte is replaced with a high-density membrane containing fibrillar collagen. This occurs because of both increased synthesis of a different type of collagen than is normally produced and a reduction in the turnover rate of existing extracellular matrix components.

The supportive tissues of the normal liver contain an extracellular matrix that, among other proteins, includes type IV collagen (which does not form fibers), glycoproteins, and proteoglycans. After a sustained insult to the liver, a threefold to eightfold increase occurs in extracellular matrix components, some of which contain fibril-producing collagen (types I and III), glycoproteins, and proteoglycans. The accumulation of these fibril-producing compounds leads to a loss of endothelial cell fenestrations and, therefore, a loss of the normal sievelike function of the basement membranes. These changes interfere with normal transmembrane metabolic exchanges between the blood and hepatocytes.

The hepatic stellate cell is the source of increased and abnormal collagen production. These cells are activated by growth factors whose secretion is induced by injury to the hepatocytes or endothelial cells. Growth factors involved in cellular activation include TGF- β_1 (which is derived from the endothelial cells, Kupffer cells, and platelets) and platelet-derived growth factor (PDGF) and epidermal growth factor (EGF) from platelets. The release of PDGF stimulates stellate cell proliferation and, in the process, increases their synthesis and release of extracellular matrix materials and remodeling enzymes. These enzymes include matrix metalloproteinases (MMPs) and tissue inhibitors of MMPs, as well as converting (activating) enzymes. This cascade leads to the degradation of the normal extracellular matrix and replacement with a much denser and more rigid type of matrix material. These changes are, in part, the result of an increase in the activity of tissue inhibitors of MMPs for the new collagen relative to the original collagen in the extracellular matrix.

One consequence of the increasing stiffness of the hepatic vascular channels through which hepatic blood must flow is a greater resistance to the free flow of blood through the liver as a whole. Resistance to intrahepatic blood flow is also increased by a loss of vascular endothelial cell fenestrations, loss of free space between the endothelial cells and the hepatocytes (space of Disse), and even loss of vascular channels per se. This increased vascular resistance leads to an elevation of intrasinusoidal fluid pressure. When this intrahepatic (portal) hypertension reaches a critical threshold, the shunting of portal blood away from the liver (portosystemic shunting) contributes further to hepatic dysfunction. If the portal hypertension cannot be reduced, portal blood will continue to bypass the liver and return to the heart through the normally low-pressure esophageal veins. When this increasing intraesophageal venous pressure becomes severe enough, the walls of these veins thin dramatically and expand to form varices, which may burst suddenly, causing life-threatening esophageal variceal hemorrhage. This is a potentially fatal complication of cirrhosis of the liver.

KEY CONCEPTS

- ◆ The liver consists of a variety of cell types, each with a different function.
 - ◆ Hepatocytes carry out the bulk of the metabolic pathways of the liver.
 - ◆ Endothelial cells line the sinusoids and release growth factors.
 - ◆ Kupffer cells are tissue macrophages that protect the liver from gut-derived particulate materials and bacterial products.
 - ◆ Stellate cells store vitamin A and regulate the contractility of the sinusoids.
 - ◆ Pit cells are liver-associated lymphocytes, which act as a defense mechanism against potentially toxic agents.
- ◆ The liver is the body's central receiving and recycling center.
 - ◆ Inactivation and detoxification of xenobiotic compounds and metabolites via cytochrome P450 systems
 - ◆ Regulation of blood glucose levels
 - ◆ Synthesis and export of cholesterol and triglyceride via VLDL
 - ◆ Synthesis and excretion of urea
 - ◆ Formation of ketone bodies from fatty acid oxidation
 - ◆ Nucleotide biosynthesis
 - ◆ Synthesis of blood proteins
- ◆ The liver highly coordinates its use of fuels versus that of the body. This is, in part, controlled by modulation of the activity of PPAR α .
- ◆ Liver disease affects amino acid, carbohydrate, and lipid metabolism, leading to abnormalities in virtually all aspects of metabolism.
- ◆ Diseases discussed in this chapter are summarized in Table 44.4.

TABLE 44.4 Diseases Discussed in This Chapter

DISEASE OR DISORDER	GENETIC OR ENVIRONMENTAL	COMMENTS
Liver failure	Both, though primarily environmental	Destruction of hepatocyte function, leading to hyperammonemia, edema, and jaundice
Amoebiasis	Environmental	Infection by amoeba <i>Entamoeba histolytica</i>
Cirrhosis	Environmental	Destruction of hepatocytes via inappropriate collagen and other fibrous protein deposition within the liver, usually in response to environmental insult
Zellweger syndrome	Genetic	Lack of functional peroxisomes in all cells of the liver, kidney, and brain
Reye's syndrome	Environmental	Both the brain and liver primarily affected, with progressive loss of nervous system function

REVIEW QUESTIONS—CHAPTER 44

1. Drinking grapefruit juice while taking statins can lead to potentially serious side effects. This is due to a component of grapefruit juice doing which one of the following?
 - A. Interfering with hepatic uptake of statins
 - B. Accelerating the conversion of the statin to a more toxic form
 - C. Inhibiting the inactivation of statins
 - D. Upregulating the HMG-CoA reductase
 - E. Downregulating the HMG-CoA reductase
2. Which one of the following characteristics of cytochrome P450 enzymes is correct?
 - A. They are all found in the Golgi apparatus and are referred to as microsomal enzymes.
 - B. They all contain a flavin-containing reductase unit that uses NADH and not NADPH as a source of electrons.
 - C. They are all inducible by oxygen, which binds to the iron of the cytochrome.
 - D. They all oxidize the substrate on which they act.
 - E. They all generate a free-radical compound as a final product of the reaction.

3. Fairly predictable changes occur in the various metabolic pathways of lipid metabolism in patients with the moderately advanced hepatocellular disease. Which one of the following changes would you expect to see under these conditions?
 - A. The activity of plasma lecithin-cholesterol acyltransferase (LCAT) is increased.
 - B. Serum cholesterol esters are increased.
 - C. HTGL activity is increased.
 - D. Serum triacylglycerol levels are increased.
 - E. Serum nonesterified fatty acid levels are decreased.
4. After a 2-week period in which alcohol was her only dietary component, **Jean T.** ingested some Tylenol to help her with a severe headache. She took three times the suggested dose because of the severity of the pain. Within 24 hours, she became very lethargic, vomited frequently, and developed severe abdominal pain. The symptoms she is experiencing are attributable to a reaction to the Tylenol due to which one of the following?
 - A. The hypoglycemia experienced by the patient
 - B. Ethanol-induced inhibition of Tylenol metabolism
 - C. The hyperglycemia experienced by the patient
 - D. Ethanol-induced acceleration of Tylenol metabolism
 - E. Acetaminophen inhibition of VLDL secretion by the liver
5. An individual displays impaired glucose tolerance; blood glucose levels remain elevated after a meal for a longer time than is normal, although they do eventually go down to fasting levels. The patient has a normal release of insulin from the pancreas in response to elevated blood glucose levels. Hepatocytes obtained from the patient display normal levels of insulin binding to its receptor and normal activation of the intrinsic tyrosine kinase activity associated with the insulin receptor. Analysis of glucose 6-phosphate formation within the hepatocytes, however, indicates a much slower rate of formation than in hepatocytes obtained from a normal control. A possible mutation that could lead to these results is which one of the following?
 - A. A decrease in the K_m of glucokinase
 - B. An increase in the V_{max} of glucokinase
 - C. A mutated glucokinase RP
 - D. An increase in hexokinase activity
 - E. A decrease in hexokinase activity
6. Individuals with cirrhosis frequently display elevated levels of amino acids in the blood. The source of these amino acids is predominantly which one of the following?
 - A. Red blood cell turnover
 - B. Liver protein turnover
 - C. Enterocyte degradation and turnover
 - D. Muscle protein turnover
 - E. Plasma protein turnover
7. Phase I reactions for xenobiotic detoxification require a reduced cofactor to donate electrons to oxygen as one atom of oxygen is incorporated into the substrate, and the other atom of oxygen is incorporated into water. The reduced cofactor for the phase I reactions is derived primarily from which one of the following pathways?
 - A. HMP shunt
 - B. Glycolysis
 - C. Fatty acid biosynthesis
 - D. TCA cycle
 - E. Fatty acid oxidation
8. A patient with a history of chronic alcohol abuse presents to their physician with complaints of lethargy. Physical exam displays a malnourished individual with yellow sclera. Blood work indicates the elevation of prealbumin, AST, and ALT. The yellow sclera is most likely due to which one of the following?
 - A. Reduction in amino acid metabolism
 - B. Reduction in glycosylation reactions
 - C. Reduction in fatty acid oxidation
 - D. Reduction in VLDL production
 - E. Reduction in urea synthesis
9. Liver disease exhibits which of the following? Choose the one best answer.

	Elevated Blood Levels of ALT and AST	Elevated Blood Levels of Bilirubin	Elevated Levels of Blood Clotting Factors	Edema	Elevated Levels of Blood Ammonia
A	No	No	Yes	No	No
B	No	Yes	Yes	Yes	Yes
C	No	No	Yes	No	No
D	Yes	Yes	No	Yes	No
E	Yes	No	No	No	Yes
F	Yes	Yes	No	Yes	Yes

0. An individual with a long-time alcohol abuse disorder has developed cirrhosis of the liver. The liver is filled with a type of collagen, interfering with appropriate liver function. Under these conditions which liver cell type has been stimulated to produce fibril-producing collagen?

- A. Kupffer cells
- B. Stellate cells
- C. Endothelial cells
- D. Hepatocytes
- E. Pit cells

1. The liver can convert the carbons of carbohydrates to which of the following? Choose the one best answer.

	Glycogen	Branched-Chain Amino Acids	Niacin	Fatty Acids	Glycerol 3-phosphate
A	No	No	Yes	No	No
B	Yes	No	No	Yes	No
C	No	Yes	Yes	No	No
D	Yes	No	No	Yes	Yes
E	No	Yes	Yes	No	Yes
F	Yes	Yes	No	Yes	Yes

2. Detoxification reactions of fatty acid-like molecules often generate molecules which have glycine

conjugated to them. A required intermediate for the production of these molecules contains which one of the following?

- A. A high-energy phosphate bond
 - B. A high-energy thioester bond
 - C. A low-energy phosphate bond
 - D. A UDP-intermediate
 - E. A disulfide bond
3. Release of AST and ALT into the blood is an indication of a liver disorder. These enzymes, which are present in high levels in the liver, are needed for which of the following processes? Choose the one best answer.

	Anaplerotic Reactions	Electron Shunt Pathways	Urea Cycle	Glycolysis
A	Yes	Yes	Yes	No
B	Yes	No	Yes	No
C	Yes	Yes	Yes	Yes
D	No	No	No	Yes
E	No	Yes	No	No
F	No	No	No	Yes

4. Patients with liver disease contain in their blood a particle which contains increased levels of triglyceride. This occurs due to reduced activity of which of the following proteins? Choose the one best answer.

	Hepatocyte Triglyceride Lipase	Lipoprotein Lipase	Lingual Lipase	Adipocyte Triglyceride Lipase
A	Yes	Yes	No	No
B	No	No	No	No
C	Yes	No	No	No
D	No	No	Yes	Yes
E	Yes	Yes	Yes	Yes
F	No	Yes	Yes	Yes

5. Liver disease is a serious condition since the liver is necessary for many critical pathways and processes in the body. These pathways and processes include which of the following? Choose the one best answer.

	Ethanol Metabolism	Detoxification Reactions	Urea Cycle	Synthesis of Triglyceride	Synthesis of Insulin and Glucagon
A	No	No	No	No	No
B	No	Yes	Yes	Yes	No
C	No	No	No	No	Yes
D	Yes	Yes	Yes	Yes	No
E	Yes	No	No	No	Yes
F	Yes	Yes	Yes	Yes	Yes

ANSWERS TO REVIEW QUESTIONS

- The answer is C.** Grapefruit juice contains a component that blocks CYP3A4 activity, which is the cytochrome P450 isozyme that converts statins to an inactive form. If the degradative enzyme is inhibited, statin levels rise above normal, accelerating the damage of muscle cells. Grapefruit juice does not affect hepatic uptake of the drug (thus, A is incorrect), nor is it accelerating statin metabolism (thus, B is also incorrect). Although HMG-CoA reductase is the target of the statins, grapefruit juice neither up- nor downregulates the amount of enzyme present in the cell (thus, D and E are incorrect).
- The answer is D.** Cytochrome P450 enzymes oxidize their substrates, transferring the electrons to molecular oxygen to form water and a hydroxylated product. The enzymes require NADPH (thus, B is incorrect) and are located in the endoplasmic reticulum membrane (thus, A is incorrect). Oxygen does not induce all cytochrome P450 members (although it is a substrate for all these isozymes; thus, C is incorrect), and although these enzymes proceed through a free-radical mechanism, the final products are not radicals (thus, E is incorrect).
- The answer is D.** Hepatocellular disease reduces protein synthesis in the liver, which leads to reduced levels of both LCAT and HTGL being produced (thus, A and C are incorrect). Because LCAT activity is reduced, cholesterol ester formation in circulating particles is reduced (thus, B is incorrect). Because a diseased liver has trouble synthesizing glucose, fatty acid release from adipocytes is increased to provide energy (thus, E is incorrect). Serum triacylglycerol levels are increased as a result of the reduced HTGL activity; LPL activity is also reduced in liver disease.
- The answer is D.** Ethanol induces the CYP2E1 system, which converts acetaminophen to NAPQI, a toxic intermediate. Under normal conditions (noninduced levels of CYP2E1), the conversion of acetaminophen to NAPQI results in low levels of NAPQI being produced, which can easily be detoxified. However, when CYP2E1 is induced, the excessive levels of NAPQI being produced when Tylenol is taken in greater than recommended amounts cannot be readily detoxified, and NAPQI binds to proteins and inactivates them, leading to hepatocyte death. The toxicity is not related to blood glucose levels (thus, A and C are incorrect), nor to the secretion of VLDL (thus, E is incorrect). Ethanol does not inhibit the detoxification of Tylenol per se but rather accelerates one of its potential metabolic fates (thus, B is also incorrect).
- The answer is C.** The glucokinase RP regulates glucokinase expression at a posttranscriptional level. A lack of appropriate regulation of the RP activity results in less glucokinase being present in the cytoplasm of the cell and a reduced overall rate of glucose phosphorylation by the liver. This results in less

circulating glucose being removed by the liver, and a longer clearance time for glucose levels to return to fasting levels. A decrease in the glucokinase K_m , or an increase in the V_{max} for glucokinase, would lead to the opposite effect, enhanced glucose phosphorylation by the liver, and an accelerated clearance from the circulation (thus, A and B are incorrect). The liver does not express hexokinase, so D and E are also incorrect.

6. **The answer is D.** The large increase in circulating amino acid levels in an individual with cirrhosis is due to two things; reduced uptake of amino acids by the liver and enhanced muscle protein turnover due to the catabolic state of the patient. The liver contains much less protein than muscle, and the entire liver would have to have its protein content degraded in order to provide the high levels of amino acids seen in the circulation under these conditions. Additionally, red blood cells, enterocytes, and circulating proteins in the blood do not provide for sufficient protein turnover for the large increase in free amino acids seen when the liver is not functioning.
7. **The answer is A.** The cofactor required for the phase I reactions is NADPH, which is derived from either malic enzyme (a minor pathway) or the oxidative reactions of the HMP shunt pathway (glucose 6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase). For each glucose 6-phosphate entering these oxidative reactions, two molecules of NADPH are produced, along with carbon dioxide and ribulose 5-phosphate. Neither glycolysis nor the TCA cycle produces NADPH (both will produce NADH). Fatty acid biosynthesis requires NADPH for the two reduction reactions along the pathway, whereas fatty acid oxidation generates NADH and FADH₂, but not NADPH.
8. **The answer is B.** The patient is exhibiting signs of liver failure (release of prealbumin, AST, and ALT) due to many years of alcohol abuse. The yellow sclera is the sign of jaundice, due to bilirubin precipitation. Normally bilirubin would be glucuronylated (using UDP-glucuronic acid) to increase its solubility, via a reaction carried out in the liver. With the failing liver, however, this reaction efficiency is reduced, and more unconjugated bilirubin (which is less soluble than the conjugated form) is found in circulation. The increased levels of free bilirubin are not due to alterations in either fatty acid or amino acid metabolism within the liver. It is also not related to VLDL production or urea biosynthesis.
9. **The answer is F.** ALT and AST, along with transaminases, are released by damaged hepatocytes. Elevated bilirubin causes jaundice, and a damaged liver cannot process bilirubin appropriately. The damaged liver has trouble synthesizing proteins, including serum albumin. Decreased blood albumin levels lead to low intravascular osmotic pressure and leakage of fluid into interstitial spaces, causing edema. The liver is the site of urea synthesis, and reduced urea synthesis leads to elevated blood ammonia levels. The liver also produces the blood clotting factors, so a damaged liver produces a reduced amount of clotting factors, leading to increased clotting time and bleeding.
10. **The answer is B.** In cirrhosis, stellate cells increase their synthesis of extracellular matrix components including fibril-producing collagen types I and III instead of type IV collagen, which does not form fibrils. The synthesis of the fibril-forming collagen leads to a loss of endothelial cell fenestrations and continuing fibrosis, eventually leading to cirrhosis. The other cells listed do not produce hepatic connective tissue and extracellular matrix material.
11. **The answer is D.** Carbohydrate carbons can be utilized by the liver to synthesize glycogen, fatty acids (via glycolysis and the pyruvate dehydrogenase reaction), and glycerol 3-phosphate (from dihydroxyacetone phosphate in glycolysis). BCAAs are essential amino acids and cannot be synthesized from carbohydrates. Niacin is a vitamin (vitamin B₃) and cannot be synthesized by humans.
12. **The answer is B.** The fatty acid-like molecules contain a carboxylic acid, which gets activated to a coenzyme A derivative in a reaction similar to the one catalyzed by fatty acyl CoA synthetases. The addition of coenzyme A leads to a high-energy thioester bond. The intermediates are not phosphorylated, do not contain a disulfide bond, nor are conjugated to UDP, as are activated sugars (nucleotide sugars).
13. **The answer is A.** ALT and AST catalyze transamination reactions and are necessary for anaplerotic reactions (aspartic acid to oxaloacetate, glutamic acid to α -ketoglutarate), an electron shunt pathway (the malate-aspartate shuttle), and the urea cycle (transferring nitrogen groups from amino acids to pyruvate or α -ketoglutarate). There are no transamination reactions in glycolysis.
14. **The answer is A.** In hepatic disease the levels of hepatocyte triglyceride lipase and lipoprotein lipase are reduced, which negatively impacts the degradation of triglyceride in VLDL and IDL particles, leading to LDL particles with elevated triglyceride amounts. Neither adipocyte triglyceride lipase (which is only found in adipocytes and not hepatocytes) nor lingual lipase (found in the saliva) is affected by liver disease.
15. **The answer is D.** The liver is the site of ethanol metabolism (both alcohol dehydrogenase and the MEOS

system), detoxification reactions through cytochrome P450 systems, the urea cycle to control blood ammonia levels, and is the primary site of triglyceride synthesis from carbohydrates, producing and secreting VLDL. The liver does not synthesize or secrete insulin or glucagon, which is the job of the pancreas.

Metabolism of Muscle at Rest and during Exercise

There are three types of muscle cells: **smooth**, **skeletal**, and **cardiac**. In all types of muscle, contraction occurs via an actin/myosin sliding filament system, which is regulated by oscillations in **intracellular calcium levels**.

Muscle cells use stored glycogen and circulating glucose, fatty acids, and amino acids as energy sources. Muscle glycolysis is regulated differently from the liver, with the key difference being the regulation of **phosphofructokinase-2 (PFK-2)**. Muscle PFK-2 is not inhibited by phosphorylation; cardiac PFK-2 is actually activated by phosphorylation by a number of protein kinases. Thus, under conditions in which liver PFK-2 is inactive, and glycolysis is running slowly, muscle glycolysis is either unaffected or even stimulated, depending on the isoform of PFK-2 being expressed.

Although muscle cells do not synthesize fatty acids, they do contain an isozyme of **acetyl CoA carboxylase (ACC-2)** to regulate the **rate of fatty acid oxidation**. ACC-2 produces malonyl CoA, which inhibits carnitine palmitoyltransferase I, thereby blocking fatty acid entry into the mitochondria. Muscle also contains **malonyl CoA decarboxylase**, which catalyzes the conversion of malonyl CoA to acetyl CoA and carbon dioxide. Thus, both the synthesis and degradation of malonyl CoA are carefully regulated in muscle cells to balance glucose and fatty acid oxidation. Both allosteric and covalent means of regulation are employed. Citrate activates ACC-2, and phosphorylation of ACC-2 by the adenosine monophosphate (AMP)-activated protein kinase inhibits ACC-2 activity. Phosphorylation of malonyl CoA decarboxylase by the AMP-activated protein kinase activates the enzyme, further enhancing fatty acid oxidation when energy levels are low.

Muscles use **creatine phosphate** to store high-energy bonds. Creatine is derived from arginine and glycine in the kidney, and the guanidinoacetate formed is methylated (using *S*-adenosyl methionine) in the liver to form creatine. The enzyme **creatine phosphokinase (CPK)** then catalyzes the reversible transfer of a high-energy phosphate from adenosine triphosphate (ATP) to creatine, forming creatine phosphate and adenosine diphosphate (ADP). Creatine phosphate is unstable and spontaneously cyclizes to form **creatinine**, which is excreted in the urine. The spontaneous production of creatinine occurs at a constant rate and is proportional to body muscle mass. Thus, the amount of creatinine excreted each day (the creatinine clearance rate) is constant and can be used as an indicator of the normalcy of the excretory function of the kidneys.

Skeletal muscle cells can be subdivided into **type I** and **type II fibers**. Type I fibers are **slow-twitch** fibers that use primarily **oxidative metabolism** for energy, whereas the type II fibers (**fast-twitch**) use **glycolysis** as their primary energy-generating pathway.

Glucose transport into muscle cells can be stimulated during exercise because of the activity of the **AMP-activated protein kinase**. Fatty acid uptake into exercising muscle is dependent on the levels of circulating fatty acids, which are increased by **epinephrine** release.

M Damaged muscle cells release myoglobin, which can be observed clinically as a reddish tint to the urine. The primary measurement for myoglobin is via a sandwich technique immunoassay. The primary antibody is linked to an insoluble support, whereas the second antibody is linked to alkaline phosphatase. Utilizing a fluorescent substrate for the phosphatase allows low levels of myoglobin to be detected. If high in the urine, muscle damage and potential renal failure could be the culprits.

Renee F., a 9-year-old girl, complained of a severe pain in her throat and difficulty in swallowing. She has chills, sweats, headache, and a fever of 102.4°F. When her symptoms persisted for several days, her mother took her to her pediatrician, who found diffuse erythema (redness) in her posterior pharynx (throat), with yellow exudates (patches) on her tonsils. Large, tender lymph nodes were present under her jaw on both sides of her neck. A throat culture was taken, and therapy with penicillin was begun.

Although the sore throat and fever improved, 10 days after the onset of the original infection, **Renee F.**'s eyes and legs became swollen and her urine suddenly turned the color of Coca-Cola. Her blood pressure was elevated. Protein and red blood cells were found in her urine. Her serum creatinine level (see Chapter 3 for how creatinine is measured) was elevated at 1.8 mg/dL (reference range, 0.3 to 0.7 for a child). Because the throat culture grew group A β -hemolytic streptococci, the doctor ordered an antistreptolysin O titer, which was positive. As a result, a diagnosis of acute poststreptococcal glomerulonephritis was made. Supportive therapy, including bed rest and treatment for hypertension, was initiated.

Seth D., a 3-year-old boy, was brought to the pediatrician by his parents because they noticed he was having difficulty running and going up stairs. He did not start walking until 16 months, and his parents noticed he is not running like other children his age. He also tends to walk on his toes and uses his hands to help him stand from a sitting position. On physical examination, the physician noted a lack of muscle strength, mostly in the lower proximal muscle groups and large calf muscles. The physician suspected that **Seth D.** had Duchenne Muscular Dystrophy (DMD), and to confirm the diagnosis his physician ordered a creatine kinase level, which was elevated, and then sent a blood sample to the human genetics laboratory for sequencing of the DMD gene.

I. Muscle Cell Types

Muscle consists of three different types: skeletal, smooth, and cardiac (Fig. 45.1). The metabolism of each is similar, but the functions of the muscles are quite different.

A. Skeletal muscle

Nuclei

B. Smooth muscle

C. Cardiac muscle

Intercalated disks

FIGURE 45.1 Structures of the three different muscle types. (Adapted with permission from Junqueira LC, Carneiro J. *Basic Histology: Text and Atlas*. 10th ed. Lange Medical Books, McGraw-Hill; 2002; permission conveyed through Copyright Clearance Center, Inc.)

The DMD gene is the largest in the human genome, consisting of 79 exons, and spanning over 2,200 kb on the X-chromosome. The DMD gene encodes dystrophin, a rod-like protein, which links the intracellular cytoskeleton with the extracellular matrix as part of the dystrophin complex. Dystrophin directly binds to actin, and to a sarcolemma protein, the beta subunit of dystroglycan. The entire dystrophin complex stabilizes the plasma membrane; with a loss of functional dystrophin, the membrane can no longer function properly and leads to the loss of myofibers in the muscle. An initial response to the membrane damage is the generation of scar tissue and fat and connective tissue in the calf muscles, giving rise to the large calf muscles observed in **Seth D**. Mutations that lead to DMD generally result from large deletions of the gene such that dystrophin is absent from the membrane. Becker muscular dystrophy, a milder form of disease, is caused by deletions that are in frame, and lead to a truncated version of dystrophin being expressed in the sarcolemma, but in a mutated form.

A. Skeletal Muscle

Skeletal muscles are those muscles that are attached to bone and facilitate the movement of the skeleton. Skeletal muscles are found in pairs, which are responsible for opposing, coordinated directions of motion on the skeleton. The muscles appear striated under the microscope and are controlled voluntarily (you think about moving a specific muscle group, and then it happens).

Skeletal muscle cells are long, cylindrical fibers that run the length of the muscle. The fibers are multinucleated because of cell fusion during embryogenesis. The cell membrane surrounding the fibers is called the sarcolemma, and the sarcoplasm is the intracellular milieu, which contains the proteins, organelles, and contractile apparatus of the cell. The sarcoplasmic reticulum is analogous to the endoplasmic reticulum in other cell types and is an internal membrane system that runs throughout the length of the muscle fiber. Another membrane structure, the transverse tubules (T-tubules), are thousands of invaginations of the sarcolemma that tunnel from the surface toward the center of the muscle fiber to make contact with the terminal cisterns of the sarcoplasmic reticulum. Because the T-tubules are open to the outside of the muscle fiber and are filled with extracellular fluid, the muscle action potential that propagates along the surface of the muscle fiber's sarcolemma travels into the T-tubules and to the sarcoplasmic reticulum.

The striations in skeletal muscle are attributable to the presence and organization of myofibrils in the cells. Myofibrils are thread-like structures consisting of thin and thick filaments. The contractile proteins actin and myosin are contained within the filaments—myosin in the thick filaments and actin in the thin filaments. The sliding of these filaments relative to each other, using myosin-catalyzed ATP hydrolysis as an energy source, allows for the contraction and relaxation of the muscle (see online Fig. 20.1).

Muscle fibers can be classified as either fast-twitch or slow-twitch. The slow-twitch fibers, or type I fibers (also called slow-oxidative fibers), contain large amounts of mitochondria and myoglobin (giving them a red color), utilize respiration and oxidative phosphorylation for energy, and are relatively resistant to fatigue. Compared with fast-twitch fibers, their glycogen content is low. The slow-twitch fibers develop force slowly but maintain contractions longer than fast-twitch muscles.

The fast-twitch fibers, or type II, can be subdivided as type IIa or type IIb. Type IIb fibers (also called fast-glycolytic fibers) have few mitochondria and low levels of myoglobin (hence, they appear white). They are rich in glycogen and use glycogenolysis and glycolysis as their primary energy source. These muscles are prone to fatigue because continued reliance on glycolysis to produce ATP leads to an increase in lactic acid levels, resulting in a drop in the intracellular pH. As the pH drops, the ability of the muscle to produce ATP also diminishes. However, fast-twitch muscle can develop greater force than slow-twitch muscle, so contractions occur more rapidly. Type IIa fibers (also called fast-oxidative glycolytic fibers) have properties of both type I and IIb fibers and thus display functional characteristics of both fiber types. The properties of types I, IIa, and IIb fibers are summarized in Table 45.1.

TABLE 45.1 Properties of Muscle Fiber Types

TYPE II FIBERS		
TYPE I FIBERS	TYPE IIA	TYPE IIB
Slow-twitch (slow speed of contraction)	Intermediate-twitch (fast speed of contraction)	Fast-twitch (fast speed of contraction)
Slow-oxidative (low glycogen content)	Fast-oxidative glycolytic fibers (intermediate glycogen levels)	Fast-glycolytic (high glycogen content)

High myoglobin content (appear red)	High myoglobin content (appear red)	Low myoglobin content (appear white)
Small fiber diameter	Intermediate fiber diameter	Large fiber diameter
Increased concentration of capillaries surrounding muscle (greater oxygen delivery)	Increased oxidative capacity on training	Limited aerobic metabolism Low mitochondrial content
High capacity for aerobic metabolism	Intermediate resistance to fatigue	More sensitive to fatigue compared with other fiber types
High resistance to fatigue		Least efficient use of energy, primarily glycolytic pathway
Used for prolonged, aerobic exercise		Used for sprinting and resistance tasks

Muscles are a mixture of the different fiber types, but depending on the function, a muscle may have a preponderance of one fiber type over another. Type I fibers are found in postural muscles such as the psoas in the back musculature or the soleus in the leg. The ratio of type I to type II varies with the muscle. The triceps, which functions phasically, has 32.6% type I, whereas the soleus, which functions tonically, has 87.7% type I. Type II fibers are more prevalent in the large muscles of the limbs that are responsible for sudden, powerful movements. Extraocular muscles would also have more of these fibers than type I.

The results of **Seth D.**'s DMD gene sequencing indicated he had a deletion of exons 48–50. Many of the mutations that lead to DMD are due to deletions within the gene. The deletion of exons 48 to 50 led to frame disrupting when exon 47 was linked to exon 51, such that a premature stop codon was generated, terminating synthesis of dystrophin, and leading to the membrane instability in striated muscle. In-frame deletions, and point mutations, lead to the less severe Becker dystrophy.

B. Smooth Muscle Cells

Smooth muscle cells are found in the digestive system, blood vessels, bladder, airways, and uterus. The cells have a spindle shape with a central nucleus (see Fig. 45.1B). The designation “smooth” refers to the fact that these cells, which contain a single nucleus, display no striations under the microscope. The contraction of smooth muscle is controlled involuntarily (the cells contract and relax without any conscious attempt to have them do so; examples of smooth muscle activity include moving food along the digestive tract, altering the diameter of the blood vessels, and expelling urine from the bladder). In contrast to skeletal muscle, these cells have the ability to maintain tension for extended periods, and do so efficiently, with a low use of energy.

C. Cardiac Muscle Cells

The cardiac cells are similar to skeletal muscle in that they are striated (contain fibers), but like smooth muscle cells, they are regulated involuntarily (we do not have to think about making our heartbeat). The cells are quadrangular in shape (see Fig. 45.1C) and form a network with multiple other cells through tight membrane junctions and gap junctions. The multicellular contacts allow the cells to act as a common unit and to contract and relax synchronously. Cardiac muscle cells are designed for endurance and consistency. They depend on aerobic metabolism for their energy needs because they contain many mitochondria and very little glycogen. These cells thus generate only a small amount of their energy from glycolysis using glucose derived from glycogen. A reduced flow of oxygen-rich blood to the heart muscle may lead to a myocardial infarction (heart attack). The amount of ATP that can be generated by glycolysis alone is not sufficient to meet the energy requirements of the contracting heart.

II. Neuronal Signals to Muscle

For an extensive review of how muscle contracts or a detailed view of the signaling to allow muscle contraction, consult a medical physiology book. Only a brief overview is presented here.

The nerve–muscle cell junction is called the neuromuscular junction (Fig. 45.2). When appropriately stimulated, the nerve cell releases acetylcholine at the junction, which binds to acetylcholine receptors on the muscle membrane. This binding stimulates the opening of sodium channels on the sarcolemma. The massive influx of sodium ions results in the generation of an action potential in the sarcolemma at the edges of the motor end plate of the neuromuscular junction. The action potential sweeps across the surface of the muscle fiber and down the transverse tubules to the sarcoplasmic reticulum, where it initiates the release of calcium from its lumen, via the ryanodine receptor (Fig. 45.3). The calcium ion binds to troponin, resulting in a

conformational change in the troponin–tropomyosin complexes so that they move away from the myosin-binding sites on the actin. When the binding site becomes available, the myosin head attaches to the myosin-binding site on the actin. The binding is followed by a conformational change (pivoting) in the myosin head, which shortens the sarcomere. After the pivoting, ATP binds the myosin head, which detaches from the actin and is available to bind another myosin-binding site on the actin. As long as calcium ion and ATP remain available, the myosin heads will repeat this cycle of attachment, pivoting, and detachment (Fig. e-45.1) .

This movement requires ATP, and when ATP levels are low (such as occurs during ischemia), the ability of the muscle to relax or contract is compromised. As the calcium release channel closes, the calcium is pumped back into the sarcoplasmic reticulum against its concentration gradient using the energy-requiring protein SERCA (sarcoplasmic reticulum Ca^{2+} ATPase), and contraction stops. This basic process occurs in all muscle cell types, with some slight variations between cell types.

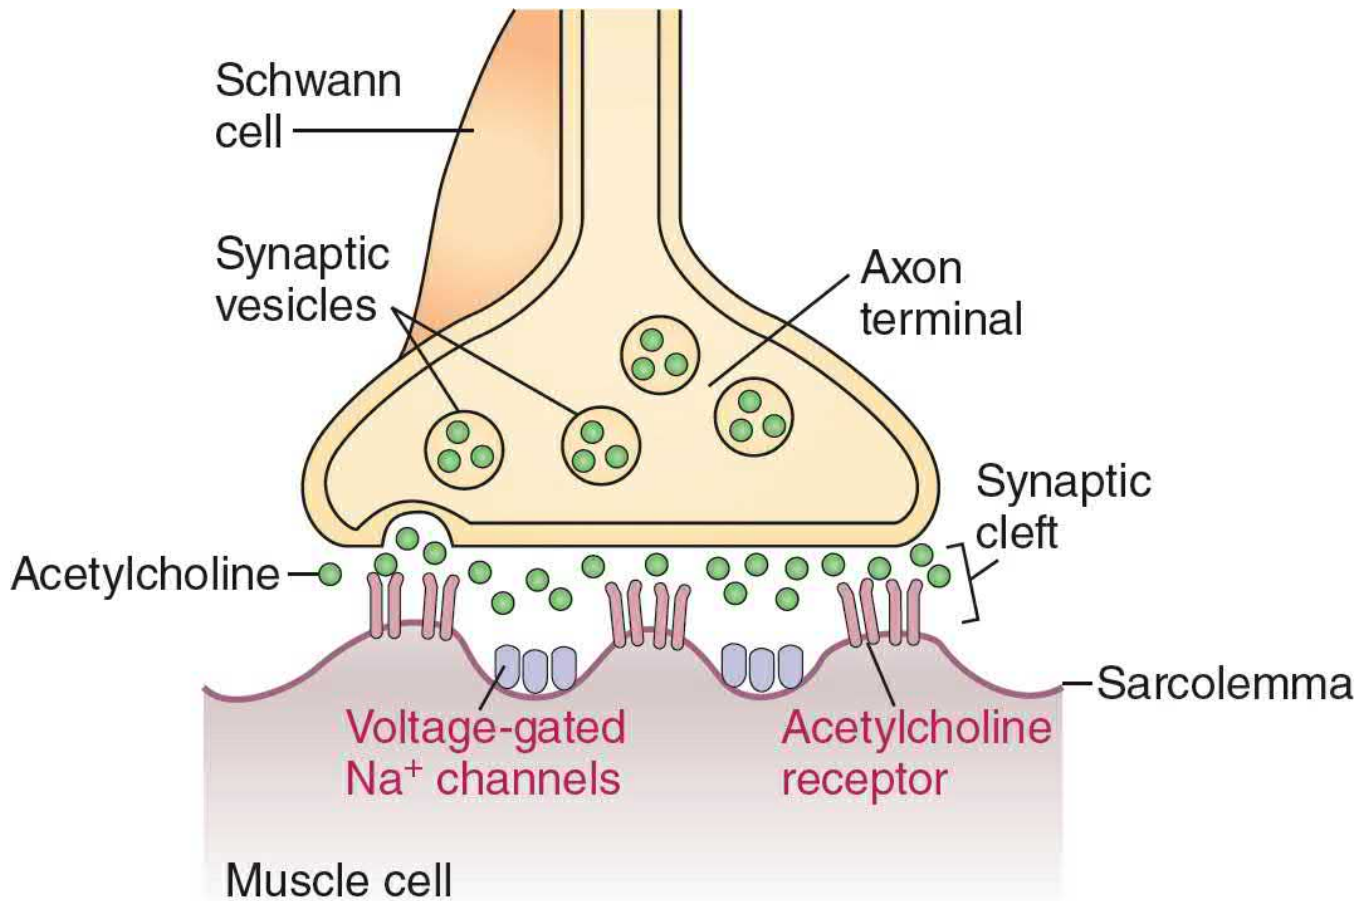

FIGURE 45.2 The neuromuscular junction. When they are stimulated appropriately, the synaptic vesicles, containing acetylcholine, fuse with the axonal membrane and release acetylcholine into the synaptic cleft. The acetylcholine binds to its receptors on the muscle cells, which initiate signaling for muscle contraction.

FIGURE 45.3 Events leading to sarcoplasmic reticulum (SR) calcium release in skeletal muscle. (1) Acetylcholine, released at the synaptic cleft, binds to acetylcholine receptors on the sarcolemma, leading to a change of conformation of the receptors so that they now act as an ion pore. This allows sodium to enter the cell and potassium to leave. (2) The membrane depolarization that results from these ion movements is transmitted throughout the muscle fiber by the T-tubule system. (3) A receptor in the T-tubules (the dihydropyridine receptor [DHPR]) is activated by membrane depolarization (a voltage-gated activation) so that activated DHPR binds physically to and activates the ryanodine receptor in the sarcoplasmic reticulum (depolarization-induced calcium release). (4) The activation of the ryanodine receptor, which is a calcium channel, leads to calcium release from the SR into the sarcoplasm. In cardiac muscle, activation of DHPR leads to calcium release from the T-tubules, and this small calcium release is responsible for the activation of the cardiac ryanodine receptor (calcium-induced calcium release) to release large amounts of calcium into the sarcoplasm.

The ryanodine receptors are calcium release channels found in the endoplasmic reticulum and sarcoplasmic reticulum of muscle cells. One type of receptor can be activated by a depolarization signal (depolarization-induced calcium release). Another receptor type is activated by calcium ions (calcium-induced calcium release). The proteins received their name because they bind ryanodine, a toxin obtained from the stem and roots of the plant *Ryania speciosa*. Ryanodine inhibits sarcoplasmic reticulum calcium release and acts as a paralytic agent. It was first used commercially in insecticides.

