This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Preface to the Sixth Edition

It has been 5 years since the fifth edition was completed. The sixth edition has some significant organizational changes, as suggested by extensive surveys of faculty and students who used the fifth edition in their classes and studies. The major pedagogic features of the text remain. They have been enhanced by the following changes for the fifth edition:

1. Every patient history has been reviewed and revised to reflect current standards of care (as of 2020). A small number of new patients have been added.
2. The Biochemical Comments associated with each chapter have been updated, where appropriate, to allow students to experience where current research efforts are headed.
3. Chapters 10 and 11 of the fifth edition have been combined into one chapter (Chapter 10 of the sixth edition), which required condensation of the material presented.
4. A new chapter (Chapter 18) on human genetics has been added to the text. The total number of chapters in the sixth edition is 47, just as in the fifth edition. The order and content of Chapters 19 to 47 in the sixth edition are the same as in the fifth edition.
5. The number of printed review questions at the end of each chapter has been increased to 15, up from 10 questions per chapter in the fifth edition (705 total questions). In addition, end-of-section questions have also been added online (15 questions per section, for a total of 105 questions). The online question bank associated with the text has also been increased to 665 questions, as compared to 560 questions associated with the fourth edition. Where possible, questions are presented in National Board of Medical Examiners format.

As stated in previous editions, in revising a text geared primarily toward medical students, the authors always struggle with new advances in biochemistry and whether such advances should be included in the text. We have taken the approach of only including advances that will enable the student to better relate biochemistry to medicine and future diagnostic tools. Although providing incomplete, but exciting, advances to graduate students is best for their education, medical students benefit more from a more directed approach—one that emphasizes how biochemistry is useful for the practice of medicine. This is a major goal of this text.

Any errors are the responsibility of the authors, and we would appreciate being notified when such errors are found.

The accompanying website for this edition of *MARKS' Basic Medical Biochemistry: A Clinical Approach* contains the aforementioned additional multiple-choice questions for review, summaries of all patients described in the text (patient cases), all chapter references and additional reading (with links to the article in PubMed, where applicable), a listing of diseases discussed in the book (with links to appropriate websites for more information), additional material for certain chapters that is ancillary to the main points of the text (they are indicated by an online icon in the text) , and a summary of all of the methods described throughout the text.

How to Use This Book

Icons identify the various components of the book: the patients who are presented at the start of each chapter; the clinical notes, methods notes, and questions and answers that appear in the margins; and the Key Concepts, Clinical Comments, and Biochemical Comments that are found at the end of each chapter.

Each chapter starts with an abstract that summarizes the information so that students can recognize the key words and concepts they are expected to learn. The next component of each chapter is The Waiting Room, describing patients with complaints and detailing the events that led them to seek medical help.

indicates a female patient

indicates a male patient

indicates a patient who is an infant or young child

As each chapter unfolds, icons appear in the margin, identifying information related to the material presented in the text:

indicates a clinical note, usually related to the patients in The Waiting Room for that chapter. These notes explain signs or symptoms of a patient or give some other clinical information relevant to the text.

indicates a methods note, which elaborates on how biochemistry is required to perform, and interpret, common laboratory tests.

Questions and answers also appear in the margin and should help to keep students thinking as they read the text:

indicates a question

indicates the answer to the question. The answer to a question is always located on the next page. If two questions appear on one page, the answers are given in order on the next page.

Each chapter ends with these three sections: Key Concepts, Clinical Comments, and Biochemical Comments:

The Key Concepts summarize the important take-home messages from the chapter.

The Clinical Comments give additional clinical information, often describing the treatment plan and the outcome.

The Biochemical Comments add biochemical information that is not covered in the text or explore some facet of biochemistry in more detail or from another angle.

Finally, Review Questions are presented. These questions are written in a United States Medical Licensing Examination–like format, and many of them have a clinical slant. Answers to the review questions, along with

detailed explanations, are provided at the end of every chapter. Additionally, there are online end-of-section questions, presented in a way to integrate material presented in each section of the text.

Acknowledgments

The authors would like to thank Dr. David A. Grahame, professor in the Department of Biochemistry at the Uniformed Services University of the Health Sciences, for his careful reading of the fifth edition and pointing out mistakes and errors that required correcting for the sixth edition. We greatly appreciate his efforts in improving the text. Dr. Sarah Pickle, associate professor in the Department of Family and Community Medicine, was invaluable in writing questions, both for the text and for the online supplement. We would also like to thank several readers who sent us e-mails pointing out confusing areas of the text in the fifth edition. We would also like to acknowledge the initial contributions of Dawn Marks, whose vision of a textbook geared toward medical students led to the first edition of this book. Her vision is still applicable today.

Contents

SECTION I

Fuel Metabolism

- 1 Metabolic Fuels and Dietary Components
- 2 The Fed or Absorptive State
- 3 Fasting

SECTION II

Chemical and Biologic Foundations of Biochemistry

- 4 Water, Acids, Bases, and Buffers
- 5 Structures of the Major Compounds of the Body
- 6 Amino Acids in Proteins
- 7 Structure–Function Relationships in Proteins
- 8 Enzymes as Catalysts
- 9 Regulation of Enzymes
- 10 Cell Structure and Signaling by Chemical Messengers
- 11 Structure of the Nucleic Acids

SECTION III

Gene Expression and the Synthesis of Proteins

- 12 Synthesis of DNA
- 13 Transcription: Synthesis of RNA
- 14 Translation: Synthesis of Proteins
- 15 Regulation of Gene Expression
- 16 Use of Recombinant DNA Techniques in Medicine
- 17 The Molecular Biology of Cancer
- 18 An Introduction to Human Genetics

SECTION IV

Carbohydrate Metabolism, Fuel Oxidation, and the Generation of Adenosine Triphosphate

- 19 Basic Concepts in the Regulation of Fuel Metabolism by Insulin, Glucagon, and Other Hormones

- 20 Cellular Bioenergetics: Adenosine Triphosphate and O₂**
- 21 Digestion, Absorption, and Transport of Carbohydrates**
- 22 Generation of Adenosine Triphosphate from Glucose, Fructose, and Galactose: Glycolysis**
- 23 Tricarboxylic Acid Cycle**
- 24 Oxidative Phosphorylation and Mitochondrial Function**
- 25 Oxygen Toxicity and Free-Radical Injury**
- 26 Formation and Degradation of Glycogen**
- 27 Pentose Phosphate Pathway and the Synthesis of Glycosides, Lactose, Glycoproteins, and Glycolipids**
- 28 Gluconeogenesis and Maintenance of Blood Glucose Levels**

SECTION V

Lipid Metabolism

- 29 Digestion and Transport of Dietary Lipids**
- 30 Oxidation of Fatty Acids and Ketone Bodies**
- 31 Synthesis of Fatty Acids, Triacylglycerols, and the Major Membrane Lipids**
- 32 Cholesterol Absorption, Synthesis, Metabolism, and Fate**
- 33 Metabolism of Ethanol**
- 34 Integration of Carbohydrate and Lipid Metabolism**

SECTION VI

Nitrogen Metabolism

I

Fuel Metabolism

In order to survive, humans must meet two basic metabolic requirements: we must be able to synthesize everything our cells need that is not supplied by our diet, and we must be able to protect our internal environment from toxins and changing conditions in our external environment. To meet these requirements, we metabolize our dietary components through four basic types of pathways: fuel oxidative pathways, fuel storage and mobilization pathways, biosynthetic pathways, and detoxification or waste disposal pathways. Cooperation between tissues and responses to changes in our external environment are communicated through transport pathways and intercellular signaling pathways (Fig. I.1).

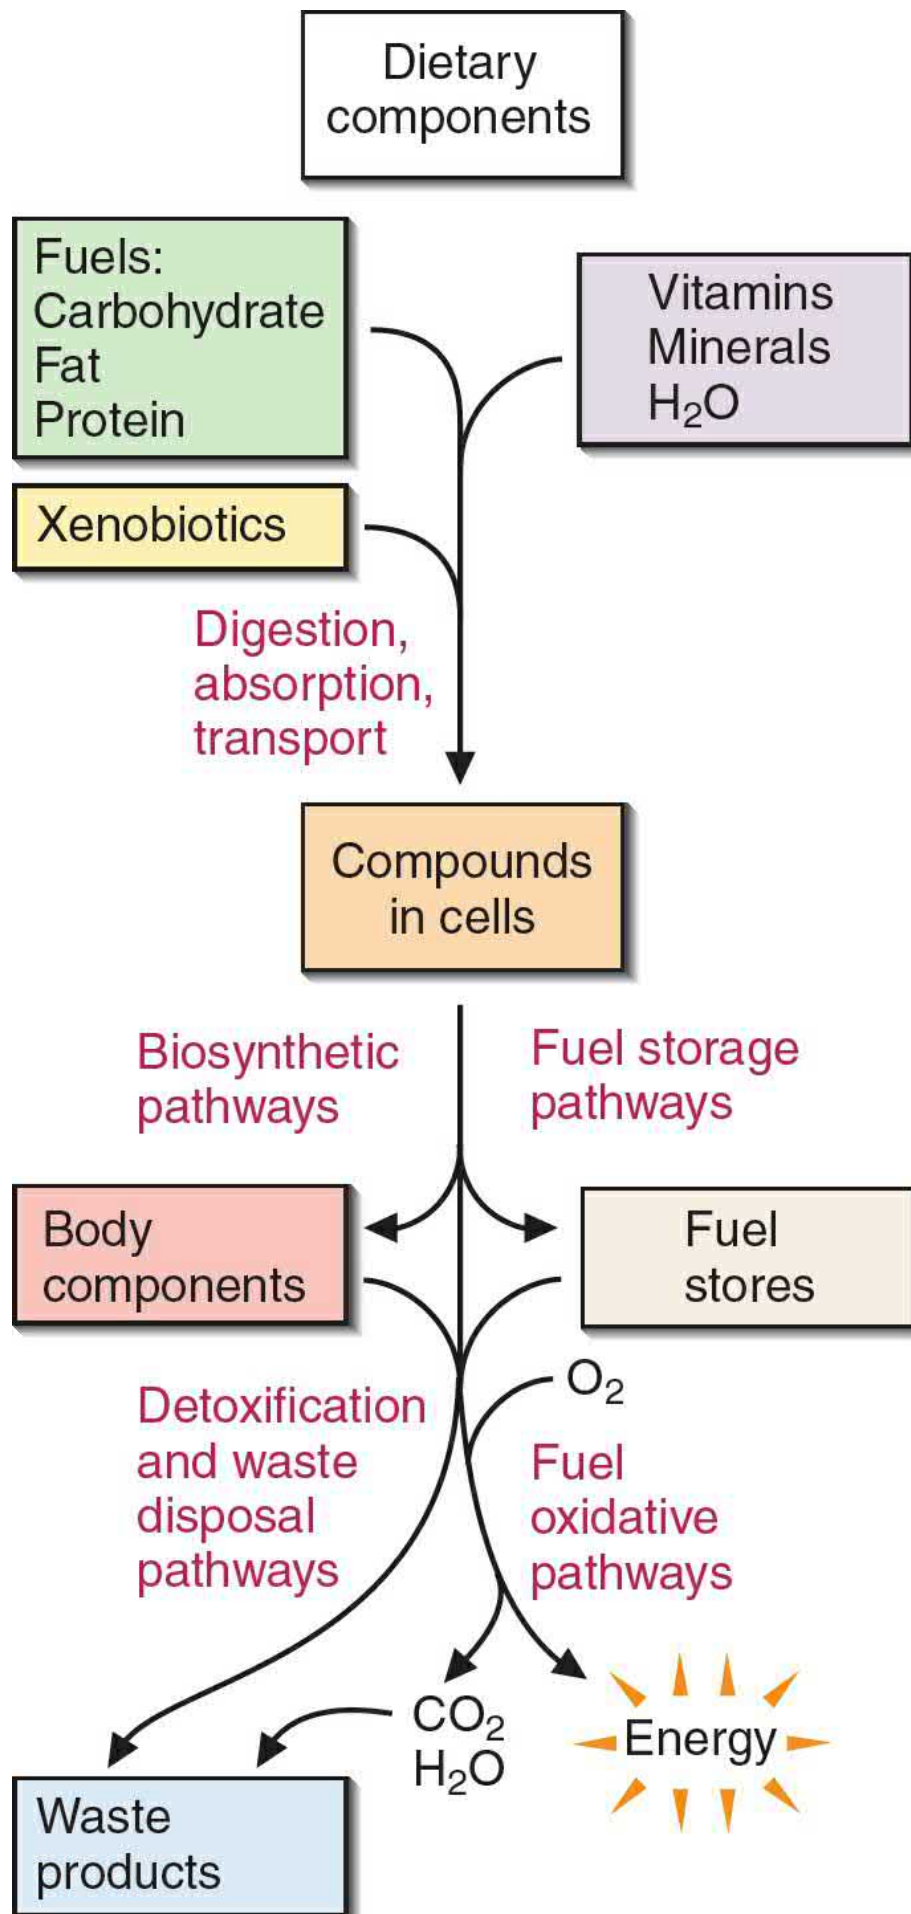

FIGURE I.1. An overview of the general metabolic routes for dietary components in the body. The types of pathways are named in red.

The foods in our diet are the fuels that supply us with energy in the form of calories. This energy is used for carrying out diverse functions such as moving, thinking, and reproducing. Thus, a number of our metabolic pathways are **fuel oxidative pathways** that convert fuels into energy that can be used for biosynthetic and mechanical work. But what is the source of energy when we are not eating, such as between meals, and while we sleep? How can a person who has fasted for multiple weeks survive so long? We have other metabolic pathways that are **fuel storage pathways**. The fuels that we store can be mobilized during periods when we are not eating or when we need more energy for exercise.

Our diet also must contain the compounds we cannot synthesize, as well as all the basic building blocks for compounds we do synthesize in our **biosynthetic pathways**. For example, we have dietary requirements for some amino acids, but we can synthesize other amino acids from our fuels and a dietary nitrogen precursor. The compounds required in our diet for biosynthetic pathways include certain amino acids, vitamins, and essential fatty acids.

Detoxification pathways and **waste disposal pathways** are metabolic pathways devoted to removing toxins that can be present in our diets or in the air we breathe, introduced into our bodies as drugs, or generated internally from the metabolism of dietary components. Dietary components that have no value to the body and must be disposed of are called **xenobiotics**.

In general, biosynthetic pathways (including fuel storage) are referred to as **anabolic pathways**, that is, pathways that synthesize larger molecules from smaller components. The synthesis of proteins from amino acids is an example of an anabolic pathway. **Catabolic pathways** are those pathways that break down larger molecules into smaller components. Fuel oxidative pathways are examples of catabolic pathways.

In humans, the need for different cells to carry out different functions has resulted in cell and tissue specialization in metabolism. For example, our adipose tissue is a specialized site for the storage of fat and contains the metabolic pathways that allow it to carry out this function. However, adipose tissue is lacking many of the pathways that synthesize required compounds from dietary precursors. To enable our cells to cooperate in meeting our metabolic needs during changing conditions of diet, sleep, activity, and health, we need **transport pathways** into the blood and between tissues and **intercellular signaling pathways**. One means of communication is for **hormones** to carry signals to tissues about our dietary state. For example, a message that we have just had a meal, carried by the hormone insulin, signals adipose tissue to store fat.

In the following section, we will provide an overview of various types of dietary components and examples of the pathways involved in utilizing these components. We will describe the fuels in our diet, the compounds produced by their digestion, and the basic patterns of fuel metabolism in the tissues of our bodies. We will describe how these patterns change when we eat, when we fast for a short time, and when we starve for prolonged periods. Patients with medical problems that involve an inability to deal normally with fuels will be introduced. These patients will appear repeatedly throughout the book and will be joined by other patients as we delve deeper into biochemistry.

It is important to note that this section of the book contains an **overview** of basic metabolism, which allows patients to be presented at an elementary level and to whet students' appetite for the biochemistry to come. Its goal is to enable students to taste and preview what biochemistry is all about. It is not designed to be all-inclusive, as all these topics will be discussed in greater detail in Sections IV through VII of the text. The next section of the text (Section II) begins with the basics of biochemistry and the relationship of basic chemistry to processes that occur in all living cells.

1

Metabolic Fuels and Dietary Components

Fuel Metabolism. We obtain our fuel primarily from the **macronutrients** (i.e., **carbohydrates**, **fats**, and **proteins**) in our diet. As we eat, our foodstuffs are **digested** and **absorbed**. The products of digestion circulate in the blood, enter various tissues, and are eventually taken up by cells and **oxidized** to produce **energy**. To completely convert our fuels to carbon dioxide (CO₂) and water (H₂O), molecular **oxygen** (O₂) is required. We breathe to obtain this oxygen and to eliminate the **carbon dioxide** (CO₂) that is produced by the oxidation of our food.

Fuel Stores. Any dietary fuel that exceeds the body's immediate energy needs is stored, mainly as **triacylglycerol** (fat) in adipose tissue; as **glycogen** (a carbohydrate) in muscle, liver, and other cells; and, to some extent, as **protein** in muscle. When we are fasting, between meals and overnight while we sleep, fuel is drawn from these stores and is oxidized to provide energy (Fig. 1.1).

FIGURE 1.1 Fate of excess dietary fuel in fed and fasting states.

Fuel Requirements. We require enough energy each day to drive the **basic functions** of our bodies and to support our **physical activity**. If we do not consume enough food each day to supply that much energy, the body's fuel stores supply the remainder and we lose weight. Conversely, if we consume more food than is required for the energy we expend, our body's fuel stores enlarge and we gain weight.

Other Dietary Requirements. In addition to providing energy, the diet provides **precursors** for the **biosynthesis** of compounds necessary for cellular and tissue structure, function, and survival. Among these precursors are the **essential fatty acids** and essential **amino acids** (those that the body needs but cannot synthesize). The diet must also supply **vitamins, minerals, and water**.

Waste Disposal. Dietary components that we can utilize are referred to as nutrients. However, both the diet and the air we breathe contain **xenobiotic compounds**, compounds that have no use or value in the human body and may be toxic. These compounds are excreted in the urine and feces

together with metabolic waste products.

THE WAITING ROOM

Percy V. is a 59-year-old school teacher who was in good health until his wife died suddenly. Since that time, he has experienced an increasing degree of fatigue and has lost interest in many of the activities he previously enjoyed. Shortly after his wife's death, one of his married children moved far from home. Since then, he has had little appetite for food. When a neighbor found him sleeping in his clothes, unkempt, and somewhat confused, she called an ambulance. **Percy V.** was admitted to the hospital psychiatry unit with a diagnosis of depression related to bereavement, dehydration, and malnutrition.

Otto S. is a 25-year-old medical student who was very athletic during high school and college but is now out of shape. Since he started medical school, he has been gaining weight. He is 5 ft 10 in tall and began medical school weighing 154 lb, within his ideal weight range. By the time he finished the last examination in his first year, he weighed 187 lb. He has decided to consult a physician at the student health service before the problem gets worse, as he would like to reduce his weight (at 187 lb, his body mass index [BMI] is 27) to his previous level of 154 lb (which would reduce his BMI to 23, in the middle of the healthy range of BMI values).

Ivan A. is a 56-year-old accountant who has been obese for a number of years. He exhibits abdominal obesity, which is caused by excess adipose tissue being disproportionately deposited around the organs in the abdomen. His major recreational activities are watching TV while drinking scotch and soda and doing occasional gardening. At a company picnic, he became very "winded" while playing softball and decided it was time for a general physical examination. At the examination, he weighed 264 lb at 5 ft 10 in tall. His blood pressure was elevated, 155 mm Hg systolic and 95 mm Hg diastolic (for **Ivan A.**'s age hypertension is defined as >130 mm Hg systolic and >80 mm Hg diastolic). For a male of these proportions, a BMI of 18.5 to 24.9 would correspond to a weight between 129 and 173 lb. **Ivan A.** is almost 100 lb overweight, and his BMI of 37.9 is in the range defined as obesity.

Ann R. is a 23-year-old buyer for a woman's clothing store. Despite the fact that she is 5 ft 7 in tall and weighs 99 lb, she is convinced she is overweight. Two months ago, she started a daily physical activity program that consists of 1 hour of jogging every morning and 1 hour of walking every evening. She also decided to consult a physician about weight loss. If patients are above (like **Ivan A.**) or below (like **Ann R.**) their ideal weight, the physician, often in consultation with a registered dietitian, prescribes a diet designed to bring the weight into the ideal range.

I. Dietary Fuels

The major fuels we obtain from our diet are the **macronutrients**, namely **carbohydrates**, **proteins**, and **fats**. When these fuels are oxidized to CO_2 and H_2O in our cells (the process of **catabolism**), energy is released by the transfer of electrons to O_2 . The energy from this oxidation process generates heat and **adenosine triphosphate (ATP)** (Fig. 1.2). Carbon dioxide travels in the blood to the lungs where it is expired, and water is excreted in urine, sweat, and other secretions. Although the heat that is generated by fuel oxidation is used to maintain body temperature, the main purpose of fuel oxidation is to generate ATP. Adenosine triphosphate provides the energy that drives most of the energy-consuming processes in the cell, including biosynthetic reactions (anabolic pathways), muscle contraction, and active transport across membranes. As these processes utilize energy, ATP is converted back to adenosine diphosphate (ADP) and inorganic phosphate (P_i). The generation and utilization of ATP is referred to as the **ATP-ADP cycle**.

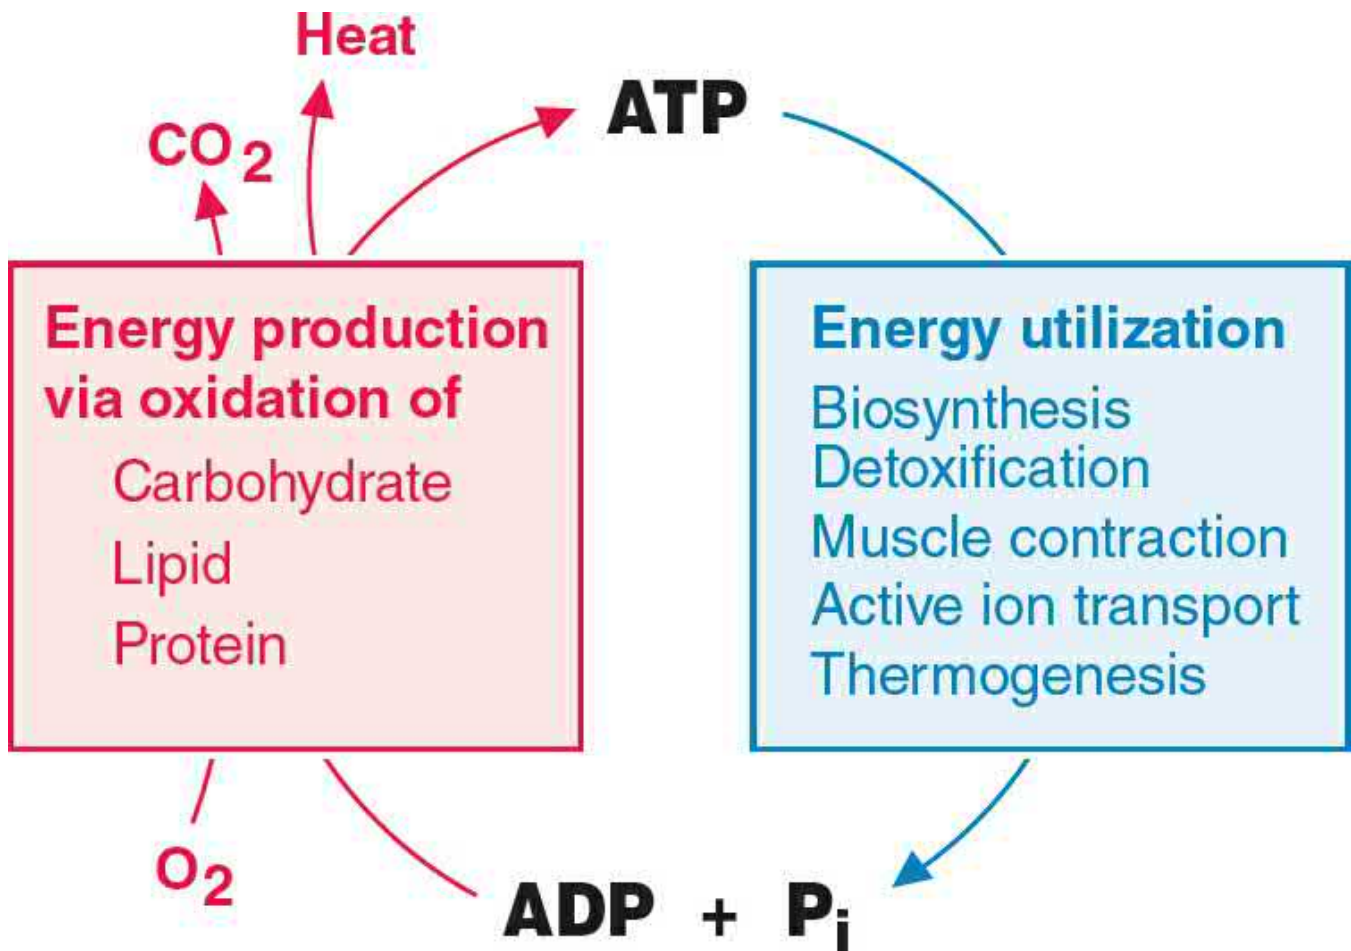

FIGURE 1.2 The ATP–ADP cycle. The energy-generating pathways are shown in *red*; the energy-utilizing pathways in *blue*. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i , inorganic phosphate.

The oxidation of fuels to generate ATP is called **respiration** (Fig. 1.3). Prior to oxidation, carbohydrates are converted principally to glucose, fat to fatty acids, and protein to amino acids. The pathways for oxidizing glucose, fatty acids, and amino acids have many features in common. They first oxidize the fuels to acetyl coenzyme A (**acetyl CoA**), a precursor of the **tricarboxylic acid (TCA)** cycle. The TCA cycle is a series of reactions that completes the oxidation of fuels to CO_2 (see Chapter 23). Electrons lost from the fuels during oxidative reactions are transferred to O_2 by a series of proteins in the electron transport chain (see Chapter 24). The energy of electron transfer is used to convert ADP and P_i to ATP by a process known as **oxidative phosphorylation**.

FIGURE 1.3 Generation of ATP from fuel components during respiration. Glucose, fatty acids, and amino acids are oxidized to acetyl CoA, a substrate for the TCA cycle. In the TCA cycle, they are completely oxidized to CO_2 . As fuels are oxidized, electrons (e^-) are transferred to O_2 by the electron transport chain, and the energy gained by the electron transfers is used to generate ATP. acetyl CoA, acetyl coenzyme A; ATP, adenosine triphosphate; TCA, tricarboxylic acid.

In discussions of metabolism and nutrition, energy is often expressed in units of **calories**. A calorie in this context (nutritional calorie) is equivalent to 1 **kilocalorie (kcal)** in energy terms. “Calorie” was originally

spelled with a capital C, but the capitalization was dropped as the term became popular. Thus, a 1-calorie soft drink actually has 1 kcal of energy. Energy is also expressed in **joules**. One kilocalorie equals 4.18 kilojoules (kJ). Physicians tend to use units of calories, in part because that is what their patients use and understand. One kilocalorie of energy is the amount of energy required to raise the temperature of 1 L of water by 1°C at atmospheric pressure.

A. Carbohydrates

The major carbohydrates in the human diet are starch, sucrose, lactose, fructose, maltose, galactose, and glucose. The polysaccharide **starch** is the storage form of carbohydrates in plants. Sucrose (table sugar), maltose, and lactose (milk sugar) are disaccharides, and fructose, galactose, and glucose are monosaccharides. Digestion converts the larger carbohydrates to monosaccharides, which can be absorbed into the bloodstream. Glucose, a monosaccharide, is the predominant sugar in human blood (Fig. 1.4).

FIGURE 1.4 Structure of starch and glycogen. Starch, our major dietary carbohydrate, and glycogen, the body's storage form of glucose, have similar structures. They are polysaccharides (many sugar units) composed of glucose, which is a monosaccharide (one sugar unit).

Oxidation of carbohydrates to CO₂ and H₂O in the body produces approximately 4 kcal/g (Table 1.1). In other words, every gram of carbohydrate we eat yields approximately 4 kcal of energy. Note that carbohydrate molecules contain a significant amount of oxygen and are already partially oxidized before they enter our bodies (see Fig. 1.4).

TABLE 1.1 Caloric Content of Fuels	
FUEL	kcal/g
Carbohydrate	4
Fat	9
Protein	4
Alcohol	7

B. Proteins

Proteins are composed of **amino acids** that are joined to form linear chains (Fig. 1.5). In addition to carbon, hydrogen, and oxygen, proteins contain approximately 16% nitrogen by weight. The digestive process breaks down proteins to their constituent amino acids, which enter the blood. The complete oxidation of proteins to CO₂, H₂O, and NH₄⁺ in the body yields approximately 4 kcal/g (see Table 1.1).

FIGURE 1.5 General structure of proteins and amino acids. Each amino acid in this figure is indicated by a different color. R = side chain. Different amino acids have different side chains. For example, R_1 might be $-\text{CH}_3$; R_2 , $-\text{CH}_2\text{OH}$; R_3 , $-\text{CH}_2-\text{COO}^-$. In a protein, the amino acids are linked by peptide bonds.

An analysis of **Ann R.**'s diet showed she ate 100 g of carbohydrate, 20 g of protein, and 15 g of fat each day. Approximately how many calories did she consume per day?

C. Fats

Fats are lipids composed of **triacylglycerols** (also called **triglycerides**). A triacylglycerol molecule contains three fatty acids esterified to one glycerol moiety (Fig. 1.6).

FIGURE 1.6 Structure of a triacylglycerol. Palmitate and stearate are saturated fatty acids—that is, they have no double bonds in the carbon chain. Oleate is monounsaturated (one double bond). Polyunsaturated fatty acids have more than one double bond.

Fats contain much less oxygen than is contained in carbohydrates or proteins. Therefore, fats are more reduced and yield more energy when oxidized. The complete oxidation of triacylglycerols to CO_2 and H_2O in the body releases approximately 9 kcal/g, more than twice the energy yield from an equivalent amount of carbohydrate or protein (see Table 1.1).

D. Alcohol

Alcohol (ethanol, in the context of the diet) has considerable caloric content. Ethanol ($\text{CH}_3\text{CH}_2\text{OH}$) is oxidized to CO_2 and H_2O in the body and yields approximately 7 kcal/g—that is, more than carbohydrate or protein but less than fat.

II. Body Fuel Stores

Humans carry supplies of fuel within their bodies (Table 1.2), which are similar to the fuel supplies in the plants and animals we eat. These fuel stores are light in weight, large in quantity, and readily converted into oxidizable substances. Most of us are familiar with fat, our major fuel store, which is located in adipose tissue. Although fat is distributed throughout our bodies, it tends to increase in quantity in our hips, thighs, and abdomens as we advance into middle age. In addition to our fat stores, we have important, although much smaller, stores of carbohydrates in the form of **glycogen** located primarily in our liver and muscles. Glycogen consists of glucose molecules joined together to form a large, branched polysaccharide (see Fig. 1.4). Body protein, particularly the protein of our large muscle masses, also serves to some extent as a fuel store, and we draw on it for energy when we fast.

TABLE 1.2 Fuel Composition of the Average 70 kg Man^a after an Overnight Fast

FUEL	AMOUNT (KG)	PERCENTAGE OF TOTAL STORED CALORIES
Glycogen		
Muscle	0.15	0.4
Liver	0.08	0.2
Protein	6.0	14.4
Triglyceride	15	85

^aIn biochemistry and nutrition, the standard reference is often the 70-kg (154 lb) man. This standard was probably chosen because in the first half of the 20th century, when many nutritional studies were performed, young healthy medical and graduate students (who were mostly men) volunteered to serve as subjects for these experiments.

Ann R. consumed

$100 \times 4 = 400$ calories as carbohydrate

$20 \times 4 = 80$ calories as protein

$15 \times 9 = 135$ calories as fat

for a total of 615 calories/day.

A. Fat

Our major fuel store is adipose triacylglycerol (triglyceride), a lipid more commonly known as fat. The average 70-kg man has approximately 15 kg of stored triacylglycerol, which accounts for approximately 85% of his total stored calories (see Table 1.2).

Two characteristics make adipose triacylglycerol a very efficient fuel store: the fact that triacylglycerol contains more calories per gram than carbohydrate or protein (9 kcal/g vs. 4 kcal/g) and the fact that adipose tissue does not contain much water. Adipose tissue contains only about 15% water, compared to tissues such as muscle that contain about 80%. Thus, the 70-kg man with 15 kg of stored triacylglycerol has only about 18 kg of adipose tissue.

B. Glycogen

Our stores of glycogen in liver, muscle, and other cells are relatively small in quantity but are nevertheless important. Liver glycogen is used to maintain blood glucose levels between meals, which is necessary for optimal functioning of the nervous system. Thus, the size of this glycogen store fluctuates during the day; an average 70-kg man might have 200 g or more of liver glycogen after a meal but only 80 g after an overnight fast. Muscle glycogen supplies energy for muscle contraction during exercise. At rest, the 70-kg man has approximately 150 g of muscle glycogen. Almost all cells, including neurons, maintain a small emergency supply of glucose as glycogen.

Ivan A. ate 585 g of carbohydrate, 150 g of protein, and 95 g of fat each day. In addition, he drank 45 g of alcohol daily. How many calories did he consume per day?

It is not practical to store all of the stored energy as glycogen instead of triacylglycerol. Glycogen being a polar molecule with hydroxyl groups binds approximately 4 times its weight as water and will require significantly more intracellular space than the same amount of energy stored as triacylglycerol, which, being

hydrophobic, contains much less water weight.

Ivan A. consumed

$585 \times 4 = 2,340$ calories as carbohydrate

$150 \times 4 = 600$ calories as protein

$95 \times 9 = 855$ calories as fat

$45 \times 7 = 315$ calories as alcohol

for a total of 4,110 calories/day.

C. Protein

Protein serves many important roles in the body; unlike fat and glycogen, it is not solely a fuel store like fat or glycogen. Muscle protein is essential for body movement. Other proteins serve as **enzymes** (catalysts of biochemical reactions) or as **structural components** of cells and tissues. Only a limited amount of body protein can be degraded, approximately 6 kg in the average 70-kg man, before our body functions are compromised.

III. Daily Energy Expenditure

If we want to stay in energy balance, neither gaining nor losing weight, we must, on average, consume an amount of food equal to our daily energy expenditure (DEE). The **daily energy expenditure** includes the energy to support our basal metabolism (basal metabolic rate [BMR] or resting metabolic rate [RMR]) and our physical activity, plus the energy required to process the food we eat (diet-induced thermogenesis [DIT]). Thus, the DEE, in kilocalories per day = BMR (or RMR) + the energy needed for physical activity + DIT.

A. Basal Metabolic Rate

Two terms have been used to define the energy required by the body: the BMR and the RMR. The BMR is a measure of the energy required to maintain life: the functioning of the lungs, kidneys, and brain; the pumping of the heart; the maintenance of ionic gradients across membranes; and the reactions of biochemical pathways. The BMR was originally defined as the energy expenditure of a person mentally and bodily at rest in a thermoneutral environment 12 to 18 hours after a meal. However, when a person is awakened and their heat production or oxygen consumption is measured, they are no longer sleeping or totally at mental rest, and their metabolic rate is called the resting metabolic rate (RMR). It is also sometimes called the resting energy expenditure (REE). The RMR and BMR differ very little in value, and for the purposes of this text, we will focus on the BMR.

The BMR, which is usually expressed in kcal/day, is affected by body size, age, sex, and other factors (Table 1.3). It is proportional to the amount of metabolically active tissue (including the major organs) and the lean (or fat-free) body mass. Obviously, the amount of energy required for basal functions in a large person is greater than the amount required in a small person. However, the BMR is usually lower for women than for men of the same weight because women usually have more adipose tissue and less muscle mass. Body temperature also affects the BMR, which increases by 12% with each degree centigrade (7% with each degree Fahrenheit) increase in body temperature (i.e., “feed a fever; starve a cold”). The ambient temperature affects the BMR, which increases slightly in colder climates as thermogenesis is activated. Excessive secretion of thyroid hormone (hyperthyroidism) causes the BMR to increase, whereas diminished secretion (hypothyroidism) causes it to decrease. The BMR increases during pregnancy and lactation. Growing children have a higher BMR per kilogram body weight than adults because a greater proportion of their bodies is composed of brain, muscle, and other more metabolically active tissues. The BMR declines in aging individuals because their metabolically active tissue is shrinking and body fat is increasing. In addition, large variations exist in BMR from one adult to another, determined by genetic factors.

TABLE 1.3 Factors Affecting BMR Expressed per kg Body Weight

Gender (males higher than females)

Body temperature (increased with fever)

Environmental temperature (increased in cold)

Thyroid status (increased in hyperthyroidism)
 Pregnancy and lactation (increased)
 Age (decreased with age)
 Body composition (increased with muscle mass)

Q What are **Ivan A.**'s and **Ann R.**'s BMR? (Compare the method for a rough estimate to values obtained with equations in Table 1.4.)

TABLE 1.4 The Mifflin–St. Joer Equation for Predicting Basal Metabolic Rate^a

Males:	$(10 \times W) + (6.25 \times H) - (5 \times A) + 5$
Females:	$(10 \times W) + (6.25 \times H) - (5 \times A) - 161$

^aBody weight (W) in kg, height (H) in cm, and age (A) in years; final result is kilocalories per day.

Data from Mifflin MD, St. Joer ST, Hill LA, Scott BJ, Daugherty SA, Koh XO. A new predictive equation for resting energy expenditure in healthy individuals. *Am J Clin Nutr.* 1990;51:241–237.

M Registered dietitians often use extensive tables for calculating energy requirements, based on height, weight, age, gender, and activity level. A more accurate calculation is based on the fat-free mass (FFM), which is equal to the total body mass minus the mass of the person's adipose tissue. With FFM, the BMR is calculated using the equation $BMR = 186 + FFM \times 23.6$ kcal/kg/day. This formula eliminates differences between sexes and between aged versus young individuals that are attributable to differences in relative adiposity. However, determining FFM is relatively cumbersome—one technique requires weighing the patient underwater and measuring the residual lung volume. More recently, dual-energy X-ray absorptiometry (DXA) is an equally accurate, but simpler technique that is used to determine the patient's total amount of fat and FFM.

Indirect calorimetry, a technique that measures O₂ consumption and CO₂ production, can be used when more accurate determinations of energy need are required for hospitalized patients. A portable indirect calorimeter is used to measure oxygen consumption and the respiratory quotient (RQ), which is the ratio of O₂ consumed to CO₂ produced. The RQ is 1.00 for individuals oxidizing carbohydrates, 0.83 for protein, and 0.71 for fat. From these values, the DEE can be determined.

A simplified method to measure the DEE also utilizes indirect calorimetry but only measures oxygen consumption. Because the oxidation of nutrients requires molecular oxygen, through the measurement of the volume of total inspired and expired air, and the amount of oxygen in that air, a very good estimate of the BMR can be determined. The device required for this method is less cumbersome than the device that measures both oxygen and carbon dioxide consumption and is easier to use, but it is less accurate.

A rough estimate of the BMR may be obtained by assuming it is either 24 or 21.6 kcal/day/kg body weight (for men or women, respectively) and multiplying by the body weight. An easy way to remember this is 1 kcal/kg/hr for men and 0.9 kcal/kg/hr for women. This estimate works best for young individuals who are near their healthy weight. More accurate methods for calculating the BMR use empirically derived equations for different gender and age groups (Table 1.4). Even these calculations do not take into account variation among individuals.

B. Physical Activity

In addition to the BMR, the energy required for **physical activity** contributes to the DEE. The difference in physical activity between a student and a lumberjack is enormous, and a student who is relatively sedentary during the week may be much more active during the weekend. Table 1.5 gives factors for calculating the approximate energy expenditures associated with typical activities.

TABLE 1.5 Typical Activities with Corresponding Hourly Activity Factors^a

ACTIVITY CATEGORY	HOURLY ACTIVITY FACTOR (FOR TIME IN ACTIVITY)
Resting: sleeping, reclining	1.0
Very light: seated and standing activities, driving, laboratory work, typing, sewing, ironing, cooking, playing cards, playing a musical instrument	1.5
Light: walking on a level surface at 2.5–3 mph, garage work, electrical trades, carpentry, restaurant trades, house cleaning, golf, sailing, table tennis	2.5
Moderate: walking 3.5–4 mph, weeding and hoeing, carrying	5.0

loads, cycling, skiing, tennis, dancing

Heavy: walking uphill with a load, tree felling, heavy manual digging, mountain climbing, basketball, football, soccer

7.0

^aThe hourly activity factor is multiplied by the basal metabolic rate per hour times the number of hours engaged in the activity to give the caloric expenditure for that activity. If this is done for all of the hours in a day, the sum over 24 hours will approximately equal the daily energy expenditure.

National Research Council. *Recommended Dietary Allowances*. 10th ed. National Academy Press; 1989.

<https://doi.org/10.17226/1349>. Adapted and reproduced with permission from the National Academy of Sciences. Courtesy of the National Academies Press, Washington, D.C.

A rough estimate of the energy required per day for physical activity can be made by using a value of 30% of the BMR (per day) for a very sedentary person (such as a medical student who does little but study) and a value of 60% to 70% of the BMR (per day) for a person who engages in about 2 hours of moderate physical activity per day (see Table 1.5). A value of 100% or more of the BMR is used for a person who does several hours of vigorous physical activity per day.

 **Ivan A.** weighs 264 lb or 120 kg (264 lb divided by 2.2 lb/kg). His estimated BMR = 24 kcal/kg/day \times 120 = 2,880 kcal/day. His BMR calculated from Table 1.4 is only 1,992 kcal ($10 \times \text{weight} + 6.25 \times \text{height} - 5 \times \text{age} + 5$, where the weight is in kg, the height in cm, and the age in years). **Ann R.** weighs 99 lb or 45 kg (99/2.2 lb/kg). Her estimated BMR = (21.6 kcal/kg/day) \times (45 kg) = 972 kcal/day. Her BMR from Table 1.4 is above this value ($10 \times \text{weight} + 6.25 \times \text{height} - 5 \times \text{age} - 161 = 1,238$ kcal/day). Thus, for **Ann R.**, the rough estimate is 78% of the more accurate calculation. For **Ivan A.**, his caloric needs are only 70% that of the rough estimate because a disproportionately larger proportion of his body weight (his adipose tissue) is relatively inactive metabolically.

C. Diet-Induced Thermogenesis

Our DEE includes a component related to the intake of food known as diet-induced thermogenesis or the thermic effect of food (TEF). DIT was formerly called the specific dynamic action (SDA). After the ingestion of food, our metabolic rate increases because energy is required to digest, absorb, distribute, and store nutrients.

The energy required to process the types and quantities of food in the typical American diet is probably equal to approximately 10% of the kilocalories ingested. This amount is roughly equivalent to the error involved in rounding off the caloric content of carbohydrate, fat, and protein to 4, 9, and 4, respectively. Therefore, DIT is often ignored, and calculations are based simply on the BMR and the energy required for physical activity.

 Based on the activities listed in Table 1.5, the average U.S. citizen is rather sedentary. Sedentary habits correlate strongly with the risk for cardiovascular disease, so it is not surprising that cardiovascular disease is the major cause of death in this country.

D. Calculations of Daily Energy Expenditure

The total DEE is usually calculated as the sum of the BMR (in kcal/day) plus the energy required for the amount of time spent in each of the various types of physical activity (see Table 1.5). An approximate value for the DEE can be determined from the BMR and the appropriate percentage of the BMR required for physical activity (given above). For example, a very sedentary medical student would have a DEE equal to the BMR plus 30% of the BMR (or $1.3 \times \text{BMR}$), and an active person's daily expenditure could be 2 times the BMR.

 What are reasonable estimates for **Ivan A.**'s and **Ann R.**'s DEE?

E. Healthy Body Weight

Ideally, we should strive to maintain a weight consistent with good health. The BMI, calculated as weight/height² (kg/m²), is currently the preferred method for determining whether a person's weight is in the healthy range. This formula, in the English system, is (weight [in lb] \times 704)/height² (with height in inches).

In general, adults with BMI values below 18.5 are considered underweight. Those with BMIs between 18.5 and 24.9 are considered to be in the healthy weight range, between 25 and 29.9 are in the overweight range, and 30 and above are in the obese range. Class I obesity is defined as a BMI of 30 to 34.9; class II as a BMI of 35 to 39.9; class III (or extreme obesity) as a BMI of 40 or greater. Degrees of protein–energy malnutrition

(marasmus) are classified according to the BMI. According to the Global Leadership Initiative on Malnutrition, a BMI of <20 (if <70 years) is stage I/moderate malnutrition; value <18.5 (if <70 years) is stage II/severe malnutrition.

F. Weight Gain and Loss

To maintain our body weight, we must stay in **caloric balance**. We are in caloric balance if the kilocalories in the food we eat equal our DEE. If we eat less food than we require for our DEE, our body fuel stores supply the additional calories and we lose weight. Conversely, if we eat more food than we require for our energy needs, the excess fuel is stored (mainly in our adipose tissue) and we gain weight.

Are **Ivan A.** and **Ann R.** in a healthy weight range?

When we draw on our adipose tissue to meet our energy needs, we lose approximately 1 lb whenever we expend approximately 3,500 calories more than we consume. In other words, if we eat 1,000 calories less than we expend per day, we will lose about 2 lb/week. Because the average individual's food intake is only about 2,000 to 3,000 calories/day, eating one-third to one-half the normal amount will cause a person to lose weight rather slowly. Fad diets that promise a loss of weight much more rapidly than this have no scientific merit. In fact, the rapid initial weight loss the fad dieter typically experiences is attributable largely to loss of body water. This loss of water occurs in part because muscle tissue protein and liver glycogen are degraded rapidly to supply energy during the early phase of the diet. When muscle tissue (which is approximately 80% water) and glycogen (approximately 70% water) are broken down, this water is excreted from the body.

IV. Dietary Requirements

In addition to supplying us with fuel and with general-purpose building blocks for biosynthesis, our diet provides us with specific nutrients that we need to remain healthy. We must have a regular supply of vitamins and minerals and the essential fatty acids and essential amino acids. "Essential" means that they are essential in the diet; the body cannot synthesize these compounds from other molecules and therefore must obtain them from the diet. Nutrients that the body requires in the diet only under certain conditions are called "conditionally essential."

The **Recommended Dietary Allowance (RDA)** and the **Adequate Intake (AI)** provide quantitative estimates of nutrient requirements. The RDA for a nutrient is the average daily dietary intake level necessary to meet the requirement of nearly all (97% to 98%) healthy individuals in a particular gender and life stage group. Life stage group is a certain age range or physiologic status (i.e., pregnancy or lactation). The RDA is intended to serve as a goal for intake by individuals. The AI is a recommended intake value that is used when not enough data are available to establish an RDA.