Acetylcholine levels in the neuromuscular junction are rapidly reduced by the enzyme acetylcholinesterase. A number of nerve gas poisons act to inhibit acetylcholinesterase (such as sarin and VX), so that muscles are continuously stimulated to contract. This leads to blurred vision, bronchoconstriction, seizures, respiratory arrest, and death. The poisons are covalent modifiers of acetylcholinesterase; therefore, recovery from exposure to such poisons requires the synthesis of new enzyme. Acetylcholinesterase inhibitors, which act reversibly (i.e., they do not form covalent bonds with the enzyme), are used to treat dementia.

III. Glycolysis and Fatty Acid Metabolism in Muscle Cells

The pathways of glycolysis and fatty acid oxidation in muscle are the same as has been previously described (see Chapters 22 and 30). The difference between muscles and other tissues is how these pathways are regulated.

Phosphofructokinase 2 (PFK-2) is negatively regulated by phosphorylation in the liver (the enzyme that catalyzes the phosphorylation is the cyclic adenosine monophosphate [cAMP]–dependent protein kinase). However, in skeletal muscle, PFK-2 is not regulated by phosphorylation. This is because the skeletal muscle isozyme of PFK-2 lacks the regulatory serine residue which is phosphorylated in the liver. However, the cardiac isozyme of PFK-2 is phosphorylated and activated by a kinase cascade initiated by insulin. This allows the heart to activate glycolysis and to use blood glucose when blood glucose levels are elevated. The AMP-activated protein kinase also activates cardiac PFK-2 (kinase activity) as a signal that energy is low.

A class of drugs known as partial fatty acid oxidation (pFOX) inhibitors has been developed to reduce the extensive fatty acid oxidation in heart after an ischemic episode. The reduction in fatty acid oxidation induced by the drug will allow glucose oxidation to occur and reduce lactate buildup in the damaged heart muscle. An example of a pFOX is trimetazidine (TMZ), which partially inhibits mitochondrial long-chain β -ketoacyl coenzyme A thiolase (the enzyme which catalyzes the release of acetyl CoA from the oxidized fatty acid chain). It can be used to decrease symptoms of angina with chronic coronary artery disease. Other possible targets of such drugs, which have yet to be developed, include ACC-2, malonyl CoA decarboxylase, and carnitine palmitoyltransferase I.

Fatty acid uptake by muscle requires the participation of fatty acid–binding proteins and the usual enzymes of fatty acid oxidation. Fatty acyl CoA uptake into the mitochondria is controlled by malonyl CoA, which is produced by an isozyme of acetyl CoA carboxylase (ACC-2; the ACC-1 isozyme is found in liver and adipose tissue cytosol and is used for fatty acid biosynthesis). ACC-2 (a mitochondrial protein, linked to carnitine palmitoyltransferase 1 [CPT1] in the outer mitochondrial membrane) is inhibited by phosphorylation by the AMP-activated protein kinase (AMP-PK) so that when energy levels are low, the levels of malonyl CoA drop, allowing fatty acid oxidation by the mitochondria. In addition, muscle cells also contain the enzyme malonyl CoA decarboxylase, which is activated by phosphorylation by the AMP-PK. Malonyl CoA decarboxylase converts malonyl CoA to acetyl CoA, thereby relieving the inhibition of CPT-I and stimulating fatty acid oxidation (Fig. 45.4). Muscle cells do not synthesize fatty acids; the presence of acetyl CoA carboxylase in muscle is exclusively for regulatory purposes. Mice that have been bred to lack ACC-2 have a 50% reduction of fat stores compared with control mice. This was shown to be attributable to a 30% increase in skeletal muscle fatty acid oxidation resulting from dysregulation of CPT1, brought about by the lack of malonyl CoA inhibition of CPT1.

FIGURE 45.4 Regulation of fatty acyl CoA entry into muscle mitochondria. (1) Acetyl CoA carboxylase-2 (ACC-2) converts acetyl coenzyme A (acetyl CoA) to malonyl CoA, which inhibits carnitine palmitoyltransferase I (CPT-I), thereby blocking fatty acyl CoA entry into the mitochondria. (2) However, as energy levels drop, adenosine monophosphate (AMP) levels rise because of the activity of the adenylate kinase reaction. (3) The increase in AMP levels activates the AMP-activated protein kinase (AMPK), which phosphorylates and inactivates ACC-2, and also phosphorylates and activates malonyl CoA decarboxylase (MCoADC). The decarboxylase converts malonyl CoA to acetyl CoA, thereby relieving the inhibition of CPT-1, and allowing fatty acyl CoA entry into the mitochondria. This allows the muscle to generate adenosine triphosphate (ATP) via the oxidation of fatty acids.

IV. Fuel Utilization in Cardiac Muscle

A. Normal Conditions

The heart uses primarily fatty acids (60% to 80%), lactate, and glucose (20% to 40%) as its energy sources. Ninety-eight percent of cardiac ATP is generated by oxidative means; 2% is derived from glycolysis. The lactate used by the heart is taken up by a monocarboxylate transporter in the cell membrane that is also used for the transport of ketone bodies. However, ketone bodies are not a preferred fuel for the heart; the heart prefers to use fatty acids.

Lactate is generated by red blood cells and working skeletal muscle. When the lactate is used by the heart, it is oxidized to carbon dioxide and water, following the pathway lactate to pyruvate, pyruvate to acetyl CoA, acetyl CoA oxidation in the tricarboxylic acid (TCA) cycle, and ATP synthesis through oxidative phosphorylation. An alternative fate for lactate is its utilization in the reactions of the Cori cycle in the liver.

Glucose transport into the cardiocyte occurs via both GLUT 1 and GLUT 4 transporters, although approximately 90% of the transporters are GLUT 4. Insulin stimulates an increase in the number of GLUT 4 transporters in the cardiac cell membrane, as does myocardial ischemia. This ischemia-induced increase in GLUT 4 transporter number is additive to the effect of insulin on the translocation of GLUT 4 transporters to the plasma membrane.

Fatty acid uptake into cardiac muscle is similar to that for other muscle cell types and requires fatty acid-binding proteins and carnitine palmitoyltransferase I for transfer into the mitochondria. Fatty acid oxidation in cardiac muscle cells is regulated by altering the activities of ACC-2 and malonyl CoA decarboxylase. Under conditions in which ketone bodies are produced, fatty acid levels in the plasma are also elevated. Because the heart preferentially burns fatty acids as a fuel rather than the ketone bodies produced by the liver, the ketone bodies are spared for use by the nervous system.

B. Ischemic Conditions

When blood flow to the heart is interrupted, the heart switches to anaerobic metabolism. The rate of glycolysis increases, but the accumulation of protons (via lactate formation) is detrimental to the heart. Ischemia also increases the levels of free fatty acids in the blood and, surprisingly, when oxygen is reintroduced to the heart,

the high rate of fatty acid oxidation in the heart is detrimental to the recovery of the damaged heart cells. Fatty acid oxidation occurs so rapidly that NADH accumulates in the mitochondria, leading to a reduced rate of NADH shuttle activity, an increased cytoplasmic NADH level, and lactate formation, which generates more protons. In addition, fatty acid oxidation increases the levels of mitochondrial acetyl CoA, which inhibits pyruvate dehydrogenase, leading to cytoplasmic pyruvate accumulation and lactate production. As lactate production increases and the intracellular pH of the heart drops, it is more difficult to maintain ion gradients across the sarcolemma. ATP hydrolysis is required to repair these gradients, which are essential for heart function. However, the use of ATP for gradient repair reduces the amount of ATP available for the heart to use in contraction, which, in turn, compromises the ability of the heart to recover from the ischemic event.

Analysis of the DMD gene indicated that for certain deletions (including the exon 48 to 50 deletion present in **Seth D.**) if exon 51 were also to be deleted an in-frame truncated protein could be produced. This led to the search for reagents which could interfere with the spliceosomes during processing of the DMD gene such that exon 51 would be skipped. The rationale for such a treatment was that a truncated, partially active dystrophin protein would be more functional than a lack of dystrophin protein. Preliminary experiments in animal models indicated that a synthetic antisense oligonucleotide, which would base-pair with exon 51 in the precursor mRNA of dystrophin, would lead to the spliceosome skipping exon 51 and producing a truncated, partially functional dystrophin molecule.

V. Fuel Utilization in Skeletal Muscle

Skeletal muscles use many fuels to generate ATP. The most abundant immediate source of ATP is creatine phosphate. ATP also can be generated from glycogen stores, either anaerobically (generating lactate) or aerobically, in which case pyruvate is converted to acetyl CoA for oxidation via the TCA cycle. All human skeletal muscles have some mitochondria and thus are capable of fatty acid and ketone body oxidation. Skeletal muscles are also capable of completely oxidizing the carbon skeletons of alanine, aspartate, glutamate, valine, leucine, and isoleucine but not other amino acids. Each of these fuel oxidation pathways plays a particular role in skeletal muscle metabolism.

A. ATP and Creatine Phosphate

ATP is not a good choice as a molecule to store in quantity for energy reserves. Many reactions are allosterically activated or inhibited by ATP levels, especially those that generate energy. Muscle cells solve this problem by storing high-energy phosphate bonds in the form of creatine phosphate. When energy is required, creatine phosphate donates a phosphate to ADP, to regenerate ATP for muscle contraction (Fig. 45.5).

FIGURE 45.5 The synthesis of creatine, and the generation of creatinine. The creatine phosphokinase reaction transfers a high-energy bond from ATP to creatine, conserving the high-energy bond. The high-energy bond is the unusual nitrogen–phosphate bond, as indicated by the *red squiggle*. Creatine is synthesized from arginine, glycine, and S-adenosyl methionine (SAM). The synthesis originates in the kidney and is completed in the liver. Creatine phosphate (and creatine) spontaneously cyclize, forming creatinine, which is excreted in the urine. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i, inorganic phosphate.

Each kidney normally contains approximately 1 million glomerular units. Each unit is supplied by arterial blood via the renal arteries and acts as a "filter." Metabolites such as creatinine leave the blood by passing through pores or channels in the glomerular capillaries and enter the fluid within the proximal kidney tubule for eventual excretion in the urine. When they are functionally intact, these glomerular tissues are impermeable to all but the smallest of proteins. When they are acutely inflamed, however, this barrier function is lost to varying degrees, and albumin and other proteins may appear in the urine.

The marked inflammatory changes in the glomerular capillaries that accompany poststreptococcal glomerulonephritis significantly reduce the flow of blood to the filtering surfaces of these vessels. As a result, creatinine, urea, and other circulating metabolites that are filtered into the urine at a normal rate (the glomerular filtration rate, GFR) in the absence of kidney disease now fail to reach the filters, and, therefore, they accumulate in the plasma. These changes explain **Renee F.**'s laboratory profile during her acute inflammatory glomerular disease (glomerulonephritis). In most patients prognosis is excellent, though in some patients recovery may not occur. Such patients may progress to chronic renal insufficiency and even renal failure.

Creatine synthesis begins in the kidney and is completed in the liver. In the kidney, glycine combines with arginine to form guanidinoacetate. In this reaction, the guanidinium group of arginine (the group that also forms urea) is transferred to glycine, and the remainder of the arginine molecule is released as ornithine. Guanidinoacetate then travels to the liver, where it is methylated by *S*-adenosyl methionine to form creatine (see Fig. 45.5).

The creatine formed is released from the liver and travels through the bloodstream to other tissues, particularly brain, heart, and skeletal muscle, where it reacts with ATP to form the high-energy compound creatine phosphate (see Fig. 45.5). This reaction, catalyzed by creatine phosphokinase (CK, also abbreviated as CPK), is reversible. Therefore, cells can use creatine phosphate to regenerate ATP.

Creatine phosphate serves as a small reservoir of high-energy phosphate that can readily regenerate ATP from ADP. As a result, it plays a particularly important role in muscle during exercise. It also carries high-energy phosphate from mitochondria, where ATP is synthesized, to myosin filaments, where ATP is used for muscle contraction.

Creatine phosphate is an unstable compound. It spontaneously cyclizes, forming creatinine (see Fig. 45.5). Creatinine cannot be further metabolized and is excreted in the urine. The amount of creatinine excreted each day is constant and depends on body muscle mass. Therefore, it can be used as a gauge for determining the amounts of other compounds excreted in the urine and as an indicator of renal excretory function. The daily volume of urine is determined by such factors as the volume of blood reaching the renal glomeruli and the amount of renal tubular fluid reabsorbed from the tubular urine back into the interstitial space of the kidneys over time. At any given moment, the concentration of a compound in a single urine specimen does not give a good indication of the total amount that is being excreted on a daily basis. However, if the concentration of the compound is divided by the concentration of creatinine, the result provides a better indication of the true excretion rate.

B. Fuel Use at Rest

Muscle fuel use at rest is dependent on the serum levels of glucose, amino acids, and fatty acids. If blood glucose and amino acids are elevated, glucose will be converted to glycogen, and branched-chain amino acid metabolism will be high. Fatty acids will be used for acetyl CoA production and will satisfy the energy needs of the muscle under these conditions.

There is a balance between glucose oxidation and fatty acid oxidation, which is regulated by citrate. When the muscle cell has adequate energy, citrate leaves the mitochondria and activates ACC-2, which produces malonyl CoA. The malonyl CoA inhibits carnitine palmitoyltransferase-1, thereby reducing fatty acid oxidation by the muscle. Malonyl CoA decarboxylase is also inactive because the AMP-PK is not active in the resting state. Thus, the muscle regulates its oxidation of glucose and fatty acids in part through monitoring of cytoplasmic citrate levels.

C. Fuel Use during Starvation

As blood glucose levels drop, insulin levels drop. This reduces the levels of GLUT 4 transporters in the muscle membrane, and glucose use by muscle drops significantly. This conserves glucose for use by the nervous system and red blood cells. In cardiac muscle, PFK-2 is phosphorylated and activated by insulin. The lack of insulin results in a reduced use of glucose by these cells as well. Pyruvate dehydrogenase is inhibited by the high levels of acetyl CoA and NADH being produced by fatty acid oxidation.

Fatty acids become the muscle's preferred fuel under starvation conditions. The AMP-PK is active because of lower-than-normal ATP levels, ACC-2 is inhibited, and malonyl CoA decarboxylase is activated, thereby retaining full activity of CPT-1. The lack of glucose reduces the glycolytic rate, and glycogen synthesis does not occur because of the inactivation of glycogen synthase by epinephrine-stimulated phosphorylation. Recall that in prolonged starvation, muscle proteolysis is induced (in part by cortisol release) for gluconeogenesis by the liver. This does not, however, alter the use of fatty acids by the muscle for its own energy needs under these conditions.

D. Fuel Utilization during Exercise

The rate of ATP utilization in skeletal muscle during exercise can be as much as 100 times greater than that in resting skeletal muscles; thus, the pathways of fuel oxidation must be rapidly activated during exercise to respond to the much greater demand for ATP. ATP and creatine phosphate would be rapidly used up if they were not continuously regenerated. The synthesis of ATP occurs from glycolysis (either aerobic or anaerobic) and oxidative phosphorylation (which requires a constant supply of oxygen).

Anaerobic glycolysis is especially important as a source of ATP in three conditions. The first is during the initial period of exercise, before exercise-stimulated increase in blood flow and substrate and oxygen delivery begin, allowing aerobic processes to occur. The second condition in which anaerobic glycolysis is important is exercise by muscle containing predominately fast-twitch glycolytic muscle fibers because these fibers have low oxidative capacity and generate most of their ATP through glycolysis. The third condition is during strenuous activity, when the ATP demand exceeds the oxidative capacity of the tissue, and the increased ATP demand is met by anaerobic glycolysis.

1. Anaerobic Glycolysis at the Onset of Exercise

During rest, most of the ATP required in all types of muscle fibers is obtained from aerobic metabolism. However, as soon as exercise begins, the demand for ATP increases. The amount of ATP present in skeletal muscle could sustain exercise for only 1.2 seconds if it were not regenerated, and the amount of phosphocreatine could sustain exercise for only 9 seconds if it were not regenerated. It takes longer than 1 minute for the blood supply to exercising muscle to increase significantly as a result of vasodilation and, therefore, oxidative metabolism of blood-borne glucose and fatty acids cannot increase rapidly at the onset of exercise. Thus, for the first few minutes of exercise, the conversion of glycogen to lactate provides a considerable portion of the ATP requirement.

2. Anaerobic Glycolysis in Type IIB Fast-Twitch Glycolytic Fibers

Although humans have no muscles that consist entirely of fast-twitch fibers, many other animals do. Examples are white abdominal muscles of fish and the pectoral muscles of game birds (turkey white meat). These muscles contract rapidly and vigorously ("fast-twitch" refers to the time to peak tension), but only for short periods. Thus, they are used for activities such as flight by birds and for sprinting and weightlifting by humans.

In such muscles, the glycolytic capacity is high because the enzymes of glycolysis are present in large amounts (thus, the overall V_{\max} [maximum velocity] is large). The levels of hexokinase, however, are low, so very little circulating glucose is used. The low levels of hexokinase in fast-twitch glycolytic fibers prevent the muscle from drawing on blood glucose to meet this high demand for ATP, thus avoiding hypoglycemia. Glucose 6-phosphate, formed from glycogenolysis, further inhibits hexokinase. The tissues rely on endogenous fuel stores (glycogen and creatine phosphate) to generate ATP, following the pathway of glycogen breakdown to glucose 1-phosphate, the conversion of glucose 1-phosphate to glucose 6-phosphate, and the metabolism of glucose 6-phosphate to lactate. Thus, anaerobic glycolysis is the main source of ATP during exercise of these muscle fibers.

3. Anaerobic Glycolysis from Glycogen

Glycogenolysis and glycolysis during exercise are activated together because both PFK-1 (the rate-limiting enzyme of glycolysis) and glycogen phosphorylase b (the inhibited form of glycogen phosphorylase) are allosterically activated by AMP.

AMP is an ideal activator because its concentration is normally kept low by the adenylate kinase (also called myokinase in muscle) equilibrium ($2\text{ADP} \leftrightarrow \text{AMP} + \text{ATP}$). Thus, whenever ATP levels decrease slightly, the AMP concentration increases manyfold (Fig. 45.6).

FIGURE 45.6 Activation of muscle glycogenolysis and glycolysis by adenosine monophosphate (AMP). As muscle contracts, adenosine triphosphate (ATP) is converted to adenosine diphosphate (ADP) and inorganic phosphate (P_i). In the adenylate kinase reaction, two ADP molecules react to form ATP and AMP. The ATP is used for contraction. As AMP accumulates, it activates glycogenolysis and glycolysis. PFK-1, phosphofructokinase.

Starting from a molecule of glucose 1-phosphate derived from glycogenolysis, three ATP molecules are produced in anaerobic glycolysis, as compared with 31 to 33 molecules of ATP in aerobic glycolysis. To compensate for the low ATP yield of anaerobic glycolysis, fast-twitch glycolytic fibers have a much higher content of glycolytic enzymes, and the rate of glucose 6-phosphate utilization is more than 12 times as fast as in slow-twitch fibers.

Muscle fatigue during exercise generally results from a lowering of the pH of the tissue to approximately 6.4. Both aerobic and anaerobic metabolism lowers the pH. Both the lowering of pH and lactate production can cause pain.

Metabolic fatigue also can occur once muscle glycogen is depleted. Muscle glycogen stores are used up in <2 minutes of anaerobic exercise. If you do pushups, you can prove this to yourself. The muscle used in pushups, a high-strength exercise, is principally fast-twitch glycolytic fibers. Time yourself from the start of your pushups. No matter how well you have trained, you probably cannot do pushups for as long as 2 minutes. Furthermore, you will feel the pain as the muscle pH drops as lactate production continues.

The regulation of muscle glycogen metabolism is complex. Recall that glycogen degradation in muscle is not sensitive to glucagon (muscles lack glucagon receptors), so there is little change in muscle glycogen stores during overnight fasting or long-term fasting if the individual remains at rest. Glycogen synthase is inhibited during exercise but can be activated in resting muscle by the release of insulin after a high-carbohydrate meal. Unlike the liver form of glycogen phosphorylase, the muscle isozyme contains an allosteric site for AMP binding. When AMP binds to muscle glycogen phosphorylase b, the enzyme is activated even though it is not phosphorylated. Thus, as muscle begins to work and the myosin ATPase hydrolyzes existing ATP stores to ADP, AMP begins to accumulate (because of the adenylate kinase reaction), and glycogen degradation is enhanced. The activation of muscle glycogen phosphorylase b is further enhanced by the release of Ca^{2+} from the sarcoplasmic reticulum, which occurs when muscles are stimulated to contract. The increase in sarcoplasmic Ca^{2+} also leads to the allosteric activation of glycogen phosphorylase kinase (through binding to the calmodulin subunit of the enzyme), which phosphorylates muscle glycogen phosphorylase b, fully activating it. And, finally, during intense exercise, epinephrine release stimulates the activation of adenylate cyclase in muscle cells, thereby activating the cAMP-dependent protein kinase (see Fig. 26.9). Protein kinase A phosphorylates and fully activates glycogen phosphorylase kinase so that continued activation of muscle glycogen phosphorylase can occur. The hormonal signal is slower than the initial activation events triggered by AMP and calcium (Fig. 45.7).

FIGURE 45.7 Stimulation of glycogenolysis in muscle by epinephrine. (1) Epinephrine binding to its receptor leads to the activation of adenylate cyclase, which increases cAMP levels. (2) cAMP binds to the regulatory subunits of protein kinase A, thereby activating the catalytic subunits. (3) Active protein kinase A phosphorylates and activates phosphorylase kinase. Phosphorylase kinase also can be activated partially by the Ca^{2+} -calmodulin complex as Ca^{2+} levels increase as muscles contract. (4) Protein kinase A phosphorylates and inactivates glycogen synthase. (5) Active phosphorylase kinase converts glycogen phosphorylase b to glycogen phosphorylase a. (6) Glycogen degradation forms glucose 1-phosphate, which is converted to glucose 6-phosphate, which enters the glycolytic pathway for energy production. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

4. Anaerobic Glycolysis during High-Intensity Exercise

Once exercise begins, the electron transport chain, the TCA cycle, and fatty acid oxidation are activated by the increase of ADP and the decrease of ATP. Pyruvate dehydrogenase remains in the active, nonphosphorylated state as long as NADH can be reoxidized in the electron transport chain and acetyl CoA can enter the TCA cycle. However, even though mitochondrial metabolism is working at its maximum capacity, additional ATP may be needed for very strenuous, high-intensity exercise. When this occurs, ATP is not being produced rapidly enough to meet the muscle's needs, and AMP begins to accumulate. Increased AMP levels activate

PFK-1 and glycogenolysis, thereby providing additional ATP from anaerobic glycolysis (the additional pyruvate produced does not enter the mitochondria but rather is converted to lactate so that glycolysis can continue). Thus, under these conditions, most of the pyruvate formed by glycolysis enters the TCA cycle, whereas the remainder is reduced to lactate to regenerate NAD^+ for continued use in glycolysis.

If **Otto S.** runs at a pace at which his muscles require approximately 500 calories per hour, how long could he run on the amount of glucose that is present in circulating blood? Assume that the blood volume is 5 L.

5. Fate of Lactate Released during Exercise

The lactate that is released from skeletal muscles during exercise can be used by resting skeletal muscles or by the heart, a muscle with a large amount of mitochondria and very high oxidative capacity. In such muscles, the NADH/NAD^+ ratio is lower than in exercising skeletal muscle, and the lactate dehydrogenase reaction proceeds in the direction of pyruvate formation. The pyruvate that is generated is then converted to acetyl CoA and oxidized in the TCA cycle, producing energy by oxidative phosphorylation.

The second potential fate of lactate is that it will return to the liver through the Cori cycle, where it is converted to glucose (see Fig. 22.12).

VI. Mild and Moderate-Intensity Long-Term Exercise

A. Lactate Release Decreases with Duration of Exercise

Mild to moderate-intensity exercise can be performed for longer periods than can high-intensity exercise. This is because of the aerobic oxidation of glucose and fatty acids, which generates more energy per fuel molecule than anaerobic metabolism, and which also produces lactic acid at a slower rate than anaerobic metabolism. Thus, during mild and moderate-intensity exercise, the release of lactate diminishes as the aerobic metabolism of glucose and fatty acids becomes predominant.

B. Blood Glucose as a Fuel

At any given time during fasting, the blood contains only approximately 5 g of glucose, enough to support a person running at a moderate pace for a few minutes. Therefore, the blood glucose supply must be constantly replenished. The liver performs this function by processes similar to those used during fasting. The liver produces glucose by breaking down its own glycogen stores and by gluconeogenesis. The major source of carbon for gluconeogenesis during exercise is, of course, lactate, produced by the exercising muscle, but amino acids and glycerol are also used (Fig. 45.8). Epinephrine released during exercise stimulates liver glycogenolysis and gluconeogenesis by causing cAMP levels to increase.

FIGURE 45.8 Production of blood glucose by the liver from various precursors during rest and during prolonged exercise. The green area represents the contribution of liver glycogen to blood glucose, and the lighter area represents the contribution of gluconeogenesis. (Reprinted by permission from Wahren J, Felig P, Hagenfeldt L, et al. Splanchnic and leg metabolism of glucose, free fatty acids and amino acids during prolonged exercise in man. In: Howald H, Poortmans JR, eds. *Metabolic Adaptation to Prolonged Physical Exercise*. Birkhauser; 1975:148. © 1975 Springer Basel AG.)

During long periods of exercise, blood glucose levels are maintained by the liver through hepatic glycogenolysis and gluconeogenesis. The amount of glucose that the liver must export is greatest at higher workloads, in which case the muscle is using a greater proportion of the glucose for anaerobic metabolism. With increasing duration of exercise, an increasing proportion of blood glucose is supplied by gluconeogenesis. For up to 40 minutes of mild exercise, glycogenolysis is mainly responsible for the glucose output of the liver. However, after 40 to 240 minutes of exercise, the total glucose output of the liver decreases. This is caused by the increased utilization of fatty acids, which are being released from adipose tissue triacylglycerols (stimulated by epinephrine release). Glucose uptake by the muscle is stimulated by the increase in AMP levels and the activation of the AMP-activated protein kinase, which stimulates the translocation of GLUT4 transporters to

the muscle membrane.

The hormonal changes that direct the increased hepatic glycogenolysis, hepatic gluconeogenesis, and adipose tissue lipolysis include a decrease in insulin and an increase in glucagon, epinephrine, and norepinephrine. Plasma levels of growth hormone, cortisol, and thyroid-stimulating hormone (TSH) also increase and may contribute to fuel mobilization as well (see Chapter 41). The activation of hepatic glycogenolysis occurs through glucagon and epinephrine release. Hepatic gluconeogenesis is activated by the increased supply of precursors (lactate, glycerol, amino acids, and pyruvate), the induction of gluconeogenic enzymes by glucagon and cortisol (this occurs only during prolonged exercise), and the increased supply of fatty acids to provide the ATP and NADH needed for gluconeogenesis and the regulation of gluconeogenic enzymes.

Remember from Chapter 1 that a food calorie (Cal) is equivalent to 1 kcal of energy. One gram of glucose can give rise to 4 kcal of energy so at a rate of consumption of 500 cal/hour we have

$$(500 \text{ cal/h}) \times (1 \text{ g glucose}/4 \text{ cal energy}) \\ \times (1 \text{ h}/60 \text{ min}) = 2 \text{ g glucose/min}$$

Thus, **Otto S.** must use 2 g of glucose per minute to run at his current pace. In the fasting state, blood glucose levels are approximately 90 mg/dL or 900 mg/L. Because blood volume is estimated at 5 L, **Otto S.** has 4.5 g glucose available. If it is not replenished, that amount of glucose will support only 2.25 minutes of running at 2 g glucose per minute.

C. Free Fatty Acids as a Source of ATP

The longer the duration of the exercise, the greater the reliance of the muscle on free fatty acids for the generation of ATP (Fig. 45.9). Because ATP generation from free fatty acids depends on mitochondria and oxidative phosphorylation, long-distance running uses muscles that are principally slow-twitch oxidative fibers, such as the gastrocnemius. It is also important to realize that resting skeletal muscle uses free fatty acids as a principal fuel. At almost anytime except the postprandial state (right after eating), free fatty acids are the preferred fuel for skeletal muscle.

FIGURE 45.9 Fuels used during exercise. The pattern of fuel utilization changes with the duration of the exercise. (From Felig P, Baxter JD, Broadus AE, Frohman LA. *Endocrinology & Metabolism*. McGraw-Hill; 1981:796.)

The preferential utilization of fatty acids over glucose as a fuel in skeletal muscle depends on the following factors:

1. The availability of free fatty acids in the blood, which depends on their release from adipose tissue

triacylglycerols by lipases. During prolonged exercise, the small decrease of insulin, and increases of glucagon, epinephrine and norepinephrine, cortisol, and possibly growth hormone all activate adipocyte tissue lipolysis.

2. Inhibition of glycolysis by products of fatty acid oxidation. Pyruvate dehydrogenase activity is inhibited by acetyl CoA, NADH, and ATP, all of which are elevated as fatty acid oxidation proceeds. As AMP levels drop, and ATP levels rise, PFK-1 activity is decreased (see Chapter 22).
3. Glucose transport may be reduced during long-term exercise. Glucose transport into skeletal muscles via the GLUT 4 transporter is greatly activated by either insulin or exercise. During long-term exercise, the effect of falling insulin levels or increased fatty acid levels may counteract the stimulation of glucose transport by the exercise itself.
4. Oxidation of ketone bodies also increases during exercise. Their utilization as a fuel is dependent on their rate of production by the liver. Ketone bodies are never, however, a major fuel for skeletal muscle (muscles prefer free fatty acids).
5. Acetyl CoA carboxylase (isozyme ACC-2) must be inactivated for the muscle to use fatty acids. This occurs as the AMP-PK is activated and phosphorylates ACC-2, rendering it inactive, and activates malonyl CoA decarboxylase, to reduce malonyl CoA levels and allow full activity of CPT-1.

D. Branched-Chain Amino Acids

Branched-chain amino acid oxidation has been estimated to supply a maximum of 20% of the ATP supply of resting muscle. Oxidation of branched-chain amino acids in muscle serves two functions. The first is the generation of ATP, and the second is the synthesis of glutamine, which effluxes from the muscle. The highest rates of branched-chain amino acid oxidation occur under conditions of acidosis, in which there is a higher demand for glutamine to transfer ammonia to the kidney and to buffer the urine as ammonium ion during proton excretion. Recall that glutamine synthesis occurs from the carbon skeletons of branched-chain amino acid oxidation (valine and isoleucine) after the initial five steps of the oxidative pathway.

E. The Purine Nucleotide Cycle

Exercise increases the activity of the purine nucleotide cycle, which converts aspartate to fumarate plus ammonia (see Fig. 39.12). The ammonia is used to buffer the proton production and lactate production from glycolysis, and the fumarate is recycled and can form glutamine.

F. Acetate

Acetate is an excellent fuel for skeletal muscle. It is treated by the muscle as a very short-chain fatty acid. It is activated to acetyl CoA in the cytosol and then transferred into the mitochondria via acetylcarnitine transferase, an isozyme of carnitine palmitoyltransferase. Sources of acetate include the diet (vinegar is acetic acid) and acetate produced in the liver from alcohol metabolism. Certain commercial power bars for athletes contain acetate.

VII. Metabolic Effects of Training on Muscle Metabolism

The effect of training depends, to some extent, on the type of training. In general, training increases the muscle glycogen stores and increases the number and size of mitochondria. The fibers thus increase their capacity for generation of ATP from oxidative metabolism and their ability to use fatty acids as a fuel. The winners in marathon races seem to use muscle glycogen more efficiently than others.

Training to improve strength, power, and endurance of muscle performance is called resistance training. Its goal is to increase the size of the muscle fibers (hypertrophy of the muscle). Muscle fibers can develop a maximal force of 3 to 4 kg/cm² of muscle area. Thus, if we could increase our muscle size from 80 to 120 cm², the maximal resistance that could be lifted would increase from 240 to 360 kg. Hypertrophy occurs by increased protein synthesis in the muscle and a reduction in existing protein turnover.

Renee F. Poststreptococcal glomerulonephritis (PSGN) may follow pharyngeal or cutaneous infection of a limited number of “nephritogenic” strains of group A β -hemolytic streptococci. The pathogenesis of PSGN involves a host immune (antibody) response to one or more of the enzymes secreted by the bacterial cells. The antigen–antibody complexes are deposited on the tissues of glomerular units, causing a local acute inflammatory response. Hypertension may occur as a consequence of sodium and water retention caused by an inability of the inflamed glomerular units to filter sodium and water into the urine. Proteinuria is usually mild if the immune response is self-limited.

Overall, one of the most useful clinical indicators of glomerular filtration rate in both health and disease is the serum creatinine concentration. The endogenous production of creatinine, which averages approximately 15 mg/kg of body weight per day, is correlated with muscle mass and, therefore, tends to be constant for a given individual if renal function is normal. Any rise in serum creatinine in a patient such as **Renee F.**, therefore, can be assumed to result from decreased excretion of this metabolite into the urine. The extent of the rise in the blood is related directly to the severity of the pathological process involving the glomerular units in the kidneys.

Seth D. was initially treated with glucocorticoids and then was started on eteplirsen, an exon 51 skipping reagent approved by the FDA in 2016 for treatment of boys with DMD, which was appropriate for exon 51 skipping (about 13% of all DMD cases). By skipping exon 51, an in-frame deletion is created, allowing a truncated form of dystrophin to be produced and targeted to the membrane of the muscle cells. **Seth D.** receives the drug intravenously on a weekly basis. The drug appeared to be working in **Seth D.**, as muscle biopsies indicated reduced inflammation, and the level of detectable dystrophin in the muscle more than doubled than before treatment. The long-term effects of eteplirsen treatment have not yet been determined.

BIOCHEMICAL COMMENTS

The SERCA Pump. The SERCA pump is a transmembrane protein of 110 kDa that is present in several different isoforms throughout the body. Three genes encode SERCA proteins, designated *SERCA1*, *SERCA2*, and *SERCA3*. The *SERCA1* gene produces two alternatively spliced transcripts, *SERCA1a* and *SERCA1b*. *SERCA1b* is expressed in the fetal and neonatal fast-twitch skeletal muscles and is replaced by *SERCA1a* in adult fast-twitch muscles. The *SERCA2* gene also undergoes alternative splicing, producing the *SERCA2a* and *SERCA2b* isoforms. The *SERCA2b* isoform is expressed in all cell types and is associated with inositol trisphosphate (IP_3)-regulated calcium stores. *SERCA2a* is the primary isoform expressed in cardiac tissue. *SERCA3* produces at least five different alternatively spliced isoforms, which are specifically expressed in different tissues.

SERCA2a plays an important role in cardiac contraction and relaxation. Contraction is initiated by the release of calcium from intracellular stores, whereas relaxation occurs as the calcium is resequestered in the sarcoplasmic reticulum, in part mediated by the *SERCA2a* protein. The *SERCA2a* pump is regulated, in part, by its association with the protein phospholamban (PLN). PLN is a pentameric molecule consisting of five identical subunits of molecular weight 22,000 Da. PLN associates with *SERCA2a* in the sarcoplasmic reticulum and reduces its pumping activity. Because new contractions cannot occur until cytosolic calcium has been resequestered into the sarcoplasmic reticulum, a reduction in *SERCA2a* activity increases the relaxation time. However, when called on, the heart can increase its rate of contractions by inhibiting the activity of phospholamban. This is accomplished by phosphorylation of phospholamban by protein kinase A (PKA). Epinephrine release stimulates the heart to beat faster. This occurs through epinephrine binding to its receptor, activating a G-protein, which leads to adenylate cyclase activation, elevation of cAMP levels, and activation of protein kinase A. PKA phosphorylates PLN, thereby reducing its association with *SERCA2a* and relieving the inhibition of pumping activity. This results in reduced relaxation times and more frequent contractions.

Mutations in PLN lead to cardiomyopathies, primarily an autosomal dominant form of dilated cardiomyopathy. This particular mutation substitutes an arginine in place of cysteine at position 9 in PLN, which forms an inactive complex with PKA and blocks PKA phosphorylation of PLN. Individuals with this form of PLN develop cardiomyopathy in their teens. In this condition, the cardiac muscle does not pump well (because of the constant inhibition of *SERCA2a*) and becomes enlarged (dilated). Because of the poor pumping action of the heart, fluid can build up in the lungs (left heart failure). The pulmonary congestion results in a sense of breathlessness (dyspnea). Eventually, progressive left heart failure leads to right heart failure and fluid

accumulation in other tissues and organs of the body, such as the legs and ankles (edema).

KEY CONCEPTS

- ◆ Muscle comprises three different types: skeletal, smooth, and cardiac.
 - ◆ Skeletal muscle facilitates movement of the skeleton.
 - ◆ Slow-twitch fibers contain large amounts of mitochondria and myoglobin and generate energy primarily via oxidative means.
 - ◆ Fast-twitch fibers have few mitochondria, low levels of myoglobin, and are rich in glycogen. These fibers generate energy primarily via glycolysis.
 - ◆ Smooth muscle cells display no striations and aid in maintaining the shape and movement of the blood vessels, airways, uterus, and digestive systems.
 - ◆ Cardiac muscle cells contain striations but are regulated involuntarily. They utilize aerobic metabolism, oxidizing fatty acids, glucose, and lactate, and they contain many mitochondria, with very little glycogen.
- ◆ Acetylcholine release at the neuromuscular junction leads to muscle contraction.
- ◆ Fatty acid oxidation in muscle is controlled by the levels of malonyl CoA produced by a muscle-specific isozyme of acetyl CoA carboxylase (ACC-2).
- ◆ Skeletal muscle utilizes many fuels to generate ATP, storing excess high-energy phosphate bonds as creatine phosphate.
- ◆ Muscle fuel use is regulated carefully.
 - ◆ At rest, the muscle uses what is available in the blood (glucose, amino acids, fatty acids).
 - ◆ During starvation, fatty acids are the preferred energy source (even over ketone bodies).
 - ◆ During exercise, stored glycogen, blood glucose, and blood fatty acids are the primary sources of energy for the skeletal muscles.
- ◆ Diseases discussed in this chapter are summarized in Table 45.2.

TABLE 45.2 Diseases Discussed in This Chapter

DISEASE OR DISORDER	GENETIC OR ENVIRONMENTAL	COMMENTS
Renal failure	Both	The lack of kidney function can lead to encephalopathy due to the buildup of toxic metabolites in the blood.
Duchenne muscular dystrophy	Genetic	The lack of dystrophin, due to deletions in the DMD gene on the X-chromosome, lead to muscle dysfunction at an early age.