A. Carbohydrates

The RDA for carbohydrates is 130 g/day for children and adults and is based on the amount of carbohydrates needed to provide the brain with an adequate supply of glucose. Another value, the Acceptable Macronutrient Distribution Range (AMDR) is the recommended range of intake for a macronutrient that is associated with a reduced risk of disease while providing adequate intake of essential nutrients. The AMDR is expressed as a percentage of caloric intake. For example, according to its AMDR, carbohydrates should provide 45% to 65% of total calories.

Ivan A.'s BMR is 1,992 kcal/day. He is sedentary, so he only requires approximately 30% more calories for his physical activity. Therefore, his daily expenditure is approximately $1,992 + (0.3 \times 1,992)$ or $1.3 \times 1,992$ or 2,590 kcal/day. **Ann R.**'s BMR is 1,238 kcal/day. She performs 2 hours of moderate physical activity per day (jogging and walking), so she requires approximately 65% more calories for her physical activity. Therefore, her daily expenditure is approximately $1,238 + (0.65 \times 1,238)$ or $1.65 \times 1,238$ or 2,043 kcal/day.

Carbohydrates can be synthesized from amino acids, and we can convert one type of carbohydrate to another. However, health problems are associated with the complete elimination of carbohydrates from the diet, partly because a low-carbohydrate diet must contain higher amounts of fat to provide us with the energy we need. High-fat diets are associated with obesity, atherosclerosis, and other health problems.

B. Essential Fatty Acids

The recommended range (AMDR) for dietary fat is 20% to 35% of total calories, with no more than 10% of total calories coming from saturated fat. Although most lipids required for cell structure, fuel storage, or hormone synthesis can be synthesized from carbohydrates or proteins, we need a minimal level of certain dietary lipids for optimal health. These lipids, known as essential fatty acids, are required in our diet because we cannot synthesize fatty acids with these particular arrangements of double bonds. The essential fatty acids α -linoleic and α -linolenic acid are supplied by dietary plant oils, and eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are supplied by fish oils. They are the precursors of the eicosanoids (a set of hormone-like molecules that are secreted by cells in small quantities and have numerous important effects on neighboring cells). The eicosanoids (see Chapter 31) include prostaglandins, thromboxanes, leukotrienes, and other related compounds.

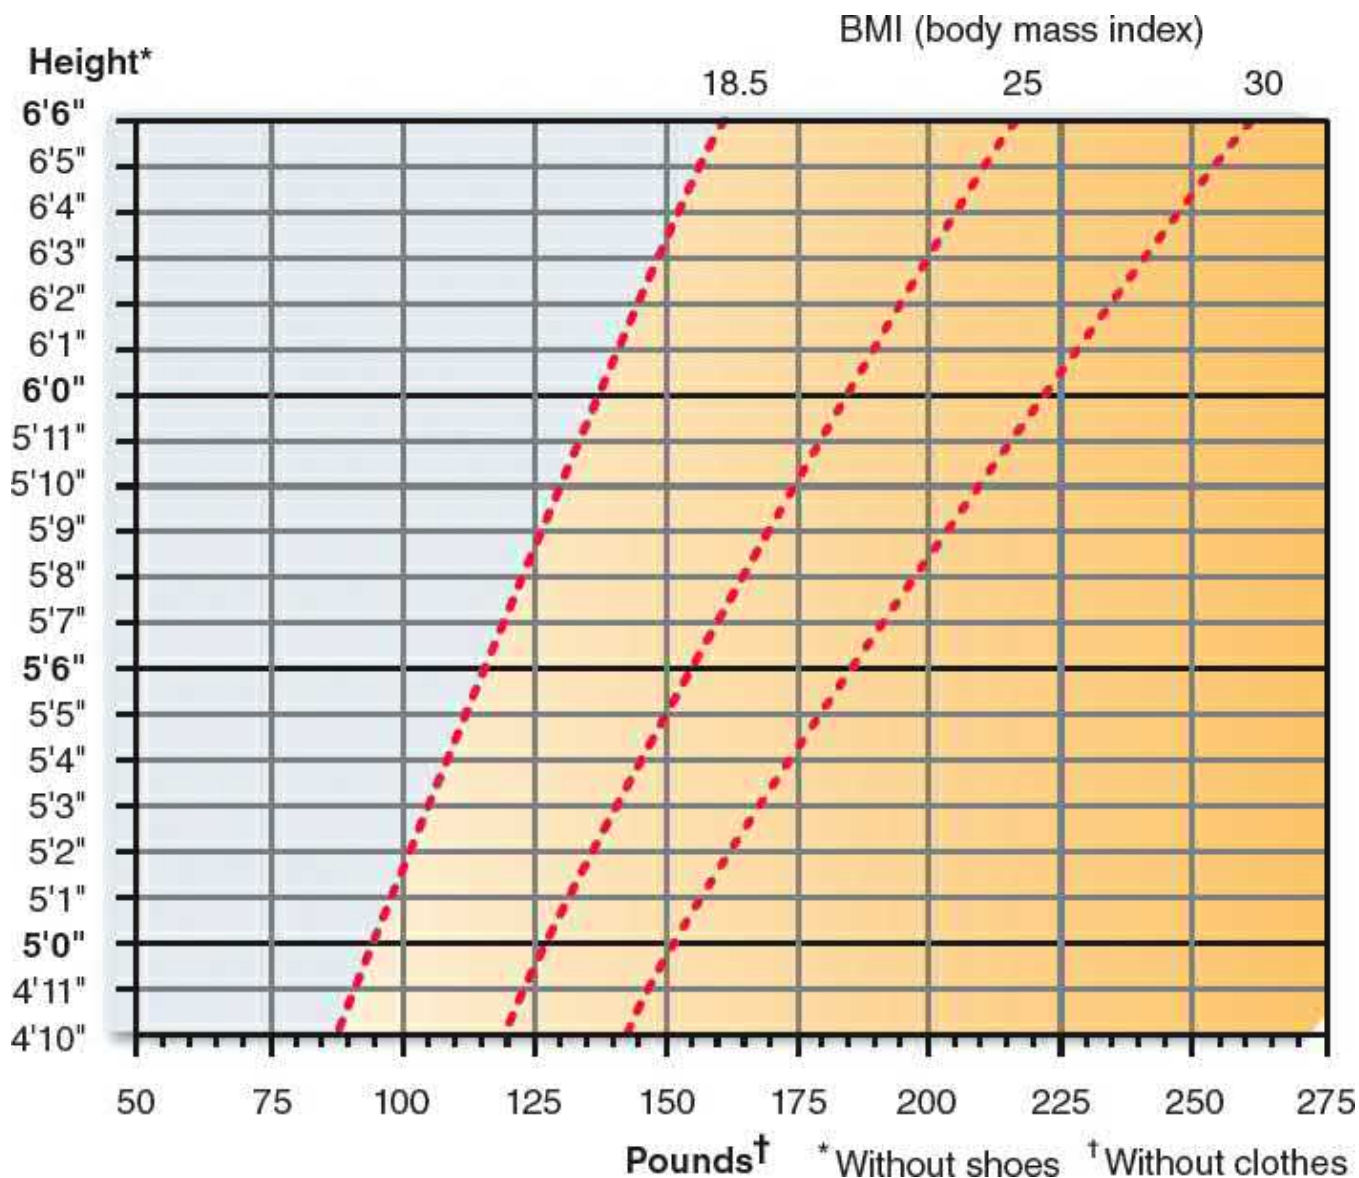

Ivan A.'s weight is classified as obese. His BMI is $(264 \text{ lb} \times 704)/(70 \text{ in})^2 = 37.9$. **Ann R.** is underweight. Her BMI is $(99 \text{ lb} \times 704)/(67 \text{ in})^2 = 15.5$.

C. Protein

The RDA for protein is approximately 0.8 g of high-quality protein per kilogram of healthy body weight or approximately 56 g/day for a 154-lb man and 46 g/day for a 126-lb woman. “High-quality” protein contains all the essential amino acids in adequate amounts for health. Proteins derived from animal sources (milk, egg, and meat products) and soy are of high quality. Most proteins in plant foods are considered of lower quality, which means they are low in one or more of the essential amino acids. Vegans may obtain adequate amounts of the essential amino acids by eating mixtures of plant-based proteins that complement each other in terms of their amino acid composition. According to its recommended AMDR, protein should contribute 10% to 35% of total caloric intake.

To evaluate a patient's weight, physicians need standards of obesity applicable in a genetically heterogeneous population. Life insurance industry statistics have been used to develop tables giving the weight ranges, based on gender, height, and body frame size, that are associated with the greatest longevity, such as the Metropolitan Height and Weight Tables. However, these tables are considered inadequate for a number of reasons (e.g., they reflect data from upper-middle-class white groups). The BMI is the classification that is currently used clinically. It is based on two simple measurements, height without shoes and weight with minimal clothing.

Patients can be shown their BMI in a nomogram and need not use calculations. The healthy weight range coincides with the mortality data derived from life insurance tables. The BMI also shows a good correlation with independent measures of body fat. The major weakness of the use of the BMI is that some very muscular individuals may be classified as obese when they are not. There are also some differences in the BMI contribution to the risk of certain diseases that vary by race or ethnicity. Other measurements to estimate body fat and other body compartments, such as weighing individuals underwater, are more difficult, expensive, and time-consuming and have generally been confined to research purposes.

If patients are above or below the healthy BMI range (such as **Ivan A.** or **Ann R.**), the physician, often in consultation with a registered dietitian, prescribes a diet designed to bring the weight into the healthy range.

1. Essential Amino Acids

Different amino acids are used in the body as precursors for the synthesis of proteins and other nitrogen-containing compounds. Of the 20 amino acids commonly required in the body for the synthesis of protein and other compounds, nine amino acids are essential in the diet of an adult human because they cannot be synthesized in the body. These are **lysine, isoleucine, leucine, threonine, valine, tryptophan, phenylalanine, methionine, and histidine.**

Certain amino acids are conditionally essential—that is, required in the diet only under certain conditions. Children and pregnant women have a high rate of protein synthesis to support growth and require some **arginine** in the diet, although it can be synthesized in the body. Histidine is essential in the diet of the adult in very small quantities because adults efficiently recycle histidine. The increased requirement of histidine in children and pregnant women is therefore much larger than their increased requirement of other essential amino acids. Tyrosine and cysteine are examples of conditionally essential amino acids. Tyrosine is synthesized from phenylalanine, and it is required in the diet if phenylalanine intake is inadequate or if an individual is

congenitally deficient in an enzyme required to convert phenylalanine to tyrosine (the congenital disease phenylketonuria). Cysteine is synthesized by using sulfur from methionine, and it also may be required in the diet under conditions of low methionine intake or malabsorption disorders.

2. Nitrogen Balance

The proteins in the body undergo constant turnover—that is, they are constantly being degraded to amino acids and resynthesized. When a protein is degraded, its amino acids are released into the pool of free amino acids in the cells. The amino acids from dietary proteins also enter this pool. Free amino acids can have one of three fates: they are used to make proteins, they serve as precursors for synthesis of essential nitrogen-containing compounds (e.g., heme, DNA, RNA), or they are oxidized as fuel to yield energy. When amino acids are oxidized, their nitrogen atoms are excreted in the urine principally in the form of urea. The urine also contains smaller amounts of other nitrogenous excretory products (creatinine and NH_4^+) derived from the degradation of amino acids and compounds synthesized from amino acids. Some nitrogen is also lost in sweat, feces, and cells that slough off.

Nitrogen balance is the difference between the amount of nitrogen taken into the body each day (mainly in the form of dietary protein) and the amount of nitrogen in compounds lost (Table 1.6). If more nitrogen is ingested than excreted, a person is said to be in positive nitrogen balance. Positive nitrogen balance occurs in growing individuals (e.g., children, adolescents, and pregnant women), who are synthesizing more protein than they are breaking down. On the other hand, if less nitrogen is ingested than excreted, a person is said to be in negative nitrogen balance. A negative nitrogen balance develops in a person who is eating either too little protein or protein that is deficient in one or more of the essential amino acids. It also results from periods of fasting, recovery from tissue injuries, or having an illness. Amino acids are continuously being mobilized from body proteins. If the diet is lacking an essential amino acid or if the intake of protein is too low, new protein cannot be synthesized, and the unused amino acids will be degraded, with the nitrogen appearing in the urine. If a negative nitrogen balance persists for too long, bodily function will be impaired by the net loss of critical proteins. In contrast, healthy adults are in nitrogen balance (neither positive nor negative), and the amount of nitrogen consumed in the diet equals its loss in urine, sweat, feces, and other excretions.

TABLE 1.6 Nitrogen Balance

Positive nitrogen balance	Growth (e.g., childhood, pregnancy)	Dietary N > Excreted N
Nitrogen balance	Normal healthy adult	Dietary N = Excreted N
Negative nitrogen balance	Dietary deficiency of total protein or amino acids: catabolic stress	Dietary N < Excreted N

Are **Ivan A.** and **Ann R.** gaining or losing weight?

Ivan A. expends about 2,590 kcal/day and consumes 4,110. By this calculation, he consumes 1,520 more kcal than he expends each day and is gaining weight. **Ann R.** expends 2,043 kcal/day while she consumes only 615. Therefore, she expends 1,428 more kcal/day than she consumes, so she is losing weight.

D. Vitamins

Vitamins are a diverse group of organic molecules required in very small quantities in the diet for health, growth, and survival (Latin *vita*, life). The absence of a vitamin from the diet or an inadequate intake results in characteristic deficiency signs and, ultimately, death. Table 1.7 lists the signs or symptoms of deficiency for each vitamin, its RDA or AI for young adults, and common food sources. The amount of each vitamin required in the diet is small (in the microgram or milligram range), compared with essential amino acid requirements (in the gram range). Vitamins are often divided into two classes, **water-soluble vitamins** and **fat-soluble vitamins**. This classification has little relationship to their function but is related to the absorption and transport of fat-soluble vitamins with lipids.

TABLE 1.7 Vitamins

VITAMIN	DIETARY REFERENCE INTAKES (DRI) FEMALES (F) MALES (M) (18–30 YEARS OLD)	SOME COMMON FOOD SOURCES	CONSEQUENCES OF DEFICIENCY (NAMES OF DEFICIENCY DISEASES ARE IN BOLD)

<i>Water-Soluble Vitamins</i>			
Vitamin C	RDA F: 75 mg M: 90 mg UL: 2 g	Citrus fruits; potatoes; peppers, broccoli, spinach; strawberries	Scurvy: defective collagen formation leading to subcutaneous hemorrhage, aching bones, joints, and muscle in adults; rigid position and pain in infants
Thiamine	RDA F: 1.1 mg M: 1.2 mg	Enriched, fortified, and whole grain cereals and breads; pork; legumes, seeds, nuts	Beriberi: (wet) edema; anorexia, weight loss; apathy, decrease in short-term memory, confusion; irritability; muscle weakness; an enlarged heart
Riboflavin	RDA F: 1.1 mg M: 1.3 mg	Dairy products; enriched, fortified, and whole grain cereals; meats, poultry, fish; legumes	Ariboflavinosis: Sore throat, hyperemia, edema of oral mucosal membranes; cheilosis, angular stomatitis; glossitis, magenta tongue; seborrheic dermatitis; normochromic normocytic anemia
Niacin ^a	RDA F: 14 mg NEQ M: 16 mg NEQ UL: 35 mg	Meat, poultry, fish; enriched and whole grain cereals and breads; all protein-containing foods	Pellagra: Pigmented rash in areas exposed to sunlight; vomiting; constipation or diarrhea; bright red tongue; neurologic symptoms
Vitamin B ₆ (pyridoxine)	RDA F: 1.3mg M: 1.3mg UL: 100mg	Meat, poultry, fish; eggs; fortified cereals, unmilled rice, oats; starchy vegetables; noncitrus fruits; peanuts, walnuts	Seborrheic dermatitis; microcytic anemia; epileptiform convulsions; depression and confusion
Folate	RDA F: 400 µg M: 400 µg UL: 1000 µg	Citrus fruits; leafy green vegetables; fortified cereals and breads; legumes	Impaired cell division and growth; megaloblastic anemia ; neural tube defects
Vitamin B ₁₂	RDA F: 2.4 µg M: 2.4 µg	Animal products ^b	Megaloblastic anemia ; Neurologic symptoms
Biotin	AI F: 30 µg M: 30 µg	Liver, egg yolk	Conjunctivitis; central nervous system abnormalities; glossitis; alopecia; dry, scaly dermatitis
Pantothenic acid	AI F: 5 mg M: 5 mg	Wide distribution in foods, especially animal tissues; whole grain cereals; legumes	Irritability and restlessness; fatigue, apathy, malaise; gastrointestinal symptoms; neurologic symptoms
Choline ^c	AI F: 425 mg M: 550 mg UL: 3.5 g	Milk; liver; eggs; peanuts	Liver damage
<i>Fat-Soluble Vitamins</i>			
Vitamin A	RDA F: 700 µg	Milk and milk products; dark green and leafy vegetables; broccoli; deep orange fruits	Night blindness; xerophthalmia ; keratinization of epithelium in

	M: 900 µg UL: 3000 µg	and vegetables (carrots, sweet potatoes, squash)	gastrointestinal, respiratory, and genitourinary tract; dry and scaly skin
Vitamin K	AI F: 90 µg M: 120 µg	Green leafy vegetables; cabbage family (brassica); vegetable oils; bacterial flora of intestine	Defective blood coagulation; hemorrhagic anemia of the newborn
Vitamin D	RDA ^d F: 15 µg M: 15 µg UL: 100 µg	Fortified milk; fortified margarine, butter, and cereals; eggs; fatty fish; exposure of skin to sunlight	Rickets (in children); inadequate bone mineralization (osteomalacia)
Vitamin E	RDA F: 15 mg M: 15 mg UL: 1 g	Vegetable oils, margarine; wheat germ; nuts; green leafy vegetables	Muscular dystrophy, neurologic abnormalities

AI, Adequate Intake; DRI, Dietary Reference Intakes; RDA, Recommended Dietary Allowance; UL, Tolerable Upper Intake Level.

^aNEQ = niacin equivalents. Niacin can be synthesized in humans from tryptophan, and this term takes into account a conversion factor for dietary tryptophan.

^bVitamin B₁₂ is found only in animal products.

^cCholine is an essential nutrient, but not a vitamin although it is grouped into the category of vitamin B₄ along with other important molecules like carnitine.

^dDietary requirement assumes the absence of sunlight.

Adapted from the Dietary Reference Intake series, National Academies Press.

This information can also be obtained via the Web, at <http://nal.usda.gov/>; click on Dietary guidance, then dietary reference intakes, and then DRI nutrient reports.

Malnutrition, deficient or excess intake of energy or nutrients, occurs in the United States principally among children of families with incomes below the poverty level, the elderly, individuals whose diet is influenced by alcohol and drug usage, and those who make poor food choices. In 2018 in the United States, about 11.8 million children lived in families with incomes below the poverty level. Of these, approximately 10% have clinical malnutrition, most often anemia resulting from inadequate iron intake. A larger percentage have mild protein and energy malnutrition and exhibit growth retardation, sometimes as a result of parental neglect. Childhood malnutrition may also lead to learning failure and chronic illness later in life. A weight-for-height measurement is one of the best indicators of childhood malnourishment because it is easy to measure, and weight is one of the first parameters to change during malnutrition.

The term **kwashiorkor** refers to a disease originally seen in African children suffering from a protein deficiency (although overall energy intake may be normal). It is characterized by marked hypoalbuminemia (low levels of albumin in the blood), anemia, edema (buildup of fluids in the interstitial spaces), potbelly, loss of hair, and other signs of tissue injury. The term **marasmus** is used for prolonged protein and energy malnutrition, particularly in young children. Marasmus is characterized by loss of weight and body fat, muscle wasting, and poor growth. Children with marasmus usually do not develop edema. The term **protein–energy malnutrition** (PEM) can be used to describe both disorders. The term **severe acute malnutrition** (SAM) refers to inadequate intake of vitamins and minerals, as well as energy and protein.

Most vitamins are used as precursors for **coenzymes**, complex organic molecules that assist enzymes in catalyzing biochemical reactions, and the deficiency symptoms reflect an inability of cells to carry out certain reactions. However, some vitamins also act as hormones. We will consider the roles played by individual vitamins as we progress through the subsequent chapters of this text.

Although the RDA or AI for each vitamin varies with age and sex, the difference is usually not very large once adolescence is reached. For example, the RDA for riboflavin is 0.9 mg/day for males between 9 and 13 years of age, 1.3 mg/day for males 19 to 30 years of age, still 1.3 mg/day for males older than 70 years, and 1.1 mg/day for females aged 19 to 30 years. The largest requirements occur during lactation (1.6 mg/day).

Vitamins, by definition, cannot be synthesized in the body or are synthesized from a very specific dietary precursor in insufficient amounts. For example, we can synthesize the vitamin niacin from the essential amino acid tryptophan, but not in sufficient quantities to meet our needs. Niacin is therefore still classified as a vitamin. This is similar to vitamin D, which is synthesized from its precursor cholesterol (see Chapter 32).

Excessive intake of many vitamins, both fat-soluble and water-soluble, may cause deleterious effects. For example, high doses of vitamin A, a fat-soluble vitamin, can cause desquamation of the skin and birth defects. Very high doses of vitamin C cause diarrhea and gastrointestinal disturbances. One of the Dietary Reference Intake values is the **Tolerable Upper Intake Level (UL)**, which is the highest level of daily nutrient intake that is likely to pose no risk of adverse effects to almost all individuals in the general population. As intake increases above the UL, the risk of adverse effects increases. Table 1.7 includes the UL for vitamins known to pose a risk at high levels. Intake above the UL occurs most often with dietary or pharmacologic supplements of single vitamins, rather than from foods.

E. Minerals

Many **minerals** are required in the diet. They are generally divided into macro or major minerals and micro or trace minerals, depending on the amounts required. Electrolytes (inorganic ions that are dissolved in the fluid compartments of the body) are macrominerals (Table 1.8).

MAJOR	TRACE
Sodium ^a	Iodine
Potassium ^a	Selenium
Chloride ^a	Copper
Calcium	Zinc
Phosphorous	Iron
Magnesium	Manganese ^b
	Fluoride ^b
	Chromium ^b
	Molybdenum ^b

^aElectrolytes

^bUltratrace minerals

 Multiple vitamin deficiencies (as will be seen in **Percy V.**) accompanying malnutrition are far more common in the United States than the characteristic deficiency diseases associated with diets lacking just one vitamin because we generally eat a variety of foods. The characteristic deficiency diseases arising from single vitamin deficiencies were often identified and described in humans through observations of populations consuming a restricted diet because that was all that was available. For example, thiamine deficiency was discovered by a physician in Java, who related the symptoms of beriberi to diets composed principally of polished rice. Today, single vitamin deficiencies usually occur as a result of conditions that interfere with the uptake or utilization of a vitamin or as a result of poor food choices or a lack of variety in the diet. For example, peripheral neuropathy associated with vitamin E deficiency can occur in children with fat malabsorption, and alcohol consumption can result in beriberi. Vegans, individuals who consume diets lacking all animal products, can develop deficiency of vitamin B₁₂.

 In the hospital, it was learned that **Percy V.** had lost 22 lb in the 8 months since his last visit to his family physician, which is a very concerning amount of involuntary weight loss (>5% in 6 months). On admission, his hemoglobin (the iron-containing compound in the blood, which carries O₂ from the lungs to the tissues) was 10.7 g/dL (reference range, males = 12 to 15.5 g/dL), his serum ferritin was 15 ng/mL (reference range, males = 40 to 200 ng/mL), and other hematologic indices that reflect nutritional status were also abnormal. These values are indicative of an iron-deficiency anemia. His serum folic acid level was 0.9 ng/mL (reference range = 3 to 20 ng/mL), indicating a low intake of this vitamin. His vitamin B₁₂ level was 190 pg/mL (reference range = 180 to 914 pg/mL). A low blood vitamin B₁₂ level can be caused by decreased intake, absorption, or transport, but usually takes several years to develop because of large total body stores. His serum albumin was 3.2 g/dL (reference range = 3.5 to 5.0 g/dL), which is an indicator of protein malnutrition, liver disease, or both.

Sodium (Na⁺), potassium (K⁺), and chloride (Cl⁻) are the major electrolytes (ions) in the body. They are used to establish ion gradients across membranes, maintain water balance, and neutralize positive and negative charges on proteins and other molecules.

A dietary deficiency of calcium can lead to osteoporosis and osteomalacia, a disorder in which bones are insufficiently

mineralized and consequently are fragile and easily fractured. Osteoporosis is a particularly common problem among elderly women. Deficiency of phosphorus results in bone loss along with weakness, anorexia, malaise, and pain. Iron deficiencies lead to anemia, a decrease in the concentration of hemoglobin in the blood.

Calcium and phosphorus serve as structural components of bones and teeth and are thus required in relatively large quantities. Calcium (Ca^{2+}) plays many other roles in the body; for example, it is involved in hormone action and blood clotting. Phosphorus is required for the formation of ATP and phosphorylated intermediates in metabolism. Magnesium activates many enzymes and also forms a complex with ATP. Iron is a particularly important mineral because it functions as a component of hemoglobin (the oxygen-carrying protein in the blood) and is required by many enzymes involved in oxidation–reduction reactions. Other minerals, such as zinc or molybdenum, are required in very small quantities (trace or ultratrace amounts).

Sulfur is ingested principally in the amino acids cysteine and methionine. It is found in connective tissue, particularly in cartilage and skin. It has important functions in metabolism, which we will describe when we consider the action of **coenzyme A**, a compound used to activate carboxylic acids. Sulfur is excreted in the urine as sulfate.

Which foods would provide **Percy V.** with good sources of folate and vitamin B_{12} ?

Minerals, like vitamins, have adverse effects if ingested in excessive amounts. Problems associated with dietary excesses or deficiencies of minerals are described in subsequent chapters in conjunction with their normal metabolic functions.

F. Water

Water constitutes one-half to four-fifths of the weight of the human body. The intake of water required per day depends on the balance between the amount produced by body metabolism and the amount lost through the skin, through expired air, and in the urine and feces.

V. Dietary Guidelines

Dietary guidelines or goals are recommendations for food choices that can reduce the risk of developing chronic diseases while maintaining an adequate intake of nutrients. Many studies have shown an association between diet and physical activity and decreased risk of certain diseases, including hypertension, atherosclerosis, stroke, diabetes, certain types of cancer, and osteoarthritis. Thus, the American Heart Institute and the American Cancer Institute, as well as several other groups, have developed diet and physical activity recommendations to decrease the risk of these diseases. The *Dietary Guidelines for Americans (2015–2020)* are prepared by an advisory committee of researchers appointed by the U.S. Department of Agriculture and the U.S. Department of Health and Human Services to review the current evidence and revise the guidelines accordingly every 5 years (you can view these at the Web site listed in the references). Recommended servings of different food groups can be customized for individuals accessing the U.S. Department of Agriculture (USDA) MyPlate Web site (see references). Physicians and dietitians can tailor the dietary guidelines to meet the needs of their patients with specific medical conditions.

A. General Recommendations

- Choose a healthy eating pattern at an appropriate calorie level to help achieve and maintain healthy body weight. For maintenance of weight, energy intake should balance energy expenditure. Accumulate at least 150 minutes of moderate physical activity (such as walking at a pace of 3 to 4 miles per hour) weekly, and engage in muscle-strengthening exercises at least two days a week. A regular physical activity program helps in achieving and maintaining healthy weight, cardiovascular fitness, and strength.
- Choose nutrient-dense foods in the amounts recommended by your personalized plan from MyPlate, including a variety of whole grains, fruits and vegetables, and fat-free or low-fat dairy products, and lean protein foods daily.
- Practice food safety by frequently cleaning hands, cutting boards, and countertops; cooking foods to safe temperatures; and refrigerating leftovers promptly.

Recent data indicate that the consumption of “ultraprocessed” food is associated with an increased risk for cardiovascular

disease. Ultraprocessed foods are those to which five or more outside ingredients have been added to improve flavor, or texture, or shelf life.

B. Carbohydrates

- A diet rich in vegetables, fruits, and grain products should be chosen, providing 45% to 65% of its calories as carbohydrates. A variety of vegetables from all the subgroups (i.e., dark green, red and orange, legumes, starchy, and other) and whole fruits should be included in a healthy eating pattern. In regard to grains (e.g., starches and other complex carbohydrates, in the form of breads, fortified cereals, rice, and pasta), at least half should be whole grains. In addition to energy, vegetables, fruits, and grains supply vitamins, minerals, phytochemicals (protective compounds such as carotenoids, flavonoids, and lycopene), and fiber. Fiber, the indigestible part of plant food, has various beneficial effects, including relief of constipation.
- The consumption of added sugars in foods and beverages should be limited to <10% of total calories. Added sugars have no nutritional value other than calories, and they promote tooth decay.

Folate is found in fruits and vegetables: citrus fruits (e.g., oranges), green leafy vegetables (e.g., spinach and broccoli), fortified cereals, and legumes (e.g., peas) (see Table 1.7). Conversely, vitamin B₁₂ is found only in foods of animal origin, including meats, eggs, and milk.

C. Fats

- Dietary fat should account for 20% to 35% of total calories, and saturated fatty acids should account for <10% of total calories. Fats derived from fish, nuts, and vegetables, which are primarily polyunsaturated and monosaturated fatty acids, are preferred. Owing to their saturated fat content, meats such as fatty beef, lamb, pork, and poultry with skin and full-fat dairy products such as cheese, whole milk, butter, and ice cream should be limited. *Trans*-fatty acids, such as the partially hydrogenated vegetable oils found in stick margarines, baked goods, and fried foods, should be avoided.
- Saturated and *trans* fats have been demonstrated to increase circulating low-density lipoprotein (LDL)-cholesterol levels but surprisingly the amount of cholesterol in the diet is not as well correlated with circulating cholesterol levels. There are no current guidelines for cholesterol consumption, other than to eat a varied diet and all foods in moderation. Major sources of dietary cholesterol in the American diet include beef, poultry, processed meats, eggs, cheese, and ice cream.

Cholesterol is obtained from the diet and synthesized in most cells of the body. It is a component of cell membranes and the precursor of steroid hormones and the bile salts used for fat absorption. High concentrations of cholesterol in the blood, particularly the cholesterol in lipoprotein particles called low-density lipoproteins (LDL), contribute to the formation of atherosclerotic plaques inside the lumen of arterial vessels, particularly in the heart and brain. These plaques (fatty deposits on arterial walls) can obstruct blood flow to these vital organs causing heart attacks and strokes. A high content of saturated fat and *trans* fat in the diet tends to increase circulatory levels of LDL cholesterol and contributes to the development of atherosclerosis.

D. Proteins

- Protein intake for adults should be approximately 0.8 g/kg healthy body weight per day. The protein should be of high quality and should be obtained from sources low in saturated fat (e.g., fish, poultry, beans, lentils, low-fat/fat-free dairy products, and soy products). Vegans should eat a mixture of plant proteins that ensures the intake of adequate amounts of the essential amino acids.

E. Alcohol

- Alcohol consumption should not exceed moderate drinking and should only be consumed by adults of legal drinking age. Moderate drinking is defined as no more than one drink per day for women and no more than two drinks per day for men. A drink is defined as 12 oz of beer, 5 oz of wine (a little over ½ cup), or 1.5 oz of an 80-proof liquor such as whiskey. Pregnant women should drink no alcohol. The ingestion of alcohol by pregnant women can result in fetal alcohol syndrome (FAS), which is marked by prenatal and postnatal growth deficiency; developmental delay; and craniofacial, limb, and cardiovascular defects.

The high content of sodium (in table salt) in the average American diet appears to be related to the development of

hypertension (high blood pressure) in individuals who are genetically predisposed to this disorder.

F. Vitamins and Minerals

- Sodium intake should be decreased in most individuals. Sodium is usually consumed as salt, NaCl. Less than 2.3 g of sodium, which is equivalent to the sodium in 1 tablespoon of salt, should be consumed daily.
- Many of the required vitamins and minerals can be obtained from eating a variety of fruits, vegetables, and grains (particularly whole grains). Low-fat or fat-free dairy products are excellent sources of calcium; some dark green leafy vegetables provide available calcium. Lean meats, shellfish, poultry, dark meat, cooked dry beans, and some leafy green vegetables are good sources of iron. Vitamin B₁₂ is found only in animal sources.
- Dietary supplementation in excess of recommended amounts (e.g., megavitamin regimens) should be avoided.
- Fluoride should be present in the diet, at least during the years of tooth formation, as a protection against dental caries. However, in addition to fluoridated water, many sources exist (toothpaste, tea, produce from plants grown with a fluorinated pharmaceutical, and others), and only small amounts (0.7 to 3 mg/day depending on age) are recommended.

VI. Xenobiotics

In addition to nutrients, our diet contains a large number of chemicals called xenobiotics (such as drugs, pesticides, cosmetics, and food additives), which have no nutritional value, are of no use in the body, and can be harmful if consumed in excessive amounts. These compounds occur naturally in foods, can enter the food chain as contaminants, or can be deliberately introduced as food additives.

Dietary guidelines of the American Cancer Society and the American Institute for Cancer Research make recommendations relevant to the ingestion of xenobiotic compounds, particularly carcinogens. The dietary advice that we eat a variety of food helps to protect us against the ingestion of toxic level of any one xenobiotic compound. It is also suggested that we minimize consumption of salt-cured, smoked, and charred foods, which contain chemicals that can contribute to the development of cancer. Other guidelines encourage the ingestion of fruits and vegetables, which contain protective phytochemicals that act as antioxidants.

CLINICAL COMMENTS

Otto S. sought help in reducing his weight of 187 lb (BMI of 27) to his previous level of 154 lb (BMI of 22, in the middle of the healthy range). He is 5 ft 10 in tall, and he calculated that his maximum healthy weight was 173 lb. He planned on becoming a family physician, and he knew that he would be better able to counsel patients in healthy lifestyle behaviors such as diet and physical activity if he practiced them himself. With this information and assurances from the physician that he was otherwise in good health, **Otto S.** embarked on a weight loss program. One of his strategies involved recording all the food he ate and the portions. To analyze his diet for calories, saturated fat, and nutrients, he used the MyPlate personalized plan (see references), available online from the USDA Center for Nutrition Policy and Promotion (CNPP). As part of his program, he met with a registered dietitian who provided the following: tips for buying and cooking nutrient-dense foods at a reasonable cost; tips for modifying eating behavior (e.g., slowing down the pace of eating); the setting of realistic achievable goals (e.g., loss of 10% of initial body weight within 6 months); and tips for dealing with relapse into prior habits.

The prevalence of obesity in the U.S. population is increasing. In 1962, 12.8% of the population had a BMI equal to or >30 and therefore were clinically obese. That number increased to 14.5% by 1980 and to 22.5% by 1998. An additional 30% were overweight in 1998 (BMI = 25.0 to 29.9). In 2012, based on BMI values, 35.1% of adults were classified as obese, and an additional 33.9% were classified as overweight. By mid-2018, >35% of the individuals in seven states were classified as obese. More than 30% of the populations in 29 states were obese, and >25% of individuals in 40 states were considered obese. It is apparent, therefore, that more than two-thirds of the U.S. population is currently overweight or obese.

An elevated BMI increases cardiovascular risk factors, including hypertension, diabetes mellitus, and alterations in blood lipid levels. It also increases the risk for respiratory problems, gallbladder disease, and certain types of cancer.

Ivan A. weighed 264 lb and was 70 in tall with a heavy skeletal frame. For a male of this height, a BMI of 18.5

to 24.9 would correspond to a weight between 129 and 173 lb. He is currently almost 100 lb overweight, and his BMI of 37.9 is in the obese range.

Ivan A.'s physician cautioned him that exogenous obesity (caused by overeating) represents a risk factor for atherosclerotic cardiovascular disease, particularly when the distribution of fat is primarily in the abdominal region (in contrast to adipose tissue deposited in the gluteal region). In addition, obesity may lead to other cardiovascular risk factors such as hypertension (high blood pressure), hyperlipidemia (high blood lipid levels), and type 2 diabetes mellitus (characterized by hyperglycemia). He already has elevated blood pressure. Furthermore, his total serum cholesterol level was 296 mg/dL, well above the normal value (200 mg/dL).

Ivan A. was referred to the hospital's weight reduction center, where a team of physicians, dietitians, and psychologists could assist him in reaching a healthy BMI.

Ann R. Because of her history and physical examination, **Ann R.** was diagnosed with anorexia nervosa, a psychiatric illness involving a disturbance in body image, which results in low body weight, malnutrition, and other medical complications. She was referred to a multidisciplinary team that included a psychiatrist with expertise in anorexia nervosa, and a program of psychotherapy and behavior modification was initiated.

Percy V. weighed 125 lb and was 71 in tall (without shoes) with a medium frame. His BMI was 17.5, which is significantly underweight. At the time his wife died, he weighed 147 lb. For his height, a BMI in the healthy weight range corresponds to weights between 132 and 178 lb.

Percy V.'s malnourished state was reflected in his admission laboratory profile. The results of hematologic studies were consistent with an iron-deficiency anemia complicated by low levels of folic acid and vitamin B₁₂, two vitamins required for the development of normal red blood cells. His low serum albumin level was caused by insufficient protein intake and a shortage of essential amino acids, which result in a reduced ability to synthesize body proteins. The psychiatrist requested a consultation with a hospital dietitian to evaluate the extent of **Percy V.**'s severe acute malnutrition (malnutrition caused by an inadequacy of protein, energy, vitamins, and minerals).

When **Ivan A.** met with the dietitian to discuss his weight loss plans, he received the following advice: tips for devising a meal plan that will provide consistent amounts of complex carbohydrates throughout the day for glucose control while limiting calories, saturated and *trans* fat, and sodium; tips for small, incremental dietary changes to achieve a diet that is lower in *trans* fat, sodium, and refined carbohydrates while high in essential nutrients via whole grains, fruits, vegetables, lean protein, and nonfat/low-fat dairy products. He was also counseled in a similar manner to **Otto S.**, with an emphasis on the importance of losing 10% of initial body weight for improvement in blood pressure, blood lipids, and glucose control.

BIOCHEMICAL COMMENTS

Dietary Reference Intakes. Dietary Reference Intakes (DRIs) are quantitative estimates of nutrient intakes that can be used in evaluating and planning diets for healthy people. They are prepared by the Standing Committee on the Scientific Evaluation of Dietary Reference Intakes of the Food and Nutrition Board, Institute of Medicine, and the National Academy of Science, with active input from Health Canada. The four reference intake values are the RDA, the Estimated Average Requirement (EAR), the AI, and the UL. Practitioners use the RDA, AI, and UL values for evaluating patients' nutrient intakes. Researchers and policymakers use the EAR values as an estimate of nutrient intakes of populations rather than individuals. For each nutrient, the Committee has reviewed available literature on studies with humans and established criteria for adequate intakes, such as prevention of certain deficiency symptoms, prevention of developmental abnormalities, or decreased risk of chronic degenerative disease. The criteria are not always the same for each life stage group. A requirement is defined as the lowest continuing intake level of a nutrient able to satisfy these criteria. The EAR is the daily intake value that is estimated to meet the requirement in half of the apparently healthy individuals in a life stage or gender group. The RDA is the EAR plus 2 standard deviations of the mean, which is the amount that should satisfy the requirement in 97% to 98% of the population. The AI level instead of an RDA is set for nutrients when there are not enough data to determine the EAR.

The UL refers to the highest level of daily nutrient intake consumed over time that is likely to pose no risks of adverse effects for almost all healthy individuals in the general population. Adverse effects are defined as any significant alteration in the structure or function of the human body. The UL does not mean that most

individuals who consume more than the UL will suffer adverse health effects, but that the risk of adverse effects increases as intake increases above the UL.

KEY CONCEPTS

- ◆ Fuel is provided in the form of carbohydrates, fats, and proteins in our diet.
- ◆ Energy is obtained from the fuel by oxidizing it to carbon dioxide and water.
- ◆ Unused fuel can be stored as triacylglycerol (fat) or glycogen (carbohydrate) within the body.
- ◆ Weight gain or loss is a balance between the energy consumed in our diet and the energy required each day to drive the basic functions of our body and our physical activity. The DEE is the amount of fuel consumed in a 24-hour period.
- ◆ BMR is a measure of the energy required to maintain involuntary bodily functions such as respiration, contraction of the heart muscle, biosynthetic processes, and establishment of ion gradients across neuronal membranes.
- ◆ The DEE is determined by the BMR and the individual's activity level while awake.
- ◆ The BMI is a weight-to-height ratio that is used to determine a healthy weight for an individual and to classify a person as underweight, healthy weight, overweight, or obese.
- ◆ In addition to macronutrients, the diet provides vitamins, minerals, essential fatty acids, and essential amino acids.
- ◆ The RDA and the AI provide quantitative estimates of nutrient requirements.
- ◆ The UL indicates the highest level of daily nutrient uptake that is likely to pose no risk of adverse effects.
- ◆ A summary of the diseases/disorders discussed in this chapter is presented in Table 1.9.

TABLE 1.9 Diseases Discussed in Chapter 1

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
Depression	Both	Diagnosed by behavioral changes, can be treated with a variety of pharmacologic agents and counseling therapy
Obesity	Both	Long-term effects of obesity affect the cardiovascular system and may lead to metabolic syndrome
Anorexia nervosa	Both	Self-induced reduction of food intake, distorted body image, considered at least in part a psychiatric disorder
Kwashiorkor	Environmental	Protein and mineral deficiency even though normal amount of calories in the diet. Leads to marked hypoalbuminemia, anemia, edema (appearance of potbelly), loss of hair, and other indications of tissue injury
Marasmus	Environmental	Prolonged calorie and protein malnutrition
Osteoporosis/osteomalacia	Both	Calcium-deficient diet leading to insufficient mineralization of the bones, which produces fragile and easily broken bones. Osteoporosis also runs in families.

Diseases that may have a genetic component are indicated as genetic; disorders caused by environmental factors (with or without genetic influences) are indicated as environmental.

REVIEW QUESTIONS—CHAPTER 1

Directions: For each question below, select the single best answer.

1. A dietitian is counseling a patient with celiac sprue (intolerance to gluten, leading to malabsorption issues in the intestine) and describing a diet with appropriate carbohydrate, fat, and protein content. Once properly absorbed, the major fate, during respiration, of these compounds is which ONE of the following?
 - A. They are stored as triacylglycerols.
 - B. They are oxidized to generate ATP.
 - C. They release energy principally as heat.

- D. They combine with CO_2 and H_2O and are stored.
- E. They combine with other dietary components in anabolic pathways.
2. A dietitian is counseling a patient with celiac sprue (intolerance to gluten, leading to malabsorption issues in the intestine) who has experienced steatorrhea (fatty stools caused by poor absorption of dietary lipids in the intestine) for a number of years. The dietitian, in addition to listing appropriate carbohydrates, lipids, and proteins that will not trigger the malabsorption issue, encourages the patient to take certain vitamins. Which ONE of the following vitamins is most likely on this list?
- A. Vitamin C
 - B. Vitamin B_3
 - C. Vitamin B_2
 - D. Vitamin A
 - E. Vitamin B_1
3. Mrs. Jones is a sedentary 83-year-old woman who is 5 ft 4 in tall and weighs 125 lb. She has been at this weight for about a year. She says that a typical diet for her includes a breakfast of toast (white bread, no butter), a boiled egg, and coffee with cream. For lunch, she often has a cheese sandwich (white bread) and a glass of whole milk. For supper, she prefers cream of chicken soup and a slice of frosted cake. Mrs. Jones's diet is most likely to be inadequate in which one of the following?
- A. Vitamin C
 - B. Protein
 - C. Calcium
 - D. Vitamin B_{12}
 - E. Calories
4. A patient is trying to lose weight and wonders what her ideal number of calories per day might be. A dietitian is helping her by estimating the BMR, the DIT, and physical activity. The BMR is best estimated by consideration of which one of the following?
- A. It is equivalent to the caloric requirement of our major organs and resting muscle.
 - B. It is approximately equivalent to the amount of physical activity.
 - C. It is approximately equivalent to the DIT.
 - D. It is dependent on the external humidity.
 - E. It is approximately equivalent to the DEE.
5. A friend of yours has decided to go on a crash diet, consuming only 700 calories/day. You advise your friend that he is at risk for certain dietary deficiencies and inform him of RDA, which is best described by which one of the following?
- A. The average amount of a nutrient required each day to maintain normal function in 50% of the U.S. population
 - B. The average amount of a nutrient ingested daily by 50% of the U.S. population
 - C. The minimum amount of a nutrient ingested daily that prevents deficiency symptoms
 - D. A reasonable dietary goal for the intake of a nutrient by a healthy individual
 - E. A reasonable dietary goal for the intake of a nutrient as based on studies with laboratory animals and extrapolated to humans
6. A 35-year-old sedentary male patient weighing 120 kg was experiencing angina (chest pain) and other signs of coronary artery disease. His physician, in consultation with a registered dietitian, conducted a 3-day dietary recall. The patient consumed an average of 585 g of carbohydrate, 150 g of protein, and 95 g of fat each day. In addition, he drank 45 g of alcohol. The patient's diet is best described by which one of the following?
- A. He consumed between 2,500 and 3,000 kcal/day.
 - B. He had a fat intake within the range recommended in current dietary guidelines.
 - C. He consumed 50% of his calories as alcohol.
 - D. He was deficient in protein intake.
 - E. He was in negative caloric balance.
7. A sedentary male weighing 75 kg is trying to lose weight and has begun a calorie-restricted diet. He has reduced his daily intake by 10 g of carbohydrates, 10 g of fat, 10 g of protein, and 10 g of ethanol. By what percentage has this man reduced his daily intake as compared to what he would require maintaining his current weight?
- A. 5%

- B. 10%
 - C. 15%
 - D. 20%
 - E. 25%
8. A 45-year-old man developed deep vein thrombosis and subsequently a pulmonary embolism. The patient, after recovery, was placed on warfarin to prevent future blood clots. The patient was counseled by a dietitian to limit his consumption of which one of the following foods, owing to the finding that eating the food could interfere with the action of warfarin?
- A. Egg yolks
 - B. Yellow vegetables
 - C. Citrus fruits
 - D. Green leafy vegetables
 - E. Skinless chicken
9. A 25-year-old female with Hashimoto thyroiditis is being treated with thyroid hormone replacement and is now euthyroid. She wishes to lose some of the weight she gained while she was in a hypothyroid state. In order to help her lose weight, her dietitian must determine her DEE in order to design a diet with fewer calories than her DEE. The patient weighs 70 kg, is moderately active (1 to 2 hours of exercise 5 days a week), and is currently consuming 2,700 calories/day. If the patient is to lose 1 lb per week, she would need to reduce her daily consumption by how many calories per day?
- A. 200
 - B. 400
 - C. 600
 - D. 800
 - E. 1,000
10. A patient with cirrhosis is having mental status changes owing to elevated ammonia levels in his blood. In prescribing a diet to reduce ammonia production in this patient, which type of nutrient should be most restricted?
- A. Ethanol
 - B. Lipids
 - C. Proteins
 - D. Carbohydrates
 - E. Water-soluble vitamins
11. A 38-year-old male had just completed his annual physical exam. His physician told him that his daily caloric intake (as estimated from a 3-day dietary history the man had completed prior to the physical exam), coupled with his calculated DEE, would lead to a weight gain of 1.5 lb per month. The patient was advised to make some dietary changes to prevent this from happening. In order to maintain his current weight, the patient was advised to reduce his current daily dietary intake by which one of the following?
- A. 25 g of carbohydrate
 - B. 20 g of protein
 - C. 20 g of fat
 - D. 10 g of ethanol
 - E. 10 g of carbohydrate and 10 g of ethanol
12. A 50-year-old woman has visited her physician owing to tiredness and a persistent tingling in her hands and feet. The patient had switched to a strict vegan diet 3 years ago and had avoided all meat and dairy products since then. She also does not take any dietary supplements as she was convinced her healthy diet should be sufficient for her needs. An analysis of her blood demonstrated a reduced red blood cell number (anemia) along with the presence of some very large cells (megaloblasts). The woman was most likely deficient in which one of the following vitamins?
- A. B₁
 - B. B₂
 - C. B₃
 - D. B₆
 - E. B₁₂
13. A well-balanced diet contains a certain percentage of calories as carbohydrate, fat, and protein, along with vitamins and minerals. Which one of the following does not contain molecules that are essential for the

human diet?