REVIEW QUESTIONS—CHAPTER 45

1. The process of stretching before exercise has which one of the following biochemical benefits?
 - A. Stimulates the release of epinephrine
 - B. Activates glycolysis in the liver
 - C. Increases blood flow to the muscles
 - D. Activates glycolysis in the muscles
 - E. Stimulates glycogenolysis in the liver
2. The major metabolic fuel for participating in a prolonged aerobic exercise event is which of the following?
 - A. Liver glycogen
 - B. Muscle glycogen
 - C. Brain glycogen
 - D. Adipose triacylglycerol
 - E. Red blood cell-produced lactate
3. A 24-hour urine collection showed that an individual's excretion of creatinine was much lower than normal. Decreased excretion of creatinine could be caused by which one of the following?
 - A. A decreased dietary intake of creatine

- B. A higher-than-normal muscle mass resulting from weight lifting
 - C. A genetic defect in the enzyme that converts creatine phosphate to creatinine
 - D. Kidney failure
 - E. A vegetarian diet
4. In the biosynthetic pathways for the synthesis of heme, creatine, and guanine, which one of the following amino acids directly provides carbon atoms that appear in the final product?
 - A. Serine
 - B. Aspartate
 - C. Cysteine
 - D. Glutamate
 - E. Glycine
 5. In skeletal muscle, increased hydrolysis of ATP during muscular contraction leads to which one of the following?
 - A. A decrease in the rate of palmitate oxidation to acetyl CoA
 - B. A decrease in the rate of NADH oxidation by the electron transport chain
 - C. Activation of PFK-1
 - D. An increase in the proton gradient across the inner mitochondrial membrane
 - E. Activation of glycogen synthase
 6. A new drug is being developed, which can specifically inhibit the acetyl CoA carboxylase-2 isozyme in muscle. This drug could potentially be used for which one of the following purposes?
 - A. To accelerate weight loss
 - B. To reduce the severity of a myocardial infarction
 - C. To enhance high-intensity exercise performance
 - D. To increase ketone body synthesis in a patient with hypoglycemia
 - E. To increase fatty acid synthesis in muscle
 7. Insulin release stimulates the hearts glycolytic rate, as increased levels of glucose are present in the circulation. The increase in glycolytic rate occurs due to which one of the following?
 - A. An increase in ATP levels
 - B. A decrease in ADP levels
 - C. A decrease in fructose 2,6 bisphosphate levels
 - D. An increase in lactate levels
 - E. An increase in fructose 2,6 bisphosphate levels
 - F. A decrease in lactate levels
 8. An athlete is actively training for her 1,500 m race. She runs a series of sprints, followed by longer distances at a slower pace. Which statement below correctly describes her muscle energy production and usage during a training session?
 - A. Muscle cells synthesize fatty acids for energy.
 - B. Skeletal muscle uses lactate and glucose for energy needs.
 - C. The heart uses glycolysis to meet 10% to 20% of its energy needs.
 - D. Fatty acids are the preferred fuel for the heart.
 - E. Ketone bodies are a preferred fuel for skeletal muscle.
 9. A person had an ischemic cardiac event caused by a clot lodged in a coronary artery. They then received tPA (a clot buster) and worsened when the ischemia was relieved (ischemia-reperfusion injury). This occurred due to which one of the following after the ischemia was relieved?
 - A. Increased glycolysis
 - B. Increased fatty acid oxidation
 - C. Increased levels of NADPH in mitochondria
 - D. Decreased levels of NADH in mitochondria
 - E. Decreased lactate production
 10. Muscle cells use creatine phosphate to store high-energy phosphate bonds instead of ATP. Creatine can be best described by which one of the following?
 - A. Creatine is synthesized in the kidney.
 - B. Creatine reacts with ATP to produce creatine phosphokinase (CPK).
 - C. Creatine cannot be further metabolized and is excreted in the urine.
 - D. Creatine excretion in the urine is constant each day.
 - E. Creatine is utilized by the brain, heart, and skeletal muscle.

- A young boy with DMD was placed on an exon-skipping reagent to ameliorate and delay the onset of severe disease. The basic mechanism for this treatment is which one of the following?
 - To remove the exon containing the mutation
 - To replace the exon containing the mutation
 - To create an in-frame deletion
 - To create an out-of-frame deletion
 - To allow ubiquitin-mediated destruction of the mutated protein
- A marathon runner is training for their next race, and in consultation with a trainer will focus on an activity that primarily enhances the performance of which one of the following?
 - Type 1 muscle fibers
 - Type 2a muscle fibers
 - Type 2b muscle fibers
 - Lactate dehydrogenase
 - Muscle glycogen phosphorylase
- Ryanodine acts as a paralytic agent in insecticides either directly or indirectly due to which one of the following?
 - Blocking acetylcholine receptors
 - Inhibiting acetylcholinesterase
 - Stimulating calcium release from the sarcoplasmic reticulum
 - Blocking troponin conformation changes
 - Blocking sodium entry into muscle cells
- The release of epinephrine leads to a faster heartbeat, which occurs due to which one of the following?
 - Activation of the AMP-activated protein kinase
 - Phosphorylation of the SERCA pump
 - Phospholamban association with the SERCA pump
 - Phosphorylation of phospholamban
 - Inhibition of protein kinase A
- AMP acts as an important modulator of muscle metabolic activity. A rise in AMP levels in muscle due to ATP utilization can lead to which of the following effects? Choose the one best answer.

	Activation of PFK-1	Activation of Glycogen Phosphorylase b	Activation of Protein Kinase A	Activation of Acetyl CoA Carboxylase
A	No	No	Yes	Yes
B	Yes	No	No	No
C	No	No	Yes	Yes
D	Yes	Yes	No	Yes
E	No	Yes	Yes	No
F	Yes	Yes	No	No

ANSWERS TO REVIEW QUESTIONS

1. **The answer is C.** Stretching aids in stimulating blood flow to the muscles, which enhances oxidative muscle metabolism (by allowing for better oxygen delivery). Stretching, per se, does not stimulate epinephrine release (thus, A is incorrect), nor does it activate glycolysis in either the liver or muscle.
2. **The answer is D.** Triacylglycerol is the largest energy store in the body and is the predominant fuel in long-term aerobic exercise. During exercise, muscle glycogen is used for bursts of speed but not for long-term energy requirements. Liver glycogen is used to maintain blood glucose levels for use by the nervous system and as a supplement for use by muscle when rapid speed is required; however, it is not designed to be a long-term energy source. The brain does not contain significant levels of glycogen, and lactic acid produced by the red blood cells is used as a gluconeogenic precursor by liver, but not as a fuel for muscle.
3. **The answer is D.** Creatine is synthesized from glycine, arginine, and S-adenosyl methionine (thus, intake of dietary creatine is not relevant). In muscle, creatine is converted to creatine phosphate, which is nonenzymatically cyclized to form creatinine (thus, C is incorrect). The amount of creatinine excreted by the kidneys each day depends on body muscle mass but is constant for each individual (therefore, if there is an increase in body muscle mass, there would be an increase in creatinine excretion). In kidney failure, the excretion of creatinine into the urine is low, and an elevation of serum creatinine would be observed.
4. **The answer is E.** Glycine is required for the synthesis of heme (combining with succinyl CoA in the initial step), for the synthesis of purine rings (the entire glycine molecule is incorporated into adenine and guanine) and for creatine, where glycine reacts with arginine in the first step.
5. **The answer is C.** A decrease in the concentration of ATP (which occurs as muscle contracts) stimulates processes that generate ATP. The proton gradient across the inner mitochondrial membrane decreases as protons enter the matrix via the ATPase to synthesize ATP; NADH oxidation by the electron transport chain increases to reestablish the proton gradient; fuel utilization also increases to generate more ATP. Glycogen synthesis is inhibited because of phosphorylation of glycogen synthase as induced by epinephrine. Palmitate is oxidized and glycolysis increases because of the activation of PFK-1 by AMP. As ATP decreases, AMP rises as a result of the myokinase reaction ($2\text{ADP} \rightarrow \text{ATP} + \text{AMP}$).
6. **The answer is A.** ACC-2 produces malonyl CoA in the muscle for the purpose of regulating fatty acid oxidation via inhibition of carnitine palmitoyltransferase I (CPT-I). When malonyl CoA cannot be synthesized, through inhibition of ACC-2, fatty acid oxidation in the muscle is rapid and not regulated. Skeletal muscle then oxidizes fatty acids instead of glucose, leading to a drop in stored fatty acids in the adipocyte. After a myocardial infarction, fatty acid oxidation must be regulated such that glucose oxidation can also occur, otherwise, lactic acid is produced (via anaerobic glycolysis), which further damages the heart. High-intensity exercise requires very rapid ATP synthesis, which can only occur by anaerobic glycolysis; as a result, increasing the rate of fatty acid oxidation by drug use will not aid in high-intensity exercise. Muscle cells do not produce either ketone bodies or fatty acids, thus inhibition of ACC-2 would not lead to those effects.
7. **The answer is E.** Insulin release leads to the activation of protein kinase B (akt), which, in the heart, will phosphorylate PFK-2. The phosphorylation of the heart isozyme of PFK-2 leads to activation of its kinase activity, thereby producing increased amounts of fructose 2,6 biphosphate, a potent activator of PFK-1 activity. Simultaneously, the phosphatase activity of cardiac PFK-2 is inhibited, thereby allowing the increased levels of fructose 2,6 biphosphate to stay elevated. The activation of PFK-1 leads to an increased glycolytic rate within the heart, taking advantage of the high glucose levels in the blood. High levels of ATP will inhibit glycolysis as an allosteric inhibitor, and high levels of lactate reduce glycolysis due to a reduction in intracellular pH. Low levels of ADP do not stimulate glycolysis (AMP will activate PFK-1), nor will low levels of lactate.
8. **The answer is D.** The heart uses primarily fatty acids (60% to 80% of energy needs) for its energy needs but can utilize lactate and glucose. Only 2% of its energy requirement is derived from glycolysis. Muscles do not synthesize fatty acids. Exercising skeletal muscles utilize glucose and fatty acids preferentially for their energy needs (glucose during sprints, and a mixture of fatty acids and glucose during longer distances). Ketone bodies are not produced when adults exercise. The lactate generated by the muscle during exercise can also be used by the heart as an energy source. The muscle, when generating lactate, does not use the lactate as a fuel.
9. **The answer is B.** During ischemia, glycolysis increases, creating lactate. However, after ischemia is relieved, the high rate of fatty acid oxidation is damaging to already damaged heart cells by rapidly increasing NADH levels in the mitochondria. This leads to even more lactate production in the cytoplasm as the high intramitochondrial NADH levels inhibit the shuttle systems that transfer electrons from

cytoplasmic NADH to mitochondrial NAD^+ . The increased cytoplasmic NADH levels lead to increased lactate production, reducing the pH of the cardiac cells. The high acetyl CoA levels in the mitochondria (due to fatty acid oxidation) inhibit pyruvate dehydrogenase, which leads to increased pyruvate in the cytoplasm, and increased lactate production. NADPH is not involved in the increase in cardiac damage after ischemia.

10. **The answer is E.** Creatine synthesis begins in the kidney and is completed in the liver. It is then released into the blood and travels particularly to brain, heart, and skeletal muscle where it is utilized to react with ATP to form creatine phosphate (catalyzed by CPK). Creatine phosphate is unstable and spontaneously cyclizes to creatinine, which is excreted in the urine. The amount of creatinine excreted each day is constant, and proportional to muscle mass.
11. **The answer is C.** Most mutations that cause DMD are deletions, which lead to an out-of-frame mRNA sequence such that a premature stop codon is present, resulting in no functional protein being produced. The premise of exon-skipping is to restore an in-frame coding sequence which will allow for the production of a truncated but partially functional protein. The presence of a partially active protein will be better than the absence of the protein, in terms of cell function and viability. Exon-skipping reagents do not remove or replace the exons which contain the mutation. Exon-skipping will produce a protein that avoids ubiquitin-mediated proteolysis so the truncated proteins produced provide partial function to the muscle cell.
12. **The answer is A.** Type 1 muscle fibers are utilized primarily for prolonged aerobic exercise. They contain high levels of myoglobin for oxygen delivery to the mitochondria, with low levels of internal glycogen stores. The fibers have a high resistance to fatigue and a high capacity for aerobic metabolism. The runner may increase type 2a fibers, which have an intermediate resistance to fatigue but not to the same extent as type 1 fibers. Type 2b muscle fibers are primarily anaerobic and used for sprinting and resistance tasks. Since type 1 fibers use primarily oxidative metabolism, they do not generate lactate (the pyruvate produced from glucose goes to acetyl CoA, not lactate, although the muscle is also significantly oxidizing fatty acids for energy during the training), so there is no need to increase the activity of lactate dehydrogenase. Similarly, there is no need to enhance the activity of glycogen phosphorylase, which is already active in muscle under training conditions due to the release of epinephrine and increase in AMP levels in the muscle.
13. **The answer is D.** Ryanodine binds to the ryanodine receptor in the sarcoplasmic reticulum and blocks its function in releasing calcium ions into the sarcoplasm when activated by the dihydropyridine receptor. The lack of sarcoplasmic calcium means that calcium cannot bind to troponin, which initiates the conformational change in troponin which allows the myosin head to bind to actin. Thus, contractions cannot occur and the result is paralysis. Ryanodine does not interact with either the acetylcholine receptor or acetylcholinesterase. Sodium entry into the muscle, in response to acetylcholine, is due to activation of the acetylcholine receptor, which is not affected by ryanodine.
14. **The answer is D.** Epinephrine, upon binding to its receptor on heart muscle cells, leads to the activation of protein kinase A, which phosphorylates phospholamban. When phosphorylated phospholamban cannot bind to the SERCA pump to inhibit it, and sarcoplasmic calcium ions are transported back into the sarcoplasmic reticulum to allow for further contractions. The SERCA pump is not directly phosphorylated, and epinephrine activates protein kinase A, not the AMP-activated protein kinase.
15. **The answer is F.** As ATP is hydrolyzed ADP accumulates, and myokinase will catalyze the conversion of 2 ADP to AMP and ATP. This results in a significant increase in AMP levels. The increase in AMP levels allosterically activates both PFK-1 and muscle glycogen phosphorylase b, as well as the AMP-activated protein kinase (not protein kinase A). The AMP-activated protein kinase will phosphorylate acetyl CoA carboxylase, inhibiting (not activating) its activity.

Metabolism of the Nervous System

The nervous system consists of various cell types. The most abundant cell in the nervous system is the **glial cell**, which consists of **astrocytes** and **oligodendrocytes** in the **central nervous system**, and **Schwann cells** in the **peripheral nervous system**. These cells provide support for the neurons and synthesize the protective **myelin sheath** that surrounds the axons emanating from the neurons. **Microglial cells** in the nervous system act as immune cells, destroying and ingesting foreign organisms that enter the nervous system. The interface between the brain parenchyma and the cerebrospinal fluid compartment is formed by the **ependymal cells**, which line the cavities of the brain and spinal cord. These cells use their cilia to allow for the circulation of the **cerebrospinal fluid (CSF)**, which bathes the cells of the central nervous system.

The cells of the brain are separated from free contact with the rest of the body by the **blood–brain barrier**. The capillaries of the brain exhibit features, such as tight endothelial cell junctions, that restrict their permeability to metabolites in the blood. This protects the brain from compounds that might be toxic or otherwise interfere with nerve impulse transmission. It also affects the entry of precursors for brain metabolic pathways such as fuel metabolism and neurotransmitter synthesis.

Neurotransmitters can be divided structurally into two categories: **small nitrogen-containing neurotransmitters** and **neuropeptides**. The small nitrogen-containing neurotransmitters are generally synthesized in the **presynaptic terminal** from amino acids and intermediates of glycolysis and the tricarboxylic acid (TCA) cycle. They are retained in storage vesicles until the neuron is depolarized. The **catecholamine** neurotransmitters (**dopamine**, **norepinephrine**, and **epinephrine**) are derived from tyrosine. **Serotonin** is synthesized from **tryptophan**. **Acetylcholine** is synthesized from **choline**, which can be supplied from the diet or is synthesized and stored as part of **phosphatidylcholine**. **Glutamate** and its neurotransmitter derivative, **γ -aminobutyric acid (GABA)**, are derived from **α -ketoglutarate** in the TCA cycle. **Glycine** is synthesized in the brain from **serine**. The synthesis of the neurotransmitters is regulated to correspond to the rate of depolarization of the individual neurons. A large number of cofactors are required for the synthesis of neurotransmitters, and deficiencies of **pyridoxal phosphate**, **thiamin pyrophosphate**, and **vitamin B12** result in a variety of neurological dysfunctions.

Brain metabolism has a high **requirement for glucose and oxygen**. **Deficiencies of either (hypoglycemia or hypoxia)** affect brain function because they influence adenosine triphosphate (ATP) production and the supply of precursors for neurotransmitter synthesis. **Ischemia** elicits a condition in which increased **calcium levels**, **swelling**, **glutamate excitotoxicity**, and **nitric oxide** generation affect brain function, and can lead to a stroke. The generation of **free radicals** and abnormalities in nitric oxide production are important players in the pathogenesis of a variety of **neurodegenerative** diseases.

Because of the restrictions posed by the blood–brain barrier to the entry of a variety of substances into the central nervous system, the brain generally synthesizes and degrades its own lipids. Essential fatty acids can enter the brain, but the more common fatty acids do not. The turnover of lipids at the synaptic membrane is very rapid, and the neuron must replace those lipids lost during exocytosis. The glial cells produce the **myelin sheath**, which is composed primarily of lipids. These lipids are of a different composition than those of the neuronal cells. Because there is considerable lipid synthesis and turnover in the brain, this organ is sensitive to **disorders of peroxisomal function** (Refsum disease; interference in very-long-chain fatty acid oxidation and α -oxidation) and **lysosomal diseases** (mucopolysaccharidoses; inability to degrade complex lipids and glycolipids).

Katie C., a 34-year-old dress designer, developed alarming palpitations of her heart while bending forward to pick up her cat. She also developed a pounding headache and started sweating profusely. After 5 to 10 minutes, these symptoms subsided. One week later, her aerobic exercise instructor, a registered nurse, noted that **Katie C.** grew very pale and was tremulous during exercise. The instructor took **Katie C.**'s blood pressure, which was 220 mm Hg systolic (normal, up to 120 at rest) and 132 mm Hg diastolic (normal, up to 80 at rest). Within 15 minutes, **Katie C.** recovered, and her blood pressure returned to normal. The instructor told **Katie C.** to see her physician the next day.

The doctor told **Katie C.** that her symptom complex coupled with severe hypertension was concerning for a pheochromocytoma, a tumor in the medulla (central area) of the adrenal glands, which can episodically secrete large amounts of catecholamines, such as norepinephrine (noradrenaline) and epinephrine (adrenaline). Her blood pressure was normal until moderate pressure to the left of her umbilicus caused her to suddenly develop a typical attack, and her blood pressure rose rapidly. In addition to ordering several biochemical tests, she also was scheduled for a magnetic resonance imaging (MRI) study of her abdomen and pelvis. The MRI showed a $3.5 \times 2.8 \times 2.6$ cm mass in the left adrenal gland, with imaging characteristics typical of a pheochromocytoma.

Ivan A.'s brother, **Evan A.**, was 6 ft tall and weighed 425 lb (BMI = 57.6 kg/m^2). He had only been successful in losing weight once in his life, in 1977, when he had lost 30 lb through a combination of diet and exercise with the support of a registered dietician. However, he quickly regained this weight over the next year. **Evan A.**'s weight was not usually a concern for him, but in 1997 he became worried when it became difficult for him to take walks or go fishing because of joint pain in his knees. He was also suffering from symptoms suggestive of a peripheral neuropathy, manifesting primarily as tingling in his legs. In 1997, **Evan A.** approached his physician desperate for help to lose weight. The physician placed **Evan A.** on a new drug, Redux, which had just been approved for use as a weight-loss agent, and a low-fat, low-calorie diet along with physical therapy to help increase his activity level. In 4 months, **Evan A.**'s weight dropped from 425 to 375 lb, his total cholesterol dropped from 250 to 185, and his serum triglycerides dropped from 375 to 130. However, Redux was withdrawn from the market by its manufacturer late in 1997 because of reports that it caused cardiovascular adverse events and abnormalities in the structure of heart valve tissue. **Evan A.** was then placed on Prozac, a drug used primarily as an antidepressant, which may cause mild weight loss.

I. Cell Types of the Nervous System

The nervous system consists of neurons, the cells that transmit signals, and supporting cells, the neuroglia. The neuroglia consists of oligodendrocytes and astrocytes (known collectively as glial cells), microglial cells, ependymal cells, and Schwann cells. The neuroglia are designed to support and sustain the neurons and do so by surrounding neurons and holding them in place, supplying nutrients and oxygen to the neurons, insulating neurons so their electrical signals are more rapidly propagated, and cleaning up any debris that enters the nervous system. The central nervous system (CNS) consists of the brain and spinal cord. This system integrates all signals emanating from the peripheral nervous system (PNS). The PNS is composed of all neurons that lie outside the CNS.

A. Neurons

Neurons consist of a cell body (soma) from which long (axons) and short (dendrites) extensions protrude. Dendrites receive information from the axons of other neurons, whereas the axons transmit information to other neurons. The axon–dendrite connection is known as a synapse (Fig. 46.1). Most neurons contain multiple dendrites, each of which can receive signals from multiple axons. This configuration allows a single neuron to integrate information from multiple sources. Although neurons also contain just one axon, most axons branch extensively and distribute information to multiple targets (divergence). The neurons transmit signals by changes in the electrical potential across their membrane. Signaling across a synapse requires the release of neurotransmitters that, when bound to their specific receptors, initiate an electrical signal in the receiving or target cell. Neurons are terminally differentiated cells and, as such, have little capability for division. As a result, injured neurons have a limited capacity to repair themselves and frequently undergo apoptosis (programmed cell death) when damaged.

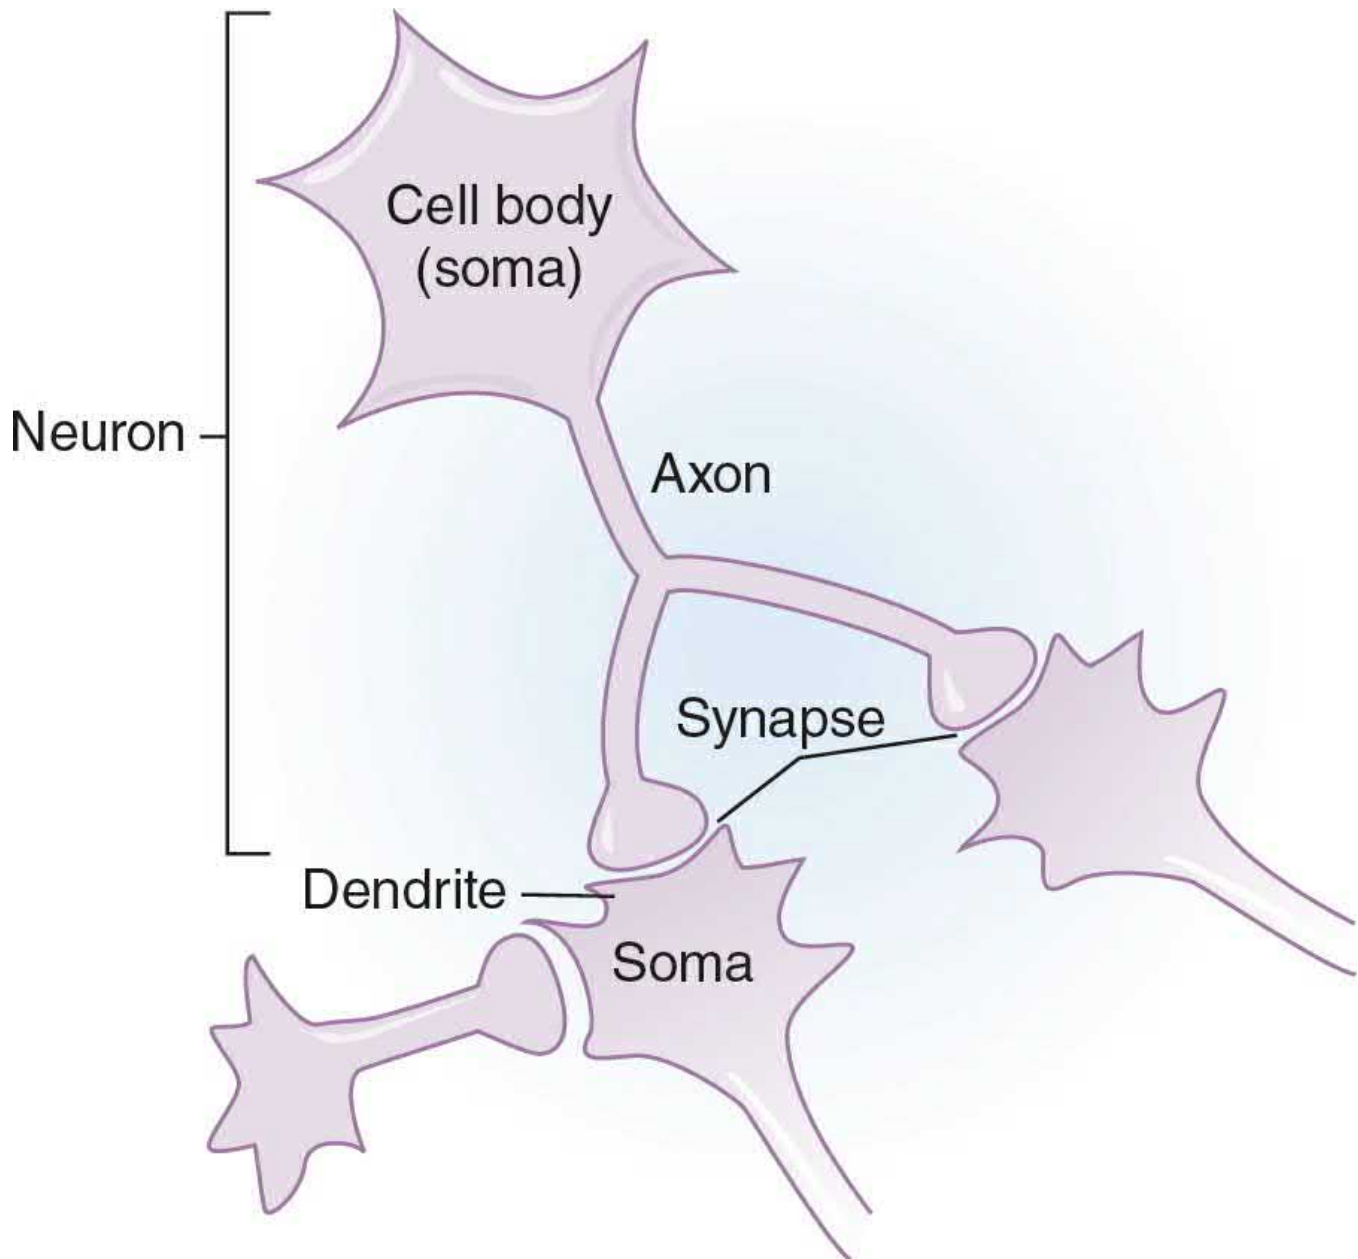

FIGURE 46.1 A neuron consists of a cell body (soma) with short extensions (dendrites) and a long extension (axon). The axon–dendrite interface is the synapse. A soma may receive input from multiple axons.

B. Neuroglial Cells

1. Astrocytes

The astrocytes are found in the CNS and are star-shaped cells that provide physical and nutritional support for neurons. During the development of the CNS, the astrocytes guide neuronal migration to their final adult position and form a matrix that keeps neurons in place. These cells serve several functions, including phagocytosing debris left behind by cells, providing lactate (from glucose metabolism) as a carbon source for the neurons, and controlling the brain extracellular ionic environment. Astrocytes help to regulate the content of the extracellular fluid (ECF) by taking up, processing, and metabolizing nutrients and waste products.

2. Oligodendrocytes

Oligodendrocytes provide the myelin sheath that surrounds the axon, acting as “insulation” for many of the neurons in the CNS. The myelin sheath is the lipid–protein covering of the axons (see Section V.B for a description of the composition and synthesis of the myelin sheath). Oligodendrocytes can form myelin sheaths around multiple neurons in the CNS by sending out processes that bind to the axons on target neurons. The

speed with which a neuron conducts its electric signal (action potential) is directly proportional to the degree of myelination. Oligodendrocytes, along with the astrocytes, form a supporting matrix for the neurons. Oligodendrocytes have a limited capacity for mitosis, and if damaged, do not replicate. If this occurs, demyelination of the axons may occur, resulting in abnormalities in signal conduction along that axon (see “Biochemical Comments”).

3. Schwann Cells

Schwann cells are the supporting cells of the PNS. Like oligodendrocytes, Schwann cells form myelin sheaths around the axons, but unlike the oligodendrocytes, Schwann cells myelinate only one axon. Schwann cells also clean up cellular debris in the PNS. The Schwann cells also provide a means for peripheral axons to regenerate if damaged. There is a synergistic interaction among the Schwann cells, secreted growth factors, and the axon that allows damaged axons to reconnect to the appropriate target axon.

4. Microglial Cells

The microglial cells are the smallest glial cells in the nervous system. They serve as immunologically responsive cells that function similarly to the action of macrophages in the circulation. Microglial cells destroy invading microorganisms and phagocytose cellular debris.

5. Ependymal Cells

The ependymal cells are ciliated cells that line the cavities (ventricles) of the CNS and the spinal cord. In some areas of the brain, the ependymal cells are functionally specialized to elaborate and secrete cerebrospinal fluid (CSF) into the ventricular system. The beating of the ependymal cilia allow for efficient circulation of the CSF throughout the CNS. The CSF acts as both a shock absorber protecting the CNS from mechanical trauma and as a system for the removal of metabolic wastes. The CSF can be aspirated from the spinal canal and analyzed to determine whether disorders of CNS function, with their characteristic CSF changes, are present.

For many years, it had been believed that damaged neurons in the CNS could not regenerate because it was thought that there are no pluripotent stem cells (cells that can differentiate into various cell types found in the CNS) in the CNS. However, recent data suggest that cells found within the ependymal layer can act as neural stem cells, which under appropriate stimulation can regenerate cells within the nervous system. Such a finding has led to significant research looking for potential treatments for diseases that alter neuronal cell function.

II. THE BLOOD–BRAIN BARRIER

A. Capillary Structure

In the capillary beds of most organs, rapid passage of molecules occurs from the blood through the endothelial wall of the capillaries into the interstitial fluid. Thus, the composition of interstitial fluid resembles that of blood, and specific receptors or transporters in the plasma membrane of the cells being bathed by the interstitial fluid may interact directly with amino acids, hormones, or other compounds from the blood. In the brain, transcapillary movement of substrates in the peripheral circulation into the brain is highly restricted by the blood–brain barrier. This barrier limits the accessibility of blood-borne toxins and other potentially harmful compounds to the neurons of the CNS.

The blood–brain barrier begins with the endothelial cells that form the inner lining of the vessels supplying blood to the CNS (Fig. 46.2). Unlike the endothelial cells of other organs, these cells are joined by tight junctions that do not permit the movement of polar molecules from the blood into the interstitial fluid bathing the neurons. They also lack mechanisms for transendothelial transport that are present in other capillaries of the body. These mechanisms include fenestrations (“windows” or pores that span the endothelial lining and permit the rapid movement of molecules across membranes) or transpinocytosis (vesicular transport from one side of the endothelial cell to another).

Inside of capillary

- 1 Tight junctions between endothelial cells
- 2 Narrow intercellular spaces
- 3 Lack of pinocytosis
- 4 Continuous basement membrane
- 5 Astrocyte extension

FIGURE 46.2 The blood–brain barrier. Compounds in the blood cannot pass freely into the brain; they must traverse the endothelial cells, basement membrane, and astrocytes, using specific carriers to gain access to the brain. Very lipophilic molecules may pass through all of these membranes in the absence of a carrier.

The endothelial cells serve actively, as well as passively, to protect the brain. Because they contain a variety of drug-metabolizing enzyme systems similar to the drug-metabolizing enzymes found in the liver, the endothelial cells can metabolize neurotransmitters and toxic chemicals and, therefore, form an enzymatic barrier to entry of these potentially harmful substances into the brain. They actively pump hydrophobic molecules that diffuse into endothelial cells back into the blood (especially xenobiotics) with P-glycoproteins, which act as transmembranous, ATP-dependent efflux pumps. Although lipophilic substances, water, oxygen, and carbon dioxide can readily cross the blood–brain barrier by passive diffusion, other molecules depend on

specific transport systems. Differential transporters on the luminal and abluminal endothelial membranes can transport compounds into, as well as out of, the brain.

Further protection against the free entry of blood-borne compounds into the CNS is provided by a continuous collagen-containing basement membrane that completely surrounds the capillaries. The basement membrane appears to be surrounded by the foot processes of astrocytes. Thus, compounds must pass through endothelial cell membranes, the enzymatic barrier in the endothelial cells, the basement membrane, and possibly additional cellular barriers formed by the astrocytes to reach the neurons in the brain.

B. Transport through the Blood–Brain Barrier

Many nonpolar substances, such as drugs and inert gases, probably diffuse through the endothelial cell membranes. A large number of other compounds are transported through the endothelial capillaries by facilitative transport, whereas others, such as nonessential fatty acids, cannot cross the blood–brain barrier. Essential fatty acids, however, are transported across the barrier.

A number of disorders of glucose transport across the blood–brain barrier are known. The most common of these is facilitated glucose transporter protein type 1 (GLUT1) deficiency syndrome. In this disorder, GLUT1 transporters are impaired, which results in a low glucose concentration in the CSF (a condition known as hypoglycorrhachia). A diagnostic indication of this disorder is that in the presence of normal blood glucose levels the ratio of CSF glucose to blood glucose levels is <0.4 . Clinical features are variable but include seizures, developmental delay, and a complex motor disorder. These symptoms are the result of inadequate glucose levels in the brain. The disorder can be treated by prescribing a ketogenic diet (high-fat, low-carbohydrate). This will force the patient to produce ketone bodies, which are easily transported into the CNS and can partially spare the brain's requirement for glucose as an energy source.

1. Fuels

Glucose, which is the principal fuel of the brain, is transported through both endothelial membranes by facilitated diffusion via the GLUT-1 transporter (see Fig. 21.9 and Table 21.5). GLUT-3 transporters present on the neurons then allow the neurons to transport the glucose from the ECF. Glial cells express GLUT-1 transporters. Although the rate of glucose transport into the ECF normally exceeds the rate required for energy metabolism by the brain, glucose transport may become rate-limiting as blood glucose levels fall below the normal range. Thus, individuals begin to experience hypoglycemic symptoms at glucose levels of approximately 60 mg/dL, as the glucose levels are reduced to the K_m , or below the K_m values of the GLUT-1 transporters in the endothelial cells of the barrier.

Monocarboxylic acids, including L-lactate, acetate, pyruvate, and the ketone bodies acetoacetate and β -hydroxybutyrate, are transported by a separate stereospecific system that is slower than the transport system for glucose. During starvation, when the level of ketone bodies in the blood is elevated, this transporter is upregulated. Ketone bodies are important fuels for the brain of both adults and neonates during prolonged starvation (>46 hours).

2. Amino Acids and Vitamins

Large neutral amino acids (LNAAs, such as phenylalanine, leucine, tyrosine, isoleucine, valine, tryptophan, methionine, and histidine) enter the CSF rapidly via a single amino acid transporter (L-[leucine preferring]-system amino acid transporter). Many of these compounds are essential in the diet and must be imported for protein synthesis or as precursors of neurotransmitters. Because a single transporter is involved, these amino acids compete with each other for transport into the brain.

The finding that the large neutral amino acids (LNAAs) have a common carrier system across the blood–brain barrier suggests that if one amino acid is in excess, it can, by competitive inhibition, result in lower transport of the other amino acids. This suggests that the intellectual disability that results from untreated phenylketonuria (PKU) and maple syrup urine disease (see Chapter 37) may be attributable to the high levels of either phenylalanine or branched-chain amino acids in the blood. These high levels overwhelm the LNAA carrier, so excessive levels of the damaging amino acid enter the CNS. In support of this theory is the finding that treatment of PKU patients with large doses of LNAAs that lack phenylalanine resulted in a decrease of phenylalanine levels in the CSF and brain, with an improvement in the patients' cognitive functions as well.

The entry of small neutral amino acids, such as alanine, glycine, proline, and GABA, is markedly restricted because their influx could dramatically change the content of neurotransmitters (see Section III). They are synthesized in the brain, and some are transported out of the CNS and into the blood via the A-(alanine-

preferring)-system carrier. Vitamins have specific transporters through the blood–brain barrier, just as they do in most tissues.

3. Receptor-Mediated Transcytosis

Certain proteins, such as insulin, transferrin, and insulin-like growth factors, cross the blood–brain barrier by receptor-mediated transcytosis. Once the protein binds to its membrane receptor, the membrane containing the receptor–protein complex is endocytosed into the endothelial cell to form a vesicle. It is released on the other side of the endothelial cell. Absorptive-mediated transcytosis also can occur. This differs from receptor-mediated transcytosis in that the protein binds nonspecifically to the membrane and not to a distinct receptor.

III. SYNTHESIS OF SMALL NITROGEN-CONTAINING NEUROTRANSMITTERS

Molecules that serve as neurotransmitters fall into two basic structural categories: (1) small nitrogen-containing molecules and (2) neuropeptides. The major small nitrogen-containing molecule neurotransmitters include glutamate, GABA, glycine, acetylcholine, dopamine, norepinephrine, serotonin, and histamine. Additional neurotransmitters that fall into this category include epinephrine, aspartate, and nitric oxide. In general, each neuron synthesizes only those neurotransmitters that it uses for transmission through a synapse or to another cell. The neuronal tracts are often identified by their neurotransmitter; for example, a dopaminergic tract synthesizes and releases the neurotransmitter dopamine.

Neuropeptides are usually small peptides that are synthesized and processed in the CNS. Some of these peptides have targets within the CNS (such as endorphins, which bind to opioid receptors and block pain signals), whereas others are released into the circulation to bind to receptors on other organs (such as growth hormone and thyroid-stimulating hormone). Many neuropeptides are synthesized as a larger precursor, which is then cleaved to produce the active peptides. Until recently, the assumption was that a neuron synthesized and released only a single neurotransmitter. More recent evidence suggests that a neuron may contain (1) more than one small-molecule neurotransmitter, (2) more than one neuropeptide neurotransmitter, or (3) both types of neurotransmitters. The differential release of the various neurotransmitters is the result of the neuron altering its frequency and pattern of firing.

A. General Features of Neurotransmitter Synthesis

Several features are common to the synthesis, secretion, and metabolism of most small nitrogen-containing neurotransmitters (Table 46.1). Most of these neurotransmitters are synthesized from amino acids, intermediates of glycolysis and the TCA cycle, and O_2 in the cytoplasm of the presynaptic terminal. The rate of synthesis is generally regulated to correspond to the rate of firing of the neuron. Once they are synthesized, the neurotransmitters are transported into storage vesicles by an ATP-requiring pump linked with the proton gradient. Release from the storage vesicle is triggered by the nerve impulse that depolarizes the postsynaptic membrane and causes an influx of Ca^{2+} ions through voltage-gated calcium channels. The influx of Ca^{2+} promotes fusion of the vesicle with the synaptic membrane and release of the neurotransmitter into the synaptic cleft. The transmission across the synapse is completed by binding of the neurotransmitter to a receptor on the postsynaptic membrane (Fig. 46.3).

TABLE 46.1 Features Common to Neurotransmitters^a

- ◆ Synthesis from amino acid and common metabolic precursors usually occurs in the cytoplasm of the presynaptic nerve terminal. The synthetic enzymes are transported by fast axonal transport from the cell body, where they are synthesized, to the presynaptic terminal.
- ◆ The synthesis of the neurotransmitter is regulated to correspond to the rate of firing of the neuron, both acutely and through long-term enhancement of synaptic transmission.
- ◆ The neurotransmitter is actively taken up into storage vesicles in the presynaptic terminal.
- ◆ The neurotransmitter acts at a receptor on the postsynaptic membrane.
- ◆ The action of the neurotransmitter is terminated through reuptake into the presynaptic terminal, diffusion away from the synapse, or enzymatic inactivation. The enzymatic inactivation may occur in the postsynaptic terminal, the presynaptic terminal, or an adjacent astrocyte or microglial cell.
- ◆ The blood–brain barrier affects the supply of precursors for neurotransmitter synthesis.

^aNot all neurotransmitters exhibit all of these features. Nitric oxide is an exception to most of these generalities. Some neurotransmitters (epinephrine, serotonin, and histamine) are also secreted by cells other than neurons. Their synthesis and secretion by non-neuronal cells follow other principles.