- A. Carbohydrate
 - B. Fat
 - C. Protein
 - D. Vitamins
 - E. Minerals
4. Triacylglycerol is a preferred energy storage form in humans owing to which of the following? Choose the one best answer.

	Owing to Its Association with Water When Stored	Owing to It Being Stored in Specialized Cells	Owing to It Being More Oxidized than Other Energy Storage Forms
A	Yes	No	Yes
B	Yes	Yes	Yes
C	Yes	No	No
D	No	Yes	No
E	No	No	Yes
F	No	Yes	Yes

5. A former Mr. Olympia (bodybuilder) was 5 ft 11 in tall (180 cm) and competed at 300 lb (136 kg). Mr. Olympia's BMI would place him in which of the following categories?
- A. Underweight
 - B. Normal
 - C. Overweight
 - D. Obese
 - E. Morbidly obese

ANSWERS TO REVIEW QUESTIONS

1. **The answer is B.** In the process of respiration, O_2 is consumed and fuels are oxidized to CO_2 and H_2O . The energy from the oxidation reactions is used to generate ATP from ADP and P_i . However, a small amount of energy is also released as heat (thus, C is incorrect). Although fuels can be stored as triacylglycerols, this is not part of respiration (thus, A is incorrect). Respiration is a catabolic pathway (fuels are degraded), as opposed to an anabolic pathway (compounds combine to make larger molecules) (thus, E is incorrect).
2. **The answer is D.** Vitamin A is a fat-soluble vitamin, and it is absorbed from the small intestine in the presence of lipids. If lipids cannot be absorbed, the fat-soluble vitamins will also not be absorbed (vitamins A, D, E, and K). The other vitamins listed (B_1 , B_2 , B_3 , and C) are all water-soluble vitamins that do not require the presence of lipid for absorption from the intestinal lumen.
3. **The answer is A.** Mrs. Jones's diet lacks fruits and vegetables, both of which are good sources of vitamin C. Her diet is adequate in protein, as eggs, milk, cheese, and cream contain significant levels of protein. Her calcium levels should be fine owing to the milk, cream, and cheese in her diet. Vitamin B_{12} is derived from foods of animal origin, such as eggs, milk, and cheese. As the patient's weight has been stable for a year, her diet contains sufficient calories to allow her to maintain this weight, which is in the normal range for a patient who is 5 ft 4 in tall, as her BMI is 21.5.
4. **The answer is A.** The BMR is the calories being expended by a recently awakened resting person who has fasted 12 to 18 hours and is at $20^\circ C$. It is equivalent to the energy expenditure of our major organs and resting skeletal muscle. The BMR increases in a cold environment because more energy is being expended to generate heat, but the humidity is not a factor in calculating the BMR. The BMR is not equivalent to our DEE, which includes BMR, physical activity, and DIT. The BMR is also not equivalent to one's physical activity (the BMR does not take into account physical activity) or to the DIT (which is rather small).
5. **The answer is D.** The RDA of a nutrient is determined from the EAR + 2 standard deviations (SD) of the

mean and should meet the needs for 97% to 98% of the healthy population. It is therefore a reasonable goal for the intake of a healthy individual. The EAR is the amount that prevents the development of established signs of deficiency in 50% of the healthy population. Although data with laboratory animals have been used to establish deficiency symptoms, RDAs are based on data collected on nutrient ingestion by humans, not in animals.

6. **The answer is B.** The recommended total fat intake is <35% of total calories, with saturated fats at <10% of calories/day. His total caloric consumption was 4,110 kcal/day (carbohydrate, $4 \times 585 = 2,340$ kcal; protein $150 \times 4 = 600$ kcal; fat, $95 \times 9 = 855$ kcal; alcohol, $45 \times 7 = 315$ kcal) (thus, A is incorrect). His fat intake was 21% ($855 \div 4,110$) of his total caloric intake. His alcohol intake was 7.7% ($315 \div 4,110$) (thus, C is incorrect). His protein intake was well above the RDA of 0.8 g/kg body weight (thus, D is incorrect). His BMR is roughly 24 kcal/day/kg body weight or 2,880 kcal/day (it will actually be less because he is obese and has a greater proportion of metabolically less active tissue than the average 70-kg man). His DEE is about 3,744 kcal/day ($1.3 \times 2,880$) or less. Thus, his intake is greater than his expenditure, and he is in positive caloric balance and is gaining weight (thus, E is incorrect).
7. **The answer is B.** The man weighs 75 kg, so a rough estimate of his daily caloric need (to maintain his weight) is $75 \times 24 \times 1.3 = 2,340$ calories/day (1.3 is the sedentary activity factor). The man has reduced his daily intake by 240 Calories (10 g of carbohydrates is 40 calories; 10 g of protein is 40 calories; 10 g of lipid is 90 calories; 10 g of ethanol is 70 calories; $40 + 40 + 90 + 70 = 240$). Thus, the man has reduced his daily intake by approximately 10% of that needed to maintain his weight ($240/2,340$).
8. **The answer is D.** Warfarin acts by inhibiting the ability of vitamin K to participate in reactions required by clotting factors. If one's diet contains additional vitamin K, the efficacy of warfarin could be reduced. Green, leafy vegetables are an excellent source of vitamin K, and their consumption should be limited while on warfarin therapy.
9. **The answer is D.** The patient's DEE is calculated as $70 \times 21.6 \times 1.6 = 2,420$ (70 kg weight \times 21.6 calories/kg/day \times 1.6 activity factor for being moderately active). Because the patient is currently consuming 2,700 calories/day, she is gaining weight despite her activity. To lose 1 lb of weight, a reduction of 3,500 calories must occur. Over a 1-week period, this works out to 500 calories/day. Thus, the patient should be consuming 1,920 calories/day to lose 1 lb a week, which is approximately 800 fewer calories/day than her current consumption.
10. **The answer is C.** Ethanol, lipids (triglycerides), and carbohydrates do not contain a nitrogen group that is converted to ammonia during its catabolism—only proteins do. Water-soluble vitamins are present at low levels and are not appreciably catabolized, so their contribution to ammonia production is low as compared to protein catabolism.
11. **The answer is C.** The patient, per month, would be consuming about 5,250 calories ($3,500 \times 1.5$) in excess of his monthly need. This calculates to approximately 175 extra calories/day ($5,250 \div 30$). Because fat has a content of 9 calories/g, reducing the diet by 20 g of fat per day would reduce the caloric intake by 180 calories/day, thereby preventing weight gain in the patient. The oxidation of carbohydrates and protein both yield 4 calories/g, whereas the oxidation of ethanol yields 7 calories/g. None of the other answers results in a loss of 175 calories/day.
12. **The answer is E.** Vitamin B₁₂ is only found in meat or meat-derived products (such as dairy). Most adults have at least a 1-year store of vitamin B₁₂, so it takes an extended period of time without any B₁₂ intake to develop the symptoms of a B₁₂ deficiency. A B₁₂ deficiency leads to neuronal effects (the tingling in the hands and feet) and megaloblastic anemia (the anemia leads to tiredness). Deficiencies in vitamins B₁, B₂, B₃, and B₆ do not lead to the combination of neurologic effects coupled with megaloblastic anemia.
13. **The answer is A.** There are no essential carbohydrates in the mammalian diet. There are two essential fatty acids (linoleic and linolenic acids) and nine essential amino acids (as well as one conditionally essential amino acid) in the human diet. Vitamins by definition are essential, as are certain minerals. The major negative aspect of eating a carbohydrate-free diet is the concomitant increase in fat content of the diet, which will increase the risks for cardiovascular disease in the future. Increased protein intake also can be an issue, as increased water intake and high urea cycle activity are required to clear excess nitrogen. Liver and kidney function would have to be optimal for such a diet.
14. **The answer is D.** Triacylglycerol is hydrophobic and does not associate with water when stored, which reduces its volume as compared to glycogen storage, which is associated with a significant number of water molecules. Triacylglycerol is stored in specialized cells (adipose cells), whereas glycogen is stored in the cytoplasm of the cells that make it (primarily the muscle and liver). The fatty acids in

triacylglycerols are more reduced than the glucose in glycogen, so more energy can be obtained from the oxidation of fatty acids than can occur from the oxidation of glucose (more electrons are released to travel through the electron transfer chain).

15. **The answer is E.** The BMI is 41.8 ($136 \div 1.8^2$), which falls into the severely obese category. This example points out a limitation of using the BMI to determine appropriate weight–height balance. Muscular individuals will have higher BMI values than individuals with a similar adipose mass as muscle is more dense than adipose tissue and will lead to increased weight despite a nonobese appearance.

The Fed or Absorptive State

The Fed State. During a **meal**, we ingest carbohydrates, lipids, and proteins, which are subsequently **digested** and **absorbed**. Some of this food is **oxidized** to meet the immediate **energy** needs of the body. The amount consumed in **excess** of the body's energy needs is transported to the **fuel depots**, where it is stored. During the period from the start of absorption until absorption is completed, we are in the **fed**, or absorptive, state. Whether a fuel is oxidized or stored in the fed state is determined principally by the concentration of two **endocrine hormones** in the blood, **insulin** and **glucagon**.

Fate of Carbohydrates. Dietary carbohydrates are digested into monosaccharides, which are absorbed into the blood. The major monosaccharide in the blood is **glucose** (Fig. 2.1). After a meal, glucose is **oxidized** by various tissues for energy, enters biosynthetic pathways, and is **stored** as **glycogen**, mainly in the liver and muscle. Glucose is the major biosynthetic precursor in the body, and the carbon skeletons of most of the compounds we synthesize can be synthesized from glucose. Glucose is also converted to **triacylglycerols**. The liver packages triacylglycerols, made from glucose or from fatty acids obtained from the blood, into **very-low-density lipoproteins (VLDL)** and releases them into the blood. The fatty acids of the VLDL are stored mainly as triacylglycerols in adipose tissue, but some may be used to meet the energy needs of cells.

FIGURE 2.1 Major fates of fuels in the fed state. TG, triacylglycerol.

Fate of Proteins. Dietary proteins are digested into **amino acids**, which are absorbed into the blood. In cells, the amino acids are converted to **proteins** or used to make various **nitrogen-containing compounds** such as neurotransmitters and heme. The carbon skeleton may also be **oxidized** for energy directly or can be converted to glucose for storage as glycogen.

Fate of Fats. Triacylglycerols are the major lipids in the diet. They are digested into fatty acids and 2-monoacylglycerols, which are resynthesized into **triacylglycerols** in intestinal epithelial cells, packaged in **chylomicrons**, and secreted by way of the lymph into the blood. The **fatty acids** of the chylomicron triacylglycerols are stored mainly as triacylglycerols in **adipose** cells. They are subsequently oxidized for energy or used in biosynthetic pathways, such as the synthesis of membrane lipids.

THE WAITING ROOM

Ivan A. returned to his doctor for a second visit. His initial efforts to lose weight and follow the dietitian's recommendations had failed dismally. In fact, he now weighs 270 lb, an increase of 6 lb since his first visit 2 months ago (see Chapter 1). He reported that the recent death of his 45-year-old brother of a heart attack had made him realize that he must pay more attention to his health. Because **Ivan A.**'s brother had a history of hyperlipidemia and because **Ivan A.**'s serum total cholesterol was significantly elevated (296 mg/dL) at his first visit, his blood lipid profile was determined, he was screened for type 2 diabetes, and a few other blood tests were ordered. (The blood lipid profile is a measure of the content of the various triacylglycerol- and cholesterol-containing particles in the blood.) His systolic blood pressure was 162 mm Hg and diastolic blood pressure 98 mm Hg, or 162/98 mm Hg (normal $\leq 120/80$ mm Hg or less, with elevated blood pressure 120 to 129/<80, and hypertension defined as >130/80). His waist circumference was 48 in (healthy values for men, <40 in; for women, <35 in).

I. Digestion and Absorption

A. Carbohydrates

Dietary carbohydrates are converted to monosaccharides. Starch, a polymer of glucose, is the major carbohydrate of the diet. It is digested by the enzyme salivary α -amylase, and then by pancreatic α -amylase, which acts in the small intestine. Enzymes are proteins that catalyze biochemical reactions (usually they increase the speed at which the reactions occur). Di-, tri-, and oligosaccharides (disaccharide refers to two linked sugars; a trisaccharide to three linked sugars, and an oligosaccharide to n linked sugars) produced by these α -amylases are cleaved to glucose by digestive enzymes located on the surface of the brush border of the intestinal epithelial cells. Dietary disaccharides also are cleaved by enzymes at the brush border. Sucrase converts the disaccharide sucrose (table sugar) to glucose and fructose, and lactase converts the disaccharide lactose (milk sugar) to glucose and galactose. Monosaccharides produced by digestion and dietary monosaccharides are absorbed by the intestinal epithelial cells via transporters and are released into the hepatic portal vein, which carries them to the liver.

The body can make fatty acids from a caloric excess of carbohydrates and protein. These fatty acids, together with the fatty acids of chylomicrons (derived from dietary fat), are deposited in adipose tissue as triacylglycerols. Thus, **Ivan A.**'s increased adipose tissue is coming from his intake of all fuels in excess of his caloric need.

The laboratory studies ordered at the time of his second office visit show that **Ivan A.** has hyperglycemia, an elevation of blood glucose above normal values. At the time of this visit, his blood glucose determined after an overnight fast was 162 mg/dL (normal 70 to 100 mg/dL). Because this blood glucose measurement was significantly above normal, a hemoglobin A1c (glycosylated hemoglobin) was ordered. This value also was elevated. These test results led to a diagnosis of type 2 diabetes mellitus. In this disease, liver, muscle, and adipose tissue are relatively resistant to the action of insulin in promoting

glucose uptake into cells and storage as glycogen and triacylglycerols. Therefore, more glucose remains in his blood. If left untreated, this can lead to nervous system dysfunction and altered cellular metabolism. The registered dietitian met with **Ivan A.** to assess his current nutrient intake and to counsel him about a heart-healthy diet with a moderate amount of carbohydrates and an emphasis on high-fiber, minimally processed foods. Based on **Ivan A.**'s metabolic needs, the dietitian then developed a meal plan that allowed for 4 to 5 carbohydrate portions at each meal, and 2 carbohydrate portions each for an afternoon and evening snack. Note that a carbohydrate portion equals 15 g of carbohydrate (60 calories).

B. Proteins

Proteins contain amino acids that are linked through peptide bonds (see Chapter 1). Dipeptides contain two amino acids, tripeptides contain three amino acids, and so on. Dietary proteins are cleaved to amino acids by enzymes known as proteases (Fig. 2.2, circle 3), which cleave the peptide bond between amino acids (see Fig. 1.5). Pepsin acts in the stomach, and the proteolytic enzymes produced by the pancreas (trypsin, chymotrypsin, elastase, and the carboxypeptidases) act in the lumen of the small intestine. Aminopeptidases and di- and tripeptidases associated with the intestinal epithelial cells complete the conversion of dietary proteins to amino acids, which are absorbed into the intestinal epithelial cells and released into the hepatic portal vein.

FIGURE 2.2 The fed state. The circled numbers indicate the approximate order in which the processes occur. AA, amino acid; Acetyl CoA, acetyl coenzyme A; ATP, adenosine triphosphate; CHO, carbohydrate; FA, fatty acid; I, insulin; RBC, red blood cell; TCA, tricarboxylic acid; TG, triacylglycerols; VLDL, very-low-density lipoprotein; ⊕, stimulated by.

C. Fats

The digestion of fats is more complex than that of carbohydrates or proteins because fats are not very soluble in water. The triacylglycerols of the diet are emulsified in the intestine by bile salts, which are synthesized in the liver, stored in the gallbladder, and released. The enzyme pancreatic lipase converts the triacylglycerols in the lumen of the intestine to fatty acids and 2-monoacylglycerols (glycerol with a fatty acid esterified at carbon 2),

which interact with bile salts to form tiny microdroplets called micelles. The fatty acids and 2-monoacylglycerols are absorbed from these micelles into intestinal epithelial cells, where they are resynthesized into triacylglycerols. The triacylglycerols are packaged with proteins, phospholipids, cholesterol, and other compounds into lipoprotein complexes known as chylomicrons, which are secreted into the lymph and ultimately enter the bloodstream (see Fig. 2.2, circle 2). Fats must be transported in the blood bound to protein or lipoprotein complexes because they are insoluble in water. Thus, both triacylglycerols and cholesterol are found in lipoprotein complexes.

II. Changes in Hormone Levels after a Meal

After a typical meal, the **pancreas** is stimulated to release the hormone **insulin**, and the release of the hormone **glucagon** is inhibited (see Fig. 2.2, circle 4). **Endocrine hormones** are released from endocrine glands, such as the pancreas, in response to a specific stimulus. They travel in the blood, carrying messages between tissues concerning the overall physiologic state of the body. At their target tissues, they adjust the rate of various metabolic pathways to meet the changing conditions. The endocrine hormone insulin, which is secreted from the β -cells of the pancreas in response to a meal, carries the message that dietary glucose is available and can be transported into the cell, utilized and stored. The release of another hormone, glucagon, from the α -cells of the pancreas, is suppressed by glucose and insulin. Glucagon carries the message that glucose must be generated from endogenous fuel stores. The subsequent changes in circulating hormone levels cause changes in the body's metabolic patterns, involving a number of different tissues and metabolic pathways.

III. Fate of Glucose

A. Conversion to Glycogen, Triacylglycerols, and CO₂ in the Liver

Because glucose leaves the intestine via the hepatic portal vein (which carries blood from the intestine to the liver), the liver is the first tissue it passes through. The liver extracts a portion of this glucose from the blood. Some of the glucose that enters **hepatocytes** (liver cells) is oxidized in adenosine triphosphate (ATP)-generating pathways to meet the immediate energy needs of these cells, and the remainder is converted to glycogen and triacylglycerols or used for biosynthetic reactions. In the liver, insulin stimulates the utilization of glucose by increasing its use as a fuel and its storage as glycogen and triacylglycerols (see Fig. 2.2, circles 5 to 7).

To generate energy and metabolic precursors, glucose is first oxidized to pyruvate in the glycolysis pathway, which consists of a series of reactions common to the metabolism of many carbohydrates (discussed in more detail in Chapter 22). Pyruvate is then oxidized to acetyl coenzyme A (acetyl CoA). The acetyl group enters the tricarboxylic acid (TCA) cycle, where it is completely oxidized to CO₂. Energy from the oxidative reactions is used to generate ATP. The ATP that is generated is used for anabolic pathways and other energy-requiring processes in the cell. Coenzyme A (CoA), which makes the acetyl group more reactive, is a cofactor derived from the vitamin pantothenic acid.

Liver glycogen stores reach a maximum of approximately 200 to 300 g after a high-carbohydrate meal, whereas the body's fat stores are relatively limitless. As the glycogen stores begin to fill, the liver also begins converting some of the excess glucose it receives to triacylglycerols. Both the glycerol and the fatty acid moieties of the triacylglycerols can be synthesized from glucose. The fatty acids are also obtained preformed from the blood (dietary fatty acids). The liver does not store triacylglycerols, however, but packages them along with proteins, **phospholipids**, and **cholesterol** into the lipoprotein complexes known as **very-low-density lipoproteins (VLDL)**, which are secreted into the bloodstream. Some of the fatty acids from the VLDL are taken up by tissues for their immediate energy needs, but most are stored in adipose tissue as triacylglycerols.

B. Glucose Metabolism in Other Tissues

Dietary glucose that is not taken up and metabolized by the liver travels in the blood to peripheral tissues (most other tissues), where it can be oxidized for energy. Glucose is the one fuel that can be utilized by cells of all tissues. Many tissues store small amounts of glucose as glycogen. Collectively, muscle has the largest body glycogen stores.

Insulin greatly stimulates the transport of glucose into the two tissues that have the largest mass in the body, muscle and adipose tissue. It has much smaller effects on the transport of glucose into other tissues.

Fuel metabolism is often discussed as though the body consisted only of brain, skeletal and cardiac muscle, liver, adipose tissue, red blood cells, kidney, and intestinal epithelial cells (“the gut”). These are the dominant tissues in terms of overall fuel economy, and they are the tissues we describe most often. However, all tissues require fuels for energy, and many have very specific fuel requirements.

1. Brain and Other Neural Tissues

The brain and other neural tissues are very dependent on glucose for their energy needs. Neurons generally oxidize glucose, via glycolysis and the TCA cycle, completely to CO_2 and H_2O , generating ATP (see Fig. 2.2, circle 8). Except under conditions of starvation, glucose is their only major fuel. Glucose is also a major precursor of **neurotransmitters**, the chemicals that convey electrical impulses (as ion gradients) between neurons. If our blood glucose drops much below normal levels, we become dizzy and light-headed. If blood glucose continues to drop, we become comatose and ultimately die. Under normal, nonstarving conditions, the brain and the rest of the nervous system require roughly 150 g of glucose each day.

2. Red Blood Cells

Glucose is the only fuel used by red blood cells because they lack **mitochondria**. Fatty acid oxidation, amino acid oxidation, the TCA cycle, the electron-transport chain, and oxidative phosphorylation (ATP generation that is dependent on oxygen and the electron-transport chain) occur principally in mitochondria. Glucose, in contrast, generates ATP from anaerobic glycolysis in the cytoplasm, and thus red blood cells obtain all their energy by this process. In anaerobic glycolysis, the pyruvate formed from glucose is reduced to **lactate** and then released into the blood (see Fig. 2.2, circle 9).

Without glucose, red blood cells could not survive. Red blood cells carry O_2 from the lungs to the tissues. Without red blood cells, most of the tissues of the body would suffer from a lack of energy because they require O_2 to completely convert their fuels to CO_2 and H_2O .

3. Muscle

Exercising skeletal muscles can use glucose from the blood or from their own glycogen stores, converting glucose to lactate through glycolysis or oxidizing it completely to CO_2 and H_2O . Muscle also uses other fuels from the blood, such as fatty acids (Fig. 2.3). Resting or lightly exercising muscle cells mostly use fatty acids as fuel. After a meal, glucose is used by muscles to replenish the glycogen stores that were depleted during exercise. Glucose is transported into muscle cells and converted to glycogen by processes that are stimulated by insulin.

FIGURE 2.3 Oxidation of fuels in exercising skeletal muscle. Exercising muscle uses more energy than resting muscle; therefore, fuel utilization is increased to supply more ATP. Acetyl CoA, acetyl coenzyme A; TCA, tricarboxylic acid.

4. Adipose Tissue

Insulin stimulates the transport of glucose into adipose cells as well as into muscle cells. Adipocytes oxidize glucose for energy, and they also use glucose as the source of the glycerol moiety of the triacylglycerols they store (see Fig. 2.2, circle 10).

IV. Lipoproteins

Two types of **lipoproteins**, **chylomicrons** and **VLDL**, are produced in the fed state. The major function of these lipoproteins is to provide a blood transport system for triacylglycerols, which are very insoluble in water. However, these lipoproteins also contain the lipid cholesterol, which is also somewhat insoluble in water. The triacylglycerols of chylomicrons are formed in intestinal epithelial cells from the products of digestion of dietary triacylglycerols. The triacylglycerols of VLDL are synthesized in the liver.

When these lipoproteins pass through blood vessels in adipose tissue, their triacylglycerols are degraded to fatty acids and glycerol (see Fig. 2.2, circle 12). The fatty acids enter the adipose cells and combine with a glycerol moiety that is produced from blood glucose. The resulting triacylglycerols are stored as large fat droplets in the adipose cells. The remnants of the chylomicrons are cleared from the blood by the liver. The remnants of the VLDL can be cleared by the liver, or they can form **low-density lipoprotein (LDL)**, which is cleared by the liver or by peripheral cells.

Most of us have not even begun to reach the limits of our capacity to store triacylglycerols in adipose tissue. The ability of humans to store fat appears to be limited only by the amount of tissue we can carry without overloading the heart.

 **Ivan A.**'s total cholesterol level is now 315 mg/dL, slightly higher than his previous level of 296 mg/dL. His triacylglycerol level is 250 mg/dL (normal is between 60 and 150 mg/dL), LDL 210 mg/dL, and HDL 27 mg/dL (normal is >40 mg/dL for a male). These lipid levels indicate that **Ivan A.** has hyperlipidemia (high level of lipoproteins in the blood) and therefore is at risk for the future development of atherosclerosis and its consequences, such as heart attacks and strokes.

V. Amino Acids

The amino acids derived from dietary proteins travel from the intestine to the liver in the hepatic portal vein (see Fig. 2.2, circle 3). The liver uses amino acids for the synthesis of serum proteins as well as its own proteins, and for the biosynthesis of nitrogen-containing compounds that need amino acid precursors, such as the nonessential amino acids, **heme**, hormones, neurotransmitters, and **purine** and **pyrimidine** bases (which are required for the synthesis of the nucleic acids ribonucleic acid [RNA] and deoxyribonucleic acid [DNA]). The liver also may oxidize the amino acids or convert the carbon skeleton to glucose or ketone bodies and dispose of the nitrogen as the nontoxic compound urea.

Many of the amino acids will go into the peripheral circulation, where they can be used by other tissues for protein synthesis and various biosynthetic pathways or can be oxidized for energy (see Fig. 2.2, circle 14). Proteins undergo **turnover**; they are constantly being synthesized and degraded. The amino acids released by protein breakdown enter the same pool of free amino acids in the blood as the amino acids from the diet. This free amino acid pool in the blood can be used by all cells to provide amino acids for protein synthesis, substrates for energy production, or precursors for the biosynthesis of other compounds.

VI. Summary of the Fed (Absorptive) State

After a meal, the macronutrients that we eat are oxidized to meet our immediate energy needs. Glucose is the major fuel for most tissues. Excess glucose and fatty acids are stored as glycogen mainly in muscle and liver, and as triacylglycerols in adipose tissue. Amino acids from dietary proteins are converted to body proteins or oxidized to provide cellular energy.

 **Ivan A.**'s waist circumference indicates that he has the android pattern of obesity (abdominal obesity). Fat stores are distributed in the body in two different patterns, android and gynecoid. After puberty, men tend to store fat within their abdominal cavity (an android pattern), whereas women tend to store fat subcutaneously in their hips and thighs (a gynecoid

pattern). Abdominal fat carries a greater risk for hypertension, cardiovascular disease, hyperinsulinemia, diabetes mellitus, gallbladder disease, stroke, and cancer of the breast and endometrium. It also carries a greater risk of overall mortality. Because more men than women have the android distribution, they are more at risk for most of these conditions. Likewise, women who deposit their excess fat in a more android manner have a greater risk than women whose fat distribution is more gynecoid.

Upper-body fat deposition tends to occur more by hypertrophy of the existing cells, whereas lower-body fat deposition is by differentiation of new fat cells (hyperplasia). This may partly explain why many women with lower-body obesity have difficulty losing weight.

CLINICAL COMMENTS

Ivan A. was advised that his obesity represents a risk factor for future heart attacks and strokes. He was told that his body has to maintain a larger volume of circulating blood to service his extra fat tissue. This expanded blood volume not only contributes to his elevated blood pressure (itself a risk factor for vascular disease) but also puts an increased workload on his heart. This increased load will cause his heart muscle to thicken and eventually to fail.

Ivan A.'s increasing adipose mass has also contributed to his development of type 2 diabetes mellitus, characterized by hyperglycemia (high blood glucose levels). The mechanism behind this breakdown in his ability to maintain normal levels of blood glucose is, at least in part, a resistance by his triacylglycerol-rich adipose cells to the action of insulin.

In addition to type 2 diabetes mellitus, **Ivan A.** has hyperlipidemia (high blood lipid level—elevated cholesterol and triacylglycerols), another risk factor for cardiovascular disease. A genetic basis for **Ivan A.**'s disorder is inferred from a positive family history of hypercholesterolemia and premature coronary artery disease in a brother.

In addition to initiating medications for his high blood pressure, treatment should include nonpharmacologic interventions. **Ivan A.**'s obesity should be treated with caloric restriction and a carefully monitored program of exercise. A reduction of dietary fat (particularly saturated fat and trans fat) and sodium would be advised to correct his hyperlipidemia and his hypertension, respectively. He should also control his carbohydrate intake because of his type 2 diabetes.

BIOCHEMICAL COMMENTS

Anthropometric Measurements. Anthropometry uses body measurements to monitor growth and nutritional health in individuals and to detect nutritional inadequacies or excesses. In adults, the measurements most commonly used are height, weight, triceps skinfold thickness (SFT), arm muscle circumference (AMC), and waist circumference. In infants and young children, length and head circumference are also measured.

M To obtain reliable measures of skinfold thickness, procedures are carefully defined. For example, in the triceps measurement, a fold of skin in the posterior aspect of the nondominant arm midway between shoulder and elbow is grasped gently and pulled away from the underlying muscle. The skinfold thickness reading is taken at a precise time, 4 seconds after applying the caliper because the caliper compresses the skin. Even when these procedures are performed by trained dietitians, reliable measurements are difficult to obtain.

Weight and Height. Weight should be measured by using a calibrated beam, lever-balance-type scale, or electronic scale, and the patient should be in minimal clothing (i.e., gown or underwear). Height for adults should be measured while the patient stands against a straight surface, without shoes, with the heels together, and with the head erect and level. Weight and height are used in the calculation of the body mass index (BMI).

Skinfold Thickness. Over half of the fat in the body is deposited in subcutaneous tissue under the skin, and the percentage increases with increasing weight. To provide an estimate of the amount of total body fat, a standardized caliper is used to pinch a fold of the skin, usually at more than one site (e.g., the thigh, triceps, subscapular, and suprailiac areas). Obesity by this physical anthropometric technique is defined as a fatfold thickness greater than the 85th percentile for young adults, that is, 18.6 mm for males and 25.1 mm for females.

Mid-Arm Anthropometry. The arm muscle circumference (AMC), also called the mid-upper arm muscle circumference (MUAMC), reflects both caloric adequacy and muscle mass and can serve as a general index of marasmic-type malnutrition. The arm circumference is measured at the midpoint of the left upper arm by a

flexible fiberglass-type tape. The AMC can be calculated from a formula that subtracts a factor related to the SFT from the arm circumference:

$$\text{MUAMC (cm)} = \text{arm circumference (cm)} - (3.14 \times \text{SFT mm})/10$$

where MUAMC is the mid-upper arm muscle circumference in centimeters and SFT is the skinfold thickness, expressed in millimeters.

M The waist-to-hip ratio has been used instead of the waist circumference as a measure of abdominal obesity in an attempt to correct for differences between individuals with respect to body type or bone structure. In this measurement, the waist circumference is divided by the hip circumference. The average waist-to-hip ratio for men is 0.93 (with a range of 0.75 to 1.10), and the average for women is 0.83 (with a range of 0.70 to 1.00). However, the waist circumference may actually correlate better with intra-abdominal fat and the associated risk factors than the waist-to-hip ratio.

MUAMC values can be compared with reference graphs available for both sexes and all ages. Protein-calorie malnutrition and negative nitrogen balance induce muscle wasting and decrease muscle circumference.

Waist Circumference. The waist circumference is another anthropometric measurement that serves as an indicator of body composition but is used as a measure of obesity and body fat distribution (abdominal obesity), not malnutrition. The measurement is made by placing a measuring tape around the abdomen at the level of the iliac crest of a standing individual. A high-risk waistline is larger than 35 in (88 cm) for women and larger than 40 in (102 cm) for men.

KEY CONCEPTS

- ◆ During a meal, we ingest carbohydrate, lipids, and proteins.
- ◆ Two endocrine hormones, insulin and glucagon, primarily regulate fuel storage and retrieval.
- ◆ The predominant carbohydrate in the blood is glucose. Blood glucose levels regulate the release of insulin and glucagon from the pancreas.
- ◆ Under the influence of insulin (fed state), glucose can be used as a fuel and also as a precursor for storage via conversion to glycogen or triacylglycerol.
- ◆ Insulin stimulates the uptake of glucose into adipose and muscle cells.
- ◆ Triacylglycerol obtained from the diet is released into circulation in the form of chylomicrons. Triacylglycerol synthesized from glucose in the liver is released as VLDL. Adipose tissue is the storage site for triacylglycerol.
- ◆ The brain and red blood cells utilize glucose as their primary energy source under normal conditions.
- ◆ Amino acids obtained from the diet are used for the biosynthesis of proteins and nitrogen-containing molecules and as an energy source.
- ◆ Diseases discussed in this chapter are summarized in Table 2.1.

TABLE 2.1 Diseases Discussed in Chapter 2

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
Hypercholesterolemia	Both	Elevated cholesterol as a result of mutation within a specific protein or excessive cholesterol production/intake
Hyperglycemia	Both	High blood glucose levels owing to either mutations in specific proteins or tissue resistance to insulin
Hyperlipidemia	Both	High levels of blood lipids, which may be caused by mutations in specific proteins or ingestion of too many calories

REVIEW QUESTIONS—CHAPTER 2

1. A patient with celiac sprue (intolerance to gluten, leading to malabsorption issues in the intestine) needs

advice on which foods should be ingested and in what proportions, as the diet must contain all essential nutrients. When the patient eats and digests a mixed meal (containing carbohydrates, lipids, and proteins), which one of the following is most likely to occur?

- A. Starch and other polysaccharides are transported to the liver.
 - B. Proteins are converted to dipeptides, which enter the blood.
 - C. Dietary triacylglycerols are transported in the portal vein to the liver.
 - D. Monosaccharides are transported to adipose tissue via the lymphatic system.
 - E. Glucose levels increase in the blood.
2. A marathon runner is training for a race. Two days before the race the runner exhausts her glycogen stores through an extensive training session, and then goes out and eats a large helping of pasta, a process known as “carb loading.” This process is designed to do which ONE of the following?
- A. Induce the release of glucagon from the pancreas
 - B. Release insulin to stimulate glucose entry into the nervous system
 - C. Stimulate glycogen synthesis in liver and muscles
 - D. Stimulate the oxidation of glucose to carbon dioxide in the muscle
 - E. Stimulate red blood cell production of carbon dioxide from glucose
3. A patient with type 2 diabetes, whose diabetes is well controlled (as determined by the hemoglobin A1c levels), takes his insulin and 15 minutes later eats his evening meal. Which of the following changes will occur as he digests his meal? Choose the ONE best answer.

	Increased Glucose Transport by Muscle	VLDL Synthesis by the Liver	Extensive Fatty Acid Synthesis in Fat Cells	Glyco-gen Syn-thesis in the Liver	Triacyl-glycerol Stor-age in Adipose Tissue
A	Yes	Yes	Yes	No	Yes
B	Yes	No	Yes	No	No
C	Yes	Yes	No	Yes	Yes
D	No	No	Yes	Yes	No
E	No	Yes	Yes	Yes	Yes
F	No	Yes	No	Yes	No

4. Elevated levels of chylomicrons were measured in a patient’s blood. To lower chylomicron levels most effectively, you would prescribe a diet that is restricted in which one of the following?
- A. Overall calories
 - B. Fat
 - C. Cholesterol
 - D. Starch
 - E. Sugar
5. An adult male patient exhibited a BMI of 33 kg/m² and a waist circumference of 47 in. What nutrition therapy would be most helpful?
- A. Decreased intake of total calories because all fuels can be converted to adipose tissue triacylglycerols

- B. The same amount of total calories, but substitution of carbohydrate calories for fat calories
 - C. The same amount of total calories, but substitution of protein calories for fat calories
 - D. A pure-fat diet because only fatty acids synthesized by the liver can be deposited as adipose triacylglycerols
 - E. A limited food diet, such as the ice cream and sherry diet
6. A 2-month-old baby is exclusively breastfed. Which ONE of the following anatomic locations contains the most important enzyme this baby needs for the absorption of carbohydrates from this diet?
- A. Salivary gland
 - B. Pancreas
 - C. Stomach
 - D. Small intestine
 - E. Liver
7. A “lipid panel” is ordered for a patient as a screening tool to help determine cardiovascular disease risk. The patient is told to fast for 12 hours before the blood draw such that which ONE of the following would be in significantly reduced amounts in the blood?
- A. Cholesterol
 - B. Triacylglycerol
 - C. Serum albumin
 - D. Chylomicrons
 - E. Fatty acids
8. A patient with type 2 diabetes mellitus takes his insulin injection, and then 15 minutes later ingests a meal of bread, potatoes, and milk. Which ONE of the following proteins is suppressed during the absorption of this meal?
- A. Glucagon
 - B. Insulin
 - C. Salivary amylase
 - D. Pancreatic amylase
 - E. Lactase
9. An athlete is competing in a 400-meter dash. Which ONE of the following is the major source of energy for the muscles used in this competition?
- A. Muscle glycogen stores
 - B. Muscle triacylglycerol stores
 - C. Muscle amino acid oxidation
 - D. Lactic acid from the red blood cells
 - E. Liver triacylglycerol stores
10. A patient with type 1 diabetes has neglected to take his insulin before eating a carbohydrate-rich meal. Which of the following tissues will metabolize glucose under these conditions? Choose the ONE best answer.

	Red Blood Cells	Brain	Skeletal Muscle	Adipose Tissue
A	Yes	Yes	No	Yes
B	No	Yes	No	No
C	Yes	Yes	No	No
D	No	No	Yes	No
E	Yes	No	Yes	Yes
F	No	No	Yes	Yes

- A 32-year-old woman has had episodes of dizziness and feeling faint. During one such episode she was taken to the Emergency Department of the local hospital and a blood test indicated significantly elevated levels of insulin, despite the woman having neither eaten for three hours nor injected insulin. Subsequent imaging studies led to the finding of a pancreatic tumor that would episodically release large amounts of insulin into the circulation (an insulinoma). The finding of the insulinoma would explain the patient's symptoms by which one of the following?

 - Increased glucose uptake from the blood by the muscle and fat cells
 - Decreased glucose uptake from the blood by the muscle and fat cells
 - Induction of hyperglycemia
 - Increased triglyceride formation in the liver
 - Reduced amino acid oxidation in the muscle
- The synthesis of numerous neurotransmitters requires precursors that contain nitrogen. Such nitrogen-containing precursors are obtained from which one of the following dietary components?

 - Carbohydrates
 - Fats
 - Proteins
 - Vitamins
 - Minerals
- The drug orlistat inhibits pancreatic lipase activity in the small intestine. Individuals taking orlistat will display which one of the following in their blood after eating a meal?

 - Increased levels of chylomicrons
 - Increased levels of free fatty acids
 - Decreased levels of chylomicrons
 - Increased levels of glycerol
 - Decreased levels of glucose
- A scientist was testing an experimental weight-loss drug designed to inhibit pancreatic amylase. In a clinical trial of this drug, a volunteer would be expected to have difficulty accomplishing which one of the following after eating a meal containing carbohydrate, lipids, and proteins?

 - Synthesizing chylomicrons
 - Converting proteins to amino acids
 - Synthesizing 2-monoacylglycerol
 - Digesting triacylglycerol
 - Synthesizing liver glycogen
- A 4-month-old girl has been diagnosed with cystic fibrosis (CF). One consequence of cystic fibrosis is a thickening and blockage of the pancreatic duct, such that pancreatic enzymes cannot be delivered to the intestine after eating. Untreated CF would therefore lead to an inability to digest which of the following? Choose the one best answer.

	Starch	Triglyceride	Protein	Lactose
A	Yes	Yes	Yes	No
B	Yes	No	Yes	No
C	Yes	Yes	Yes	Yes
D	No	No	No	Yes
E	No	Yes	No	No
F	No	No	No	Yes

ANSWERS TO REVIEW QUESTIONS

- The answer is E.** During digestion of a mixed meal, starch and other carbohydrates, proteins, and dietary triacylglycerols are broken into their monomeric units (carbohydrates into simple monosaccharides; protein into amino acids; triacylglycerols into fatty acids and 2-monacylglycerol) in the small intestine. Glucose is the principal sugar in dietary carbohydrates, and thus it increases in the blood. Amino acids and monosaccharides enter the portal vein and go to the liver first. After digestion of fats and absorption of the fatty acids by the intestinal epithelial cells, most of the fatty acids are converted back into triacylglycerols and subsequently into chylomicrons by the intestinal cells. Chylomicrons go through lymphatic vessels to reach the blood, where the triacylglycerol content is principally stored in adipose tissue.
- The answer is C.** After a high-carbohydrate meal, glucose is the major fuel for most tissues, including skeletal muscle, adipose tissue, and liver. The increase in blood glucose levels stimulates the release of insulin, not glucagon. Insulin stimulates the transport of glucose in skeletal muscle and adipose tissue, not brain. Liver, not skeletal muscle, converts glucose to fatty acids. Although the red blood cell utilizes glucose as its only fuel at all times, it generates ATP from the conversion of glucose to lactate, not CO_2 . When the muscle depletes its glycogen stores through exercise, and then a meal containing carbohydrate is ingested, the muscle and liver will synthesize glycogen to replete those stores. In the case of muscle, the amount of glycogen synthesized is greater than normal, leading to higher-than-normal glycogen stores in the muscle for a brief period of time, and an advantage for the muscle during exercise.
- The answer is C.** In the fed state, and in the presence of insulin, glucose transport into both the adipocyte and muscle cell will be increased. Insulin will also stimulate the liver to synthesize both glycogen and fatty acids, which leads to enhanced triglyceride synthesis, and VLDL production to deliver the fatty acids to other tissues of the body. Insulin will stimulate glucose uptake in fat cells but does not stimulate significant fatty acid synthesis in the fat cells (that is unique to the liver), but will lead to enhanced triglyceride synthesis in the fat cells.
- The answer is B.** Chylomicrons are the lipoprotein particles formed in intestinal epithelial cells from dietary fats and contain principally triacylglycerols formed from components of dietary triacylglycerols. A decreased intake of calories, in general, would include a decreased consumption of fat, carbohydrate, and protein, which might not lower chylomicron levels. Dietary cholesterol, although found in chylomicrons, is not their principal component.
- The answer is A.** The patient's BMI is in the obese range, with large abdominal fat deposits. He should be advised to decrease his intake of total calories because an excess of calories ingested as carbohydrate, fat, or protein results in deposition of triacylglycerols in adipose tissue. If he keeps his total caloric intake the same, substitution of one type of food for another will help very little with weight loss. (However, a decreased intake of fat may be advisable for other reasons.) Limited food diets, such as the ice cream and sherry diet, or a high-protein diet of shrimp, work if they decrease appetite, and therefore ingestion of

total calories.

6. **The answer is D.** Milk contains lactose (milk sugar) that is converted by the enzyme lactase (located on the brush border of intestinal epithelial cells) to glucose and galactose. The salivary glands produce amylase, which digests starch, but not lactose. The pancreas also produces amylase, but not an enzyme that can digest lactose. The pancreas does produce insulin, which is not needed for the absorption of lactose but is needed for the absorption of glucose into muscle and fat cells. The stomach produces hydrochloric acid and pepsin for protein digestion but does not digest disaccharides. The liver does not synthesize any enzymes that digest dietary carbohydrates.
7. **The answer is D.** The purpose of fasting is to measure circulating triglycerides and cholesterol without complication from recently ingested food. Upon eating a mixed meal (protein, lipid, and carbohydrate), the intestine synthesizes chylomicrons to distribute the recently ingested lipid throughout the body. Upon fasting, chylomicrons are not present, and what the lipid panel is measuring is the cholesterol content of the blood, the subset of particles carrying the cholesterol (high-density lipoprotein [HDL] and low-density lipoprotein [LDL]), and the triglyceride content (primarily from very-low-density lipoprotein [VLDL]). Serum albumin is the major serum protein and will bind to free fatty acids, but its levels are not measured in a lipid panel (measurement of albumin is done to check liver function). The fatty acids are a part of the triacylglycerol in the circulating lipoprotein particles in the blood, and their content would be reflected in the chylomicron and/or VLDL levels in the blood.
8. **The answer is A.** Bread and potatoes are high in starch/carbohydrates. A high-carbohydrate meal stimulates the release of insulin from the β -cells of the pancreas to help use and store this available glucose. Glucose and insulin suppress the release of glucagon from the α -cells of the pancreas. Glucagon helps to generate glucose from endogenous stores, which is unnecessary with such high levels of glucose from dietary sources. Salivary and pancreatic amylase are both required in the breakdown of the dietary starches into glucose. Lactase is required to convert lactose to glucose and galactose (from the milk sugar in the meal).
9. **The answer is A.** The 400-meter dash is primarily an anaerobic activity, and the major source of energy for the muscle is glucose from its own glycogen stores (this pathway is also the one that produces energy at the fastest rate). The muscle does not store triacylglycerol (adipose tissue does). During the exercise, the muscle will generate lactic acid that will be secreted in the blood. The muscle will not use lactate as an energy source. Under these conditions, the muscle will not degrade its own proteins to generate amino acids to utilize as an energy source.
10. **The answer is C.** Insulin is required for glucose transport into both skeletal muscle and adipose tissue but is not required for glucose uptake into the red blood cells or brain (nervous tissue). The tissues that cannot transport glucose will be unable to metabolize it under these conditions. The inability of skeletal muscle and adipose tissue to take up glucose in the absence of insulin contributes to the high blood glucose levels seen in a patient with type 1 diabetes who has neglected an insulin dose.
11. **The answer is A.** The episodic release of large levels of insulin from the pancreas leads to severe hypoglycemia (low blood glucose levels) owing to the muscle and fat cells being stimulated by the insulin to remove the glucose from the blood. This reduces blood glucose levels to a level insufficient for effective functioning of the nervous system, leading to dizziness and fainting episodes (the nervous system cannot take up sufficient glucose from the blood to meet its energy needs). Increased insulin secretion will stimulate triglyceride formation in the liver, as well as increase amino acid oxidation, but those consequences do not lead to the observed symptoms in the patient.
12. **The answer is C.** Proteins are digested to individual amino acids in the intestine. The amino acids contain nitrogen, whereas the carbohydrates and lipids do not contain nitrogen. Vitamins can contain nitrogen, but they are not used as substrates in biosynthetic reactions; after activation, vitamins are used to help enzymes catalyze reactions. Nitrogen is not considered a mineral.
13. **The answer is C.** Inhibiting pancreatic lipase means that dietary triglyceride degradation in the intestine is reduced and the triglycerides are lost from the body in the feces. Without triglyceride digestion in the small intestine, the intestinal epithelial cells have fewer fatty acids and 2-monoacylglycerol to absorb, such that the synthesis of chylomicrons will be reduced. VLDL is produced from triglyceride synthesized from dietary carbohydrate, which is not affected by orlistat. Free fatty acids are not released from the intestine after eating a meal (chylomicrons are). Orlistat would not affect the blood glucose levels after eating a meal as carbohydrate digestion is not affected.
14. **The answer is E.** Amylase digests starch, so in the presence of the experimental drug very little of the starch in the diet will be converted to glucose, such that glucose levels in the blood will not be as elevated

after a meal in someone taking the drug as compared to someone not taking the drug. The lower blood glucose levels would lead to less glucose uptake by the liver and a reduction in glycogen synthesis in the liver owing to lower glucose available for glycogen synthesis. Blocking amylase activity would have no effect on the digestion and uptake of triglycerides or proteins, or the ability of the intestinal epithelial cells to produce chylomicrons.