FIGURE 46.3 Action of neurotransmitters.

 Drugs have been developed that block neurotransmitter uptake into storage vesicles. Reserpine, which blocks catecholamine uptake into vesicles, had been used as an antihypertensive and antiepileptic drug for many years, but it was noted that a small percentage of patients on the drug became depressed and even suicidal. Animals treated with reserpine showed signs of lethargy and poor appetite, similar to depression in humans. Thus, a link was forged between monoamine release and depression in humans.

The action of the neurotransmitter is terminated through reuptake into the presynaptic terminal, uptake into glial cells, diffusion away from the synapse, or enzymatic inactivation. The enzymatic inactivation may occur in the postsynaptic terminal, the presynaptic terminal or an adjacent astrocyte microglia cell, or in endothelial cells in the brain capillaries.

Not all neurotransmitters exhibit all of these features. Nitric oxide, because it is a gas, is an exception to most of these generalities. Some neurotransmitters are synthesized and secreted by both neurons and other cells (e.g., epinephrine, serotonin, histamine).

B. Dopamine, Norepinephrine, and Epinephrine

1. Synthesis of the Catecholamine Neurotransmitters

The three neurotransmitters dopamine, norepinephrine, and epinephrine are synthesized in a common pathway from the amino acid L-tyrosine. Tyrosine is supplied in the diet or is synthesized in the liver from the essential amino acid phenylalanine by phenylalanine hydroxylase (see Chapter 37). The pathway of catecholamine biosynthesis is shown in Figure 46.4.

FIGURE 46.4 The pathways of catecholamine and melanin biosynthesis. The *dark boxes* indicate the enzymes, which, when defective, lead to albinism. BH₂, dihydrobiopterin; BH₄, tetrahydrobiopterin; Dopa, dihydroxyphenylalanine; PLP, pyridoxal phosphate.

The first and rate-limiting step in the synthesis of these neurotransmitters from tyrosine is the hydroxylation of the tyrosine ring by tyrosine hydroxylase (encoded by the TH gene), a tetrahydrobiopterin (BH₄)-requiring enzyme. The product formed is dihydroxyphenylalanine (L-DOPA). The phenyl ring with two adjacent –OH groups is a catechol, and hence dopamine, norepinephrine, and epinephrine are called catecholamines.

The second step in catecholamine synthesis is the decarboxylation of L-DOPA to form dopamine. This reaction, like many decarboxylation reactions of amino acids, requires pyridoxal phosphate. Dopaminergic neurons (neurons that use dopamine as a neurotransmitter) stop the synthesis at this point because these neurons do not synthesize the enzymes required for the subsequent steps.

Neurons that secrete norepinephrine synthesize it from dopamine in a hydroxylation reaction catalyzed by dopamine β-hydroxylase (DBH). This enzyme is present only within the storage vesicles of these cells. Like tyrosine hydroxylase, it is a mixed-function oxidase that requires an electron donor. Ascorbic acid (vitamin C) serves as the electron donor and is oxidized in the reaction. Copper (Cu²⁺) is a bound cofactor that is required for the electron transfer.

Although the adrenal medulla is the major site of epinephrine synthesis, epinephrine is also synthesized in a few neurons that use it as a neurotransmitter. These neurons contain the above pathway for norepinephrine synthesis and in addition contain the enzyme that transfers a methyl group from S-adenosyl methionine (SAM) to norepinephrine to form epinephrine. Thus, epinephrine synthesis is dependent on the presence of adequate levels of vitamin B₁₂ and folate to produce the SAM (see Chapter 38).

2. Storage and Release of Catecholamines

Ordinarily, only low concentrations of catecholamines are free in the cytosol, whereas high concentrations are found within the storage vesicles. Conversion of tyrosine to L-DOPA and that of L-DOPA to dopamine occurs in the cytosol. Dopamine is then taken up into the storage vesicles. In norepinephrine-containing neurons, the final β-hydroxylation reaction occurs in the vesicles.

Chromogranins are required for the biogenesis of the secretory vesicles. When chromogranins are released from the vesicles, they can be proteolytically clipped to form bioactive peptides. Elevated levels of chromogranins in the circulation may be found in patients who have neuroendocrine tumors, such as pheochromocytomas.

The catecholamines are transported into vesicles by the protein VMAT2 (vesicle **m**onoamine **t**ransporter **2**) (Fig. 46.5). The vesicle transporters contain 12 transmembrane domains and are homologous to a family of bacterial drug-resistance transporters, including P-glycoprotein. The mechanism that concentrates the catecholamines in the storage vesicles is an ATP-dependent process linked to a proton pump (secondary active transport). Protons are pumped into the vesicles by a vesicular ATPase (V-ATPase). The protons then exchange for the positively charged catecholamine via the transporter VMAT2. The influx of the catecholamine is thus driven by the H⁺ gradient across the vesicular membrane. The intravesicular concentration of catecholamines is approximately 0.5 M, roughly 100 times the cytosolic concentration. In the vesicles, the catecholamines exist in a complex with ATP and acidic proteins known as chromogranins.

FIGURE 46.5 Transport of catecholamines into storage vesicles. This is a secondary active transport based on the generation of a proton gradient across the vesicular membrane. ADP, adenosine diphosphate; ATP, adenosine triphosphate; DBH, dopamine β -hydroxylase; NT⁺, positively charged neurotransmitter (catecholamine); V-ATPase, vesicular ATPase; VMAT2, vesicle monoamine transporter 2.

The vesicles play a dual role: They maintain a ready supply of catecholamines at the nerve terminal that is available for immediate release, and they mediate the process of release. When an action potential reaches the nerve terminal, Ca²⁺ channels open, allowing an influx of Ca²⁺, which promotes the fusion of vesicles with the neuronal membrane. The vesicles then discharge their soluble contents, including the neurotransmitters, ATP, chromogranins, and DBH, into the extraneuronal space by the process of exocytosis. In some cases, the catecholamines affect other neurons. In other cases, they circulate in the blood and initiate responses in peripheral tissues.

3. Inactivation and Degradation of Catecholamine Neurotransmitters

The action of catecholamines is terminated through reuptake into the presynaptic terminal and diffusion away from the synapse. Degradative enzymes are present in the presynaptic terminal, and in adjacent cells, including glial cells and endothelial cells.

In albinism, either the copper-dependent tyrosinase (encoded by the TYR gene) of melanocytes (which is distinct from the tyrosine hydroxylase enzyme [encoded by the TH gene] found in the adrenal medulla) or other enzymes that convert tyrosine to melanins may be defective. Individuals with albinism suffer from a lack of pigment in the skin, hair, and eyes and have vision problems, and they are sensitive to sunlight.

Two of the major reactions in the process of inactivation and degradation of catecholamines are catalyzed by monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT). MAO is present on the outer mitochondrial membrane of many cells and oxidizes the carbon containing the amino group to an aldehyde, thereby releasing ammonium ion (Fig. 46.6). In the presynaptic terminal, MAO inactivates catecholamines that are not protected in storage vesicles. (Thus, drugs that deplete storage vesicles indirectly increase catecholamine degradation.) There are two isoforms of MAO with different specificities of action: MAO-A preferentially deaminates norepinephrine and serotonin, whereas MAO-B acts on a wide spectrum of phenylethylamines (“phenylethyl” refers to a $-\text{CH}_2\text{CH}_2-$ group linked to a phenyl ring). MAO in the liver and other sites protects against the ingestion of dietary biogenic amines such as the tyramine found in many cheeses.

FIGURE 46.6 Inactivation of catecholamines. Methylation and oxidation may occur in any order. Methylated and oxidized derivatives of norepinephrine and epinephrine are produced, and 3-methoxy-4-hydroxymandelic acid is the final product. These compounds are excreted in the urine. COMT, catechol-O-methyltransferase; MAO, monoamine oxidase; SAH, S-adenosyl homocysteine; SAM, S-adenosyl methionine.

Tyramine is a degradation product of tyrosine that can lead to headaches, palpitations, nausea and vomiting, and elevated blood pressure if it is present in large quantities. Tyramine stimulates norepinephrine release, which binds to norepinephrine receptors, stimulating them. Tyramine is inactivated by MAO-A, but if a person is taking an MAO inhibitor, foods containing tyramine should be avoided.

COMT is also found in many cells, including erythrocytes. It works on a broad spectrum of extraneuronal catechols and those that have diffused away from the synapse. COMT transfers a methyl group from SAM to a hydroxyl group on the catecholamine or its degradation product (see Fig. 46.6). Because the inactivation reaction requires SAM, it is indirectly dependent on vitamin B₁₂ and folate. The action of MAO and COMT can occur in almost any order, resulting in a large number of degradation products and intermediates, many of which appear in the urine. Cerebrospinal homovanillylmandelic acid (HVA) is an indicator of dopamine degradation. Its concentration is decreased in the brain of patients with Parkinson's disease.

Katie C.'s doctor ordered plasma fractionated metanephrine (epinephrine methylated on a ring oxygen by COMT) levels and also had **Katie C.** collect a 24-hour urine specimen for the determination of catecholamines and their degradation products (in particular, metanephrine). All of these tests showed unequivocal elevations of these compounds in **Katie C.**'s blood and urine. **Katie C.** was placed on phenoxybenzamine, an α_1 - and α_2 -adrenergic receptor antagonist that blocks the pharmacological effect of the elevated catecholamines on these receptors. Once stable on the α -blockers she was started on an agent that blocked β -adrenergic receptors (propranolol). After ruling out evidence to suggest metastatic disease to the liver or other organs (in case her tumor was malignant), the doctor referred her to a surgeon with extensive experience in adrenal surgery. Her doctor also ordered diagnostic studies to rule out multiple endocrine neoplasm syndrome (MEN). The tests for the presence of MEN were negative.

4. Regulation of Tyrosine Hydroxylase

Efficient regulatory mechanisms coordinate the synthesis of catecholamine neurotransmitters with the rate of firing. Tyrosine hydroxylase, the first committed step and rate-limiting enzyme in the pathway, is regulated by feedback inhibition that is coordinated with depolarization of the nerve terminal. Tyrosine hydroxylase is inhibited by free cytosolic catecholamines that compete at the binding site on the enzyme for the pterin cofactor (tetrahydrobiopterin, BH₄; see Chapter 37).

Depolarization of the nerve terminal activates tyrosine hydroxylase. Depolarization also activates a number of protein kinases (including protein kinase C, protein kinase A [the cAMP-dependent protein kinase], and CAM kinases [Ca²⁺-calmodulin-dependent kinases]) that phosphorylate tyrosine hydroxylase. These activation steps result in an enzyme that binds BH₄ more tightly, making it less sensitive to end-product inhibition.

In addition to these short-term regulatory processes, a long-term process involves alterations in the amounts of tyrosine hydroxylase and dopamine β -hydroxylase present in nerve terminals. When sympathetic neuronal activity is increased for a prolonged period, the amounts of mRNA that code for tyrosine hydroxylase and dopamine β -hydroxylase are increased in the neuronal perikarya (the cell body of the neuron). The increased gene transcription may be the result of phosphorylation of CREB (cAMP response element-binding protein; see Chapter 19) by protein kinase A or by other protein kinases. CREB then binds to the CRE (cAMP response element) in the promoter region of the gene (similar to the mechanism for the induction of gluconeogenic enzymes in the liver). The newly synthesized enzyme molecules are then transported down the axon to the nerve terminals. The concentration of dopamine decarboxylase in the terminal does not appear to change in response to neuronal activity.

C. Metabolism of Serotonin

The pathway for the synthesis of serotonin from tryptophan is very similar to the pathway for the synthesis of norepinephrine from tyrosine (Fig. 46.7). The first enzyme of the pathway, tryptophan hydroxylase, uses an enzymatic mechanism similar to that of tyrosine and phenylalanine hydroxylase and requires BH₄ to hydroxylate the ring structure of tryptophan. The second step of the pathway is a decarboxylation reaction catalyzed by the same enzyme that decarboxylates DOPA. Serotonin, like the catecholamine neurotransmitters, can be inactivated by MAO.

FIGURE 46.7 Synthesis and inactivation of serotonin. Acetyl CoA, acetyl coenzyme A; CoA, coenzyme A; DOPA, dihydroxyphenylalanine; MAO, monoamine oxidase; NAD, nicotinamide adenine dinucleotide; PLP, pyridoxal phosphate; SAH, S-adenosyl homocysteine; SAM, S-adenosyl methionine.

The neurotransmitter melatonin is also synthesized from tryptophan (see Fig. 46.7). Melatonin is produced in the pineal gland in response to the light–dark cycle, its level in the blood rising in a dark environment. It is probably through melatonin that the pineal gland conveys information about light–dark cycles to the body, organizing seasonal, and circadian rhythms. Melatonin also may be involved in regulating reproductive functions.

 In addition to the catecholamines, serotonin is also inactivated by monoamine oxidase. The activity of a number of antipsychotic drugs is based on inhibiting MAO. The first generation of drugs (exemplified by iproniazid, which was originally developed as an antituberculosis drug and was found to induce mood swings in patients) were irreversible inhibitors of both the A and B forms of MAO. Although they did reduce the severity of depression (by maintaining higher levels of serotonin), these drugs suffered from the “cheese” effect. Cheese and other foods that are processed over long periods (such as red wine) contain tyramine, a degradation product of tyrosine. Usually, tyramine is inactivated by MAO-A, but if an individual is taking an MAO inhibitor, tyramine levels increase. Tyramine induces the release of norepinephrine from storage vesicles, which leads to potentially life-threatening hypertensive episodes. When it was realized that MAO existed in two forms, selective irreversible inhibitors were developed; examples include clorgyline for MAO-A, and deprenyl for MAO-B. Deprenyl has been used to treat Parkinson’s disease (which is caused by a lack of dopamine, which is also inactivated by MAO). Deprenyl, however, is not an antidepressant. Clorgyline is an antidepressant but suffers from the “cheese” effect. This led to the development of the third generation of MAO inhibitors, which are reversible inhibitors of the enzyme, as typified by moclobemide. Moclobemide is a specific, reversible inhibitor of MAO-A and is effective as an antidepressant. More important, because of the reversible nature of the drug, the “cheese” effect is not observed, because as tyramine levels increase, they displace the drug from MAO, and the tyramine is safely inactivated. However, it has not been approved for use in the United States.

 A potential complication of using heparin as an anticoagulant is the generation of anti-heparin antibodies in the patients. The production of such antibodies leads to the patient developing heparin-induced thrombocytopenia (HIT). The anti-heparin antibodies bind to the heparin platelet factor 4 complex, and also to the platelet surface. The antibody-induced binding leads to platelet activation, serotonin release, and thrombin activation. The platelet number drops (the thrombocytopenia), but thrombus formation (due to thrombin activation) increases. To determine if a patient has developed HIT the serotonin-release assay has emerged as the gold standard. Platelets store serotonin in granules and release the serotonin upon activation. Anti-heparin antibody-sensitive platelets are obtained from donors and incubated with radioactively labeled serotonin, for the platelets to incorporate the serotonin. The treated platelets are then incubated with two samples of the patient’s sera, one with a high level of exogenous heparin, and the second with a low level of heparin. Serotonin release is then measured by determining the percentage of total radioactivity released by the platelets into the assay buffer. A positive result is obtained if, when using a low concentration of heparin, >20% of the radioactivity incorporated into the platelets is released, and, when using the high concentration of heparin <20% of the incorporated radioactivity is released. The rationale behind the use of high heparin levels is to titrate out the antibody in the sera such that it cannot bind to the platelet cell surface, and to demonstrate that the release is due to antibody binding to platelets.

D. Metabolism of Histamine

Within the brain, histamine is produced both by mast cells and by certain neuronal fibers. Mast cells are a family of bone marrow–derived secretory cells that store and release high concentrations of histamine. They are prevalent in the thalamus, hypothalamus, dura mater, leptomeninges, and choroid plexus. Histaminergic neuronal cell bodies in the human are found in the tuberomammillary nucleus of the posterior basal hypothalamus. The fibers project into nearly all areas of the CNS, including the cerebral cortex, the brainstem, and the spinal cord.

 The catecholamines exert their physiological and pharmacological effects by circulating in the bloodstream to target cells whose plasma membranes contain catecholamine receptors. This interaction initiates a biochemical cascade leading to responses that are specific for different types of cells. Patients such as **Katie C.** experience palpitations, excessive sweating, hypertensive headaches, and a host of other symptoms when a catecholamine-producing tumor of the adrenal medulla suddenly secretes supraphysiological amounts of epinephrine and/or norepinephrine into the venous blood draining the neoplasm.

Histamine is synthesized from histidine in a single enzymatic step. The enzyme histidine decarboxylase requires pyridoxal phosphate, and its mechanism is very similar to that of DOPA decarboxylase (Fig. 46.8).

FIGURE 46.8 Synthesis and inactivation of histamine; note the different pathways for brain and peripheral tissues. MAO,

monoamine oxidase; NAD, nicotinamide adenine dinucleotide; PLP, pyridoxal phosphate; SAH, S-adenosyl homocysteine; SAM, S-adenosyl methionine.

Like other neurotransmitters, newly synthesized neuronal histamine is stored in the nerve terminal vesicles. Depolarization of nerve terminals activates the exocytotic release of histamine by a voltage-dependent as well as a calcium-dependent mechanism.

 **Evan A.** was placed on Redux, which increased the secretion of serotonin. Serotonin has been implicated in many processes, including mood control and appetite regulation. Serotonin agonists are thought to exert their hypophagic actions via stimulation of receptors located on pro-opiomelanocortin (POMC) containing neurons within the arcuate (ARC) nucleus of the hypothalamus. When serotonin levels are high satiety results; when serotonin levels are low increased appetite, or depression, or both, can occur. Thus, drugs that can increase serotonin levels may be able to control appetite and depression. Redux was a second-generation drug developed from fenfluramine, a known appetite suppressant. When it was first used, fenfluramine could not be resolved between two distinct optical isomers (d versus l). The l-isomer induced sleepiness, so to counteract this effect fenfluramine was often given with phentermine, which elevated norepinephrine levels to counteract the drowsiness (the combination of drugs was known as fen/phen). Once the two isomers of fenfluramine could be resolved, Redux, dexfenfluramine, was developed, though this and fenfluramine were eventually removed from the market because of cardiovascular side effects. Because levels of serotonin have been linked to mood, many antidepressant drugs were developed that affect serotonin levels. The first of these is the MAO inhibitors; a second class is the tricyclics, and the third class is known as SSRIs (selective serotonin reuptake inhibitors). The SSRIs block reuptake of serotonin from the synapse, leading to an elevated response to serotonin. Redux not only acted as an SSRI but also increased the secretion of serotonin, leading to elevated levels of this compound in the synapse. None of the other drugs that affect serotonin levels has this effect.

Once it is released from neurons, histamine is thought to activate both postsynaptic and presynaptic receptors. Unlike other neurotransmitters, histamine does not appear to be recycled into the presynaptic terminal to any great extent. However, astrocytes have a specific high-affinity uptake system for histamine and may be the major sites of the inactivation and degradation of this monoamine.

 Histamine elicits a number of effects on different tissues. Histamine is the major mediator of the allergic response, and when it is released from mast cells (a type of white blood cell found in tissues) it leads to vasodilation and an increase in the permeability of blood vessel walls. This leads to the allergic symptoms of a runny nose and watering eyes. When histamine is released in the lungs, the airways constrict in an attempt to reduce the intake of the allergic material. The ultimate result of this, however, is bronchospasm, which can lead to difficulty in breathing. In the brain, histamine is an excitatory neurotransmitter. Antihistamines block histamine from binding to its receptor. In the tissues, this counteracts histamine's effect on vasodilation and blood vessel wall permeability, but in the brain, the effect is to cause drowsiness. The new generation of "nondrowsy" antihistamines have been modified so that they cannot pass through the blood-brain barrier. Thus, the effects on the peripheral tissues are retained, with no effect on CNS histamine response.

The first step in the inactivation of histamine in the brain is methylation (see Fig. 46.8). The enzyme histamine methyltransferase transfers a methyl group from SAM to a ring nitrogen of histamine to form methylhistamine. The second step is oxidation by MAO-B, followed by an additional oxidation step. In peripheral tissues, histamine undergoes deamination by diamine oxidase, followed by oxidation to a carboxylic acid (see Fig. 46.8).

E. Acetylcholine

1. Synthesis

The synthesis of acetylcholine from acetyl coenzyme A (acetyl CoA) and choline is catalyzed by the enzyme choline acetyltransferase (ChAT) (Fig. 46.9). This synthetic step occurs in the presynaptic terminal. The compound is stored in vesicles and later released through calcium-mediated exocytosis. Choline is taken up by the presynaptic terminal from the blood via a low-affinity transport system (high K_m) and from the synaptic cleft via a high-affinity transport mechanism (low K_m). It is also derived from the hydrolysis of phosphatidylcholine (and possibly sphingomyelin) in membrane lipids. Thus, membrane lipids may form a storage site for choline, and their hydrolysis, with the subsequent release of choline, is highly regulated.

FIGURE 46.9 Acetylcholine synthesis and degradation. CoA, coenzyme A.

 It is believed that the vitamin B₁₂ requirement for choline synthesis contributes to the neurological symptoms of vitamin B₁₂ deficiency. The methyl groups for choline synthesis are donated by SAM, which is converted to S-adenosyl homocysteine in the reaction. Recall that formation of SAM through recycling of homocysteine requires both tetrahydrofolate and vitamin B₁₂ (unless extraordinary amounts of methionine are available to bypass the B₁₂-dependent methionine synthase step).

 The supply of choline in the brain can become rate-limiting for acetylcholine synthesis, and supplementation of the diet with lecithin (phosphatidylcholine) has been used (though without clear effects) to increase brain acetylcholine in patients suffering from *tardive dyskinesia* (often persistent involuntary movements of the facial muscles and tongue). The neonate has a very high demand for choline, for both brain lipid synthesis (phosphatidylcholine and sphingomyelin) and acetylcholine biosynthesis. High levels of phosphatidylcholine in maternal milk and a high activity of a high-affinity transport system through the blood–brain barrier for choline in the neonate help to maintain brain choline concentrations. The fetus also has a high demand for choline, and there is a high-affinity transport system for choline across the placenta. The choline is derived from maternal stores, maternal diet, and synthesis primarily in the maternal liver. Because choline synthesis is

dependent on folate and vitamin B₁₂, the high fetal demand may contribute to the increased maternal requirement for both vitamins during pregnancy.

An inherited pyruvate dehydrogenase deficiency, a thiamin deficiency, or hypoxia deprives the brain of a source of acetyl CoA for acetylcholine synthesis, as well as a source of acetyl CoA for ATP generation from the TCA cycle.

Choline is a common component of the diet but also can be synthesized in the human as part of the pathway for the synthesis of phospholipids (see Chapter 31). The only route for choline synthesis is via the sequential addition of three methyl groups from SAM to the ethanolamine portion of phosphatidylethanolamine to form phosphatidylcholine. Phosphatidylcholine is subsequently hydrolyzed to release choline or phosphocholine. Conversion of phosphatidylethanolamine to phosphatidylcholine occurs in many tissues, including liver and brain. This conversion is folate- and vitamin B₁₂-dependent.

The acetyl group used for acetylcholine synthesis is derived principally from glucose oxidation to pyruvate and decarboxylation of pyruvate to form acetyl CoA via the pyruvate dehydrogenase reaction. This is because neuronal tissues have only a limited capacity to oxidize fatty acids to acetyl CoA, so glucose oxidation is the major source of acetyl groups. Pyruvate dehydrogenase is found only in mitochondria. The acetyl group is probably transported to the cytoplasm as part of citrate, which is then cleaved in the cytosol to form acetyl CoA and oxaloacetate.

2. Inactivation of Acetylcholine

Acetylcholine is inactivated by acetylcholinesterase, which is a serine esterase that forms a covalent bond with the acetyl group. The enzyme is inhibited by a wide range of compounds (pharmacological agents and neurotoxins) that form a covalent bond with this reactive serine group. Neurotoxins such as Sarin (the gas used in Japanese subways by a terrorist group) and the nerve gas in the movie *The Rock* work through this mechanism. Acetylcholine is the major neurotransmitter at the neuromuscular junctions; inability to inactivate this molecule leads to constant activation of the nerve–muscle synapses, a condition that leads to varying degrees of paralysis.

F. Glutamate and GABA

1. Synthesis of Glutamate

Glutamate functions as an excitatory neurotransmitter within the central nervous system, leading to the depolarization of neurons. Within nerve terminals, glutamate is generally synthesized *de novo* from glucose rather than taken up from the blood, because its plasma concentration is low and it does not readily cross the blood–brain barrier.

Glutamate is synthesized primarily from the TCA cycle intermediate α -ketoglutarate (Fig. 46.10). This process can occur via either of two routes. The first is via the enzyme glutamate dehydrogenase, which reduces α -ketoglutarate to glutamate, thereby incorporating free ammonia into the carbon backbone. The ammonia pool is provided by amino acid/neurotransmitter degradation or by diffusion of ammonia across the blood–brain barrier. The second route is through transamination reactions in which an amino group is transferred from other amino acids to α -ketoglutarate to form glutamate. Glutamate also can be synthesized from glutamine, using glutaminase. The glutamine is derived from glial cells as described in Section III.F.2.

FIGURE 46.10 Synthesis of glutamate and γ -aminobutyric acid (GABA), and the GABA shunt. α -KG, α -ketoglutarate; AA, amino acid; Acetyl CoA, acetyl coenzyme A; GDH, glutamate dehydrogenase; NAD, nicotinamide adenine dinucleotide; PLP, pyridoxal phosphate; TCA, tricarboxylic acid.

Like other neurotransmitters, glutamate is stored in vesicles, and its release is Ca^{2+} -dependent. It is removed from the synaptic cleft by high-affinity uptake systems in nerve terminals and glial cells.

2. GABA

GABA is the major inhibitory neurotransmitter in the central nervous system. Its functional significance is far-reaching, and altered GABAergic function plays a role in many neurological and psychiatric disorders.

Tiagabine is a drug that inhibits the reuptake of GABA from the synapse. It has been used as adjunctive therapy to treat epilepsy as well as other convulsant disorders. Because GABA is an inhibitory neurotransmitter in the brain, its prolonged presence can block neurotransmission by other agents, thereby reducing the frequency of convulsions.

GABA is synthesized by the decarboxylation of glutamate (see Fig. 46.10) in a single step catalyzed by the enzyme glutamic acid decarboxylase (GAD). GABA is recycled in the central nervous system by a series of reactions called the GABA shunt, which conserves glutamate and GABA (see Fig. 46.10).

Much of the uptake of GABA occurs in glial cells. The GABA shunt in glial cells produces glutamate, which is converted to glutamine and transported out of the glial cells to neurons, where it is converted back to glutamate. Glutamine thus serves as a transporter of glutamate between cells in the CNS (see Chapter 40). Glial cells lack GAD and cannot synthesize GABA.

G. Other Amino Acid Neurotransmitters

1. Aspartate

Aspartate, like glutamate, is an excitatory neurotransmitter, but it functions in far fewer pathways. It is synthesized from the TCA cycle intermediate oxaloacetate via transamination reactions. Like glutamate synthesis, aspartate synthesis uses oxaloacetate that must be replaced through anaplerotic reactions. Aspartate cannot pass through the blood–brain barrier.

2. Glycine

Glycine is the major inhibitory neurotransmitter in the spinal cord. Most of the glycine in neurons is synthesized *de novo* within the nerve terminal from serine by the enzyme serine hydroxymethyltransferase, which requires folic acid. Serine, in turn, is synthesized from the intermediate 3-phosphoglycerate in the glycolytic pathway. The action of glycine is probably terminated via uptake by a high-affinity transporter.

3. Conversion of Arginine to Nitric Oxide

Nitric oxide (NO) is a biological messenger in a variety of physiological responses, including vasodilation, neurotransmission, and the ability of the immune system to kill tumor cells and parasites. NO is synthesized from arginine in a reaction catalyzed by NO synthase (see Fig. 25.10).

NO synthase exists as tissue-specific forms of two families of enzymes. The form present in macrophages is responsible for overproduction of NO, leading to its cytotoxic actions on parasites and tumor cells. The enzyme present in nervous tissue, vascular endothelium, platelets, and other tissues is responsible for the physiological responses to NO such as vasodilation and neural transmission. In target cells, NO activates a soluble guanylate cyclase, which results in increased cellular levels of cGMP (3',5'-cyclic GMP) (Fig. 46.11). In smooth muscle cells, cGMP, like cAMP, activates one or more protein kinases, which are responsible for the relaxation of smooth muscle and the subsequent dilation of vessels. NO stimulates penile erection by acting as a neurotransmitter, stimulating smooth muscle relaxation that permits the corpus cavernosum to fill with blood. Nitric oxide can readily cross cell membranes because it is a gas. As a result, its effect may not necessarily be limited to the neuron that synthesizes it (Fig. 46.12). There is ample evidence that NO may function as a retrograde messenger that can influence neurotransmitter release from the presynaptic terminal after diffusing from the postsynaptic neuron (where it is synthesized). There is also evidence supporting retrograde messenger roles for both arachidonic acid and carbon monoxide in the CNS.

FIGURE 46.11 Action of nitric oxide (NO) in vasodilation. The synthesis of NO occurs in response to a stimulator binding to a receptor on some cells or to a nerve impulse in neurons. NO enters smooth muscle cells, stimulating guanylate cyclase to produce cGMP, which causes smooth muscle cell relaxation. When the smooth muscle cells relax, blood vessels dilate. cGMP, cyclic guanosine monophosphate; GTP, guanosine triphosphate.

FIGURE 46.12 Nitric oxide (NO) as a retrograde messenger. Cell A releases a neurotransmitter, which stimulates cell C to produce NO. NO, being a gas, can diffuse back and regulate cell A's production and release of neurotransmitters. NO can also diffuse to cell B, and stimulate cell B to produce a different neurotransmitter to elicit a response from cell D. NT, neurotransmitter.

IV. Metabolic Encephalopathies and Neuropathies

The brain has an absolute dependence on the blood for its supply of glucose and oxygen. It uses approximately 20% of the oxygen supply of the body. During the developmental period and during prolonged fasting, ketone bodies can be used as a fuel, but they cannot totally substitute for glucose. Glucose is converted to pyruvate in glycolysis, and the pyruvate is oxidized in the TCA cycle. Anaerobic glycolysis, with a yield of two molecules of ATP per molecule of glucose, cannot sustain the ATP requirement of the brain, which can be provided only by the complete oxidation of glucose to CO_2 , which yields approximately 32 ATP/glucose. However, during periods of mild hypoglycemia or mild hypoxia, decreased neurotransmitter synthesis contributes as much, if not more, to the development of symptoms as does an absolute deficiency of ATP for energy needs.

A. Hypoglycemic Encephalopathy

Hypoglycemia is sometimes encountered in medical conditions such as malignancies producing insulin, insulin-like growth factors, or chronic alcohol abuse. Early clinical signs in hypoglycemia reflect the appearance of physiological protective mechanisms initiated by hypothalamic sensory nuclei such as sweating, palpitations, anxiety, and hunger. If these symptoms are ignored, they proceed to a more serious CNS disorder, progressing through confusion and lethargy to seizures and eventually coma. Prolonged hypoglycemia can lead to irreversible brain damage.

During the progression of hypoglycemic encephalopathy, as blood glucose falls <2.5 mM (45 mg/dL), the brain attempts to use internal substrates such as glutamate and TCA cycle intermediates as fuels. Because the

pool size of these substrates is quite small, they are quickly depleted. If blood glucose levels continue to fall to <1 mM (18 mg/dL), ATP levels become depleted.

As the blood glucose drops from 2.5 to 2.0 mM (45 to 36 mg/dL, before electroencephalographic [EEG] changes are observed), the symptoms appear to arise from decreased synthesis of neurotransmitters in particular regions of the brain rather than a global energy deficit. The oxidation of glucose in glycolysis provides 3-phosphoglycerate, a precursor for the neurotransmitter glycine. Pyruvate entry into the mitochondria and conversion to acetyl CoA can generate α -ketoglutarate (for glutamate and GABA synthesis) and oxaloacetate, for the synthesis of the neurotransmitter aspartate. A lack of glucose could disrupt the synthesis of these neurotransmitters.

As hypoglycemia progresses below 1 mM (18 mg/dL) and high-energy phosphate levels are depleted, the EEG becomes isoelectric, and neuronal cell death ensues. As is the case in some other metabolic encephalopathies, cell death is not global in distribution; rather, certain brain structures, in particular hippocampal and cortical structures, are selectively vulnerable to hypoglycemic insult. Pathophysiological mechanisms responsible for neuronal cell death in hypoglycemia include the involvement of glutamate excitotoxicity. Glutamate excitotoxicity occurs when the cellular energy reserves are depleted. The failure of the energy-dependent reuptake pumps results in a buildup of glutamate in the synaptic cleft and overstimulation of the postsynaptic glutamate receptors. The prolonged glutamate receptor activation leads to prolonged opening of the receptor ion channel and the influx of lethal amounts of Ca^{2+} ion, which can activate cytotoxic intracellular pathways in the postsynaptic neuron.

B. Hypoxic Encephalopathy

Experimental studies with human volunteers show that cerebral energy metabolism remains normal when mild to moderate hypoxia (partial pressure of oxygen, or $\text{PaO}_2 = 25$ to 40 mm Hg) results in severe cognitive dysfunction. The diminished cognitive function is believed to result from impaired neurotransmitter synthesis. In mild hypoxia, cerebral blood flow increases to maintain oxygen delivery to the brain. In addition, anaerobic glycolysis is accelerated, resulting in maintenance of ATP levels. This occurs, however, at the expense of an increase of lactate production and a fall of pH. Acute hypoxia ($\text{PaO}_2 \leq 20$ mm Hg) generally results in a coma.

Hypoxia can result from insufficient oxygen reaching the blood (e.g., at high altitudes or with lung disease), severe anemia (e.g., iron deficiency), or a direct insult to the oxygen-utilizing capacity of the brain (e.g., cyanide poisoning). All forms of hypoxia result in diminished neurotransmitter synthesis. Inhibition of pyruvate dehydrogenase diminishes acetylcholine synthesis, which is acutely sensitive to hypoxia. Glutamate and GABA syntheses, which depend on a functioning TCA cycle, are decreased as a result of elevated NADH levels, which inhibit TCA cycle enzymes. NADH levels are increased when oxygen is unavailable to accept electrons from the electron transport chain and NADH cannot be readily converted back into NAD^+ . Even the synthesis of catecholamine neurotransmitters may be decreased because the hydroxylase reactions require O_2 .

C. Relationship between Glutamate Synthesis and the Anaplerotic Pathways of Pyruvate Carboxylase and Methylmalonyl CoA Mutase

Synthesis of glutamate removes α -ketoglutarate from the TCA cycle, thereby decreasing the regeneration of oxaloacetate in the TCA cycle. Because oxaloacetate is necessary for the oxidation of acetyl CoA, oxaloacetate must be replaced by anaplerotic reactions. There are two major types of anaplerotic reactions: (1) pyruvate carboxylase and (2) the degradative pathway of the branched-chain amino acids, valine, and isoleucine, which contribute succinyl CoA to the TCA cycle. This pathway uses vitamin B_{12} (but not folate) in the reaction catalyzed by methylmalonyl CoA mutase.

V. Lipid Synthesis in the Brain and Peripheral Nervous System

A number of features of lipid synthesis and degradation in the nervous system distinguish it from most other tissues. The first is that the portion of the neuronal cell membrane involved in synaptic transmission has a unique role and a unique composition. At the presynaptic terminal, the lipid composition changes rapidly as storage vesicles containing the neurotransmitter fuse with the cell membrane and release their contents. Portions of the membrane are also lost as endocytotic vesicles. On the postsynaptic terminal, the membrane contains the receptors for the neurotransmitter as well as a high concentration of membrane signaling

components, such as phosphatidylinositol. A second important feature of brain lipid metabolism is that the blood–brain barrier restricts the entry of nonessential fatty acids, such as palmitate, that are released from adipose tissue or present in the diet. Conversely, essential fatty acids are taken up by the brain. Because of these considerations, the brain is constantly synthesizing those lipids (cholesterol, fatty acids, glycosphingolipids, and phospholipids), which it needs for various neurological functions. Neuronal signaling also requires that non-neuronal glial cells synthesize myelin, a multilayered membrane that surrounds the axons of many neurons. Myelin is lipid-rich and has a different lipid composition than the neuronal membranes. The white matter in the brain contains significantly more myelin than the gray matter; it is the presence of myelin sheaths that is responsible for the characteristic color differences that exist between the two types of brain tissue.

A. Brain Lipid Synthesis and Oxidation

Because the blood–brain barrier significantly inhibits the entry of certain fatty acids and lipids into the CNS, virtually all lipids found there must be synthesized within the CNS. The exceptions are the essential fatty acids (linoleic and linolenic acid), which do enter the brain, where they are elongated or further desaturated. The uptake of fatty acids into the CNS is insufficient to meet the energy demands of the CNS—hence the requirement for aerobic glucose metabolism. Thus, cholesterol, glycerol, and sphingolipids, glycosphingolipids, and cerebrosides are all synthesized using pathways discussed previously in this text. Of particular note is that very-long-chain fatty acids are synthesized in the brain, where they play a major role in myelin formation.

Oxidation and turnover of brain lipids occurs as described previously (see Chapter 30). Peroxisomal fatty acid oxidation is important in the brain because the brain contains very-long-chain fatty acids and phytanic acid (from the diet), both of which are oxidized in the peroxisomes by α -oxidation. Thus, disorders that affect peroxisome biogenesis (such as Refsum disease) severely affect brain cells because of the inability to metabolize both branched-chain and very-long-chain fatty acids. If there is a disorder in which the degradation of glycosphingolipids or mucopolysaccharides is impaired, lysosomes in brain cells become engorged with partially digested glycolipids, leading to varying degrees of neurological dysfunction.

B. Myelin Synthesis

A rapid rate of nerve conduction in the peripheral and central motor nerves depends on the formation of myelin, a multilayered lipid and protein structure that is formed from the plasma membrane of glial cells. In the peripheral nervous system, the Schwann cell is responsible for myelinating one portion of an axon of one nerve cell. The Schwann cell does this by wrapping itself around the axon multiple times so that a multilayered sheath of membrane surrounds the axon. In the central nervous system, the oligodendrocyte is responsible for myelination. Unlike the Schwann cell, oligodendrocytes can myelinate portions of numerous axons (up to 40), and do so by extending a thin process that wraps around the axon multiple times. Thus, CNS axons are surrounded only by the membranes of oligodendrocytes, whereas axons in the PNS are surrounded by the entire Schwann cell. A generalized view of myelination is depicted in Figure 46.13. To maintain the myelin structure, the oligodendrocyte synthesizes four times its own weight in lipids per day.

FIGURE 46.13 A composite diagram indicating a Schwann cell that has wrapped around a portion of an axon, forming the myelin sheath. The expansion represents a portion of the myelin sheath. Central nervous system (CNS) myelin is shown, although it is similar to peripheral nervous system (PNS) myelin except that P0 replaces proteolipid protein (PLP). Recall that there are multiple layers of membrane surrounding the axon; PLP protrudes into the extracellular space and aids in compaction of the membranes through hydrophobic interactions. Myelin basic proteins (MBPs) help to stabilize the structure from within the membrane.

1. Myelin Lipids

As the plasma membrane of the glial cell is converted into myelin, the lipid composition of the brain changes (Table 46.2). The lipid-to-protein ratio is greatly increased, as is the content of sphingolipids. The myelin is a tightly packed structure, and there are significant hydrophobic interactions between the lipids and proteins to allow this to occur. Cerebrosides constitute approximately 16% of total myelin lipid and are almost completely absent from other cell-type membrane lipids. The predominant cerebroside, galactosylcerebroside, has a single sugar attached to the hydroxyl group of the sphingosine. In contrast, sphingomyelin, which one might guess is the predominant lipid of myelin, is present in roughly the same low concentration in all membranes. Galactocerebrosides pack more tightly together than phosphatidylcholine; the sugar, although polar, carries no positively charged amino group or negatively charged phosphate. The brain synthesizes very-long-chain fatty acids (>20 carbons long); these long uncharged side chains develop strong hydrophobic associations, allowing close packing of the myelin sheath. The high cholesterol content of the membrane also contributes to the tight packing, although the myelin proteins are also required to complete the tightness of the packing process.

TABLE 46.2 Protein and Lipid Composition of CNS Myelin and Human Brain

SUBSTANCE ^a	MYELIN	WHITE MATTER	GRAY MATTER
Protein	30.0	39.0	55.3
Lipid	70.0	54.9	32.7
Cholesterol	27.7	27.5	22.0
Cerebroside	22.7	19.8	5.4
Sulfatide	3.8	5.4	1.7
Total galactolipid	27.5	26.4	7.3

2. Myelin Structural Proteins

The layers of myelin are held together by protein–lipid and protein–protein interactions, and any disruption can lead to demyelination of the membrane (see “Biochemical Comments”). Although numerous proteins are found in both the CNS and PNS, only the major proteins are discussed here. The major proteins in the CNS and PNS are different. In the CNS, two proteins constitute between 60% and 80% of the total proteins—proteolipid protein (PLP) and myelin basic proteins (MBPs). The PLP is a very hydrophobic protein that forms large aggregates in aqueous solution and is relatively resistant to proteolysis. Its molecular weight, based on sequence analysis, is 30,000 Da. PLP is highly conserved in sequence among species. Its role is thought to be one of promoting the formation and stabilization of the multilayered myelin structure.

The MBPs are a family of proteins. Unlike PLP, MBPs are easily extracted from the membrane and are soluble in aqueous solution. The major MBP has no tertiary structure and has a molecular weight of 15,000 Da. MBP is located on the cytoplasmic face of myelin membranes. Antibodies directed against MBPs elicit experimental allergic encephalomyelitis (EAE), which has become a model system for understanding multiple sclerosis, a demyelinating disease. A model of how PLP and MBPs aid in stabilizing myelin is shown in Figure 46.13.

In the PNS, the major myelin protein is P0, a glycoprotein that accounts for >50% of the PNS myelin protein content. The molecular weight of P0 is 30,000 Da, the same as PLP. P0 is thought to play a similar structural role in maintaining myelin structure as PLP does in the CNS. Myelin basic proteins are also found in the PNS, with some similarities and differences to the MBPs found in the CNS. The major PNS-specific MBP has been designated P2.

CLINICAL COMMENTS

Katie C. Catecholamines affect nearly every tissue and organ in the body. Their integrated release from nerve endings of the sympathetic (adrenergic) nervous system plays a critical role in the reflex responses we make to sudden changes in our internal and external environment. For example, under stress, catecholamines appropriately increase heart rate, blood pressure, myocardial (heart muscle) contractility, and conduction velocity of the heart.

Episodic, inappropriate secretion of catecholamines in supraphysiological amounts, such as occurs in patients with pheochromocytomas, like **Katie C.**, causes an often acute and alarming array of symptoms and signs of a hyperadrenergic state.

Most of the signs and symptoms related to catecholamine excess can be masked by phenoxybenzamine, a long-acting α_1 - and α_2 -adrenergic receptor antagonist, combined with a β_1 - and β_2 -adrenergic receptor blocker such as propranolol. Pharmacological therapy alone is reserved for patients with inoperable pheochromocytomas (e.g., patients with malignant tumors with metastases and patients with severe heart disease). Because of the sudden, unpredictable, and sometimes life-threatening discharges of large amounts of catecholamines from these tumors, definitive therapy involves surgical resection of the neoplasms(s) after appropriate preoperative preparation of the patient with the agents mentioned above. **Katie C.**'s tumor was resected without intraoperative or postoperative complications. After surgery, she remained free of symptoms, and her blood pressure decreased to normal levels.

Evan A., after stopping Redux, was placed on Prozac, an antidepressant that acts as a specific serotonin reuptake inhibitor (SSRI) but does not lead to increased synthesis or secretion of serotonin, as did dexfenfluramine in Redux. Thus, the mechanism of action of these two drugs is different, even if the end result (elevated levels of serotonin) is the same. Unfortunately, Prozac did not work as well for **Evan A.** as did Redux, and he regained his 50 lb within one year after switching medications. There were other medical treatment options for **Evan A.**, including orlistat, a partial inhibitor of dietary fatty acid absorption from the gastrointestinal tract and a number of medications used to treat other

conditions, including diabetes, seizures, depression, that also lead to weight loss. After a short course with some other medications with minimal success, the physician referred **Evan A.** for bariatric surgery.

BIOCHEMICAL COMMENTS

Demyelinating Diseases of the CNS. The importance of myelin in nerve transmission is underscored by the wide variety of demyelinating diseases, all of which lead to neurological symptoms. The best-known disease in this class is multiple sclerosis (MS). MS can be a progressive disease of the CNS in which demyelination of CNS neurons is the key anatomic and pathologic finding. The cause of MS has yet to be determined, although it is believed that an event occurs that triggers an autoimmune process directed against components of the nervous system. This event could be a bacterial or viral infection that stimulates the immune system to fight off the invaders. Unfortunately, this stimulus may also be an immunologic response against the myelin sheath. The unusual geographical distribution of MS is of interest. Patients are concentrated in northern and southern latitudes, yet its incidence is almost nil at the Equator. Clinical presentation of MS varies widely. It can be a mild disease that has few or no obvious clinical manifestations. At the other end of the spectrum is a rapidly progressive and fatal disease. The most well-known presentation is the relapsing-remitting type. In this type, early in the course of the disease, the natural history is one of exacerbations followed by remission. Eventually, the CNS cannot repair the damage that has accumulated through the years, and remissions occur less and less frequently. Available treatments for MS target the relapsing-remitting type of disease.

The primary injury to the CNS in MS is the loss of myelin in the white matter, which interferes with nerve conduction along the demyelinated area (the insulator is lost). The CNS compensates by stimulating the oligodendrocyte to remyelinate the damaged axon, and when this occurs, remission is achieved. Often remyelination leads to a slowing in conduction velocity because of a reduced myelin thickness (speed is proportional to myelin thickness) or a shortening of the internodal distances (the action potential has to be propagated more times). Eventually, when it becomes too difficult to remyelinate large areas of the CNS, the neuron adapts by upregulating and redistributing along with its membrane ion pumps, to allow nerve conductance along demyelinated axons. Eventually, this adaptation also fails, and the disease progresses.

Treatment of MS is now based on blocking the action of the immune system, and agents that interfere with immune responses have had various levels of success in keeping patients in remission for extended periods.

Other demyelinating diseases also exist, and their cause is much more straightforward. These are relatively rare disorders. In all of these diseases, there is no fully effective treatment for the patient. Inherited mutations in P0 (the major PNS myelin protein) leads to a version of Charcot–Marie–Tooth polyneuropathy syndrome. The inheritance pattern for this disease is autosomal dominant, indicating that the expression of one mutated allele leads to the expression of the disease. Mutations in PLP (the major myelin protein in the CNS) lead to Pelizaeus–Merzbacher disease and X-linked spastic paraplegia type 2 disease. These diseases display a wide range of phenotypes, from a lack of motor development and early death (most severe) to mild gait disturbances. The phenotype displayed depends on the precise location of the mutation within the protein. An altered function of either P0 or PLP leads to demyelination and its subsequent clinical manifestations.

KEY CONCEPTS

- ◆ The nervous system consists of a variety of cell types with different functions.
 - ◆ Neurons transmit and receive signals from other neurons at synaptic junctions.
 - ◆ Astrocytes, found in the central nervous system, provide physical and nutritional support for the neurons.
 - ◆ Oligodendrocytes provide the myelin sheath that coats the axon, providing insulation for the electric signal that is propagated along the axon.
 - ◆ Myelin has a lipid composition that is distinct from that of cellular membranes.
 - ◆ A lack of myelin leads to demyelinating diseases as a result of impaired signal transmission across the axon.
 - ◆ Schwann cells are the supporting cells (and myelin-producing cells) of the peripheral nervous system.
 - ◆ Microglial cells destroy invading microorganisms and phagocytose cellular debris.
 - ◆ Ependymal cells line the cavities of the CNS and spinal cord.
- ◆ The brain is protected against blood-borne toxic agents by the blood–brain barrier.

- ◆ Glucose, amino acids, vitamins, ketone bodies, and essential fatty acids (but not other fatty acids) can all be transported across the blood–brain barrier.
- ◆ Proteins, such as insulin, can cross the blood–brain barrier by receptor-mediated transcytosis.
- ◆ Neurotransmitters are synthesized primarily from amino acids in the nervous system; others are derived from intermediates of glycolysis and the TCA cycle.
- ◆ Neurotransmitters are synthesized in the cytoplasm of the presynaptic terminal and then transported into storage vesicles for release upon receiving the appropriate signal.
- ◆ Neurotransmitter action is terminated by reuptake into the presynaptic terminal, or diffusion away from the synapse, or by enzymatic inactivation.
- ◆ Monoamine oxidase is a key enzyme for the inactivation of the catecholamines and serotonin.
- ◆ An encephalopathy will develop if the nervous system cannot generate sufficient ATP:
 - ◆ Hypoglycemic encephalopathy (lack of glucose to the brain)
 - ◆ Hypoxic encephalopathy (lack of oxygen to the brain)
- ◆ Diseases discussed in this chapter are summarized in Table 46.3.

TABLE 46.3 Diseases Discussed in This Chapter

DISEASE OR DISORDER	GENETIC OR ENVIRONMENTAL	COMMENTS
Albinism	Genetic	A lack of melanocyte tyrosinase leads to the inability to produce DOPA, a required precursor to melanin production, such that pigment formation is blocked.
Hypercholesterolemia	Both	Elevated cholesterol levels in the blood may be regulated by appropriate pharmacological agents.
Multiple sclerosis	Environmental/may have genetic predisposition	An autoimmune induced loss of myelin sheath formation around neurons.
Pheochromocytoma	Both	Tumor of the adrenal gland leading to episodic and excessive epinephrine and norepinephrine release.
Facilitated glucose transporter protein type 1 deficiency syndrome	Genetic	Infantile seizures related to low glucose levels in the nervous system (low glucose in the cerebrospinal fluid).
Tyramine poisoning	Environmental	Tyramine, a compound found in aged cheeses (for example), is degraded by monoamine oxidase. In the presence of monoamine oxidase inhibitors tyramine levels can accumulate, triggering the release of high levels of norepinephrine, leading to a hypertensive crisis.
Depression	Both	Drugs used to elevate serotonin levels may alleviate depression, and may also lead to appetite suppression
Appetite suppression	Both	A variety of drugs have been used to treat obesity, although many have side effects which need to be carefully monitored.

REVIEW QUESTIONS—CHAPTER 46

1. A patient with a tumor of the adrenal medulla experienced palpitations, excessive sweating, and hypertensive headaches. His urine contained increased amounts of vanillylmandelic acid. His symptoms are probably caused by an overproduction of which of the following?
 - A. Acetylcholine
 - B. Norepinephrine and epinephrine
 - C. Dopa and serotonin
 - D. Histamine
 - E. Melatonin
2. The two lipids found in highest concentration in myelin are which of the following?
 - A. Cholesterol and cerebrosides such as galactosylceramide
 - B. Cholesterol and phosphatidylcholine
 - C. Galactosylceramide sulfatide and sphingomyelin

- D. Plasmalogens and sphingomyelin
 - E. Triacylglycerols and lecithin
3. Myelin basic protein can be best described by which one of the following?
- A. It is synthesized in Schwann cells, but not in oligodendrocytes.
 - B. It is a transmembrane protein found only in peripheral myelin.
 - C. It attaches the two extracellular leaflets together in central myelin.
 - D. It contains basic amino acid residues that bind the negatively charged extracellular sides of the myelin membrane together.
 - E. It contains lysine and arginine residues that bind the negatively charged intracellular sides of the myelin membrane together.
4. A patient presented with dysmorphia and cerebellar degeneration. Analysis of his blood indicated elevated levels of phytanic acid and very-long-chain fatty acids, but no elevation of palmitate. His symptoms are consistent with a defect in an enzyme involved in which of the following?
- A. α -Oxidation
 - B. Mitochondrial β -oxidation
 - C. Transport of enzymes into lysosomes
 - D. Degradation of mucopolysaccharides
 - E. Elongation of fatty acids
5. One of the presenting symptoms of vitamin B₆ deficiency is dementia. This may result from an inability to synthesize serotonin, norepinephrine, histamine, and GABA from their respective amino acid precursors. This is because vitamin B₆ is required for which type of reaction?
- A. Hydroxylation
 - B. Transamination
 - C. Deamination
 - D. Decarboxylation
 - E. Oxidation
6. In a patient with a damaged blood–brain barrier, such that the barrier was now leaky, which one substance below would be able to cross this damaged barrier that normally could not cross an intact blood–brain barrier?
- A. Ammonia
 - B. Pyruvate
 - C. Large neutral amino acids
 - D. Nonessential fatty acids
 - E. Ketone bodies
7. A patient is deficient in vitamin B₁₂ and folate. The production of which one of the following would therefore be expected to be impaired in this patient, as compared to a patient with no vitamin deficiencies?
- A. GABA
 - B. Serotonin
 - C. Dopamine
 - D. Norepinephrine
 - E. Epinephrine
8. Lack of vitamin B₁₂ leads to neuropathy. Which one of the following neurotransmitters will exhibit reduced synthesis when this vitamin is deficient?
- A. Serotonin
 - B. Glycine
 - C. GABA
 - D. Nitric oxide
 - E. Norepinephrine
9. A patient presents with headaches, palpitations, nausea and vomiting, and elevated blood pressure. These symptoms appear after the person has eaten a large meal containing aged cheeses and wine. The patient's history indicates that they are on a medication for a different condition. Assuming that the medication is in some way involved in these symptoms, which enzyme might be the target of this drug?
- A. Catechol O-methyl transferase
 - B. Tyrosine hydroxylase
 - C. Glutamate decarboxylase

- D. Monoamine oxidase
 - E. DOPA decarboxylase
0. A 2-year-old patient presents with a history of frequent seizures, developmental delay, and difficulty in moving their arms and legs. Analysis of the cerebrospinal fluid (CSF) demonstrated a ratio of CSF glucose to blood glucose of 0.25. A potential treatment for this disorder would be which one of the following?
 - A. A high-fat, low-carbohydrate diet to produce ketone bodies as a fuel for the brain.
 - B. A high-carbohydrate diet to increase glucose transport into the brain.
 - C. A high-protein diet to enhance gluconeogenesis and increase blood glucose levels.
 - D. Insulin therapy to increase the number of glucose transporters in the endothelial cells lining the blood-brain barrier.
 - E. A high-fat, high-carbohydrate diet to increase free fatty acid levels in the blood for use by the nervous system.
 1. The transport of blood-borne glucose to the neurons requires which of the following? Choose the one best answer.
 - A. GLUT 1 transporters
 - B. GLUT 3 transporters
 - C. GLUT 4 transporters
 - D. GLUT 1 and GLUT 3 transporters
 - E. GLUT 3 and GLUT 4 transporters
 - F. GLUT 1 and GLUT 4 transporters
 - G. GLUT 1, GLUT 3, and GLUT 4 transporters
 2. Albinism can be due to a mutation in the conversion of tyrosine to L-DOPA. Interestingly, studies in patients with such albinism do not demonstrate an inability to synthesize catecholamines, which require the same metabolic step. This is most likely due to which one of the following?
 - A. Alternative splicing of the tyrosine hydroxylase gene (TH gene)
 - B. Cell-specific regulation of TH expression
 - C. Epigenetic regulation silencing the TH gene in melanocytes
 - D. The enzymes which convert tyrosine to L-DOPA are encoded by different genes
 - E. The mutation affects the iron-dependent tyrosine hydroxylase isozymes
 3. The use of dinitrophenol as a mitochondrial uncoupling agent was discussed previously in this text. The effect of dinitrophenol on catecholamine storage vesicles in the adrenal medulla would be best described by which one of the following?
 - A. The vesicular ATPase would be directly inhibited
 - B. Catecholamine entry into the vesicles would be enhanced
 - C. Catecholamine entry into the vesicle would be reduced
 - D. There would be a direct inhibition of VMat2 by dinitrophenol
 - E. Catecholamine synthesis would be increased
 4. A newborn infant, upon initial newborn screening, was shown to have elevated phenylalanine levels in their blood. Further testing demonstrated reduced levels of blood tyrosine, with abnormal levels of pterin derivatives found in the urine. If not treated the child will have difficulty in synthesizing which of the following neurotransmitters?

	Sero- tonin	Epineph- rine	Dopa- mine	γ - aminobu- tyrate	Acetyl- choline
A	Yes	Yes	Yes	No	Yes
B	Yes	No	Yes	Yes	Yes
C	Yes	Yes	Yes	No	No
D	No	No	No	Yes	No
E	No	Yes	No	No	Yes
F	No	No	No	Yes	No

5. A reduction in oxygen levels (hypoxia) will lead to a reduction of acetyl CoA levels, thereby reducing acetylcholine synthesis in neurons. The reduction of acetyl CoA levels during hypoxia occurs due to which one of the following?
- Inhibition of glycolysis
 - Stimulation of the electron transfer chain
 - Inhibition of the TCA cycle
 - Activation of pyruvate dehydrogenase
 - Inhibition of pyruvate carboxylase

ANSWERS TO REVIEW QUESTIONS

- The answer is B.** The symptoms exhibited by the patient are due to excessive release of epinephrine or norepinephrine. Vanillylmandelic acid is also the degradation product of norepinephrine; thus, these hormones are being overproduced. Acetylcholine degradation leads to the formation of acetic acid and choline, which are not observed (thus, A is incorrect). Although DOPA degradation could lead to vanillylmandelic acid production, serotonin degradation does not (it leads to 5-hydroxyindole acetic acid), and the symptoms exhibited by the patient are not consistent with DOPA or serotonin overproduction (thus, C is incorrect). Histamine and melatonin also do not produce the symptoms exhibited by the patient (thus, D and E are incorrect).
- The answer is A.** Myelin contains very high levels of cholesterol and cerebrosides, particularly galactosylcerebrosides.
- The answer is E.** Myelin basic protein is a basic protein, indicating that it must contain a significant number of lysine and arginine residues. MBP is found on the intracellular side of the myelin membrane, and its role is to compact the membrane by binding to negative charges on both sides of it, thereby reducing the “width” of the membrane. Both Schwann cells and oligodendrocytes synthesize myelin (thus, A is incorrect). MBP is not a transmembrane protein (PLP in the CNS and Po in the PNS are, so B is incorrect), and because MBP is found intracellularly, answers C and D cannot be correct.
- The answer is A.** The accumulation of both phytanic acid and very-long-chain fatty acids indicates a problem in peroxisomal fatty acid oxidation, which is where α -oxidation occurs. Lysosomal transport is, therefore, not required to metabolize these fatty acids (thus, C is incorrect). The finding that palmitate levels are low indicates that β -oxidation is occurring; therefore, answer B is incorrect. The compounds that accumulate are not mucopolysaccharides, nor is fatty acid elongation required in the metabolism of these compounds (thus, D and E are incorrect).
- The answer is D.** Vitamin B₆ participates in transamination and decarboxylation reactions (and indirectly

in deamination reactions). The one common feature in the synthesis of serotonin, GABA, norepinephrine, and histamine is decarboxylation of an amino acid, which requires vitamin B₆. The other reactions are not required in the biosynthesis of these neurotransmitters.

6. **The answer is D.** Normally, only essential fatty acids can be transported across the blood–brain barrier, whereas nonessential fatty acids do not cross the barrier to any appreciable extent. Ammonia, in its uncharged form, can freely diffuse across the blood–brain barrier. Pyruvate can cross the barrier through the monocarboxylic acid transport protein. Large neutral amino acids are transported through the L system of amino acid transport. Ketone bodies can also cross the blood–brain barrier when their concentration is increased in the blood, as under fasting conditions.
7. **The answer is E.** To form epinephrine, a methyl group from S-adenosyl methionine (SAM) is transferred to norepinephrine. SAM production is dependent upon adequate levels of both vitamin B₁₂ and folate. Without B₁₂ and folate (and therefore SAM), epinephrine synthesis is blocked. Inactivation of catecholamines (and serotonin) is also dependent on SAM, so a lack of B₁₂ and folate (and therefore SAM) would result in a higher level of serotonin, dopamine, and norepinephrine. GABA synthesis is not affected by a B₁₂ or folate deficiency.
8. **The answer is B.** A B₁₂ deficiency leads to FH₄ being trapped as N⁵-methyl-FH₄, thereby producing a functional folate deficiency. Folate is required for the synthesis of glycine from serine. Glycine in the circulation cannot pass through the blood–brain barrier so it must be synthesized from serine within the brain. In the absence of B₁₂, this reaction will not occur. In addition, due to the lack of B₁₂ and the functional folate deficiency, levels of SAM will drop. Thus, while norepinephrine synthesis is normal, epinephrine synthesis would be reduced. There is no effect on serotonin synthesis (from tryptophan), nor for GABA and NO synthesis, as none of their biosynthetic steps requires either vitamin B₁₂ or a folate derivative.
9. **The answer is D.** Aged cheese contains a degradation product of tyrosine, tyramine, which stimulates catecholamine release if not degraded. Monoamine oxidase B inactivates the tyramine but if the patient is taking a monoamine oxidase inhibitor for another reason, the tyramine would not be degraded and symptoms of catecholamine excess will be exhibited. None of the other enzymes listed as answers inactivate or metabolize tyramine.
10. **The answer is A.** The patient exhibits hypoglycorrhachia, a deficiency of the GLUT1 transporters in the endothelial cells lining the blood–brain barrier. This results in insufficient glucose in the CSF, and a lack of energy for the brain to function properly. Ingesting a high-fat, low-carbohydrate diet will force ketone body production (a ketogenic diet), a fuel source that the brain can utilize in place of glucose. Such a diet will aid in alleviating the symptoms brought about by the lack of the glucose transporter. Any diet which increases glucose levels (high carbohydrate, or high protein) will not increase the amount of glucose entering the CSF, as the transporter is defective. Insulin will increase the number of GLUT 4 transporters, but those transporters are not expressed in the nervous system. The brain also cannot transport most fatty acids across the blood–brain barrier, so increasing fat content in the diet to increase fatty acid levels will not increase the levels of fatty acids in the brain.
11. **The answer is D.** The endothelial cells of the blood–brain barrier utilize GLUT 1 transporters to accumulate glucose from the blood, while the neurons utilize GLUT 3 transporters to obtain the glucose from the cerebrospinal fluid. GLUT 4 transporters are the insulin-responsive transporters and are found predominantly in the muscle and adipose tissue.
12. **The answer is D.** Melanocytes express a copper-dependent tyrosinase, encoded by the TYR gene, which catalyzes the same reaction as tyrosine hydroxylase, an iron-dependent enzyme encoded by the TH gene, which is expressed in the adrenal medulla. While the TH gene has four different alternatively spliced mRNAs, none of them are expressed in melanocytes. Epigenetic regulation of the TH gene does not apply, as tyrosinase in melanocytes is encoded by a different gene.
13. **The answer is C.** Catecholamine uptake into the storage vesicles is driven by VMAT2, which catalyzes the entry of the neurotransmitter in exchange for a proton leaving the storage vesicle. A proton gradient is established across the vesicle membrane by the V-ATPase, which hydrolyzes ATP to pump protons into the vesicle. The use of dinitrophenol would destroy the proton gradient (without inhibiting the activities of the V-ATPase and VMAT2) by allowing free proton transfer across the membrane. In the absence of a proton gradient catecholamines cannot enter the storage vesicle. Dinitrophenol would not enhance the synthesis of the neurotransmitters.
14. **The answer is C.** The infant has an inability to either synthesize, or regenerate, tetrahydrobiopterin,

which is required for ring hydroxylation reactions (the clue for this is the finding of abnormal pterin levels in the urine, which distinguishes the metabolic defect from that of a phenylalanine hydroxylase deficiency). Ring hydroxylation reactions are required for the synthesis of catecholamines (epinephrine and dopamine) and serotonin (via 5-hydroxytryptophan). γ -Aminobutyric acid and acetylcholine synthesis do not require ring hydroxylation reactions.

15. **The answer is C.** Under hypoxic conditions, the electron transfer chain will be inhibited (due to the lack of the terminal electron acceptor) leading to an increase of NADH levels in the mitochondria. NADH is an allosteric inhibitor of pyruvate dehydrogenase, thereby reducing acetyl CoA production. The elevated NADH also inhibits the TCA cycle. Glycolysis is not inhibited under hypoxic conditions (lactate would be produced), and NADH does not inhibit pyruvate carboxylase (acetyl CoA activates pyruvate carboxylase activity).

The Extracellular Matrix and Connective Tissue

Many of the cells in tissues are embedded in an **extracellular matrix** that fills the spaces between cells and binds cells and tissue together. In so doing, the extracellular matrix aids in determining the shape of tissues as well as the nature of the partitioning between tissue types. In the skin, loose connective tissue beneath epithelial cell layers consists of an extracellular matrix in which fibroblasts, blood vessels, and other components are distributed (Fig. 47.1). Other types of connective tissue, such as tendon and cartilage, consist largely of extracellular matrix, which is principally responsible for their structure and function. This matrix also forms the sheetlike **basal laminae**, or basement membranes, on which layers of epithelial cells rest, and which act as supportive tissue for muscle cells, adipose cells, and peripheral nerves.

FIGURE 47.1 An overview of connective tissue extracellular matrix. Supporting the epithelial cell layer is a basal lamina, beneath which are collagen, elastic fibers, and proteoglycans. The cell types present in connective tissue, such as fibroblasts and macrophages, have been removed from the diagram for clarity.

Basic components of the extracellular matrix include fibrous structural proteins, such as **collagens**, **proteoglycans** containing long glycosaminoglycan chains attached to a protein backbone, and **adhesion proteins** linking components of the matrix to each other and to cells.

These **fibrous structural proteins** are composed of repeating elements that form a linear structure. **Collagens**, **elastin**, and **laminin** are the principal structural proteins of connective tissue.

Proteoglycans consist of a core protein covalently attached to many long, linear chains of **glycosaminoglycans**, which contain repeating disaccharide units. The repeating disaccharides

usually contain a **hexosamine** and a **uronic acid**, and these sugars are frequently **sulfated**. Synthesis of the proteoglycans starts with the attachment of a sugar to a serine, threonine, or asparagine residue of the protein. Additional sugars, donated by **UDP-sugar precursors**, add sequentially to the nonreducing end of the molecule.

Proteoglycans, as is the case for glycoproteins and glycolipids, are **synthesized in the endoplasmic reticulum (ER)** and the **Golgi complex**. The glycosaminoglycan chains of proteoglycans are **degraded by lysosomal enzymes** that cleave one sugar at a time from the nonreducing end of the chain. An inability to degrade proteoglycans leads to a set of diseases known as the **mucopolysaccharidoses**.

Adhesion proteins, such as fibronectin and laminin, are extracellular glycoproteins that contain separate distinct binding domains for proteoglycans, collagen, and fibrin. These domains allow these adhesion proteins to bind the various components of the extracellular matrix. They also contain specific binding domains for cell surface receptors known as **integrins**. These integrins bind to **fibronectin** on the external surface, span the plasma membrane of cells, and adhere to proteins, which, in turn, bind to the intracellular **actin** filaments of the **cytoskeleton**. Integrins also provide a mechanism for signaling between cells via both internal signals and through signals generated via the extracellular matrix.

Cell movement within the extracellular matrix requires remodeling of the various components of the matrix. This is accomplished by a variety of **matrix metalloproteinases (MMPs)** and regulators of the MMPs, **tissue inhibitors of matrix metalloproteinases (TIMPs)**. Dysregulation of this delicate balance of the regulators of cell movement allows cancer cells to travel to other parts of the body (**metastasize**) as well as to spread locally to contiguous tissues.

THE WAITING ROOM

Sarah L. (first introduced in Chapter 14) noted a moderate reduction in pain and swelling in the joints of her fingers while she was taking her immunosuppressant medication. At her next checkup, her rheumatologist described to **Sarah L.** the underlying inflammatory tissue changes that her systemic lupus erythematosus (SLE) was causing in the joint tissues.

Deborah S., a patient with type 2 diabetes (see Chapter 34), complained of a declining appetite for food as well as severe weakness and fatigue. The reduction in her kidneys' ability to maintain normal daily total urinary net acid excretion contributed to a metabolic acidosis. This, plus her declining ability to excrete nitrogenous waste products, such as creatinine and urea, into her urine ("azotemia") were responsible for many of her symptoms. Her serum creatinine level was rising steadily. As it approached a level of 4 mg/dL, she developed a litany of complaints caused by the multisystem dysfunction associated with her worsening metabolic acidosis and retention of nitrogenous waste products ("uremia"). Her physicians discussed with **Deborah S.** the need to consider peritoneal dialysis or hemodialysis.

I. Composition of the Extracellular Matrix

A. Fibrous Proteins

1. Collagen

Collagen, a family of fibrous proteins, is produced by a variety of cell types but principally by fibroblasts (cells found in interstitial connective tissue), muscle cells, and epithelial cells. Type I collagen, collagen(I), the most abundant protein in mammals, is a fibrous protein that is the major component of connective tissue. It is found in the extracellular matrix (ECM) of loose connective tissue, bone, tendons, skin, blood vessels, and the cornea of the eye. Collagen(I) contains approximately 33% glycine and 21% proline and hydroxyproline. Hydroxyproline is an amino acid produced by posttranslational modification of peptidyl proline residues.

Procollagen(I), the precursor of collagen(I), is a triple helix composed of three polypeptide (pro- α) chains

that are twisted around each other, forming a ropelike structure. Polymerization of collagen(I) molecules forms collagen fibrils, which provide great tensile strength to connective tissues (see Fig. 7.22). The individual polypeptide chains each contain approximately 1,000 amino acid residues. The three polypeptide chains of the triple helix are linked by interchain hydrogen bonds. Each turn of the triple helix contains three amino acid residues, such that every third amino acid is in close contact with the other two strands in the center of the structure. Only glycine, which lacks a side chain, can fit in this position, and indeed, every third amino acid residue of collagen is glycine. Thus, collagen is a polymer of (Gly-X-Y) repeats, where Y is frequently proline or hydroxyproline and X is any other amino acid found in collagen.

Procollagen(I) is an example of a protein that undergoes extensive posttranslational modifications. Hydroxylation reactions produce hydroxyproline residues from proline residues and hydroxylysine from lysine residues. These reactions occur after the protein has been synthesized (Fig. 47.2) and require vitamin C (ascorbic acid) as a cofactor of the enzymes prolyl hydroxylase and lysyl hydroxylase. Hydroxyproline residues are involved in hydrogen bond formation that helps to stabilize the triple helix, whereas hydroxylysine residues are the sites of attachment of disaccharide moieties (galactose-glucose). The role of carbohydrates in collagen structure is still controversial. In the absence of vitamin C (scurvy), the melting temperature of collagen drops from 42°C to 24°C because of the loss of interstrand hydrogen bond formation, which is in turn caused by the lack of hydroxyproline residues.

FIGURE 47.2 Hydroxylation of proline and lysine residues in collagen. Proline and lysine residues within the collagen chains are hydroxylated by reactions that require vitamin C.

The side chains of lysine residues also may be oxidized to form the aldehyde, allysine. These aldehyde residues produce covalent cross-links between collagen molecules (Fig. 47.3). An allysine residue on one collagen molecule reacts with the amino group of a lysine residue on another molecule, forming a covalent Schiff base that is converted to more stable covalent cross-links. Aldol condensation also may occur between two allysine residues, which forms the structure lysinonorleucine.

FIGURE 47.3 Formation of cross-links in collagen. **A.** Lysine residues are oxidized to allysine (an aldehyde). Allysine may react with an unmodified lysine residue to form a Schiff base (**B**), or two allysine residues may undergo an aldol condensation (**C**).

a. Types of Collagen

At least 28 different types of collagen have been characterized (Table e-47.1) . Although each type of collagen is found only in particular locations in the body, more than one type may be present in the ECM at a given location. The various types of collagen can be classified as fibril-forming (types I, II, III, V, XI, XXIV, and XXVII), network-forming (types IV, VIII, and X), those that associate with fibril surfaces (types IX, XII, XIV, XXI, and XXII), those that are transmembrane proteins (types XIII, XVII, XXIII, and XXV), endostatin-forming (types XV and XVIII), and those that form periodic beaded filaments (type VI).

TABLE 47.1 Steps in Collagen Biosynthesis

LOCATION	PROCESS
Rough endoplasmic reticulum	Synthesis of procollagen; insertion of the procollagen molecule into the lumen of the ER
Lumen of ER	Hydroxylation of proline and lysine residues; glycosylation of selected hydroxylysine residues
Lumen of ER and Golgi apparatus	Self-assembly of the procollagen molecule, initiated by disulfide bond formation in the carboxyl-terminal extensions; triple helix formation
Secretory vesicle	Procollagen prepared for secretion from cell
Extracellular	Cleavage of the propeptides, removing the amino- and carboxyl-terminal extensions, and self-assembly of the tropocollagen molecules into fibrils, and then fibers

ER, endoplasmic reticulum.

 Endostatins block angiogenesis (new blood vessel formation) by inhibiting endothelial cell migration. Because endothelial cell migration and proliferation are required to form new blood vessels, inhibiting this action blocks angiogenesis. Tumor growth is dependent on a blood supply; inhibiting angiogenesis can reduce tumor cell proliferation.

All collagens contain three polypeptide chains with at least one stretch of triple helix. The non-triple helical domains can be short (as in the fibril-forming collagens), or they can be rather large, such that the triple helix is actually a minor component of the overall structure (examples are collagen types XII and XIV). The FACIT (fibril-associated collagens with interrupted triple helices, collagen types IX, XII, and XIV) collagen types associate with fibrillar collagens, without themselves forming fibers. The endostatin-forming collagens are cleaved at their C-terminus to form endostatin, an inhibitor of angiogenesis. The network-forming collagens (type IV) form a meshlike structure, because of large (~230 amino acids) noncollagenous domains at the carboxy terminus (Fig. 47.4). And finally, a number of collagen types are actually transmembrane proteins (XIII, XVII, XXIII, and XXV) found on epithelial or epidermal cell surfaces, which play a role in a number of cellular processes, including adhesion of components of the ECM to cells embedded within it. Type XXV collagen has been associated with the neuronal plaques, which develop during Alzheimer disease.

A. Protomer

B. Dimer

C. Type IV collagen tetramer

D. Suprastructure

FIGURE 47.4 Type IV collagen contains a globular carboxyl-terminal domain (**A**), which forms tropocollagen dimers (hexamers of collagen, **B**). Four dimers associate at the amino-terminal domains to form a 7S domain (**C**), and the tetramers form a lattice (**D**), which provides structural support to the basal lamina.

Types I, II, and III collagens form fibrils that assemble into large insoluble fibers. The fibrils (see below) are strengthened through covalent cross-links between lysine residues on adjacent fibrils. The arrangement of the fibrils gives individual tissues their distinct characteristics. Tendons, which attach muscles to bones, contain collagen fibrils aligned parallel to the long axis of the tendon, thus giving the tendon tremendous tensile strength.

The types of collagen that do not form fibrils perform a series of distinct roles. Fibril-associated collagens bind to the surface of collagen fibrils and link them to other matrix-forming components. The transmembrane collagens form anchoring fibrils that link components of the extracellular matrix to underlying connective tissue. The network-forming collagens (type IV) form a flexible collagen that is part of the basement membrane and basal lamina that surround many cells.

b. Synthesis and Secretion of Collagen

Collagen is synthesized within the ER as a precursor known as procollagen. The presequence acts as the signal sequence for the protein and is cleaved, forming procollagen within the ER. From there, it is transported to the Golgi apparatus (Table 47.1). Three procollagen molecules associate through the formation of inter- and intrastrand disulfide bonds at the carboxy terminus; once these disulfides are formed, the three molecules can align properly to initiate the formation of the triple helix. The triple helix forms from the carboxy end toward the amino end, forming procollagen. The procollagen contains a triple-helical segment between two globular ends, the amino- and carboxyl-terminal extensions. The procollagen is secreted from the cell, the extensions are removed using extracellular proteases, and the tropocollagen takes its place within the ECM. The individual fibrils of tropocollagen line up in a highly ordered fashion to form the collagen fiber.

2. Elastin

Elastin is the major protein found in elastic fibers, which are located in the ECM of connective tissue of smooth muscle cells, endothelial and microvascular cells, chondrocytes, and fibroblasts. Elastic fibers allow tissues to expand and contract; this is of particular importance to blood vessels, which must deform and reform repeatedly in response to the changes in intravascular pressure that occur with the contraction of the left ventricle of the heart. It is also important for the lungs, which stretch each time a breath is inhaled and return to their original shape with each exhalation. In addition to elastin, the elastic fibers contain microfibrils, which are composed of a number of acidic glycoproteins, the major ones being fibrillin-1 and fibrillin-2.

a. Tropoelastin

Elastin has a highly cross-linked, insoluble, amorphous structure. Its precursor, tropoelastin, is a molecule of high solubility, which is synthesized on the rough endoplasmic reticulum (RER) for eventual secretion. Tropoelastin contains two types of alternating domains. The first domain consists of a hydrophilic sequence that is rich in lysine and alanine residues. The second domain consists of a hydrophobic sequence that is rich in valine, proline, and glycine, which frequently occur in repeats of VPGVG or VGGVG. The protein contains approximately 16 regions of each domain, alternating throughout the protein (Fig. 47.5).

FIGURE 47.5 The cDNA encoding elastin, indicating the repeating cross-linking and hydrophobic domains.

Supravalvular aortic stenosis (SVAS) results from an insufficiency of elastin in the vessel wall, leading to a narrowing of the large elastic arteries. Current theory suggests that the levels of elastin in the vessel walls may regulate the number of smooth muscle cell rings that encircle the vessel. If the levels of elastin are low, smooth muscle hypertrophy results, leading to a narrowing and stenosis of the artery.

Upon secretion from the cell, the tropoelastin is aligned with the microfibrils, and lysyl oxidase initiates the reactions that cross-link elastin molecules, using lysine residues within the hydrophilic alternating domains in the proteins. This cross-linking reaction is the same as that which occurs in collagen. In this reaction, two, three, or four lysine residues are cross-linked to form a stable structure. The net result of the cross-linking is the generation of a fibrous mesh that encircles the cells.

One form of osteogenesis imperfecta (OI) is caused by a mutation in a gene that codes for collagen. The phenotype of affected individuals varies greatly, depending on the location and type of mutation. See the Biochemical Comments for more information concerning this type of OI.

b. Elastic Properties of Elastin

Elastic fibers have the ability to stretch and then to re-form without requiring an obvious energy source to do so. The mechanism by which this stretching and relaxing actively occurs is still controversial but does relate to the basic principles of protein folding described in Chapter 7. When the elastic fibers are stretched (such as when a breath is taken in and the lung fills up with air), the amorphous elastin structure is stretched. This stretching exposes the repeating hydrophobic regions of the molecule to the aqueous environment. This, in turn, leads to a decrease in the entropy of water, because the water molecules need to rearrange to form cages about each hydrophobic domain. When this stretching force within the lung is removed (e.g., when the subject exhales), the elastin takes on its original structure because of the increase in entropy that occurs because the water no longer needs to form cages about hydrophobic domains. Thus, the hydrophobic effect is the primary force that allows this stretched structure to reform. Elastin is inherently stable, with a half-life of up to 70 years.