15. **The answer is A.** When the pancreatic duct is blocked, pancreatic enzymes cannot reach the intestine. These enzymes include amylase (to digest starch), lipase (to digest triglyceride), and proteases (to digest proteins). Lactose is a disaccharide that is cleaved to its monosaccharide components by an intestinal enzyme, so the digestion of lactose would not be impaired by a blockage of the pancreatic duct, whereas digestion of starch, triglyceride, and proteins would be impaired by this block.

Fasting

The Fasting State. Fasting begins approximately 2 to 4 hours after a meal, when blood glucose levels return to basal levels, and continues until blood glucose levels begin to rise after the start of the next meal. Within about 1 hour after a meal, blood glucose levels begin to fall. Consequently, **insulin** levels decline and **glucagon** levels rise. These changes in hormone levels trigger the **release of fuels** from the body stores. **Liver glycogen** is **degraded** by the process of **glycogenolysis**, which supplies glucose to the blood. **Adipose triacylglycerols** are **mobilized** by the process of **lipolysis**, which releases fatty acids and glycerol into the blood. Use of **fatty acids** as a fuel increases with the length of the fast; they are the **major fuel** oxidized during overnight fasting.

Fuel Oxidation. During fasting, glucose continues to be **oxidized** by **glucose-dependent tissues** such as the brain (nervous system tissues) and red blood cells, and **fatty acids** are oxidized by tissues such as muscle and liver. Muscle and most other tissues oxidize fatty acids completely to CO_2 and H_2O . However, in an extended fast, the **liver** partially oxidizes fatty acids to smaller molecules called **ketone bodies**, which are released into the blood. Muscle, kidney, and certain other tissues derive energy from completely oxidizing ketone bodies in the tricarboxylic acid (TCA) cycle.

Maintenance of Blood Glucose. As fasting progresses, the **liver produces glucose** not only by **glycogenolysis** (the release of glucose from glycogen) but also by a second process called **gluconeogenesis** (the synthesis of glucose from noncarbohydrate compounds). The major **sources of carbon** for gluconeogenesis are **lactate**, **glycerol**, and **amino acids**. When the carbons of the amino acids are converted to glucose by the liver, their **nitrogen** is converted to **urea**.

Starvation. When we fast for 3 or more days, we are in a starved state. **Muscle** continues to burn fatty acids but **decreases** its use of **ketone bodies**. As a result, the concentration of ketone bodies rises in the blood to a level at which the **brain** begins to **oxidize** them for energy. The brain then needs less glucose, so the liver decreases its rate of gluconeogenesis. Consequently, less **protein** in muscle and other tissues is degraded to supply amino acids for gluconeogenesis. Protein sparing preserves vital functions for as long as possible. Because of these changes in the fuel utilization patterns of various tissues, humans can survive for extended periods without ingesting food.

THE WAITING ROOM

Percy V. had been admitted to the hospital with a diagnosis of depression related to bereavement and malnutrition (see Chapter 1). At the time of admission, his body weight of 125 lb gave him a body mass index (BMI) of 17.5 (healthy range, 18.5 to 24.9). His serum albumin was 10% below the low end of the normal range, and he exhibited signs of iron and vitamin deficiencies.

Percy V. has stage II/severe protein–energy malnutrition. At his height of 71 in, his body weight would have to be >132 lb to achieve a BMI >18.5. **Ann R.** also has stage II/severe malnutrition. At 67 in, she needs a body weight >118 lb to achieve a BMI of 18.5. The Global Leadership on Malnutrition degrees of protein–energy malnutrition are classified as stage I/moderate and stage II/severe, according to BMI. Stage I refers to a BMI <20 (if age <70); stage II to a BMI <18.5 (if age <70).

Additional tests were done to help evaluate **Percy V.**'s degree of malnutrition and his progress toward recovery. His arm circumference and triceps skinfold were measured, and his mid-upper arm muscle circumference (MUAMC) was calculated (see Chapter 2, Anthropometric Measurements). His serum

prealbumin and his serum albumin were measured. Fasting blood glucose and serum ketone body concentration were determined on blood samples drawn the next day before breakfast. A urine specimen was collected to determine ketone body excretion, and a 24-hour creatinine excretion can be used for calculation of the creatinine–height index (CHI), a measure of protein depletion from skeletal muscle.

Creatinine, a creatine/phosphocreatine degradation product, is usually released from the muscles at a constant rate, and it is proportional to muscle mass. The creatinine is removed from the circulation by the kidneys and is eliminated in the urine. Thus, elevated creatinine in the blood relates to impaired renal function. To measure creatinine in biologic specimens, the Jaffe reaction is used. Creatinine is reacted with picric acid in an alkaline solution to form a red-orange product, which can be quantitated via spectrophotometry. To increase specificity, a kinetic Jaffe reaction is run, and the rate of formation of the product is determined. Creatinine can be measured in plasma, serum, and urine.

Ann R. was receiving psychological counseling for anorexia nervosa, but with little success (see Chapter 1). She continues to want to lose weight despite being underweight. She saw her gynecologist because she had not had a menstrual period for 5 months. She also complained of becoming easily fatigued. The physician recognized that **Ann R.**'s body weight of 85 lb was now <65% of her ideal weight, and he calculated that her BMI was now 13.7. The physician recommended immediate hospitalization. The admission diagnosis was severe malnutrition (protein–energy malnutrition) secondary to anorexia nervosa. Clinical findings included decreased body core temperature, blood pressure, and pulse (adaptive responses to malnutrition). Her physician ordered measurements of blood glucose as well as other blood tests to check electrolytes and her kidney function, and an electrocardiogram to see if there were any effects on the electrical activity of the heart.

I. The Fasting State

Blood glucose levels peak about 1 hour after eating (the postprandial state) and then decrease as tissues oxidize glucose or convert it to storage forms of fuel. By 2 hours after a meal, the level returns to the fasting range (between 70 and 100 mg/dL). This decrease in blood glucose causes the pancreas to decrease its secretion of insulin, and the serum insulin level decreases. The liver responds to this hormonal signal by starting to degrade its glycogen stores (glycogenolysis) and release glucose into the blood.

If we eat another meal within a few hours, we return to the fed state. However, if we continue to fast for 12 hours, we enter the basal state (also known as the postabsorptive state). A person is generally considered to be in the basal state after an overnight fast when no food has been eaten since dinner the previous evening. By this time, the serum insulin level is low and glucagon is rising. Figure 3.1 illustrates the main features of the basal state.

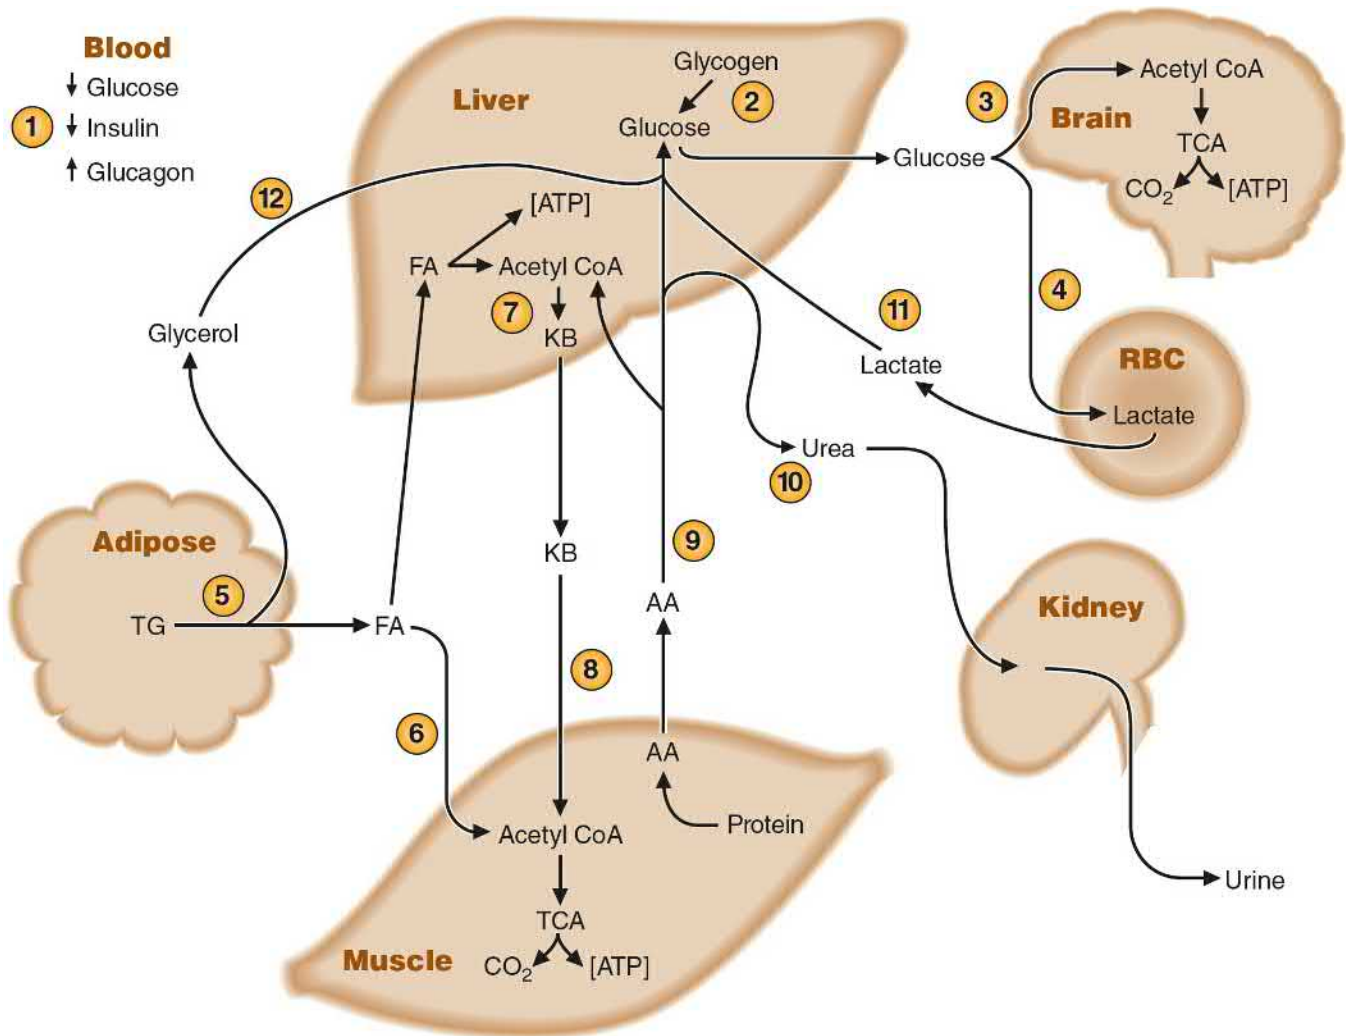

FIGURE 3.1 Basal state. This state occurs after an overnight (12-hour) fast. The circled numbers serve as a guide indicating the approximate order in which the processes begin to occur. It is important to note that certain amino acids can also give rise to acetyl CoA (not just glucose). AA, amino acid; ATP, adenosine triphosphate; acetyl CoA, acetyl coenzyme A; FA, fatty acids; KB, ketone bodies; RBC, red blood cells; TCA, tricarboxylic acid; TG, triacylglycerols.

A. Blood Glucose and the Role of the Liver during Fasting

The liver maintains blood glucose levels during fasting, and its role is thus critical. Glucose is the major fuel for tissues such as the brain and neural tissue, and the sole fuel for red blood cells. Most neurons lack enzymes required for the oxidation of fatty acids, but they can use ketone bodies to a limited extent. Red blood cells lack mitochondria, which contain the enzymes of fatty acid and ketone body oxidation, and can use only glucose as a fuel. Therefore, it is imperative that blood glucose not decrease too rapidly nor fall too low.

Initially, liver glycogen stores are degraded to supply glucose to the blood, but these stores are limited. This pathway is known as **glycogenolysis** (the lysis, or splitting, of glycogen to form glucose subunits). Although liver glycogen levels may increase to 200 to 300 g after a meal, only approximately 80 g remain after an overnight fast. Fortunately, the liver has another mechanism for producing blood glucose, known as **gluconeogenesis**. Gluconeogenesis means the formation (genesis) of new (neo) glucose, and, by definition, converts new (noncarbohydrate) precursors to glucose. In gluconeogenesis, lactate, glycerol, and amino acids are used as carbon sources to synthesize glucose. As fasting continues, gluconeogenesis progressively adds to the glucose produced by glycogenolysis in the liver.

Percy V. had not eaten much on his first day of hospitalization. His fasting blood glucose determined on the morning of his second day of hospitalization was 72 mg/dL (normal, overnight fasting = 70 to 100 mg/dL). Thus, in spite of his malnutrition and his overnight fast, his blood glucose was being maintained at nearly normal levels through gluconeogenesis using amino acid precursors. If his blood glucose had decreased to <50 to 60 mg/dL during fasting, his brain would have been unable to absorb glucose fast enough to obtain the glucose needed for energy and neurotransmitter synthesis, resulting in coma and eventual death. Although many other tissues, such as red blood cells, are also totally or partially dependent on

glucose for energy, they function at lower concentrations of blood glucose than the brain.

Lactate is a product of glycolysis in red blood cells and exercising muscle; **glycerol** is obtained from lipolysis of adipose triacylglycerols; and **amino acids** are generated by the breakdown of protein. Because our muscle mass is so large, most of the amino acids are supplied from the degradation of muscle protein. These compounds travel in the blood to the liver, where they are converted to glucose by gluconeogenesis. Because the nitrogen of the amino acids can form ammonia, which is toxic to the body, the liver converts this nitrogen to urea. Urea has two amino groups for just one carbon (Fig. 3.2). It is a very soluble, nontoxic compound that can be readily excreted by the kidneys and thus is an efficient means for disposing of excess ammonia.

FIGURE 3.2 The structure of urea, the highly soluble nitrogen disposal molecule.

As fasting progresses, gluconeogenesis becomes increasingly more important as a source of blood glucose. After a day or so of fasting, liver glycogen stores are depleted and gluconeogenesis is the only source of blood glucose.

B. Role of Adipose Tissue during Fasting

Adipose triacylglycerols are the major source of energy during fasting. They supply fatty acids, which are quantitatively the major fuel for the human body. Fatty acids are oxidized not only directly by various tissues of the body; the products of fatty acid oxidation are also utilized in the liver to synthesize four-carbon products called **ketone bodies**. Ketone bodies are subsequently oxidized as fuel by other tissues to help reduce the body's demand for glucose as a fuel.

As blood insulin levels decrease and blood glucagon levels rise, adipose triacylglycerols are mobilized by a process known as **lipolysis** (lysis of triacylglycerol). They are converted to fatty acids and glycerol, which enter the blood.

It is important to realize that it is only the glycerol and not the fatty acid component of triacylglycerols that provides the carbon for gluconeogenesis. Thus, of the vast store of food energy in adipose tissue triacylglycerols, only the small glycerol portion travels to the liver to enter the gluconeogenic pathway.

Fatty acids serve as fuel for muscle, kidney, and most other tissues. They are oxidized to acetyl coenzyme A (acetyl CoA), and subsequently to CO₂ and H₂O in the TCA cycle, producing energy in the form of adenosine triphosphate (ATP). In addition to the ATP required to maintain cellular integrity, muscle uses ATP for contraction and the kidney uses ATP to drive its transport of metabolites across the nephron membrane.

The fatty acids that enter the liver are converted to acetyl CoA prior to being completely oxidized to CO₂ via the Krebs TCA cycle. The process of conversion of fatty acids to acetyl CoA (β oxidation) produces a considerable amount of energy (ATP), which drives the reactions of the liver under these conditions. The major ATP-requiring process occurring in the liver at this time is gluconeogenesis. The acetyl CoA derived from fatty acid oxidation can also be converted to the ketone bodies **acetoacetate** and **β -hydroxybutyrate**, which are released into the blood (Fig. 3.3).

FIGURE 3.3 The ketone bodies β -hydroxybutyrate, acetoacetate, and acetone. β -hydroxybutyrate and acetoacetate are formed in the liver. Acetone is produced by nonenzymatic decarboxylation of acetoacetate. However, acetone is expired in the breath and is not metabolized to a significant extent in the body, whereas β -hydroxybutyrate and acetoacetate are utilized by muscle and the nervous system as an energy source.

The liver lacks an enzyme required for ketone body oxidation. However, ketone bodies can be further oxidized by most other cells with mitochondria, such as muscle and neurons. In these tissues, acetoacetate and β -hydroxybutyrate are converted to acetyl CoA and then oxidized in the TCA cycle, with subsequent

generation of ATP.

 On his second day of hospitalization, **Percy V.**'s serum ketone body level was 110 μM . (Normal value after a 12-hour fast is approximately 70 μM .) No ketone bodies were detectable in his urine. At this early stage of protein–energy malnutrition, he still has remaining fat stores. After 12 hours of fasting, most of his tissues are using fatty acids as a major fuel, and the liver is beginning to produce ketone bodies from fatty acids. As these ketone bodies increase in the blood, their use as a fuel will increase.

C. Summary of the Metabolic Changes during a Brief Fast

In the initial stages of fasting, stored fuels are used for energy (see Fig. 3.1). The liver plays a key role in maintaining blood glucose levels in the range of 70 to 100 mg/dL, first by glycogenolysis (Fig. 3.1, circle 2) and subsequently by gluconeogenesis (Fig. 3.1, circles 9, 11, and 12). Lactate, glycerol, and amino acids serve as carbon sources for gluconeogenesis. Amino acids are supplied by muscle (via **proteolysis**, lysis of proteins to individual amino acids). Their nitrogen is converted to urea in the liver (Fig. 3.1, circle 10), which is excreted by the kidneys.

Fatty acids, which are released from adipose tissue by the process of lipolysis (Fig. 3.1, circle 5), serve as the body's major fuel during fasting. The liver oxidizes its fatty acids to acetyl CoA. Some of the acetyl CoA is utilized for the production of ketone bodies (Fig. 3.1, circle 7), which are released into the blood. Thus, during the initial stages of fasting, blood levels of fatty acids and ketone bodies begin to increase. Muscle uses fatty acids, ketone bodies (Fig. 3.1, circles 6 and 8), and (when exercising and while supplies last) glucose from muscle glycogen. Many other tissues use either fatty acids or ketone bodies. However, red blood cells, the brain, and other neural tissues use mainly glucose (Fig. 3.1, circles 3 and 4). The metabolic capacities of different tissues with respect to pathways of fuel metabolism are summarized in Table 3.1.

TABLE 3.1 Metabolic Capacities of Various Tissues

PROCESS	LIVER	ADIPOSE TISSUE	KIDNEY CORTEX	MUSCLE	BRAIN	RED BLOOD CELLS
TCA cycle (acetyl CoA \rightarrow CO ₂ + H ₂ O)	+++	++	+++	+++	+++	--
β -Oxidation of fatty acids	+++	++	++	+++	--	--
Ketone body formation	+++	--	--	--	--	--
Ketone body utilization	--	+	+	+++	+++ (Prolonged starvation)	--
Aerobic glycolysis (glucose \rightarrow CO ₂ + H ₂ O)	+++	++	++	+++	+++	--
Anaerobic glycolysis (glucose \rightarrow lactate)	+	+	---	+++ (Exercise)	+	+++
Glycogen metabolism (synthesis and degradation)	+++	+	+	+++	+	--
Gluconeogenesis (lactate, amino acids, glycerol \rightarrow glucose)	+++	--	+	--	--	--
Urea cycle (ammonia \rightarrow urea)	+++	--	--	--	--	--
Lipogenesis (glucose \rightarrow fatty acids)	+++	+	--	--	--	--

Acetyl CoA, acetyl coenzyme A; TCA, tricarboxylic acid.

++ indicates use of the fuel; +++ indicates maximal use, whereas + indicates minimal use. – indicates no use of the fuel.

II. Metabolic Changes during Prolonged Fasting

If the pattern of fuel utilization that occurs during a brief fast were to persist for an extended period, the body's protein would be quite rapidly consumed to the point at which critical functions would be compromised. Fortunately, metabolic changes occur during prolonged fasting that conserves (spare) muscle protein by causing muscle protein turnover to decrease. Figure 3.4 shows the main features of metabolism during prolonged fasting (starvation).

FIGURE 3.4 Starved state. Broken blue lines indicate processes that have decreased, and the heavy red solid line indicates a process that has increased relative to the fasting state. As with Figure 3.1 certain amino acids can also give rise to acetyl CoA, which the liver can use for energy, but not for glucose synthesis. AA, amino acid; acetyl CoA, acetyl coenzyme A; ATP, adenosine triphosphate; FA, fatty acids; KB, ketone bodies; RBC, red blood cells; TCA, tricarboxylic acid; TG, triacylglycerols.

 The liver synthesizes a number of serum proteins and releases them into the blood. The synthesis of these proteins decreases during protein malnutrition, leading to a decrease in their concentration in the blood. Two of these serum proteins, albumin and prealbumin (a liver-derived protein that transports thyroid hormone), are often measured to assess the state of protein malnutrition. A measurement of serum albumin levels is the traditional standard used to assess protein malnutrition, but serum albumin levels respond slowly to changes in protein status owing to its relatively long half-life of 14 to 20 days. Prealbumin levels, however, have a half-life of 2 to 3 days, and so provide a more sensitive indicator of changes in protein status. Neither measurement is specific for protein malnutrition. Serum albumin and prealbumin levels decrease with hepatic disease (although prealbumin levels are less affected by liver disease than albumin levels), certain renal diseases, surgery, and a number of other conditions, in addition to protein malnutrition. **Percy V.**'s values were below the normal range for both of these proteins, indicating that his muscle mass was unable to supply sufficient amino acids to sustain both gluconeogenesis and the synthesis of serum proteins by the liver.

A. Role of Liver during Prolonged Fasting

After 3 to 5 days of fasting, when the body enters the starved state, muscle decreases its use of ketone bodies and depends mainly on fatty acids for its fuel. The liver, however, continues to convert acetyl CoA (from fatty acid oxidation) to ketone bodies. The result is that the concentration of ketone bodies rises in the blood (Fig. 3.5). The brain begins to take up these ketone bodies from the blood and oxidize them for energy. Therefore, the brain needs less glucose than it did after an overnight fast (Table 3.2).

TABLE 3.2 Metabolic Changes during Prolonged Fasting Compared with Fasting for 24 Hours

Muscle use of ketone bodies	Decreases
-----------------------------	-----------

Brain use of ketone bodies	Increases
Brain use of glucose	Decreases
Liver gluconeogenesis	Decreases
Muscle protein degradation	Decreases
Liver production of urea	Decreases

FIGURE 3.5 Changes in the concentration of fuels in the blood during prolonged fasting.