3. Laminin

After type IV collagen, laminin is the most abundant protein in basal laminae. Laminin provides additional structural support for the tissues through its ability to bind to type IV collagen, to other molecules present in the ECM, and also to cell surface-associated proteins (the integrins; see Section I.D).

a. Laminin Structure

Laminin is a heterotrimeric protein that is shaped, for the most part, like a cross (Fig. 47.6). The trimer is composed of α -, β , and γ -subunits. There are five possible α -proteins (designated α_1 through α_5), three different versions of the β -subunit (β_1 through β_3), and three different γ -forms (γ_1 through γ_3). Thus, there is a potential for the formation of as many as 45 different combinations of these three subunits. However, only 18 have been discovered. Laminin 111, composed of $\alpha_1\beta_1\gamma_1$, is typical of this class of proteins. The major feature of the laminin structure is a coiled α -helix, which joins the three subunits together and forms a rigid rod. All three chains have extensions at the amino-terminal end. Only the α -chain has a significant carboxyl-terminal extension past the rod-like structure. It is the laminin extensions that allow laminin to bind to other components within the ECM and to provide stability for the structure. Components of the ECM that are bound by laminin include collagen, sulfated lipids, and proteoglycans.

FIGURE 47.6 The structure of laminin.

b. Laminin Biosynthesis

Like other secreted proteins, laminin is synthesized with a leader sequence that targets the three chains to the ER. Chain association occurs within the Golgi apparatus before secretion from the cell. After laminin is secreted by the cell, the amino-terminal extensions promote self-association as well as the binding to other ECM components. Disulfide linkages are formed to stabilize the trimer, but there is much less posttranslational processing of laminin than there is of collagen and elastin.

B. Proteoglycans

The fibrous structural proteins of the ECM are embedded in gels formed from proteoglycans. Proteoglycans consist of polysaccharides called glycosaminoglycans (GAGs) linked to a core protein. The GAGs are composed of repeating units of disaccharides (Fig. 47.7). One sugar of the disaccharide is either *N*-acetyl glucosamine or *N*-acetyl galactosamine, and the second is usually acidic (either glucuronic acid or iduronic acid). These sugars are modified by the addition of sulfate groups to the parent sugar. A proteoglycan may contain >100 GAG chains and consist of up to 95% carbohydrate by weight.

Hyaluronate

Chondroitin 6-sulfate

Heparin

Keratan sulfate

Dermatan sulfate

FIGURE 47.7 Repeating disaccharides of some glycosaminoglycans. These repeating disaccharides usually contain an *N*-acetylated sugar and a uronic acid, which usually is glucuronic acid or iduronic acid. Sulfate groups are often present and are included in the sugar names in this figure. Iduronic acid and glucuronic acid are epimers at position 5 of the sugar.

Defects in the structures of laminin 5 or laminin 6 (proteins that contribute to the cohesion of the dermis and epidermis) lead to the disorder referred to as junctional epidermolysis bullosa (JEB). In this disorder, there can be severe spontaneous blistering of the skin and mucous membranes. A severe form of the disease, JEB gravis, is often fatal early in life. Death occurs as a result of epithelial blistering of the respiratory, digestive, and genitourinary systems.

Congenital muscular dystrophy (CMD) results from a defect in laminin 2, which is a component of the bridge that links the muscle cell cytoskeleton to the extracellular matrix. Lack of this bridge triggers muscle cell apoptosis, which results in weakened muscles.

The negatively charged carboxylate and sulfate groups on the proteoglycan bind positively charged ions and form hydrogen bonds with trapped water molecules, thereby creating a hydrated gel. The gel provides a flexible mechanical support for the ECM. The gel also acts as a filter that allows the diffusion of ions (e.g., Ca^{2+}), H_2O , and other small molecules, but slows diffusion of proteins and movement of cells. The gel also acts as a lubricant. Hyaluronan is the only GAG that occurs as a single long polysaccharide chain and is the only GAG that is not sulfated.

1. Structure and Function of the Proteoglycans

Proteoglycans are found in interstitial connective tissues—for example, the synovial fluid of joints, the vitreous humor of the eye, arterial walls, bone, cartilage, and cornea. They are major components of the ECM in these tissues. The proteoglycans interact with a variety of proteins in the matrix, such as collagen and elastin, fibronectin (which is involved in cell adhesion and migration), and laminin.

Proteoglycans are proteins that contain many chains of GAGs (formerly called mucopolysaccharides). After synthesis, proteoglycans are secreted from cells; thus, they function extracellularly. Because the long, negatively charged glycosaminoglycan chains repel each other, the proteoglycans occupy a very large space and act as “molecular sieves,” determining which substances enter or leave cells (Table 47.2). Their properties also give resilience and a degree of flexibility to substances such as cartilage, permitting compression and re-expansion of the molecule to occur.

TABLE 47.2 Some Specific Functions of the Glycosaminoglycans and Proteoglycans

GLYCOSAMINOGLYCAN	FUNCTION
Hyaluronic acid	Cell migration in: Embryogenesis Morphogenesis Wound healing
Chondroitin sulfate proteoglycans	Formation of bone, cartilage, cornea
Keratan sulfate proteoglycans	Transparency of cornea
Dermatan sulfate proteoglycans	Transparency of cornea
	Binds LDL to plasma walls
Heparin	Anticoagulant (binds antithrombin III)
	Causes release of lipoprotein lipase from capillary walls
Heparan sulfate (syndecan)	Component of skin fibroblasts and aortic wall; commonly found on cell surfaces

At least seven types of glycosaminoglycans exist, which differ in the monosaccharides present in their repeating disaccharide units: chondroitin sulfate, dermatan sulfate, heparin, heparan sulfate, hyaluronic acid, and keratan sulfates I and II. Except for hyaluronic acid, the glycosaminoglycans are linked to proteins, usually attached covalently to serine or threonine residues. Keratan sulfate I is attached to asparagine.

The ECM is not simply a glue that holds cells together; it also serves to keep cells from moving to other locations and to prevent large molecules and other particles, such as microorganisms, from reaching contiguous and distant cells. This confining property of the matrix is medically important. For example, infections spread, in part, because the infectious agent alters the “containing” capacity of the ECM. Cancer cells that metastasize (migrate to other tissues) can do so only by altering

the integrity of the matrix. Diseases such as rheumatoid arthritis (an autoimmune destruction of articular and periarticular tissues) and osteoarthritis (degenerative joint disease often associated with aging) involve damage to the functional capacity of the matrix. Alterations in the structural characteristics of the matrix of the renal glomerulus may allow proteins to be excreted into the urine, an indication of inexorable decline in renal function. Genetic defects may cause components of the matrix to be structurally and functionally abnormal, resulting in connective tissue disorders such as the Ehlers–Danlos syndrome (caused by a number of mutations that affect specific collagen genes) and Marfan syndrome (a defect in the protein, fibrillin, in which >330 different mutations, many of which give rise to different phenotypes, have been identified). Deficiencies of lysosomal enzymes involved in normal degradation of molecules of the matrix result in diseases such as the mucopolysaccharidoses.

2. Synthesis of the Proteoglycans

The protein component of the proteoglycans is synthesized on the ER. It enters the lumen of this organelle, where the initial glycosylations occur. UDP-sugars serve as the precursors that add sugar units, one at a time, first to the protein and then to the nonreducing end of the growing carbohydrate chain (Fig. 47.8). Glycosylation occurs initially in the lumen of the ER and subsequently in the Golgi complex. Glycosyltransferases, the enzymes that add sugars to the chain, are specific for the sugar being added, the type of linkage that is formed, and the sugars already present in the chain. Once the initial sugars are attached to the protein, the alternating action of two glycosyltransferases adds the sugars of the repeating disaccharide to the growing glycosaminoglycan chain. Sulfation occurs after addition of the sugar. 3'-Phosphoadenosine 5'-phosphosulfate (PAPS), also called active sulfate, provides the sulfate groups (see Fig. 31.34). An epimerase converts glucuronic acid residues to iduronic acid residues.

FIGURE 47.8 Synthesis of chondroitin sulfate. Sugars are added to the protein one at a time, with uridine diphosphate (UDP)-sugars serving as the precursors. Initially, a xylose residue is added to a serine in the protein. Then two galactose residues are

added, followed by a glucuronic acid (GlcUA) and an *N*-acetylglucosamine (GalNAc). Subsequent additions occur by the alternating action of two enzymes that produce the repeating disaccharide units. One enzyme **⑥** adds GlcUA residues, and the other **⑦** adds GalNAc. As the chain grows, sulfate groups are added by phosphoadenosine phosphosulfate (PAPS). (Modified from Rodèn L. Biosynthesis of acidic glycosaminoglycans: mucopolysaccharides. In: Fishman WH, ed. *Metabolic Conjugation and Metabolic Hydrolysis*. Vol. II. Academic Press; 1970:401. © 1970 Elsevier. With permission.)

The functional properties of a normal joint depend, in part, on the presence of a soft, well-lubricated, deformable, and compressible layer of cartilaginous tissue covering the ends of the long bones that constitute the joint.

In **Sarah L.**'s case, the pathological process that characterizes SLE disrupted the structural and functional integrity of her articular (joint) cartilage.

After synthesis, the proteoglycan is secreted from the cell. Its structure resembles a bottlebrush, with many glycosaminoglycan chains extending from the core protein (Fig. 47.9). The proteoglycans may form large aggregates, noncovalently attached by a "link" protein to hyaluronic acid (Fig. 47.10). The proteoglycans interact with the adhesion protein, fibronectin, which is attached to the cell membrane protein integrin. Cross-linked fibers of collagen also associate with this complex, forming the ECM (Fig. 47.11).

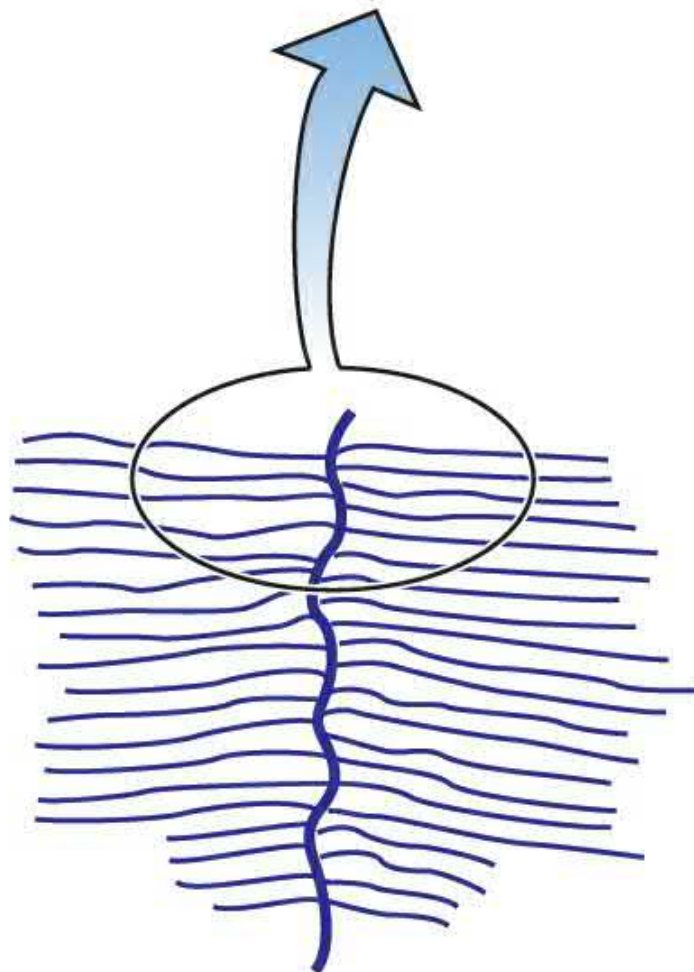

FIGURE 47.9 Bottlebrush structure of a proteoglycan, with a magnified segment.

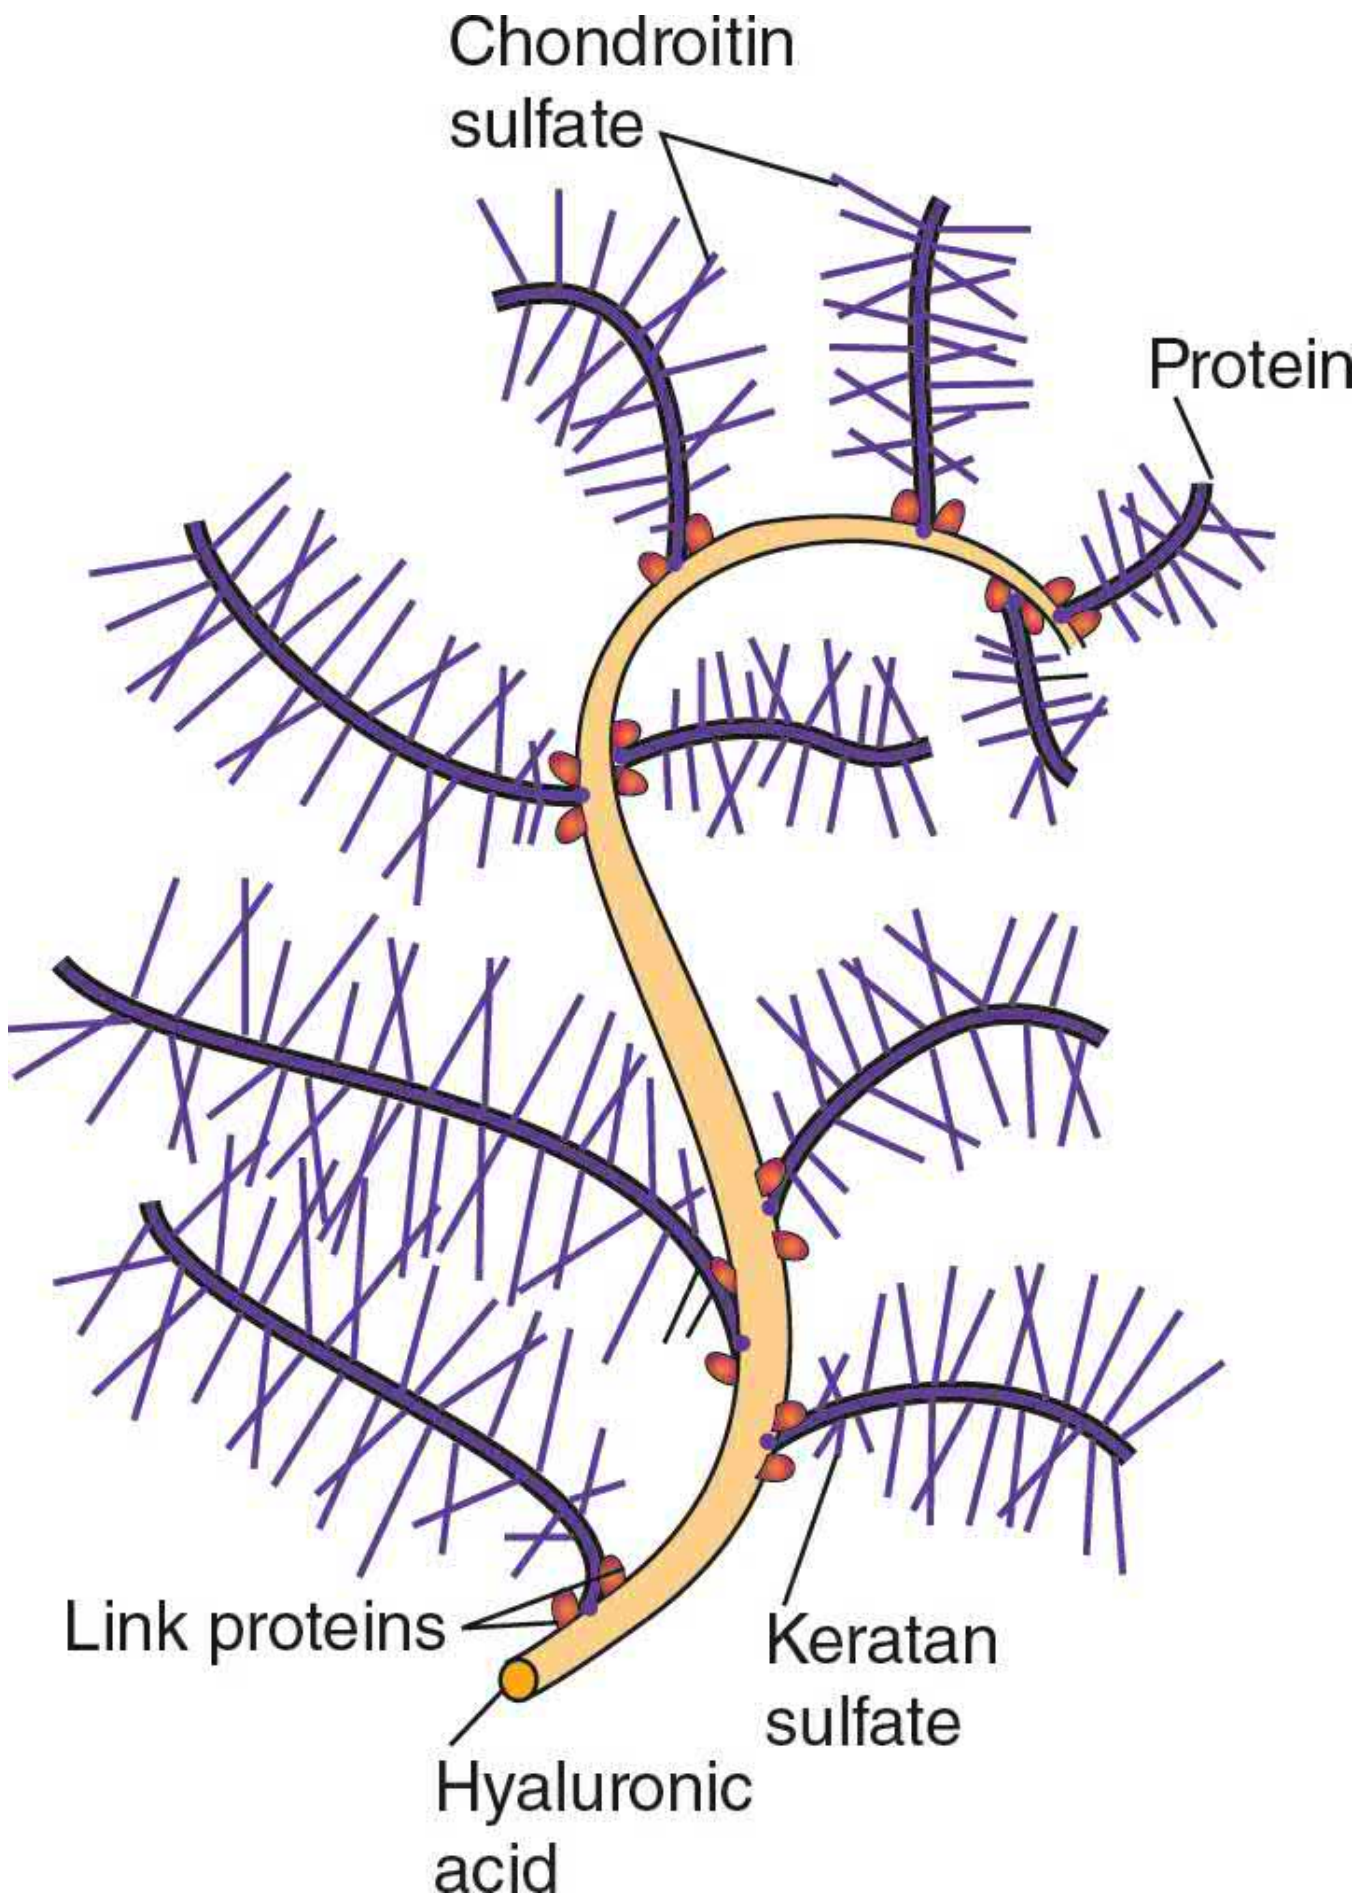

FIGURE 47.10 Proteoglycan aggregate.

FIGURE 47.11 Interactions between the cell membrane and the components of the extracellular matrix.

The long polysaccharide side chains of the proteoglycans in cartilage contain many anionic groups. This high concentration of negative charges attracts cations that create a high osmotic pressure within cartilage, drawing water into this specialized connective tissue and placing the collagen network under tension. At equilibrium, the resulting tension balances the swelling pressure caused by the proteoglycans. The complementary roles of this macromolecular organization give cartilage its resilience. Cartilage can thus withstand the compressive load of weight bearing and then re-expand to its previous dimensions when that load is relieved.

3. Degradation of Proteoglycans

Lysosomal enzymes degrade proteoglycans, glycoproteins, and glycolipids, which are brought into the cell by the process of endocytosis. Lysosomes fuse with the endocytic vesicles, and lysosomal proteases digest the protein component. The carbohydrate component is degraded by lysosomal glycosidases.

Lysosomes contain both endoglycosidases and exoglycosidases. The endoglycosidases cleave the chains into shorter oligosaccharides. Then exoglycosidases, specific for each type of linkage, remove the sugar residues, one at a time, from the nonreducing ends.

Deficiencies of lysosomal glycosidases cause partially degraded carbohydrates from proteoglycans, glycoproteins, and glycolipids to accumulate within membrane-enclosed vesicles inside cells. These “residual

bodies” can cause marked enlargement of the organ, with impairment of its function.

In the clinical disorders known as the mucopolysaccharidoses (caused by accumulation of partially degraded glycosaminoglycans), deformities of the skeleton may occur (Table 47.3). Developmental delay, impaired cognitive abilities and other complications can also accompany these skeletal changes.

TABLE 47.3 Defective Enzymes in the Mucopolysaccharidoses

DISEASE	ENZYME DEFICIENCY	ACCUMULATED PRODUCTS
Hunter	Iduronate sulfatase	Heparan sulfate, dermatan sulfate
Hurler + Scheie	α -L-iduronidase	Heparan sulfate, dermatan sulfate
Maroteaux–Lamy	<i>N</i> -acetylgalactosamine sulfatase	Dermatan sulfate
Mucopolipidosis VII	β -Glucuronidase	Heparan sulfate, dermatan sulfate
Sanfilippo A	Heparan sulfamidase	Heparan sulfate
Sanfilippo B	<i>N</i> -acetylglucosaminidase	Heparan sulfate
Sanfilippo D	<i>N</i> -acetylglucosamine 6-sulfatase	Heparin sulfate

These disorders share many clinical features, although there are significant variations between disorders, and even within a single disorder, based on the amount of residual activity remaining. In most cases, multiple organ systems are affected (with bone and cartilage being a primary target). For some disorders, there is significant neuronal involvement, leading to impaired cognitive abilities.

II. Integrins

Integrins are the major cellular receptors for ECM proteins and provide a link between the internal cytoskeleton of cells (primarily the actin microfilament system) and extracellular proteins, such as fibronectin, collagen, and laminin. Integrins consist of an α - and a β -subunit. There are 18 distinct α - and 8 distinct β -gene products. Twenty-four unique α/β -dimers have been discovered. Mice have been genetically engineered to be unable to express many of the integrin genes (one gene at a time), and the phenotypes of these knockout mice vary from embryonic lethality (the α_5 gene is an example) to virtually no observable defects (as exemplified by the α_1 gene). In addition to anchoring the cell’s cytoskeleton to the ECM, thereby providing a stable environment in which the cell can reside, the integrins are also involved in a wide variety of cell signaling options.

Certain integrins, such as those associated with white blood cells, are normally inactive because the white cell must circulate freely in the bloodstream. However, if an infection occurs, cells located in the area of the infection release cytokines, which activate the integrins on the white blood cells, allowing them to bind to vascular endothelial cells (leukocyte adhesion) at the site of infection. Leukocyte adhesion deficiency (LAD) is a genetic disorder that results from mutations in the β_2 -integrin such that leukocytes cannot be recruited to the sites of infection. Conversely, drugs have been developed to block either the β_2 - or α_4 -integrins (on lymphocytes) to treat inflammatory and autoimmune disorders by interfering with the normal white blood cell response to cytokines. These drugs can have significant side effects because of the multiple roles integrins play in the inflammatory process.

Integrins can be activated by “inside-out” mechanisms, whereby intracellular signaling events activate the molecule, or by “outside-in” mechanisms, in which a binding event with the extracellular portion of the molecule initiates intracellular signaling events. For those integrins that bind cells to ECM components, activation of specific integrins can result in migration of the affected cell through the ECM. This mechanism is operative during growth, during cellular differentiation, and in the process of metastasis of malignant cells to neighboring tissues.

III. Adhesion Proteins

Adhesion proteins are found in the ECM and link integrins to ECM components. Adhesion proteins, of which fibronectin is a prime example, are large multidomain proteins that allow binding to many different components simultaneously. In addition to integrin-binding sites, fibronectin contains binding sites for collagen and glycosaminoglycans. As the integrin molecule is bound to intracellular cytoskeletal proteins, the adhesion proteins provide a bridge between the actin cytoskeleton of the cell and the cells’ position within the ECM. Loss of adhesion protein capability can lead to either physiological or abnormal cell movement. Alternative splicing of fibronectin allows many different forms of this adhesion protein to be expressed, including a soluble

form (vs. cell-associated forms), which is found in the plasma. The metabolic significance of these products remains to be determined.

M The movement of tumor cells from its tissue of origin (metastasis) through the blood or lymph system, and colonization of a target tissue, requires degradation of the extracellular matrix to allow for cell movement. This is accomplished by a family of proteins known as matrix metalloproteinases (MMPs). The MMPs degrade specific extracellular matrix components (such as collagen, or elastin), thereby allowing cells access through this compartment. One assay for determining if MMPs are present in a biological sample is the gelatin zymography assay; a newer, more sensitive assay is based on fluorescence resonance energy transfer (FRET). In the zymography assay, polyacrylamide gels containing the protein gelatin are prepared, and the enzyme samples are run through the gel, in the presence of SDS. After the gel has run enzyme activity is reconstituted by substituting Triton X-100 for the SDS. An assay buffer is then placed over the gel, which is left overnight. During this part of the procedure, if a lane on the gel contained MMP activity, the MMP would be digesting the gelatin in the area of the gel where the MMP resided. After the activity phase is complete the gel is developed with Coomassie stain, which binds to the proteins in the gel, including the gelatin. A positive result would appear as white bands on a blue background. The white bands are due to the absence of gelatin in that region of the gel, as the MMPs present at that region have digested the gelatin such that Coomassie stain has nothing to bind to in that area of the gel. The FRET assay utilizes a peptide substrate that contains both a fluorophore and a quencher, in close proximity. When excited, the quencher blocks fluorescence emittance from the fluorophore due to the close proximity of the two molecules on the peptide. After MMP treatment, however, the peptide is cleaved between the fluorophore and quencher, such that the quencher is no longer in close proximity to the fluorophore. This results in a strong fluorescence emittance. Thus, fluorescence intensity will increase as the peptide is cleaved in the presence of the MMP. This is a very sensitive assay, detecting sub-nanogram levels of a wide variety of members of the MMP family.

Fibronectin was first discovered as a large, external transformation-sensitive protein (LETS), which was lost when fibroblasts were transformed into tumor cells. Many tumor cells secrete less than normal amounts of adhesion protein material, which allows for more movement within the extracellular milieu. This, in turn, increases the potential for the tumor cells to leave their original location and take root at another location within the body (metastasis).

IV. Matrix Metalloproteinases

The ECM contains a series of proteases known as the matrix metalloproteinases or MMPs. These are zinc-containing proteases that use the zinc to appropriately position water to participate in the proteolytic reaction. Over 20 different types of human MMPs exist, and they cleave all proteins found in the ECM, including collagen and laminin.

Because MMPs degrade extracellular matrix (ECM) components, their expression is important to allow cell migration and tissue remodeling during growth and differentiation. In addition, many growth factors bind to ECM components and, as bound components, do not exhibit their normal growth-promoting activity. Destruction of the ECM by the MMPs releases these growth factors, allowing them to bind to cell surface receptors to initiate growth of tissues. Thus, coordinated expression of the MMPs is required for appropriate cell movement and growth. Cancer cells that metastasize require extensive ECM remodeling and usually use MMP activity to spread throughout the body.

A propeptide is present in newly synthesized MMPs that contains a critical cysteine residue. The cysteine residue in the propeptide binds to the zinc atom at the active site of the protease and prevents the propeptide from exhibiting proteolytic activity. Removal of the propeptide is required to activate the MMPs. Once they are activated, certain MMPs can activate other forms of MMP.

Regulation of MMP activity is quite complex. These regulatory processes include transcriptional regulation, proteolytic activation, inhibition by the circulating protein α_2 -macroglobulin, and regulation by a class of inhibitors known as tissue inhibitors of metalloproteinases, or TIMPs. It is important that the synthesis of TIMPs and MMPs be coordinately regulated, because dissociation of their expression can facilitate various clinical disorders, such as certain forms of cancer and atherosclerosis.

CLINICAL COMMENTS

Sarah L. Articular cartilage is a living tissue with a turnover time determined by a balance between the rate of its synthesis and that of its degradation (Fig. 47.12). The chondrocytes that are embedded in the matrix of intra-articular cartilage participate in both its synthesis and its enzymatic degradation. The latter occurs as a result of cleavage of proteoglycan aggregates by enzymes produced and secreted by the chondrocytes.

FIGURE 47.12 Synthesis and degradation of proteoglycans by chondrocytes. (Reprinted from Cohen RD, Lewis B, Alberti KGMM, et al. *The Metabolic and Molecular Basis of Acquired Disease*. Vol. 2. Baillière Tindall; 1990:1859. © 1990 Elsevier. With permission.)

SLE, the condition that affects **Sarah L.**, involves an autoimmune-induced inflammation. The inflammation can damage the kidneys, skin, and several other parts of the body. Joint pain is very common and results from inflammation around the joint. The inflammatory process excites the local release of cytokines such as interleukin-1 (IL-1), which can increase the proteolytic activity of the chondrocytes, causing loss of articular proteins such as the proteoglycans. This can result in joint damage and pain.

Deborah S. The microvascular complications of both type 1 and type 2 diabetes mellitus involve the small vessels of the retina (diabetic retinopathy), the renal glomerular capillaries (diabetic nephropathy), and the vessels that supply blood to the peripheral nerves (autonomic neuropathy). The lack of adequate control of **Deborah S.**'s diabetic state over many years caused a progressive loss of the filtering function of the approximately 1.5 million glomerular capillary-mesangial units that are present in her kidneys.

Chronic hyperglycemia is postulated to be a major metabolic initiator or inducer of diabetic microvascular disease, including those renal glomerular changes that often lead to end-stage renal disease ("glucose toxicity").

For a comprehensive review of the four postulated molecular mechanisms by which chronic hyperglycemia causes these vascular derangements, the reader is referred to a number of excellent reviews suggested in the online references.

Regardless of which of the postulated mechanisms (increased flux through the aldose reductase or polyol pathway [see Chapter 27], the generation of advanced glycosylation end products [AGEs], the generation of reactive oxygen intermediates [see Chapter 25], or excessive activation of protein kinase C [see Chapter 17]) will eventually be shown to be the predominant causative mechanism, each can lead to the production of critical intracellular and extracellular signaling molecules (e.g., cytokines). These, in turn, can cause pathological changes within the glomerular filtration apparatus that reduce renal function. These changes include increased synthesis of type IV collagen, fibronectin, and some of the proteoglycans, causing the glomerular basement membrane (GBM; Fig. 47.13) to become diffusely thickened throughout the glomerular

capillary network. This membrane thickening alters certain specific filtration properties of the GBM, preventing some of the metabolites that normally enter the urine from the glomerular capillary blood (via the fenestrated capillary endothelium) from doing so (a decline in glomerular filtration rate, GFR). As a result, these potentially toxic substances accumulate in the blood and contribute to the overall clinical presentation of advancing uremia. In spite of the thickening of the GBM, this membrane becomes “leaky” for some macromolecules (e.g., albumin) that normally do not enter the urine from the glomerular capillaries (microalbuminuria). Suggested mechanisms for this increased permeability or leakiness include reduced synthesis of the specific proteoglycan, heparan sulfate, as well as increased basement membrane production of vascular endothelium growth factor (VEGF), a known angiogenic and permeability factor; and expansion of the extracellular matrix in the mesangium. The mesangium consists of specialized tissue containing collagen, proteoglycans, and other macromolecules that surround the glomerular capillaries and that, through its gel-like and sieving properties, determine, in part, the glomerular capillary hydraulic filtration pressure as well as the functional status of the capillary endothelium–mesangial GBM filtration apparatus (see Fig. 47.13). As the mesangial tissue expands, the efficiency of glomerular filtration diminishes proportionately. The cause of these mesangial changes is, in part, the consequence of increased expression of certain growth factors, especially transforming growth factor β (TGF- β) and connective tissue growth factor (CTGF). Future therapeutic approaches in patients with early diabetic nephropathy may include the use of antibodies that neutralize TGF- β .

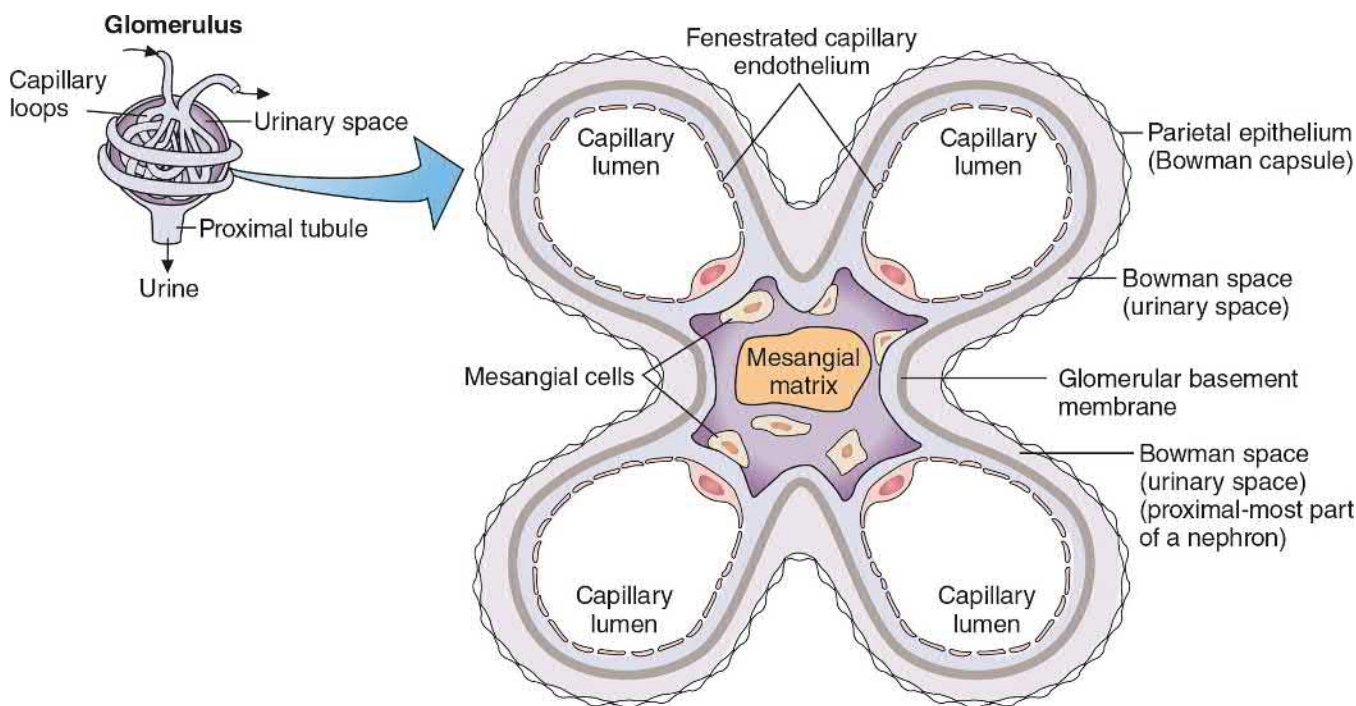

FIGURE 47.13 A cross section of a normal renal glomerulus showing four capillary tufts delivering blood to the glomerulus for filtration across the fenestrated capillary endothelium, then through the glomerular basement membrane into the Bowman space to form urine. The urine then enters the proximal tubule of the nephron. This filtration removes potentially toxic metabolic end products from the blood. The mesangium, by contracting and expanding, controls the efficiency of these filtering and excretory functions by regulating the hydraulic filtration pressures in the glomerulus. An intact basement membrane must be present to maintain the integrity of the filtering process.

BIOCHEMICAL COMMENTS

Osteogenesis Imperfecta. Osteogenesis imperfecta (OI) is a heterogeneous group of genetic diseases that have in common a defect in collagen production. This defect can be either of two types: The first type is associated with a reduction in the synthesis of normal collagen (resulting from a gene deletion or splice-site mutation). The second type is associated with the synthesis of a mutated form of collagen. Most of the mutations have a dominant-negative effect, leading to an autosomal dominant mode of transmission.

In the second type of OI, many of the known mutations involve substitutions of another amino acid for glycine. This results in an unstable collagen molecule because glycine is the only amino acid that can fit between the other two chains within the triple helix of collagen. If the mutation is near the carboxyl-terminal

end of the molecule, the phenotype of the disease is usually more severe than if the mutation is near the amino-terminal end (recall that triple helix formation proceeds from the carboxyl- to the amino-terminal end of the molecule). Of interest are mutations that replace glycine with either serine or cysteine. Such mutations are more stable than expected, because of the hydrogen bonding capabilities of serine and the ability of cysteine to form disulfide bonds. Both would aid in preventing the strands of the triple helix from unwinding.

OI can occur due to mutations in genes other than collagen. Mutations in CRTAP (cartilage-associated protein) or LEPRE1 (prolyl 3-hydroxylase 1, or PH3-1) lead to defective collagen fibers being produced. CRTAP forms a complex with PH3-1 and cyclophilin to hydroxylate a specific proline residue in types I and II collagen. Failure to hydroxylate this proline residue leads to unstable collagen, and moderate to severe forms of OI. The pattern of inheritance for both CRTAP and LEPRE1 mutations is autosomal recessive.

Children with OI can be treated with a class of compounds known as bisphosphonates, which consist of two phosphates linked by a carbon or nitrogen bridge (thus, they are analogs of pyrophosphate, in which the two phosphates are linked by oxygen). Normal bone remodeling is the result of a coordinated “coupling” between osteoclast activity (cells that resorb bone) and osteoblast activity (cells that form bone). In OI, bone resorption outpaces bone formation because osteoclast activity is enhanced (perhaps because of the reduced levels of normal collagen present to act as nucleating sites for bone formation). This leads to a net loss of bone mass and fragility of the skeleton. Bisphosphonates inhibit osteoclast action with the potential to increase bone mass and its tensile strength.

KEY CONCEPTS

- ◆ The extracellular matrix (ECM) consists of fibrous structural proteins, proteoglycans, and adhesion proteins.
- ◆ The ECM provides support to the tissues and restricts movement of cells.
- ◆ Collagen is the most abundant fibrous protein, and it consists of a triple helix stabilized by hydrogen bonds and intramolecular cross-links. There are over 25 different types of collagen.
- ◆ Elastin is the major protein found in elastic fibers, and it is responsible for the contractility exhibited by these fibers.
- ◆ Laminin provides structural support to tissues via binding to various components of the ECM.
- ◆ Proteoglycans consist of polysaccharides (glycosaminoglycans) bound to a core protein.
 - ◆ The polysaccharides are usually a repeating disaccharide unit, containing negative charges.
 - ◆ Because of charge repulsion, the proteoglycans form a hydrated gel that provides flexible mechanical support to the ECM.
- ◆ Integrins are cellular membrane receptors for ECM proteins, and they link the cellular cytoskeleton to extracellular proteins.
- ◆ Integrins are also signaling proteins when they are bound to appropriate components.
- ◆ Adhesion proteins link the integrins to ECM components.
- ◆ Matrix metalloproteinases are the only proteases that can degrade ECM components, and they are carefully regulated by the tissue inhibitors of matrix metalloproteinases (TIMPS).
- ◆ Diseases discussed in this chapter are summarized in Table 47.4.

TABLE 47.4 Diseases Discussed in This Chapter

DISEASE OR DISORDER	GENETIC OR ENVIRONMENTAL	COMMENTS
Systemic lupus erythematosus	Both (genetic predisposition)	Alterations in cell matrix components due to an autoimmune-induced trigger.
Type 2 diabetes	Both	Cell matrix interactions can be altered due to elevated glucose levels, and nonenzymatic glycosylation.
Osteogenesis imperfecta	Genetic	Inherited mutations in collagen genes which disrupt the function of the altered collagen.
Supravalvular aortic stenosis, as part of Williams–Beuren	Genetic	An inherited mutation in the elastin gene, leading to narrowing of the aorta above the aortic valve and other cardiac defects.

syndrome		
Junctional epidermolysis bullosa	Genetic	A blistering skin condition due to a mutation in either one form of collagen or laminin.
Mucopolysaccharidoses	Genetic	Defects in the breakdown of mucopolysaccharides, found primarily in the extracellular matrix. See Table 47.3 for more details on these diseases.
Scurvy	Environmental	Lack of vitamin C leading to weakened collagen due to an inability to hydroxylate proline or lysine residues in procollagen.

REVIEW QUESTIONS—CHAPTER 47

- Individuals who develop scurvy suffer from sore and bleeding gums and loss of teeth. This is a result, in part, of the synthesis of a defective collagen molecule. The step that is affected in collagen biosynthesis attributable to scurvy is which one of the following?
 - The formation of disulfide bonds, which initiates tropocollagen formation
 - The formation of lysyl cross-links between collagen molecules
 - Transcription of the collagen genes
 - The formation of collagen fibrils
 - The hydroxylation of proline residues, which stabilizes the collagen structure
- The underlying mechanism that allows elastin to exhibit elastic properties (expand and contract) is which one of the following?
 - Proteolysis during expansion, and resynthesis during contraction
 - Breaking of disulfide bonds during expansion, and re-formation of these bonds during contraction
 - A decrease in entropy during expansion, and an increase in entropy during contraction
 - The breaking of salt bridges during expansion, and re-formation of the salt bridges during contraction
 - Hydroxylation of elastin during expansion, and decarboxylation of elastin during contraction
- The underlying mechanism by which glycosaminoglycans allow for the formation of a gel-like substance in the extracellular matrix is which one of the following?
 - Charge attraction between glycosaminoglycan chains
 - Charge repulsion between glycosaminoglycan chains
 - Hydrogen bonding between glycosaminoglycan chains
 - Covalent cross-linking between glycosaminoglycan chains
 - Hydroxylation of adjacent glycosaminoglycan chains
- The movement of tumor cells from their site of origin to other locations within the body requires the activity of which one of the following proteins?
 - Collagen
 - Laminin
 - Proteoglycans
 - Elastin
 - Matrix metalloproteinases
- Fibronectin is frequently absent in malignant fibroblast cells. One of the major functions of fibronectin is which one of the following?
 - To inhibit the action of matrix metalloproteinases
 - To coordinate collagen deposition within the extracellular matrix
 - To fix the position of cells within the extracellular matrix
 - To regulate glycosaminoglycan production
 - To extend glycosaminoglycan chains using nucleotide sugars
- Which one of the following alterations would reduce the ability of cartilage to cushion weight-bearing activities at joints?
 - Loss of negative charges on the proteoglycans
 - Loss of positive charges on the proteoglycans
 - Gain of negative charges on the proteoglycans
 - Increased concentration of glucuronic acid residues
 - Increased concentration of sulfated sugars on the proteoglycans
- A newborn displays the symptoms of a moderate case of OI. Analysis of the child's collagen by SDS-PAGE

indicates a molecular species with a greater than normal molecular weight. Treatment of the child's collagen with β -mercaptoethanol before SDS-PAGE results in a normal-sized collagen. The mutation in this child is most likely which one of the following?

- A. Proline to hydroxyproline
 - B. Glycine to cysteine
 - C. Proline to glycine
 - D. Glycine to proline
 - E. Serine to proline
8. Bisphosphonate treatment of children with OI is based on which one of the following?
- A. Stimulation of osteoclast activity
 - B. Inhibition of osteoclast activity
 - C. Stimulation of osteoblast activity
 - D. Inhibition of osteoblast activity
 - E. Stimulation of laminin synthesis
 - F. Inhibition of laminin synthesis
9. Collagen provides great tensile strength to connective tissue by its structure as a triple helix. Which amino acid is critical in allowing triple helix formation?
- A. Proline
 - B. Hydroxyproline
 - C. Lysine
 - D. Glycine
 - E. Elastin
10. A common feature of the mucopolysaccharidoses is the accumulation of heparin sulfate. Which of the following disorders leads to an accumulation of that particular GAG? Choose the one best answer.

	Maroteaux– Lamy	Hunter	Sanfilippo A	Muco- lipidosis VII	Sanfilippo D
A	Yes	Yes	Yes	Yes	Yes
B	No	No	Yes	Yes	Yes
C	Yes	No	No	Yes	Yes
D	No	Yes	Yes	Yes	No
E	Yes	Yes	No	Yes	No
F	No	Yes	Yes	Yes	Yes

1. The stability of collagen is enhanced by cross-linking reactions between different tropocollagen molecules. Which one of the following is required to generate such cross-links? Choose the one best answer.

	Oxygen	Lysine side Chain	Vitamin C	Proline Side Chain
A	Yes	No	No	Yes
B	No	No	Yes	No
C	Yes	Yes	No	No
D	No	Yes	Yes	No
E	Yes	Yes	No	Yes
F	No	No	Yes	Yes

2. Which of the following pathways require the use of a nucleotide sugar? Choose the one best answer.

	Glycogen Synthesis	Glycoprotein Synthesis	Ganglioside Synthesis	Glycosaminoglycan Synthesis
A	Yes	Yes	Yes	No
B	Yes	No	No	No
C	Yes	Yes	Yes	Yes
D	No	No	No	Yes
E	No	Yes	Yes	No
F	No	No	No	No

3. An inactivating mutation in lysyl oxidase would have a deleterious effect on the synthesis of which one of the following?
- Laminin A
 - Fibronectin
 - Hyaluronic acid
 - Elastin
 - Dystrophin
4. The lack of an extracellular matrix adhesion protein, such as fibronectin, ultimately breaks the link between which two of the following, which is important for a cell to maintain its position in a tissue? Choose the one best answer.
- Extracellular matrix and collagen
 - Collagen and laminin
 - Actin cytoskeleton and the extracellular matrix
 - Actin cytoskeleton and myosin

E. Collagen and glycosaminoglycans

5. The mucopolysaccharidoses are similar, in terms of mechanism of disease causation, to which of the following? Choose the one best answer.

	I-cell Disease	Tay–Sachs Disease	Pompe Disease	Duchenne Muscular Dystrophy
A	Yes	Yes	Yes	No
B	No	Yes	No	Yes
C	Yes	Yes	Yes	Yes
D	No	No	No	Yes
E	Yes	No	Yes	No
F	No	No	No	No

ANSWERS TO REVIEW QUESTIONS

- The answer is E.** Scurvy is caused by a deficiency of vitamin C. Vitamin C is a required cofactor for the hydroxylation of both proline and lysine residues in collagen. The hydroxyproline residues that are formed stabilize the collagen fiber through the formation of hydrogen bonds with other collagen triple helices within the fiber. The loss of this stabilizing force greatly reduces the strength of the collagen fibers. The hydroxylation of lysine allows carbohydrates to be attached to collagen, which appear to be necessary for efficient transport of tropocollagen from the cell to the extracellular matrix. Vitamin C is not required for disulfide bond formation, the formation of lysyl cross-links (that enzyme is lysyl oxidase), transcription of the collagen genes, or the formation of collagen fibrils. Thus, all the other choices are incorrect.
- The answer is C.** When elastin expands as a result of outside forces (such as the respiratory muscles causing the lungs to expand with air), hydrophobic regions of elastin are exposed to the aqueous environment, resulting in a decrease in the entropy of water. When the outside force is removed (by relaxation of the respiratory muscles), the driving force for contraction of elastin is an increase in the entropy of water, so that the hydrophobic residues of elastin are again shielded from the environment. The expansion and contraction of elastin does not involve covalent modifications (thus, A, B, and E are incorrect), nor does it involve extensive changes in salt bridge formation (thus, D is also incorrect).
- The answer is B.** Glycosaminoglycan chains contain negative charges, resulting from the presence of acidic sugars and the sulfated sugars in the molecule. Thus, in their characteristic bottleneck structure, the chains repel each other (thus, A is incorrect), yet they also attract positively charged cations and water into the spaces between the chains. The water forms hydrogen bonds with the sugars and a gel-like space is created. This gel acts as a diffusion sieve for materials that leave, or enter, this space. Hydroxylation and cross-linking of chains does not occur (thus, D and E are incorrect), nor does hydrogen bonding between chains (they are too far apart because of the charge repulsion, but they do form hydrogen bonds with water).
- The answer is E.** For cells to migrate, they must free themselves from the extracellular matrix material, which requires remodeling of the matrix components. Because of the unique structural aspects of these components, only a small subset of proteases, the metalloproteinases, is capable of doing this. The other answers listed are all components of the matrix, which must be remodeled for cell migration to occur.
- The answer is C.** Fibronectin binds to integrins on the cell surface, as well as to various extracellular matrix components (collagen and glycosaminoglycans). This binding fixes the position of the cell within

the matrix. Loss of these binding components can lead to undesirable cell movement. Fibronectin plays no role in any of the other functions listed as possible answers.

6. **The answer is A.** The proteoglycans, containing the glycosaminoglycans, are highly negatively charged. The sugars often contain a carboxylic acid group (glucuronic and iduronic acids) and are often sulfated. This high level of negative charges attracts cations to the proteoglycans, bringing with the cations water through an osmotic effect. When weight is placed on the joint the water in the space cushions the force generated, and when the weight is removed, water can return to the space. Losing negative charges would reduce the amount of water in the joint, and the ability of the joint to prevent bone-bone interactions. The proteoglycans are not positively charged and do not attract anions. Increasing the negative charges exhibited by the proteoglycans would enhance the cushioning effect, as would increasing the concentration of glucuronic acid residues and sulfated sugars (since both of those changes increase the concentration of negative charges in the joint).
7. **The answer is B.** Glycine is present at every third residue within a collagen monomer, as it is the only amino acid sidechain which can fit in the triple helix when the three chains wind about each other. Substitution of glycine with any other amino acid can lead to a weakened collagen structure. However, when cysteine is present instead of a glycine the cysteine has the capability of forming disulfide bonds, which can stabilize the unstable collagen triple helix. A glycine to cysteine substitution requires the change of only one nucleotide in the DNA sequence. When the child's collagen is run on an SDS-PAGE gel the molecular weight is greater than native collagen because of the cross-links in the collagen. Mercaptoethanol will break those links, so after treating with mercaptoethanol the molecular weight of collagen would appear normal in the gel. Conversion of proline to hydroxyproline is a normal event in collagen biosynthesis and allows for hydrogen bonding to occur which will stabilize the collagen triple helix. Proline to glycine will not lead to cross-links in collagen, nor will glycine or serine to proline. The latter mutations may disrupt triple helix formation, and lead to a form of OI, but they would not lead to the biochemical findings of cross-linking.
8. **The answer is B.** Osteoclasts resorb bone, while osteoblasts produce bone. Normally there is a balance between osteoclast and osteoblast activity within bones, allowing the appropriate amount of bone tissue to be generated, and then turned over and resynthesized. However, certain conditions can lead to enhanced osteoclast activity, such as reduced levels of collagen being produced, or altered collagen molecules being produced. Under these conditions the osteoclasts resorb more bone than the osteoblasts can synthesize, leading to weak and fragile bones. Bisphosphonates inhibit osteoclast activity, thereby allowing more bone to be produced, even if the collagen being produced is not normal. Laminin is not involved in bone formation. Inhibition of osteoblast activity would lead to reduced bone formation, which is the opposite of what one wants to occur under these conditions.
9. **The answer is D.** The three polypeptide chains of the triple helix are linked by interchain hydrogen bonds. Each turn of the helix contains three amino acid residues with every third amino acid in close contact with the other two strands in the center of the structure. Only glycine, which lacks a side chain, can fit in this position. The other amino acids listed are important amino acids in collagen but cannot fit into the central position critical for the triple helix. Elastin is a protein, not an amino acid. The proline is required for each chain to form a polyprolyl helix, but the glycine is essential for allowing triple helix formation.
10. **The answer is F.** Maroteaux–Lamy is deficient in *N*-acetylgalactosamine sulfatase and accumulates dermatan sulfate. All the others listed accumulate heparin sulfate (with or without the accumulation of dermatan sulfate).
11. **The answer is C.** Collagen cross-links occur between two lysine side chains. One of the side chains needs to be oxidized by lysyl oxidase, which requires molecular oxygen, but not vitamin C (vitamin C is required for proline and lysine hydroxylation reactions). Proline side chains do not play a role in collagen cross-linking but are important for hydroxylation, such that hydroxyproline side chains stabilize collagen's structure through the formation of hydrogen bonds between different tropocollagen molecules.
12. **The answer is C.** The synthesis of glycogen, glycoproteins, gangliosides, and glycosaminoglycans all require nucleotide sugars.
13. **The answer is D.** Lysyl oxidase is important for the cross-linking of two extracellular proteins, collagen, and elastin. Lysyl oxidase has no role in the maturation of laminins, fibronectin, dystrophin, or the glycosaminoglycans.
14. **The answer is C.** Adhesion proteins, such as fibronectin, have binding sites for collagen, glycosaminoglycans, and integrins. Integrins bind to proteins that link the integrin to the actin

cytoskeleton, so adhesion proteins allow the actin cytoskeleton to be linked to extracellular matrix components. Such linkages fix the cells within the extracellular matrix and prevent their movement and escape from their location. While adhesion proteins can bind collagen and glycosaminoglycans such binding does not fix the cell into its present location. Linkages between collagen and other extracellular matrix components, such as laminin, do not fix cells in position.

15. **The answer is A.** The mucopolysaccharidoses are due to mutations in lysosomal enzymes, leading to a lysosomal storage disease. Pompe disease (lack of lysosomal α -glucosidase), Tay–Sachs disease (lack of lysosomal β -hexosaminidase), and I-cell disease (mistargeting of lysosomal proteins, leading to a lysosomal storage disease) are all lysosomal storage diseases. Duchenne muscular dystrophy is a mutation in the protein dystrophin, which is found in the sarcolemma, and does not impact lysosomal function.

- polyuria in, 55
- sorbitol levels in, 482
- type I diabetes mellitus in, 200
- urinary tract infection in, 234, 235, 249

E

Edna R.

- diphtheria vaccine for daughter, 280, 288, 292
- hepatitis B vaccine for, 325, 341, 345
- work in blood bank, 589, 600, 604–605

Edward R.

- enlarged spleen in, 935, 951–952
- reticulocytes in, 935
- spectrin deficiency in, 951–952
- spherocytosis in, 935, 951–952
- splenectomy for, 952

Emma W.

- asthma treatment for, systemic vs. inhaled, 682, 707
- glucocorticoid-induced hyperglycemia in, 614, 617, 623, 631

Erin G.

- galactosemia in, 477, 483, 484, 493
- jaundice in, 477, 595

Evan A.

- referral for bariatric surgery, 1042
- serotonin levels in, 1034, 1042
- weight-loss drugs for, 1023, 1034, 1042

G

Gretchen C.

- Apgar score of, 569
- bradycardia in, 569
- glycogen stores of, 575, 578, 581
- maternal malnutrition and, 569, 575, 581
- neonatal hypoglycemia in, 569, 575, 578, 581

H

Horace S.

- biochemical studies in, 833
- cystathionine β -synthase activity, 837, 843
- homocystinuria in, 833, 837, 838, 843
- inborn error of metabolism in, 830
- skeletal mineralization in, 830
- vascular events/cerebral infarct in, 830, 843
- vitamin B₆ for, 843

I

Isabel S.

- HIV in, 213, 225
- HIV testing for friend of, 325, 329
- HIV treatment for, 215, 234, 236, 237, 249, 536, 540
- myopathy in, 524, 536, 540
- tuberculosis in, 257, 265, 272–273, 325
- zidovudine (AZT) therapy for, 536, 540

Ivan A.

- aspirin therapy for, 692, 708
- dental caries in, 477, 485, 492
- diabetes mellitus type 2 in, 26, 30, 428
- dietary plans for, 19, 26, 30
- ethanol metabolism in, 756, 761, 764
- HDL levels in, 740
- hyperglycemia in, 26, 30
- lipid levels in, 26, 30, 738
- lipid-lowering therapy for, 747
- metabolic syndrome in, 30, 717, 747
- weight and obesity of, 4, 10, 11, 13, 19, 26, 30
- basal metabolic rate of, 9, 10, 11
- hypertension in, 4, 26
- dietary analysis for, 7, 8
- daily energy expenditure of, 10, 11

J

Jay S.

- genetic testing in, 280, 292
- hexosaminidase A deficiency in, 280, 292, 605
- psychomotor development of, 280, 589
- Tay–Sachs disease in, 280, 292, 589, 605

Jean T.

- alcohol-induced cirrhosis in, 765–766, 979, 993
- blood glucose levels of, 994–995
- ethanol consumption by, 756, 979
- fatty acid metabolism in, 994–995
- folate deficiency and anemia in, 850, 851, 855, 856, 860–861
- ketone body production in, 994–995
- vomiting of blood, 979

Jim B.

- anabolic steroid use by, 569, 581–582
- insulin overdose in, 569–570, 581–582

K

Katherine B.

- negative nitrogen balance in, 889, 899
- sepsis and hypercatabolic state in, 886, 889, 899–900

Katie C.

- adrenal surgery for, 1032, 1042
- catecholamine levels in, 1032, 1033, 1042
- hypertension in, 1023
- phenoxybenzamine for, 1032, 1042
- pheochromocytoma in, 1023, 1032, 1033, 1042
- propranolol for, 1042

L

Les G.

- catecholamine measurements in, 548
- lipofuscin in, 551
- monoamine oxidase inhibitor for, 550, 561
- Parkinson disease in, 547, 550, 551, 561

Linda F.

- COPD in, 476–477, 486
- hypotension in, 477, 491
- hypoxemia in, 477, 485, 486, 491

Lisa N.

- β -thalassemia in, 257, 272, 280, 292, 294t
 - genetic mutations in, 261, 265, 272, 283–284, 294t, 952
 - intermediate type of, 257, 261, 272, 280, 292
 - stem (precursor) cells in, 318, 319
- fetal hemoglobin persistence in, 935, 952
- osteoporosis and fracture in, 935

Lola B.

- fasting effects on, 655–656, 672
- fatty acid metabolism in, 656, 662, 667, 672
- MCAD deficiency in, 662, 672

Lotta T.

- gout in, 68, 81, 137, 151, 183, 196, 205, 868, 879
 - allopurinol for, 81, 137, 150, 151, 183, 205, 868, 879
 - colchicine for, 81, 151, 183, 191, 205, 868
 - inflammatory response in, 79, 189, 205
 - uric acid/urate crystals in, 79, 189, 879

M

Mannie W.

- chronic myelogenous leukemia in, 300, 313, 318, 353, 373, 393
- hemorrhagic signs in, 353
- interferon therapy for, 313, 373
- lymphocyte percentage in, 300
- Philadelphia chromosome in, 300, 308, 318, 319, 353, 357, 373
- white blood cell count of, 300, 373

Martha W.

- mitochondrial disorder in, 381–382, 390, 392, 393, 401

Mia S.

myasthenia gravis in, 184, 192, 194, 206
Michael T.
brain metastases in, 353, 373
lung cancer in, 234, 250, 353, 373
smoking history of, 234, 242, 250, 373
TNM staging in, 373

N

Nina M.
fructose malabsorption in, 456–457, 461, 469
hydrogen breath test for, 461

O

Otto S.
basal metabolic rate of, 434, 438
body mass index (BMI) of, 4, 18
daily energy requirement of, 440
dietary plan for, 18, 444, 448
dietary supplements for, 655, 660
ethanol intake of, 444
exercise/physical conditioning by
blood glucose levels in, 630
electron-transport chain in, 492, 502, 509, 515–516, 665, 672
fatty acid metabolism in, 656, 665, 672
improved capacity in, 500, 509, 515, 614, 672
insulin and counterregulatory hormones in, 656
ketosis in, 672
lactate production in, 490, 491–492, 515–516, 672
muscle metabolism of glucose in, 1013, 1014
oxidative phosphorylation in, 490
recommendation for, 448
succinate as fuel for, 504
training for race, 477
tricarboxylic acid cycle in, 490, 502, 504, 509, 515–516
MyPlate Personalized Plan for, 18
weight gain in, 4, 434, 438, 448, 477, 614
weight goals of, 4, 18–19, 614
weight loss in, 500

P

Paul T.
pneumonia in, 213, 280
antibiotic sensitivity of, 280, 287
azithromycin for, 213, 225, 280, 287, 292
sputum culture in, 213, 280
Percy V.
anthropometric measurements of, 37
counseling for, 42
creatinine-height index of, 37, 42
dehydration, 62
depression-related malnutrition in, 4, 14, 19, 37, 38, 42
glucose levels of, 38, 42
hypercaloric diet in, 682, 699, 707
hyperventilation in, 52, 60, 61
ketone body levels of, 39
liver enzyme levels in, 811, 814
nutrient deficiencies in, 14, 16, 19, 42
paresthesias in, 61
protein levels of, 40, 42
viral hepatitis (hepatitis A) in, 810, 811, 814, 816, 819
Peter K.
factor VIII deficiency in, 961, 965
factor VIII therapy for, 971–972
hematoma in, 961, 971
hemophilia A in, 961, 971–972
Petria Y.
dietary intervention for, 842–843

Guthrie bacterial inhibition assay in, 830
phenylketonuria in, 830, 842–843

R

Renee F.

creatinine level in, 1002, 1009, 1016
glomerular filtration rate in, 1009, 1016
poststreptococcal glomerulonephritis in, 1002, 1009, 1016

S

Sam A.

diabetes mellitus in, 915, 928
growth hormone levels in, 914, 928
pituitary tumor and acromegaly in, 911, 913, 914, 915, 928

Sarah L.

anti-inflammatory therapy for, 273
antibody assay in, 268
butterfly rash of, 257
immunosuppressive therapy for, 273
joint inflammation in, 1049, 1059–1060
proteolytic action of chondrocytes in, 1059–1060
systemic lupus erythematosus in, 257, 268, 273, 1049, 1059–1060

Seth D.

glucocorticoids, 1016
sitting position, 1002, 1016

Stanley T.

fuel oxidation in, 442, 448
goiter in, 448, 523
Graves disease in, 523, 539
heart rate and beat in, 434, 448
heat intolerance in, 434, 442, 523, 539
hyperthyroidism in, 434, 440, 442, 448, 523, 539
thyroid hormone levels in, 434, 440, 448

Susan F.

chloride channel defect in, 325, 797
cystic fibrosis in, 325, 336, 345, 458, 795, 797, 801–802
genetic testing in, 336, 337, 345
protein malnutrition/metabolism in, 795, 801–802
Pseudomonas aeruginosa infection in, 325, 795

V

Vera L.

androgen excess in, 746, 747
hirsutism in, 719, 746
virilization in, 719, 741, 747

Victoria T.

DNA fingerprinting in case, 340, 345
rape and murder of, 325
semen/DNA samples from, 325, 334, 340, 345

W

Will S.

bilirubin levels in, 88, 89, 641, 644, 647, 948
cholecystitis/gallstones in, 88, 641, 644, 647, 948
iron chelation for, 129
sickle cell disease in, 381, 387
 genetic mutation in, 93, 96, 97, 222, 283, 326
 hemoglobin S (HbS) in, 93, 96, 97, 100–101, 118, 128, 222, 949
 vaso-occlusive crisis in, 88, 97, 100, 129
steatorrhea in, 645
stroke prevention in, 129

Subject Index

NOTE: Page numbers followed by *f* denote figures; page numbers followed by *t* denote tables.

A

- Abbreviations, for amino acids, 90, 91*f*
- Abdominal fat, 30–31
- Abetalipoproteinemia, 648, 650*t*, 696, 712*t*
- ABO blood groups, 588–589, 602–605, 602*f*, 604*t*
- Absorption, 3, 25, 26–27, 27*f*
 - amino acid, 25, 26, 794, 797–798
 - carbohydrate, 25, 26, 455, 464–468
 - cholesterol, 719–720
 - glucose, 455, 464–468, 624
 - iron, 940–941
 - lipid (fat), 26–27, 27*f*, 643–644
 - vitamin B₁₂, 856–857, 856*f*
- Absorptive state. *See* Fed state
- Abzymes, 141
- Acarbose, 458
- Acceptable macronutrient distribution range (AMDR), 11
- Acetaldehyde
 - adducts of, 755
 - in alcohol use disorder, 151, 190
 - ethanol oxidation to, 147, 147*f*, 151, 160, 163, 190, 755–760
 - metabolism to acetate, 755, 757
 - toxicity of, 755, 763–764
- Acetaldehyde dehydrogenase (ALDH), 755, 757
- Acetaminophen, 694*f*
 - detoxification, 984–985, 985*f*
- Acetate
 - acetaldehyde metabolism to, 755, 757
 - acetyl coenzyme A from, 511, 755, 757
 - fate of, 758
 - as fuel for skeletal muscle, 1014
- Acetic acid, 55, 56*t*, 57*f*
- Acetoacetate, 39, 39*f*, 68–70, 654, 668–669
 - alternative pathways of metabolism, 669
 - amino acid degradation to, 829, 829*f*, 838–842, 839*f*, 840*f*
 - assays/identification of, 68, 69, 79
 - oxidation of, 669
 - synthesis of, 668–669, 668*f*
- Acetoacetate decarboxylase, 615
- Acetoacetic acid, 56*t*, 60
- Acetoacetyl-CoA thiolase, 658*t*
- Acetoacetyl coenzyme A (acetoacetyl CoA), 668–669, 716
- Acetone, 39*f*, 68, 69, 668*f*
 - in diabetic ketoacidosis, 52, 68, 615, 616, 656
- Acetylation, 99*f*, 100, 290
 - and fatty acid oxidation, 673, 674*f*
 - histone, 299, 306, 306*f*, 673
- Acetylcholine (ACh), 191–192, 1034–1035
 - inactivation and degradation of, 1035, 1035*f*
 - in malathion poisoning, 148, 151
 - in muscle contraction, 1004–1005, 1005*f*
 - in myasthenia gravis, 183, 192, 205–207
 - as neurotransmitter, 191–192, 191*f*, 896–897, 1022, 1027, 1034–1035
 - paracrine signaling by, 192
 - synthesis of, 896–897, 1022, 1034–1035, 1035*f*
 - in tardive dyskinesia, 1035
- Acetylcholine receptors

- muscarinic, 192, 202
- in myasthenia gravis, 192, 205–207
- nicotinic, 191–192, 192*f*, 202
- Acetylcholinesterase, 148, 151, 192, 205–207, 1005, 1035, 1035*f*
- Acetylcholinesterase inhibition/inhibitors, 148, 148*f*, 192, 205–207, 1005
- Acetyl coenzyme A (acetyl CoA), 4*f*, 5, 28, 39
 - acetate conversion to, 511, 755, 757
 - acetylcholine synthesis from, 1034–1035, 1035*f*
 - amino acid conversion to, 413, 829, 829*f*, 838–842, 838*f*, 890, 891–892, 893*f*
 - in cellular respiration, 410–412, 412*f*
 - in cholesterol synthesis, 716, 720*f*, 721
 - fatty acid oxidation to, 413, 511, 656, 660–667 (*See also* Fatty acid oxidation)
 - in fatty acid synthesis, 679, 682–686
 - in gluconeogenesis, 617–618, 622
 - high-energy bonds of, 441, 441*f*
 - ketone bodies from and to, 511, 654, 655*f*, 668–669, 668*f*
 - mevalonate synthesis from, 721, 721*f*
 - PDC kinase inhibition by, 512–513
 - precursors of, 511–513
 - pyruvate carboxylase activation by, 513
 - pyruvate oxidation to, 511–513
 - release in β -oxidation, 660–661, 660*f*
 - sources of, 511, 512*f*
 - transport of, 513
 - in tricarboxylic acid cycle, 499, 500*f*, 501*f*, 511–513, 617–618
- Acetyl coenzyme A (acetyl-CoA) carboxylase, 775–777, 776*f*, 783*t*
 - in fatty acid synthesis, 679, 684, 684*f*, 775–777
 - in heart (cardiac muscle), 1007
 - in hepatic fibrosis, 767
 - in muscle, 1001, 1006, 1006*f*
- Achondroplasia, 385
- Acid anhydride, 69*f*
- Acid-base catalysis, 136, 140, 141, 143
- Acidic amino acids, 87, 91*f*, 92*t*, 93–95
- Acidosis
 - diabetic (*See* Diabetic ketoacidosis)
 - lactic (*See* Lactic acidosis)
- Acidosis, alcohol-induced (ketoacidosis), 755, 756, 762–763
- Acid(s), 51, 54–57. *See also specific acids*
 - blood, in healthy individual, 56*t*
 - conjugate, 55
 - dissociation of, 55–57, 56*f*
 - inorganic, 51, 55
 - metabolic, 51, 55, 57–60
 - metabolic production of, 888–889
 - organic, 55
 - strong, 51, 55–57, 56*t*
 - undissociated, 51
 - urinary excretion of, 51, 60
 - weak, 51, 55–57, 56*t*
- Aconitase, 501, 509
- Acquired immune deficiency syndrome. *See* HIV/AIDS
- Acrocentric chromosomes, 391
- Acromegaly, 913, 914, 915, 930*t*
- Actin
 - erythrocyte, 944, 945*f*
 - G-actin, 112, 113*f*
 - integrin binding to, 1048
 - in muscle contraction, 1001, 1005
- Actin filaments, 181, 190
- Actin fold, 107, 112–113, 113*f*
- Actin microfilaments, 181
- Action potential, 191, 191*f*, 1004–1005
- Activated protein C complex (APC), 969, 970
- Activation, 773, 783*t*. *See also specific processes*
- Activation energy, for enzymes, 136, 140, 140*f*
- Activation-transfer coenzymes, 142–144, 143*f*, 145*f*
- Activators, 261, 299, 308, 309*f*. *See also specific substances and processes*

- allosteric, 159, 165, 166–167, 167*f*
- Active site, of enzymes, 136, 138, 138*f*
- Active sulfate. *See* 3'-Phosphoadenosine 5'-phosphosulfate
- Active transport, 180, 186, 186*f*
 - of amino acids, 794
 - carbohydrate transport via, 455
 - and cell death, 449*f*
 - energy transformation for, 438
 - Na⁺-dependent, 455, 465
 - secondary, 190
- Active transport pumps, 186
- Acute cholecystitis, 641
- Acute pancreatitis, 641, 643, 648
- Acylcarnitine disorders, 659
- Acyl carrier protein (ACP), 685
- Acyl-CoA-cholesterol acyltransferase (ACAT), 725, 725*f*, 735
- Acyl-CoA dehydrogenases, 658*t*, 661
- Acyl-CoA synthetase, 654, 657–660, 657*f*, 658*t*, 663
- Acylglycerols, 75–76
- Acyltransferase, 152, 658*t*
- Adaptation, gene expression regulation for, 300
- Adaptive thermogenesis, 442
- Adducts, 755
- Adenine, 78, 80*f*, 214*t*
 - degradation of, 877–878
 - in DNA, 212, 214–217, 214*f*, 216*f*
 - pairing of, 215–217, 216*f*
 - in RNA, 222, 222*f*
- Adenine nucleotide translocase (ANT), 523, 538, 538*f*, 539, 539*f*
- Adenine phosphoribosyltransferase (APRT), 867, 872, 873*f*
- Adenocarcinoma, 227*t*
 - colon, 213, 222, 225, 353, 354
 - intestinal, 376*t*
 - lung, 234, 353, 354
- Adenoma, 213
- Adenomatous polyposis coli (APC), 365, 365*f*, 371
- Adenosine accumulation, in ADA deficiency, 879
- Adenosine deaminase (ADA)
 - defect or deficiency, 341, 867, 879–880, 881*t*
 - measuring activity of, 872
 - polyethylene glycol-modified, therapeutic use of, 879–880
 - in purine base salvage, 867, 872, 873*f*
- Adenosine diphosphate (ADP), 4, 4*f*
 - as allosteric activator, 166–167
 - ATP synthesis from, 433 (*See also* Adenosine triphosphate (ATP) generation)
 - concentration relationship with ATP and AMP, 488–489, 488*f*
 - cycle with ATP, 4, 4*f*, 433–450
 - in deoxyribonucleotide production, 867, 877
 - PDC kinase inhibition by, 512
 - in platelet, 963
 - in platelet activation, 964
 - regulation of, 867
 - in tricarboxylic acid cycle, 499, 510–511
- Adenosine diphosphate (ADP)-ribosylating factor, 189, 203
- Adenosine diphosphate (ADP)-ribosylation, 99*f*, 100, 290
- Adenosine kinase, 867, 872, 873*f*
- Adenosine monophosphate (AMP)
 - as allosteric activator, 166–167, 476, 489
 - concentration relationship with ATP and ADP, 488–489, 488*f*
 - degradation of, 877–878, 878*f*
 - in glycogen metabolism, 580–581, 580*f*, 1011, 1011*f*
 - glycogen phosphorylase activation by, 569, 1011–1012, 1011*f*
 - in muscle metabolism, 1011–1012, 1011*f*

 - phosphorylation of, 871
 - protein kinase activated by (*See* AMP-activated protein kinase)
 - in purine synthesis, 867, 869–872
 - synthesis of, 869, 869*f*

Adenosine monophosphate (AMP) deaminase, 877–878

Adenosine triphosphate (ATP)

- actin fold binding of, 112–113, 113*f*
- in aminoacyl-tRNA formation, 284, 284*f*
- available free energy from, 433
 - for biochemical work, 433
 - for mechanical work, 433
 - for transport work, 433
- buffer function of, 60
- cAMP synthesis from, 202–203, 203*f*
- chemical bond energy from
 - for biochemical work, 438–441
- change in free energy during reaction, 434–438
 - for mechanical work, 438
 - for transport work, 438
- cleavage or hydrolysis of, 433, 435, 435*f*, 441
- concentration relationship with ADP and AMP, 488–489, 488*f*
- in deoxyribonucleotide production, 877
- depletion, in hypoxia and cell death, 449, 449*f*
- electron transport chain for, 407–413, 522–531, 522*f*
- electron-transport chain for, 5
- energy available to do work, 434–438
 - as energy currency, 414, 433, 434
 - estimated daily use by tissue, 440
 - in glycogen metabolism, 579–581, 580*f*
 - in insulin secretion, 421, 422*f*
 - for muscle contraction, 438, 1005
 - PFK-1 regulation by, 476, 489, 489*f*
 - in platelets, 963
 - in purine synthesis, 867, 868*f*, 869
 - in pyrimidine synthesis, 874, 875*f*
 - as RNA precursor, 257

Adenosine triphosphate (ATP)-binding cassette (ABC) protein family, 719

Adenosine triphosphate (ATP) generation, 4–5, 4*f*, 28, 413, 442–446. *See also specific processes*

 - digestion of, 25, 26, 27*f*, 794–797
 - electrophoresis identifying, 95, 97
 - essential, 3, 11, 12, 827
 - fasting state, 38, 39, 40, 809*f*, 887–890, 887*f*
 - fed state, 25, 26*f*, 30, 809*f*
 - free, 12, 30, 827, 885–890
 - interorgan flux in postabsorptive state, 887–890, 887*f*
 - maintenance of pool in blood, 886–890, 887*f*
 - membrane attack/lipid peroxidation by, 551–552, 551*f*, 552*f*
 - source of, 885, 886, 887*f*
 - functional groups of, 87, 88*f*, 142, 142*t*
 - general properties of, 87
 - glucagon regulation by, 423
 - glucogenic, 612, 616, 621, 828, 829*f*
 - insulin regulation by, 422–423
 - ketogenic, 669, 828–829, 829*f*, 838–842, 839*f*
 - large neutral, 1026–1027
 - L-configuration of, 87, 89, 89*f*
 - modified, 88, 98–100, 99*f*, 279, 289–290
 - neurotransmitter, 896–897
 - nonessential, 827, 828*f*
 - nonpolar aliphatic, 90, 92*t*
 - oxidation of, 4–5, 4*f*, 413
 - peptide bonds of, 87, 89–90, 90*f*
 - posttranslational modifications of, 88
 - properties of, 92*t*
 - protein synthesis from, 279–294 (*See also* Protein synthesis)
 - replenishing pool of (protein turnover), 30, 40, 126, 794, 799–801
 - side chains of, 87, 88*f*, 89–90
 - classification of, 87, 90–95, 91*f*

- hydrophobicity of, 87, 90, 91*f*
- polarity of, 87, 90, 91*f*
- small neutral, 1027
- structure of, 6, 6*f*, 67, 78, 80*f*, 87, 88*f*, 89–90
- substitutions in primary structure, 87–88, 95–98
- sulfur-containing, 91*f*, 92*t*, 93, 93*f*
- synthesis of (*See* Amino acid synthesis)
- transport of, 794
 - active, 794
 - blood-brain barrier and, 1026–1027
 - into cells, 798
 - defects in, 798, 799, 802, 804*t*
 - facilitative transporters for, 794, 797, 797*f*, 798
 - sodium-dependent transporters for, 794, 797–798, 797*f*
 - systems of, 798*t*
- uncharged polar, 87, 91*f*, 92*t*
- zwitterions, 87, 88*f*, 89

Amino acid sequence. *See* Primary structure of proteins

Amino acid synthesis, 827

- α -ketoglutarate in, 828*f*, 833–836
- glucose conversion in, 407, 409*f*, 413, 827, 828–829, 831–833
- glutamate and, 812, 812*f*, 833–836, 835*f*
- glycolytic pathway of, 827, 828–829, 831–833, 832*f*
- oxaloacetate in, 828*f*, 833, 836, 836*f*
- regulation of, 827
- TCA cycle intermediates and, 513, 514*f*, 827, 833–836

Aminoacyl (A) site, on ribosome, 285, 285*f*, 287, 289*f*

Aminoacyl-transfer RNA, 279, 281, 283–288

- binding to A site, 287, 289*f*
- formation of, 283–284, 284*f*

Aminoacyl-tRNA synthetases, 283–284, 284*f*

Amino groups, 67, 69*f*, 87, 88*f*, 89–90

Aminolevulinic acid (ALA), 939–940, 940*f*

Aminopeptidases, 794

Amino sugars, 67, 74, 74*f*

Amino terminal, 90

Aminotransferases, 152, 153*f*, 810. *See also specific types*

Ammonia

- blood concentration of, 813–814
- conversion to urea, 38, 813–814, 986 (*See also* Urea cycle)
- fixing of, 812, 818–819
- nitrogen removal as, 36, 810–812, 811*f*
- renal metabolism of, 891, 891*f*

Ammonia toxicity, 38, 813–814, 816, 818–819, 822*t*, 889, 896–897

Ammonium ions, 51, 56*t*, 60, 810

Amniocentesis, 393–394, 401

Amoebiasis, 979, 980, 981, 982, 996*t*

AMP-activated protein kinase (AMPK), 705, 784–785, 908

- activation of, 767
- in autophagy, 800*f*
- in fatty acid oxidation, 665*f*, 1001
- in hepatic fibrosis, 767
- in muscle metabolism, 1001, 1006, 1006*f*, 1009–1010

Amphipathic compounds, 642, 680

Amplification

- of DNA sequences, 332–334
 - cloning for, 332–333, 332*f*
 - libraries for, 333
 - polymerase chain reaction for, 333–334, 334*f*
- feedback, in coagulation, 968–969
- of genes, 306, 307–308, 324
- of proto-oncogenes, 356–357
- in signal transduction, 426

Amygdalin (Laetrile), 532

Amylase, 641

- blockers of, 458
- pancreatic, 641
- pancreatic α , 455, 458, 459*f*

- salivary, 641
- salivary α -, 26, 455, 458, 459*f*
- Amylin, 911, 925*t*
- Amylin analog, 911
- Amylo-1,6-glucosidase, 573, 574*t*
- Amylo-4,6-glucosidase, 574*t*
- Amyloid, 108, 111, 121
- Amyloidosis, 108, 111, 121, 129, 132*t*
- Amylopectin, 75, 455
 - consumption of, 458
 - digestion of, 458, 459*f*
 - structure of, 455, 456*f*, 458
- Amylose, 455
 - consumption of, 458
 - digestion of, 458, 459*f*
 - structure of, 456*f*, 458
- Amyotrophic lateral sclerosis (ALS), 557, 564*t*
- Anabolic hormone, insulin as, 414, 417, 569–570, 581, 909, 910*t*
- Anabolic pathways, 1, 433, 438, 478
- Anabolic steroids, 569–570
- Anaerobic glycolysis, 407, 408*f*, 442, 446, 446*f*, 475–477, 475*f*, 484–485
 - acid production in, 485
 - energy yield of, 530–531
 - during exercise, 1011–1013
 - in eye, 486
 - in heart, 486
 - lactate dehydrogenase in, 475, 484*f*, 485–486
 - lactate fate in, 486, 1011–1012
 - NADH fate in, 484
 - pyruvate fate in, 485
 - in skeletal muscle, 485, 1007, 1011–1013
 - AMP activation in, 1011, 1011*f*
 - from glycogen, 1011, 1011*f*
 - during high-intensity exercise, 1012–1013
 - at onset of exercise, 1010
 - in type IIB fast-twitch glycolytic fibers, 1010
 - tissues dependent on, 485, 485*t*
- Analbuminemia, 961
- Anaplerotic reactions, 499, 513–514, 515*f*, 1039
- Andersen disease, 574*t*
- Androgen insensitivity, 313, 320*t*
- Androgen(s), 744*f*
 - synthesis of, 741*t*, 743*f*
- Android pattern, of fat storage, 30
- Androstenedione, 742, 743*f*, 744*f*, 745
- Anemia(s), 907, 934, 937
 - in anorexia nervosa, 300, 319, 320*t*, 516
 - classification of, 937, 937*t*
 - electron transport in, 523
 - hemolytic, 907, 937, 944, 949, 951–952
 - hereditary, 907, 934
 - hypochromic, 319, 937, 937*t*
 - iron-deficiency (*See* Iron deficiency)
 - macrocytic, 937, 937*t*
 - megaloblastic, 14*t*, 849–850, 850, 855, 948
 - microcytic, 937, 937*t*
 - normochromic, 937, 937*t*
 - normocytic, 937, 937*t*
 - nutritional, 948
 - pernicious, 856, 858, 863*t*
 - sickle cell (*See* Sickle cell anemia)
 - thalassemia (*See* Thalassemia)
- Aneuploid, 392
- Aneuploidy, 380, 382, 392, 392*t*
- Angelman syndrome, 307, 320*t*, 399, 3944
- Angina, 88
- Angina pectoris, 88, 434
- Angiogenesis, tumor, 354, 1050

Angiogenesis inhibitors, 1050
Anhydride, formation of, 70, 71*f*
Animals
 carbohydrates from, 458
 transgenic, 340, 343
Anion gap, 81, 756
Anion(s)
 in biomolecules, 69, 70*f*
 distribution in body fluids, 53, 54*t*
Ankyrin, 944, 945*f*, 952
Annealing (hybridization), 219, 220*f*, 327, 327*f*
Anorexia nervosa, 20*t*, 42–43, 175*t*, 208*t*
 anemia in, 300, 319, 320*t*, 500, 516
 ATP generation in, 413
 chemical messengers in, 183, 191, 195, 196, 206
 glucokinase activity in, 162, 163
 glucose levels in, 614, 625, 633*t*
 metabolism in, 160, 172, 174
 transcription factors in, 313, 314*f*
 vitamin deficiencies in, 500, 505, 516, 518*t*
Anoxia, 413
Anthropometric measurements, 31
Antibiotics
 for pneumonia, 280, 287, 292
 protein synthesis as target of, 224, 225, 287, 293–294, 293*t*
 resistance to, 293–294
Antibodies, 962. *See also* Immunoglobulin(s)
 catalytic, 141
 production of
 gene rearrangement in, 307, 307*f*
 posttranscriptional processing in, 314, 315*f*
Antibody-antigen complex, 962
Antibonding electrons, 548
Anti-CD20 antibody, 300
Anticholinergic agents, 151
Anticipation, 381, 397

 - to glucose, 479, 621, 623–624
 - to glyceraldehyde 3-phosphate, 587*f*, 588
 - to triose phosphates, 479, 480*f*
 - to UDP-glucose, 409, 410*f*
 - deficiency of, 939
 - in fasting state, 627–628
 - feedback regulation of, 161, 162
 - formation of, 407, 421, 475
 - genetic mutations in, 939
 - in gluconeogenesis, 479, 615, 616*f*, 779*f*
 - glucose conversion to, 407, 421, 446, 446*f*, 475, 479, 479*f*, 568
 - glucose 1-phosphate conversion to and from, 568, 570, 571, 579
 - in glycogen metabolism, 479, 568, 570, 571, 571*f*, 579
 - in glycolysis, 407, 475–476, 475*f*, 479, 479*f*, 480*f*, 779*f*
 - hexokinase inhibited by, 475, 488–489
 - metabolism of, 161, 162, 407–409, 479, 479*f*
 - in pentose phosphate pathway, 408*f*, 409, 409*f*, 479, 587–594, 587*f*, 589*f*
 - polarity and solubility of, 70, 71*f*
 - product inhibition by, 165
 - in red blood cells, 939
 - supply of, regulation of, 487
- Glucose 6-phosphate dehydrogenase, 593–594, 683, 775, 776*f*, 777, 783*t*, 939, 988
 - deficiency, 588–589, 593, 603–604, 607*t*, 955*t*
- Glucose tolerance, impaired, 61
- “Glucose toxicity,” 1060
- Glucose transporters, 421, 455, 464–468
 - blood-brain barrier and, 468, 468*f*, 1026
 - cardiac, 1007
 - cholera and, 470
 - deficiency of, 1026, 1044*t*
 - facilitative, 455, 466, 466*f*, 467*t*
 - fructose, 481
 - galactose and fructose absorption through, 466
 - Na⁺-dependent, 455, 465, 466*f*, 470
 - tissue specificity of, 467–468, 467*f*
- Glucosidase, 573, 574*t*
- Glucuronate, 595–597, 595*f*, 596*f*
- Glucuronic acid, 74, 75*f*, 1054*f*, 1055
- Glucuronides, 588, 595–597, 596*f*, 597*t*, 944
- Glutamate, 91*f*, 92*t*, 93, 1035–1036
 - α-ketoglutarate conversion to, 513, 817, 1035–1036
 - in amino acid nitrogen metabolism, 810–812, 810*f*, 811*f*, 812*f*, 813*f*
 - amino acids related through, 812, 812*f*, 833–836, 835*f*
 - ammonia toxicity and, 818
 - deamination of, 810–812, 811*f*
 - degradation of, 829, 829*f*, 833–835
 - excitotoxicity of, 1022, 1038
 - functions of, 827
 - GABA synthesis from, 1036, 1036*f*
 - histidine conversion to, 829
 - as neurotransmitter, 896, 1022, 1027, 1035–1036
 - in sickle cell hemoglobin, 93, 95
 - storage and release of, 1036

- synthesis of, 827, 828*f*, 833–835, 1035–1036, 1036*f*
- TCA cycle intermediates and, 513, 1039
- transamination to, 810, 810*f*
- transport of, 1036
 - in urea cycle, 812, 813*f*
- Glutamate dehydrogenase, 808, 810–812, 812*f*, 835, 1035, 1036*f*
- Glutamate-oxaloacetate transaminase, 153*f*
- Glutamate semialdehyde, 816, 816*f*, 835–836, 835*f*
- Glutaminase, 808, 812, 813, 814*f*, 818, 835, 835*f*
- Glutamine, 91*f*, 92*t*, 93
 - α -ketoglutarate conversion to, 513, 817
 - ammonia toxicity and, 818
 - deamination of, 812
 - degradation of, 829, 829*f*, 835, 835*f*
 - functions of, 885, 889, 890*t*
 - glutamate synthesis from, 1036, 1036*f*
 - glutamate transport in, 1036
 - metabolism of
 - brain, 897, 897*f*
 - fasting state, 887–890, 887*f*
 - hypercatabolic states, 898–899
 - muscle, 885, 889, 891–894
 - renal, 891, 891*f*, 892*f*
 - in sepsis and trauma, 885, 885*f*, 898–899
 - nitrogen transport by, 808, 812–813, 885
 - oxidation of, 808
 - in purine synthesis, 867, 867*f*, 868*f*, 869–872, 869*f*
 - in pyrimidine synthesis, 874, 875*f*
 - synthesis of, 808, 813, 814*f*, 828*f*, 835, 835*f*
 - and TCA cycle, 513
- Glutamine phosphoribosylamidotransferase, 869, 869*f*, 871–872, 871*f*
- Glutamine synthase, 808, 812, 813, 814*f*
- Glutamine synthetase, 835, 835*f*
- Glutathione
 - defense system, 547, 557–558, 558*f*, 587, 592–593, 593*f*
 - hepatic usage of, 987
 - synthesis of, 802–803, 803*f*, 833–835
- Glutathione peroxidase, 547, 557–558, 558*f*
- Glutathione reductase, 557–558, 558*f*, 987
- GLUT 1 transporter, 466, 467*t*, 468, 1007, 1026
- GLUT 2 transporter, 421, 466, 467*t*, 468
- GLUT 3 transporter, 466, 467*t*, 468, 1026
- GLUT 4 transporter, 466, 467*f*, 467*t*, 468, 1007
- GLUT 5 transporter, 466, 467*t*, 481
- GLUT 1 transporter deficiency, 1026, 1044*t*
- Glycated hemoglobin (A1C), 127, 129
- Glycated proteins, 126*f*, 127
- Glycation. *See* Glycosylation
 - nonenzymatic, 126*f*, 127
- Glycemic index, 464, 465*t*
- Glyceraldehyde, D- and L-forms of, 71–72, 72*f*
- Glyceraldehyde 3-phosphate, 479, 480*f*, 481–482, 482*f*, 587*f*, 588, 779*f*
 - generation of ribose 5-phosphate from, 592, 592*f*
 - ribulose 5-phosphate conversion to, 590–591, 591*f*
- Glyceraldehyde-3-phosphate dehydrogenase, 480, 484, 493–494, 494*f*
- Glycerol, 67
 - fasting state, 36, 38, 39, 628
 - for gluconeogenesis, 612, 616, 617, 617*f*, 621
 - synthesis of phospholipids containing, 699–703
 - as triacylglycerol backbone, 6, 6*f*, 75–76, 77*f*, 640, 641, 641*f*
 - triacylglycerol release of, 680, 680*f*
- Glycerolipids. *See also* Glycerophospholipids
- Glycerol kinase, 695, 696*f*
- Glycerol 3-phosphate
 - in gluconeogenesis, 614, 617*f*
 - in glycerophospholipid synthesis, 680
 - shuttle, in glycolysis, 475, 475*f*, 530, 530*f*
 - in triacylglycerol synthesis, 680, 695, 696*f*

Glycerol 3-phosphate acyltransferase (GPAT), 784

Glycerophospholipids

- degradation of, 704
- ether, 680–681
- metabolism of, 680–681, 699–704
- structure of, 680, 681*f*
- synthesis of, 680–681, 699–701, 700–702*f*
- types of, 700*f*

Glycine, 90, 91*f*, 92*t*, 1037

- in bile salt conjugation, 726, 728*f*
- in collagen, 1049, 1062
- in creatine synthesis, 1008*f*, 1009
- degradation of, 828–829, 829*f*, 832*f*, 833
- disorders of, 844*t*
- functions of, 827
- in heme synthesis, 907, 934, 939–940, 940*f*
- as neurotransmitter, 896, 1022, 1027, 1037
- as one-carbon group recipient, 853, 854*f*, 854*t*
- as one-carbon group source, 849, 849*f*, 853, 853*f*, 854*t*
- in osteogenesis imperfecta, 1062
- in purine synthesis, 867, 867*f*, 868*f*, 869, 869*f*
- synthesis of, 827, 828*f*, 831–833, 832*f*, 1022, 1037

Glycine transaminase, 844*t*, 845*t*

Glycocalyx, 184, 184*f*

Glycochenodeoxycholic acid, 726

Glycocholic acid, 726, 728*f*

Glycogen, 3, 5, 5*f*, 7–8, 7*t*, 568–586, 773

- anorexia nervosa and, 161
- degradation of, 568–573, 571*f*, 573*f* (*See also* Glycogenolysis)
- as emergency fuel in glycolysis, 476–477, 570
- fasting state, 36–40, 573–574, 575*t*, 612, 627
- fed state, 25, 26*f*, 574, 575*t*, 612, 774–777
- function of, 570–571
- glycosidic bonds of, 568, 568*f*, 572, 572*f*
- hepatic metabolism of, 36–40, 569, 570, 573–579, 575*t*, 577*f*, 612, 774–777
 - blood glucose levels and, 578
 - calcium and, 578, 579*f*
 - diabetes mellitus and, 578
 - epinephrine and, 577*f*, 578–579, 579*f*, 917, 918*f*
 - fasting state, 36–40, 573–574, 575*t*, 612, 627
 - fed state, 774–777
 - glucagon in, 569, 573–574, 576–578, 577*f*, 909, 912
 - insulin in, 569, 573–574, 575, 578, 909, 911
 - mechanisms affecting, 774–777
 - nomenclature for enzymes in, 576
 - phosphorylation in, 576, 577*f*
 - protein phosphatases in, 577–578
- hepatic stores of, 7, 7*t*, 28, 409, 568, 570, 570*f*, 774
- metabolic capacities of various tissues, 40*t*
- metabolic disorders of, 573, 574*t*
- muscle metabolism of, 568–570, 570*f*, 574, 575*t*, 579–581, 580*f*, 1011–1012
 - AMP activation of, 1011, 1011*f*
 - ATP availability and, 579–580
 - calcium and, 569, 574, 581
 - diabetes mellitus and, 578
 - epinephrine and, 569, 574, 917, 918*f*, 1011–1012, 1012*f*
- muscle stores of, 7, 7*t*, 409, 568–569, 570, 570*f*, 1011
- neonatal stores of, 569, 581
- nonreducing ends of, 570, 572, 572*f*
- polymers and particles of, 570
- structure of, 568, 568*f*, 570
- synthesis of (*See* Glycogen synthesis)

Glycogenin, 572

Glycogenolysis, 36–40, 161, 410, 410*f*, 414, 568–581, 571*f*, 573*f*

- debranching enzyme in, 568, 571, 571*f*, 572–573, 573*f*
- disorders of, 573, 574*t*
- epinephrine in, 569
- gluconeogenesis activation with, 570

glucose 6-phosphate in, 479, 568, 570
 in liver, 569, 570, 570*f*, 573–579, 575*t*, 577*f*
 blood glucose levels and, 578, 985–986
 calcium and, 578, 579*f*
 diabetes mellitus and, 578
 epinephrine and, 577*f*, 578–579, 579*f*
 fasting state, 36–40, 574, 575*t*, 612, 627
 glucagon and, 569, 573–574, 576–578, 577*f*, 909, 912
 insulin and, 569, 573–574, 576, 578, 909, 911
 nomenclature for enzymes in, 576
 phosphorylation and, 576, 577*f*
 protein phosphatases and, 577–578
 regulation of, 573–579, 575*t*
 in muscle, 568–570, 570*f*, 574, 575*t*, 579–580, 580*f*, 1011–1012
 AMP activation of, 1011, 1011*f*
 ATP availability and, 579–580
 calcium and, 569, 574, 581
 diabetes mellitus and, 578
 epinephrine and, 569, 574, 1011, 1012*f*
 regulation of, 574, 575*t*, 579–581
 regulation of, 573–581
 Glycogen phosphorylase, 568–569, 571*f*, 572, 573*f*, 574*t*, 783*t*
 covalent modification of, 576
 disorders of, 573, 574*t*
 in liver, 576–578, 577*f*
 in muscle, 168, 169, 169*f*, 569, 580–581, 1011–1012, 1011*f*
 protein phosphatases and, 577–578
 Glycogen phosphorylase a, 576
 Glycogen phosphorylase b, 576
 Glycogen phosphorylase kinase, 169
 Glycogen storage diseases, 573, 574*t*, 583*t*
 type II, 573
 type III, 575
 type V, 574, 574*t*
 type VI, 574*t*
 von Gierke disease, 574*t*, 578
 Glycogen synthase, 152, 568, 571*f*, 572, 572*f*, 574*t*, 576–578, 775, 1011
 covalent modification of, 576
 diabetes mellitus and, 578
 inhibition of, 576, 577*f*, 582
 muscle, 580
 protein phosphatases and, 577–578
 regulation of, 775, 775*f*, 783*t*
 Glycogen synthase a, 576
 Glycogen synthase b, 576, 578
 Glycogen synthase kinase-3 (GSK-3), 582
 Glycogen synthesis, 28, 409, 410*f*
 activated intermediates in, 439–440, 439*f*
 branching enzyme in, 568, 571*f*, 572
 energetics of, 439–440, 439*f*
 Gibbs free energy change in, 439–440
 glucose 6-phosphate in, 479, 568, 571, 571*f*
 in liver, 36–40, 569, 570, 570*f*, 574–579, 575*t*, 577*f*
 blood glucose levels and, 578, 985–986
 calcium and, 578, 579*f*
 diabetes mellitus and, 578
 epinephrine and, 577*f*, 578–579, 579*f*
 fasting state, 36–40, 573–574, 575*t*, 612, 627
 fed state, 774–777
 glucagon in, 569, 573–574, 576–578, 577*f*, 909, 912
 insulin in, 569, 573–574, 576, 578, 909, 911
 mechanisms affecting, 774–777
 nomenclature for enzymes in, 576
 phosphorylation in, 576, 577*f*
 protein phosphatases in, 577–578
 in muscle, 568–570, 570*f*, 574, 575*t*, 579–580, 580*f*
 ATP availability and, 579–580
 calcium and, 569, 574, 581

- diabetes mellitus and, 578
- epinephrine and, 569, 574
- phosphoglucomutase reaction in, 437, 441, 571, 571*f*
- phosphoglucomutase reaction in, 437*f*, 568–581, 571*f*, 572*f*
- phosphoryl transfer reactions in, 439–440, 439*t*
- regulation of, 571, 573–581
 - insulin/glucagon ratio in, 569, 573–574
 - in liver, 574–579, 575*t*
 - in muscle, 574, 575*t*, 579–581
- UDP-glucose in, 409, 439, 439*f*, 568, 571–572, 571*f*, 572*f*
- Glycolipids, 67, 184, 184*f*, 602–603
 - as cell recognition factors, 588
 - digestion of, 455
 - function of, 602
 - structure of, 602, 602*f*, 681*f*
 - synthesis of, 409, 410*f*, 588, 681
 - sugar precursors for, 598, 598*t*, 600*f*
- Glycolysis, 28, 29, 407–409, 413*f*, 475–495, 989
 - as anabolic pathway, 478
 - anaerobic (*See* Anaerobic glycolysis)
 - anorexia nervosa and, 161
 - ATP generated in, 29, 407, 413, 446, 446*f*, 475, 475*f*, 530–531
 - ATP-generating phase of, 478, 478*f*
 - biosynthetic function of, 478, 486, 487*f*
 - capacities of various tissues, 40*t*
 - for fatty acid synthesis, 683, 683*f*
 - functions other than ATP generation, 476, 486, 487*f*
 - gluconeogenesis as reversal of, 612, 613*f*, 615–616, 618
 - glucose conversion to glucose 6-P in, 479, 479*f*, 480*f*
 - glucose 6-P conversion to triose phosphates in, 479, 480*f*
 - glycogen as emergency fuel in, 476–477, 570
 - hexokinase initiation of, 475, 475*f*
 - high-energy bonds in, 480–481, 493–494
 - intermediates of
 - amino acids from, 827, 828–829, 831–833, 832*f*
 - fructose conversion to, 476, 476*f*, 478, 481–482, 482*f*
 - galactose conversion to, 476, 478, 482, 483*f*
 - generation of ribose 5-phosphate from, 592, 592*f*
 - ribulose 5-phosphate conversion to, 590–591, 590*f*, 591*f*
 - muscle, 489, 1006
 - in cardiac muscle, 486, 490, 1006, 1007
 - in skeletal muscle, 486, 1006, 1007, 1010–1013
 - overview of, 475, 475*f*
 - oxidation in, 479–4481, 480*f*
 - oxidative fates of pyruvate and NADH in, 84, 483*f*
 - pentose phosphate pathway and, 587–594, 587*f*
 - preparative phase of, 478, 478*f*, 480*f*
 - pyruvate generated for fatty acid synthesis in, 476, 478, 486
 - rate-limiting enzyme in (PFK-1), 475–476, 476, 476*f*, 480*f*, 487, 490–491
 - reactions of, 478–481
 - in red blood cells, 907, 934, 938–939, 938*f*
 - regulation of, 487–491
 - enzyme activity/amount in, 621, 622*f*, 623*t*
 - isoenzymes in, 487–489
 - major sites of, 487, 488*f*
 - PFK-1, 488*f*, 490–491, 490*f*, 779*f*
 - regulation of hexokinases, 488–489, 488*f*
 - regulation of pyruvate kinase, 491
 - relationships among ATP, ADP, and AMP concentrations, 487, 488*f*
 - shuttle systems in, 475, 475*f*, 484
 - substrate-level phosphorylation in, 413, 475, 476*f*, 477–481, 480*f*
 - summary of pathway, 481
 - TCA cycle link to, 499, 511, 513
- Glycopeptide transpeptidase, 148*f*
- Glycophorin, 185*f*
- Glycoprotein Ia, 964
- Glycoprotein(s), 67, 75, 184, 184*f*, 600–602
 - distribution in body, 588

- function of, 600
- in hepatic fibrosis, 995–996
- plasma, 961 (*See also* Plasma proteins)
- structure of, 600, 600*f*
- synthesis of, 409, 410*f*, 588, 600–602, 987
 - dolichol phosphate in, 600–602, 601*f*
 - sugar precursors for, 598, 598*t*, 600*f*
- Glycosaminoglycans, 74, 595*f*, 908, 1048, 1053–1057
 - functions of, 1055, 1055*t*
 - repeating disaccharides of, 1053–1055, 1054*f*
 - types of, 1055

N

- N*-acetyl cysteine, 985, 985*f*
- N*-acetyl galactosamine, 600, 602*f*, 603, 1053, 1054*f*
- N*-acetyl glucosamine, 600, 1053–1055, 1054*f*
- N*-acetylglucosamine 6-phosphate, 598, 600*f*
- N*-acetyl glutamate (NAG), 816, 817*f*
- N*-acetylneuraminic acid (NANA), 588, 598–603, 704
- N*-acetyl-*p*-benzoquinoneimine (NAPQI), 984–985, 985*f*
- N*-acetyltransferases, 598
- NAD⁺

- in ATP-ADP cycle, 433
- binding fold for, 112*f*, 113
- in cellular respiration, 410, 412*f*
- as coenzyme, 146–147, 146*f*, 152
- in electron transport chain, 433
- in ethanol metabolism, 147, 160, 165, 755, 761–763
- in glycolysis, 478, 480
- NADH reoxidation to, 484
- in oxidation-reduction reactions, 442–443, 443*f*, 445–446
- synthesis of, 147
- in tricarboxylic acid cycle, 499, 501, 504–505
- Na⁺-dependent transporters, 455, 465, 466*f*, 470
 - amino acid transport in, 794, 797–798, 797*f*
- NADH, 524
 - in amino acid oxidation, 413
 - in anaerobic glycolysis, 475, 484–485
 - in β-oxidation, 413
 - in electron transport chain, 413, 522–523, 524, 529
 - in ethanol metabolism, 147, 160, 165, 755, 761–763
 - in fatty acid desaturation, 686, 689*f*
 - in fatty acid oxidation, 654, 655*f*
 - β, 660–661, 660*f*, 663–664
 - peroxisomal, 666–667, 990
 - in fuel oxidation, 442–445
 - in gluconeogenesis, 617, 617*f*
 - in glycolysis, 413, 475, 475*f*, 480
 - in hemoglobin synthesis, 934
 - in ischemic conditions, 1007
 - isocitrate dehydrogenase regulation by, 510–511, 511*f*
 - in ketone body metabolism, 669, 670, 671*f*
 - in lactic acidosis, 533
 - in oxidation-reduction reactions, 442–444, 443*f*
 - oxidative fate of, 484
 - in oxidative phosphorylation, 522–523, 522*f*, 524, 530
 - PDC kinase inhibition by, 512–513
 - in pentose phosphate pathway, 588
 - product inhibition by, 165
 - shuttle systems for, 475, 475*f*, 483*f*, 484, 530, 531*f*
 - in tricarboxylic acid cycle, 499, 500*f*, 501, 505, 510–511
- NADH:CoQ oxidoreductase, 524, 524*f*, 526, 528–529
- NADH dehydrogenase, 524, 526, 527*f*
- NADH/NAD⁺ ratio, ethanol and, 761–763
- NADPH
 - in cholesterol synthesis, 721, 722–723, 723–724
 - in fatty acid β-oxidation, 667
 - in fatty acid synthesis, 587, 592–594, 679, 683–686, 683*f*
 - in fuel oxidation, 434, 442
 - functions of, 587, 592–593
 - generation in pentose phosphate pathway, 409, 409*f*, 587, 587*f*, 589–590, 589*f*, 592–594, 988
 - generation of, 710, 710*f*
 - in glutathione defense system, 587, 592–593, 593*f*
 - hepatic demand for, 988
 - in insulin release, 421
 - in oxidation-reduction reactions, 443*f*, 445–446
 - pathways requiring, 593*t*
 - and red blood cells, 592–593, 593*f*, 907, 934

Phosphodiester bonds, 212, 212f, 216f, 219, 222
 cleavage of, 326, 326f
Phosphoenolpyruvate carboxykinase (PEPCK), 314f, 317, 428, 619, 619f, 622–623, 623t, 779f, 783t
Phosphoenolpyruvate (PEP)
 conversion to fructose 1,6-bisphosphate, 620, 620f
 conversion to pyruvate, 480–481, 480f
 enzyme activity states and, 621–623
 in fasting state, 627
 generation from gluconeogenic precursors, 619, 619f
 in gluconeogenesis, 618–623, 618f, 779f
 in glycolysis, 480–481, 480f, 779f
 high-energy bonds of, 441f
 oxaloacetate conversion to, 619, 619f
 pyruvate conversion to, 618–619, 618f, 621–623
Phosphoester, 69f, 70, 71f
Phosphofructokinase-1 (PFK-1), 775, 779f
 deficiency of, 574t
 in glycolysis, 475–476, 475f, 480, 480f, 487, 490–491, 989
 inhibition at citrate site, 491
 isoenzyme subunits of, 490
 in muscle metabolism, 1011, 1011f, 1012, 1015
 regulation of, 488f, 490–491, 490f, 783t
Phosphofructokinase-2 (PFK-2), 490–491, 775, 783t, 989, 1001, 1006, 1009
Phosphoglucomutase, 437, 437f, 441, 571, 571f, 573
 inhibition, 597, 598
Phosphoglycerate mutase, 574t
Phosphoglycerides. *See* Phosphoacylglycerols
Phospholamban, 427
Phospholipase A₁
 in degradation of glycerophospholipids, 704, 704f
Phospholipase A₂, 640, 643, 688, 643f, 690f
 in degradation of glycerophospholipids, 704, 704f
Phospholipase C, 688, 690f
Phospholipase(s), 680
Phospholipids, 28
 in coagulation, 960
 digestion of, 640
 in plasma membrane, 184–185, 184f
Phosphoribosyl pyrophosphate (PRPP), 867, 868f, 869–872, 874, 876–877
 in gout, 879
 reaction with glutamine, 869, 869f
 regulation of, 871–872, 871f
 synthesis of, 869, 869f
 synthetase, 867, 869, 869f, 871–872, 871f
Phosphoribosyltransferases, 867, 872, 873f
Phosphorus
 functional groups, 67
 function of, 15
Phosphorus deficiency, 15
Phosphorylase kinase, 574t, 576–578, 577f, 783t
Phosphorylases. *See also specific types*

- purine nucleotide cycle in, 867, 872, 874*f*, 891–894, 894*f*, 1015
- striations of, 1002, 1003*f*
- thyroid hormone and, 923
- training effects in, 1015–1016

Skin cancer, 355

- melanoma, 234, 243, 249, 252*t*, 353, 373
- UV radiation and, 243, 355

Skinfold thickness, 31

Sliding filament system, in muscle contraction, 1001, 1005

Slow-oxidative fibers, 490, 908, 1001–1003, 1003*t*

Smad proteins, 197, 197*f*, 313, 371

Small interfering RNA (siRNA), 324, 340

Small intestinal disaccharidases, 458–461

Small neutral amino acids, 1027

Small nitrogen-containing neurotransmitters, 1022, 1027–1037

Small nuclear ribonucleoproteins (snRNPs), 225, 267*f*, 268

Smith-Magenis syndrome, 394*t*

Smith proteins, 268

Smoking

- and COPD, 476
- and lung cancer, 234, 242, 250, 371

Smooth endoplasmic reticulum, 180*f*, 190, 190*f*

Smoothened receptors, 364–365, 365*f*, 371

Smooth muscle, 1001, 1003–1004, 1003*f*

Smooth muscle contraction, eicosanoids in, 688

Snurps (small nuclear ribonucleoproteins), 225, 267*f*, 268

SOCS (suppressor of cytokine signaling), 947, 947*f*

Sodium chloride, dissociation of, 54

Sodium-iodide transporter, 920–921

Sodium (Na⁺)-dependent transporters, 455, 465, 466*f*, 470

- amino acid transport in, 794, 797–798, 797*f*

Sodium-potassium-ATPase pump, 433, 438, 465, 798, 924

Sodium-potassium pump, 53

Sodium/sodium ions (Na⁺)

- in action potential, 191–192, 192*f*
- cotransport with amino acids, 797–798, 797*f*
- dietary guidelines on, 18
- distribution in body fluids, 53, 54*t*
- function of, 15
- in hypoxia and cell death, 449, 449*f*

Solenoid, 220, 221*f*

Solubility

- bond polarity and, 70, 71*f*
- of globular proteins, 113–114

Soluble fiber, 463
Solvent(s)
 protein denaturation in, 127
 water as, 51, 52, 53
Soma, 1024, 1024*f*
Somatic cells, 380
Somatocrinin (GHRH), 914
Somatomedins (insulin-like growth factors), 907, 913, 914–917, 915*f*, 916*f*
Somatostatin, 910*t*, 912–913, 925*t*
 biochemistry of, 912
 counterregulation by, 907, 909, 910*t*
 and growth hormone, 913, 914
 physiologic effects of, 912–913
 secretion of, 912
Somatostatin analogs, 913
Sorbitol, 74, 75*f*, 476, 482
SOS, 198, 198*f*
Southern, E. M., 328
Southern blots, 328, 329*f*
Specialization, cellular and tissue, 1
Specificity, 426
 of enzymes, 137, 138–140, 138*f*, 144
 of β -oxidation, 658*t*, 661, 990
 of receptors, 183
Spectrin, 185*f*, 186, 944–945, 945*f*
Spectrin deficiency, 935, 951–952
Spermatozoa, fructose as fuel for, 482
Sperm cells, 220
S phase of cell cycle, 233, 238, 238*f*
Spherocytes, 934, 935
Spherocytosis, 935, 951–952, 955*t*
Sphingolipidoses, 292, 603, 603*t*, 607*t*. *See also* Tay-Sachs disease
Sphingolipids
 degradation of, 704
 in intercellular communication, 704
 metabolism of, 699–704
 synthesis of, 704
 types of, 700*f*
Sphingolipid(s), 67, 76–77, 78*f*, 602
 in brain, 1040
 metabolism of, 681
 in plasma membrane, 184
 structure of, 681*f*
 synthesis of, 588, 602–603, 681
Sphingomyelin, 77, 78*f*, 184–185, 681, 681*f*
 in brain, 1040–1041
Sphingosine, 76–77, 78*f*, 184, 602, 681, 681*f*
Spina bifida, 850, 859–860
Spino and bulbar muscular dystrophy, 397
Spinocerebellar ataxia, 397
Spin restriction, 548
Spleen
 enlarged, 935, 951–952
 in sickle cell anemia, 97, 644
Splice-junction mutations, in β -thalassemia, 266, 949
Splice junction(s), 266, 266*f*
Spliceosome, 266
Splicing reactions, 256, 265, 267*f*, 314, 315*f*
Sporadic retinoblastoma, 363, 363*f*
Squalene, 716, 721–723
 condensation of isoprenes to, 721–722, 723*f*
 conversion to steroid nucleus, 722–723, 723*f*
 structure of, 722–723, 723*f*
SREBP cleavage-activating protein (SCAP), 724, 724*f*
Stability
 of mRNA, 317–318
 of protein, 107, 115
Stable conformation, 107

Staphylococcus aureus, 588–589, 603–604
Starch, 5, 5f, 407
 consumption of, 458
 digestion of, 26, 455, 458, 459f
 indigestible, 461, 462f
 metabolism by colonic bacteria, 461
 structure of, 455, 456f, 458
Starch blockers, 458
Starling's forces, 961
Start codon, 223, 223f, 279
Start point of transcription, 256, 256f, 257–258
Starvation (prolonged fasting), 36, 39–42, 41f, 42t
 adipose tissue in, 40–42
 anorexia nervosa and, 42–43
 death vs. survival, 41–42
 fuel usage during, 780t
 glucose levels and metabolism in, 40, 41, 614f, 624, 625t, 629, 629f, 630, 630f
 ketone bodies in, 629, 670
 liver in, 40
 protein synthesis in, 40
 skeletal muscle metabolism in, 1009–1010
Statins, 721, 723, 740, 745, 748t, 983
STAT receptors, 197, 197f, 313, 947–948
Stearate, 6f, 656–657
Stearic acid, 75, 77f, 686, 990
Stearyl coenzyme A (stearyl CoA), 686, 688f
Steatorrhea, 644, 645
Stellate (Ito) cells, 766–767, 767f, 980–981, 995
Stem cells
 differentiation of, 319, 945, 946f
 hematopoietic, 907, 934, 945–948, 946f
Stem cell transplantation, 373
Stereoisomers, 67, 71–72, 73f
Steroid hormones, 67, 195–196, 195f, 196, 741–746
 synthesis of, 716, 717, 725, 741–742, 743f
 types of, 717
Steroid hormone/thyroid hormone superfamily, 195–196, 195f, 310–311, 310f
Steroid nucleus, 77, 80f
 squalene conversion to, 722–723, 723f
Steroid(s), structure of, 67, 77–78, 80f
Sterol-regulatory element-binding proteins (SREBPs), 724, 724f, 736
Sterol-regulatory element (SRE), 724, 724f, 736
Stomach
 hydrochloric acid of, 61
 protein digestion in, 794, 795–796, 795f
Stop codons, 223, 223f, 279
Streptococcus mutans, 492
Streptococcus pneumoniae, 213, 280, 292

- degradation pathway of, 878–879
- modifications in tRNA, 269
- production of, 245

Urate, 878

Urea, 813

- arginine cleavage for production of, 814–815, 815f
- measurement of, 43
- nitrogen conversion to, 36, 38, 39, 40, 808, 813–821 (*See also* Urea cycle)
- structure of, 38, 38f
- synthesis of, 885

Urea cycle, 36, 38, 39, 40, 40t, 808, 813–821, 986

- arginine cleavage in, 814–815, 815f
- arginine production in, 808, 814–815, 815f, 819
- capacities of various tissues, 40t
- carbamoyl phosphate synthesis in, 814, 815f
- disorders of, 818–819, 822t, 877
 - arginine therapy for, 819
 - benzoic acid for, 819, 820f
 - gene therapy for, 819
 - phenylbutyrate for, 819, 820f
- fasting state, 817–818, 817f
- feed-forward regulation of, 808
- glutamate in, 812, 813f
- nitrogen transport to liver for, 808, 812–813, 813f, 885
- ornithine origin in, 816
- reactions of, 814–816, 815f
- regulation of, 816, 817f
- steps in, 815f
- TCA cycle and, 816f, 817

Uremia, 1049, 1060–1061

Uric acid, 183

- allopurinol and, 150–151, 150f, 878, 878f
- as antioxidant, 560
- blood measurement of, 183
- elevated levels of, 79, 868, 878 (*See also* Gout)
- ethanol and, 763
- purine ring degradation to, 868
- tautomers of, 79, 80f
- xanthine conversion to, 878

Uricase, 183

Uridine diphosphate (UDP), 867, 876–877

Uridine diphosphate (UDP)-galactose, 409, 482, 483f, 588

- formation of, 594f
- glycolipids synthesis from, 602–603
- lactose synthesis from, 597–598, 597f
- synthesis of, 597, 597f

Uridine diphosphate (UDP)-glucose, 594–597

- formation of, 409, 439, 571–572, 571f
- functions/products of, 409, 410f
- in glycogen synthesis, 409, 439, 439f, 568, 571–572, 571f, 572f
- glycolipids synthesis from, 602–603
- high-energy bonds of, 439, 440f, 441
- in interconversion of sugars, 588
- lactose synthesis from, 588
- metabolism of, 594f
- reactions of, 594–595
 - UDP-galactose from, 594f, 597, 597f
 - UDP-glucuronate from, 594–597, 594f, 595f

Uridine diphosphate (UDP)-glucuronate, 409, 588, 594–597

- formation of, 594f, 595, 595f
- glucuronate/glucuronides from, 595–597, 595f, 596f

Uridine diphosphate (UDP)-sugar precursors, 1048, 1055–1056, 1056f

Uridine diphosphate (UDP)-xylose, 595f

Uridine monophosphate (UMP), 867, 874, 875f, 876f

Uridine monophosphate (UMP) synthase, 874

Uridine phosphorylase, 876, 876f

Uridine triphosphate (UTP), 257, 441, 568, 571, 571f, 572f

- in pyrimidine synthesis, 874, 875f, 876–877

Urinalysis, 234
Urinary bladder, cancer of, 354
Urinary tract infections, 234, 235, 249, 252t