Glucose is still required, however, as an energy source for red blood cells, and the brain continues to use a limited amount of glucose, which it oxidizes for energy and uses as a source of carbon for the synthesis of neurotransmitters. Overall, however, glucose is “spared” (conserved). Less glucose is used by the body and therefore the liver needs to produce less glucose per hour during prolonged fasting than during shorter periods of fasting.

Because the stores of glycogen in the liver are depleted by approximately 20 to 30 hours of fasting, gluconeogenesis is the only process by which the liver can supply glucose to the blood if fasting continues. The amino acid pool, produced by the breakdown of protein, continues to serve as a major source of carbon for gluconeogenesis. A fraction of this amino acid pool is also used for biosynthetic functions (e.g., synthesis of heme and neurotransmitters) and new protein synthesis, processes that must continue during fasting. However, as a result of the decreased rate of gluconeogenesis during prolonged fasting, protein is “spared”; less protein is degraded to supply amino acids for gluconeogenesis.

When converting amino acid carbon to glucose in gluconeogenesis, the liver also converts the nitrogen of these amino acids to urea. Consequently, because glucose production decreases during prolonged fasting compared with early fasting, urea production also decreases.

B. Role of Adipose Tissue during Prolonged Fasting

During prolonged fasting, adipose tissue continues to break down its triacylglycerol stores, providing fatty acids and glycerol to the blood. These fatty acids serve as the major source of fuel for the body. The glycerol is converted to glucose, whereas the fatty acids are oxidized to CO_2 and H_2O by tissues such as muscle. In the liver, fatty acids are converted to ketone bodies that are oxidized by many tissues, including the brain.

Ann R.'s admission laboratory studies revealed a blood glucose level of 65 mg/dL (normal fasting blood glucose = 70 to 100 mg/dL). If checked, her serum ketone body concentration would be elevated and her urine ketones would be positive. In her starved state, ketone body use by her brain instead of glucose is helping to conserve protein in her muscles and vital organs.

Several factors determine how long we can fast and still survive. The amount of adipose tissue is one factor because adipose tissue supplies the body with its major source of fuel. However, body protein levels can also determine the length of time we can fast. Glucose is still used during prolonged fasting (starvation), but in significantly reduced amounts. Although we degrade protein to supply amino acids for gluconeogenesis at a slower rate during starvation than during the first days of a fast, we are still losing protein that serves vital functions for our tissues. Protein can become so depleted that the heart, kidney, and other vital tissues stop functioning, or we can develop an infection and not have adequate reserves to mount an immune response. In addition to fuel problems, we are deprived of the vitamin and mineral precursors of coenzymes and other compounds necessary for tissue function. Because of either a lack of ATP or a decreased intake of electrolytes, the electrolyte composition of the blood or cells could become incompatible with life. Ultimately, we die of starvation.

CLINICAL COMMENTS

Percy V. As a result of his severely suppressed appetite for food, **Percy V.** developed a mild degree of protein–energy malnutrition. When prolonged, this type of protein malnutrition can cause changes in the villi of the small intestine that reduce its absorptive capacity for what little food is ingested.

Death by starvation occurs with loss of roughly 40% of body weight, when approximately 30% to 50% of body protein has been lost, or 70% to 95% of body fat stores. Generally, this occurs at BMIs of approximately 13 for men and 11 for women.

Despite his insufficient intake of dietary carbohydrates, **Percy V.**'s blood glucose level was 72 mg/dL, close to the lower limit (70 mg/dL) of the normal range for a well-nourished, healthy person after a 12-hour fast. This is the finding you would expect; it reflects the liver's capacity to maintain adequate levels of blood glucose by means of gluconeogenesis, even during prolonged and moderately severe caloric restriction. Amino acids from the degradation of protein, principally in skeletal muscle, supply most of the precursors for gluconeogenesis.

Percy V. had several indicators of his protein malnutrition: his serum albumin and prealbumin levels were below normal, his MUAMC was at the 12th percentile, and his CHI was at 85%. The low levels of serum proteins reflect a low dietary protein intake and possibly diminished capacity to absorb dietary amino acids. Consequently, amino acids were being mobilized from the degradation of protein in muscle and other tissues to supply precursors for new protein synthesis as well as gluconeogenesis. The result was a loss of muscle mass, indicated by the MUAMC and decreased levels of serum proteins.

Creatinine–height index. A biochemical marker used for estimating body muscle mass is the 24-hour urinary creatinine excretion. Creatinine is formed in active muscle at a constant rate, generally in proportion to the amount of muscle tissue present in a patient. In a protein-malnourished individual, urinary creatinine will decrease in proportion to the decrease in muscle mass. To assess depletion of muscle mass, the amount of creatinine excreted is expressed relative to the height of the patient, yielding a creatinine–height index (CHI). The amount of creatinine (in milligrams) excreted by the subject

in 24 hours is divided by the amount of creatinine excreted by a normal, healthy subject of the same height and sex. The resulting ratio is multiplied by 100 to express it as a percentage. **Percy V.**'s CHI was 85% (80% to 90% of normal indicates a mild deficit; 60% to 80% of normal indicates a moderate deficit; and <60% of normal indicates a severe deficit of muscle mass).

Fatty acids mobilized from adipose tissue are the major source of energy for most tissues. Because **Percy V.** was eating, and not in total starvation, his ketone bodies were only moderately elevated in the blood (110 μM vs. normal of 70 μM) and did not appear in the urine.

Percy V. had several psychological counseling sessions, as well as a number of discussions with a registered dietitian to help him improve and maintain his nutrient uptake. The dietitian suggested that **Percy V.** add nutritional drinks (such as Boost, Ensure, or an instant breakfast drink) to provide essential nutrients. He was advised that small frequent feedings (3 meals and 2 snacks) can provide adequate calories, proteins, and other nutrients throughout the day. The dietitian also suggested that **Percy V.** use frozen dinners in combination with a fresh salad and a glass of milk, and engage in physical activity to enhance mood and increase appetite.

After several psychological counseling sessions and the promise of an extended visit from his grandchild, **Percy V.** resumed his normal eating pattern.

Ann R. meets the diagnostic criteria for anorexia nervosa. She has low body weight with continual fear of gaining weight. Such patients also have body image disturbance or a lack of recognition of the seriousness of their illness.

Amenorrhea (lack of menses) usually develops during anorexia nervosa and other conditions when a woman's body fat content falls to approximately 22% of her total body weight. The immediate cause of amenorrhea is reduced production of the gonadotropic protein hormones (luteinizing hormone and follicle-stimulating hormone) by the anterior pituitary; this is likely related to leptin levels, a hormone predominantly made by adipose tissue.

Ann R. is suffering from the consequences of prolonged and severe protein and caloric restriction. Fatty acids, released from adipose tissue by lipolysis, are being converted to ketone bodies in the liver and the level of ketone bodies in the blood can be extremely elevated. Excretion of ketone bodies from her kidneys would be reflected in a positive urine test for ketone bodies.

Although **Ann R.**'s blood glucose is below the normal fasting range (65 mg/dL vs. normal of 70 mg/dL), she is experiencing only a moderate degree of hypoglycemia (low blood glucose) despite her severe, near-starvation diet. Her blood glucose level reflects the ability of the brain to use ketone bodies as a fuel when they are elevated in the blood, thereby decreasing the amount of glucose that must be synthesized from amino acids provided by protein degradation. This is a clear example of protein sparing in prolonged fasting.

Ann R.'s BMI showed that she is at a high risk of death through starvation (severe protein–energy malnutrition). She was therefore hospitalized and placed on enteral nutrition (nutrients provided through tube feeding). The general therapeutic plan, outlined in Chapter 1, of nutritional restitution and treatment of the emotional factors leading to the patient's anorectic behavior, was continued. She slowly started to eat small amounts of food while hospitalized. As part of her eating disorder team, the dietitian's role included helping the patient to recognize and address disordered eating patterns, and for **Ann R.** to focus on health rather than weight gain. The dietitian also determined the proper amount of calories needed for a slow, gradual weight gain to prevent the complications of refeeding syndrome (causing deleterious effects if refeeding is done improperly) and to devise an individualized eating plan for **Ann R.** to reach target goals.

Refeeding syndrome refers to severe metabolic dysfunction that occurs when a starving individual consumes too much food. Cardiac, pulmonary, and neurologic problems can result from fluid and electrolyte imbalance if the person does not follow a planned diet to reintroduce food slowly. The hallmark clinical indicator of refeeding syndrome is hypophosphatemia, but the syndrome is complex. Other possible features include abnormal levels of sodium, potassium, and magnesium; thiamin deficiency; and alterations in the metabolism of glucose, protein, and fat.

BIOCHEMICAL COMMENTS

Clinical Use of Metabolite Measurements in Blood and Urine. When a patient develops a metabolic problem, it is difficult to examine cells to determine the cause. To obtain tissue for metabolic studies, biopsies must be performed. These procedures can be difficult, dangerous, or even impossible, depending on the tissue. Cost is an additional problem. However, both blood and urine can be

obtained readily from patients, and measurements of substances in the blood and urine can help in diagnosing a patient's problem. Concentrations of substances that are higher or lower than normal indicate which tissues are malfunctioning. For example, if blood urea nitrogen (BUN) levels are low, a problem centered in the liver might be suspected because urea is produced in the liver. Conversely, high blood levels of urea suggest that the kidneys are not excreting this compound normally. Decreased urinary and blood levels of creatinine indicate diminished production of creatinine by skeletal muscle. However, high blood creatinine levels could indicate an inability of the kidney to excrete creatinine, resulting from renal disease. If high levels of ketone bodies are found in the blood or urine, and blood sugar is low, the patient's metabolic pattern is that of the starved state. If the high levels of ketone bodies are coupled with elevated levels of blood glucose, the problem is most likely a deficiency of insulin; that is, the patient probably has type 1 diabetes (these patients are usually young). Without insulin, fuels are mobilized from tissues rather than being stored.

These relatively easy and inexpensive tests on blood and urine can be used to determine which tissues need to be studied more extensively to diagnose and treat the patient's problem. A solid understanding of fuel metabolism helps in the interpretation of these simple tests.

KEY CONCEPTS

- ◆ During fasting, when blood glucose levels drop, glucagon is released from the α -cells of the pancreas. Glucagon signals the liver to utilize its stored carbohydrate to release glucose into the circulation, primarily for use by the brain and red blood cells.
- ◆ After fasting for about 3 days, the liver releases ketone bodies (derived from fat oxidation) as an alternative fuel supply for the brain. Liver glycogen stores are depleted and gluconeogenesis provides glucose to the body.
- ◆ Glucagon also signals the fat cell to degrade triacylglycerol, supplying the body with fatty acids for energy and glycerol for gluconeogenesis.
- ◆ The substrates for liver gluconeogenesis are lactate (from the red blood cells), amino acids (from muscle protein degradation), and glycerol (from triacylglycerol degradation).
- ◆ In prolonged starvation, the brain can adapt to using ketone bodies for energy, which reduces the body's demand for glucose. This reduces the rate of muscle protein degradation to provide precursors for gluconeogenesis and allows extended survival times under starvation conditions.
- ◆ The major disease discussed in this chapter is summarized in Table 3.3.

TABLE 3.3 A Summary of the Major Disorder Discussed in Chapter 3

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
Malnutrition	Both	Reduced nutrient uptake may be caused by genetic mutation in specific proteins or dietary habits leading to reduced nutrient intake. May lead to increased ketone body production and reduced liver protein synthesis.

REVIEW QUESTIONS—CHAPTER 3

You will need some information from Chapters 1 and 2, as well as Chapter 3, to answer these questions.

1. A hiker who has become lost on the Appalachian Trail has consumed the last of his rations and has only water to drink. By 24 hours after his last meal, which one of the following is most likely to occur?
 - A. Gluconeogenesis in the liver will be the major source of blood glucose.
 - B. Muscle glycogenolysis provides glucose to the blood.
 - C. Muscles convert amino acids to blood glucose.
 - D. Fatty acids released from adipose tissue provide carbon for the synthesis of glucose.
 - E. Ketone bodies provide carbon for gluconeogenesis.
2. A physician is treating a patient with type 1 diabetes who has neglected to take her insulin for 5 days. The patient demonstrates elevated blood glucose and ketone body levels. Ketone bodies are indirectly elevated

- owing to which one of the following?
- A. Elevated glucose levels
 - B. Reduced blood urea nitrogen
 - C. Decreased fatty acid release from the adipocyte
 - D. Inhibition of liver oxidation of ketone bodies
 - E. Reduced muscle utilization of fatty acids
3. In a well-nourished individual, as the length of fasting increases from overnight to 1 week, which one of the following is most likely to occur?
- A. Blood glucose levels decrease by approximately 50%.
 - B. Red blood cells switch to using ketone bodies.
 - C. Muscles decrease their use of ketone bodies, which increase in the blood.
 - D. The brain begins to use fatty acids as a major fuel.
 - E. Adipose tissue triacylglycerols are nearly depleted.
4. A hospitalized patient had low levels of serum albumin and high levels of blood ammonia. His creatinine–height index (CHI) was 98%. His BMI was 20.5. Blood urea nitrogen was in the normal range, consistent with normal kidney function. The diagnosis most consistent with these findings is which one of the following?
- A. A loss of hepatic function (e.g., alcohol-induced cirrhosis)
 - B. Anorexia nervosa
 - C. Kwashiorkor (protein malnutrition)
 - D. Marasmus (protein–energy malnutrition)
 - E. Decreased absorption of amino acids by intestinal epithelial cells (e.g., celiac disease)
5. **Otto S.**, an overweight medical student (see Chapter 1), discovered that he could not exercise enough during his summer clerkship rotations to lose 2 to 3 lb per week. He decided to lose weight by eating only 300 kcal/day of a dietary supplement that provided half the calories as carbohydrate and half as protein. In addition, he consumed a multivitamin supplement. During the first 3 days on this diet, which statement best represents the state of **Otto S.**'s metabolism?
- A. His protein intake met the Recommended Dietary Allowance (RDA) for protein.
 - B. His carbohydrate intake met the fuel needs of his brain.
 - C. Both his adipose mass and muscle mass decreased.
 - D. He remained in nitrogen balance.
 - E. He developed severe hypoglycemia.
6. A pregnant woman is having an oral glucose tolerance test done to diagnose gestational diabetes. The test consists of ingesting a concentrated solution of glucose (75 g of glucose) and then having her blood glucose levels measured at various times after ingesting the sugar. Her test results come back normal. At what time after consuming the oral sugar solution will she have the highest blood glucose level?
- A. Immediately
 - B. 1 Hour
 - C. 2 Hours
 - D. 3 Hours
 - E. 4 Hours
7. A patient with frequent sweating and tremors is diagnosed with “reactive hypoglycemia” and has been prescribed a small meal every 4 hours throughout the day. The patient most likely is impaired in carrying out which one of the following?
- A. Glycogenesis of liver glycogen stores
 - B. Glycogenolysis of muscle glycogen stores
 - C. Glycogenolysis of liver glycogen stores
 - D. Glycogenesis of muscle glycogen stores
 - E. Glycogenesis of adipose tissue glycogen stores
8. An activist is on a hunger strike to bring attention to her cause, and she has only consumed H₂O and vitamins for the past 5 days. Which ONE of the following organs/structures has begun to utilize ketone bodies as a major secondary fuel source?
- A. Red blood cells
 - B. Brain
 - C. Liver
 - D. Heart

- E. All of the above
9. You are evaluating a patient who has a mutation that hinders the ability to carry out liver glycogenolysis. One initial finding shortly after entering the fasting state in this patient would be which ONE of the following?
- Hyperglycemia
 - Ketosis (elevated levels of ketone bodies)
 - Significantly increased urea synthesis
 - Reduced blood lactate levels
 - Hypoglycemia
10. A prisoner has gone on a hunger strike, drinking only water. Careful monitoring of the prisoner demonstrated a drop in blood urea nitrogen during the second week of the fast. This occurred owing to which one of the following?
- Enhanced glycogenolysis
 - Reduced ketone body formation
 - A decrease in the rate of gluconeogenesis
 - An increase in the rate of gluconeogenesis
 - Enhanced glucose metabolism in the brain
11. During an extended fast (5 to 7 days), protein degradation in the muscle is reduced as compared to the initial days of the fast. Consequences of this shift include which of the following? Choose the one best answer.

	Increased Urea Production	Increased Fatty Acid Oxidation by the Nervous System	Increased Ketone Body Synthesis by the Muscle	Ketone Body Oxidation in the Liver
A	No	No	No	No
B	No	Yes	No	Yes
C	No	No	No	Yes
D	Yes	Yes	Yes	No
E	Yes	No	Yes	Yes
F	Yes	Yes	Yes	No

12. As the insulin-to-glucagon ratio decreases during an extended fast (from day 1 to day 3), which of the following metabolic pathways will be altered as indicated? Choose the one best answer.

	Glycogen Synthesis in the Muscle	Triglyceride Synthesis in the Liver	Liver Gluconeogenesis	Fat Cell Triglyceride Formation
A	Increased	Increased	Decreased	Increased
B	Increased	Decreased	Increased	Decreased
C	Increased	Increased	Increased	Increased
D	Decreased	Decreased	Increased	Increased
E	Decreased	Increased	Decreased	Decreased
F	Decreased	Decreased	Increased	Decreased

Questions 3.13 to 3.15 are based on the following case. You are evaluating a 24-year-old patient who has, in the past 3 months, experienced a drop in BMI from 19.0 to 16.7. The patient is 1.8 m tall.

- What is the weight loss of the patient over this past 3 months?
 - 2.5 kg
 - 5.0 kg
 - 7.5 kg
 - 10.0 kg
 - 12.5 kg
- Under current conditions, the patient's liver has had its metabolism altered such that it is now doing which of the following? Choose the one best answer.

	Export Fatty Acids	Export Amino Acids	Synthesize Ketone Bodies	Oxidize Glucose for Energy
A	No	No	Yes	Yes
B	No	Yes	No	Yes
C	No	No	Yes	No
D	Yes	Yes	No	No
E	Yes	No	Yes	Yes
F	Yes	Yes	No	No

- The patient, during the past 3 months, had switched to a diet that was almost totally lacking triglyceride—a high-protein high-carbohydrate diet for weight loss. Such a diet has the potential to lead to which one of the

following unintended side effects?

- A. Increased chylomicron formation
- B. Vitamin A deficiency
- C. Vitamin C deficiency
- D. Fasting hypoglycemia between meals
- E. Increased triglyceride formation as a result of the high-carbohydrate content of the diet

ANSWERS TO REVIEW QUESTIONS

1. **The answer is A.** By 24 hours after a meal, hepatic (liver) gluconeogenesis is the major source of blood glucose because hepatic glycogen stores have been nearly depleted. Muscle and other tissues lack an enzyme necessary to convert glycogen or amino acids to glucose for export (thus, B is incorrect). The liver is the only significant source of blood glucose. Glucose is synthesized in the liver from amino acids (provided by protein degradation), from glycerol (provided by hydrolysis of triacylglycerols in adipose tissue), and from lactate (provided by anaerobic glycolysis in red blood cells and other tissues). Glucose cannot be synthesized from fatty acids or ketone bodies (thus, D and E are incorrect).
2. **The answer is A.** The liver will produce ketone bodies when fatty acid oxidation is increased, which occurs when glucagon is the predominant hormone (glucagon leads to fatty acid release from the fat cells, for oxidation in the liver and muscle). This would be the case in an individual who cannot produce insulin and is not taking insulin injections. However, in this situation, the ketone bodies are not being used by the nervous system (brain) because of the high levels of glucose in circulation. This leads to severely elevated ketone levels owing to nonutilization. The absence of insulin is also allowing the fat cells to continuously release fatty acids for energy, thereby allowing increased fatty acid oxidation by the liver and increased ketone body production. The glucose is high because, in the absence of insulin, muscle and fat cells are not utilizing the glucose in circulation as an energy source. Recall, while the liver produces ketone bodies, it lacks a necessary enzyme to utilize ketone bodies as an energy source. There is no relation between blood urea nitrogen levels and the rate of ketone body production. The muscle reduces its use of ketone bodies under these conditions, but not its use of fatty acids.
3. **The answer is C.** The major change during prolonged fasting is that as muscles decrease their use of ketone bodies; ketone bodies increase enormously in the blood and are utilized by the brain as a fuel. However, even during starvation, glucose is still required by the brain, which cannot oxidize fatty acids to an appreciable extent (thus, D is incorrect). Red blood cells can use only glucose as fuel (thus, B is incorrect). Because the brain, red blood cells, and certain other tissues are glucose-dependent, the liver continues to synthesize glucose, and blood glucose levels are maintained at only slightly less than fasting levels (thus, A is incorrect). Adipose tissue stores (approximately 135,000 kcal) are not depleted in a well-nourished individual after 1 week of fasting (thus, E is incorrect).
4. **The answer is A.** Decreased serum albumin could have a number of causes, including hepatic disease that decreases the ability of the liver to synthesize serum proteins, protein malnutrition, marasmus, or diseases that affect the ability of the intestine to digest protein and absorb the amino acids. However, his BMI is in the healthy weight range (thus, B and D are incorrect). His normal CHI indicates that he has not lost muscle mass and is, therefore, not suffering from protein malnutrition (thus, B, C, D, and E are incorrect).
5. **The answer is C.** His protein intake of 150 kcal is about 37 g protein ($150 \text{ kcal} \div 4 \text{ kcal/g} = 37 \text{ g}$), below the Recommended Dietary Allowance (RDA) of 0.8 g protein per kilogram body weight (thus, A is incorrect, as **Otto S.** weighs approximately 88 kg). His carbohydrate intake of 150 kcal is below the glucose requirements of his brain and red blood cells (about 150 g/day; see Chapter 2) (thus, B is incorrect). Therefore, he will be breaking down muscle protein to synthesize glucose for the brain and other glucose-dependent tissues and adipose tissue mass to supply fatty acids for muscle and tissues able to oxidize fatty acids. Because he will be breaking down muscle protein to amino acids and converting the nitrogen from both these amino acids and his dietary amino acids to urea, his nitrogen excretion will be greater than his intake and he will be in negative nitrogen balance (thus, D is incorrect). It is unlikely that he will develop hypoglycemia while he is able to supply gluconeogenic precursors.
6. **The answer is B.** Blood glucose levels peak approximately 1 hour after eating and return to the fasting range by about 2 hours. If the blood glucose levels remain elevated for an extended period of time, it is an indication of impaired glucose transport (insulin stimulates glucose transport into muscle and adipose tissue). If the blood glucose levels are below 140 mg/dL 2 hours after the test, the result is considered

normal. If the levels are between 140 and 200 mg/dL, the patient is considered to have “impaired glucose tolerance,” and if the levels are above 200 mg/dL after 2 hours, a diagnosis of diabetes is confirmed.

7. **The answer is C.** Blood glucose levels return to the fasting range about 2 hours after a meal. The decrease in blood glucose causes a decrease in insulin and an increase in glucagon production. Glucagon stimulates the liver to degrade its glycogen stores (glycogenolysis) and release glucose into the bloodstream. If the patient eats another meal within a few hours, the patient returns to the fed state. Glycogenesis is the synthesis of glycogen. While the muscle contains glycogen stores, degradation of muscle glycogen only benefits the muscle; the muscle cannot export glucose to maintain blood glucose levels. Adipose tissue does not contain significant levels of glycogen.
8. **The answer is B.** After 24 to 48 hours of the fast, the activist’s liver has run out of glycogen, and all glucose is being produced from gluconeogenesis. The liver is oxidizing fatty acids as an energy source and producing ketone bodies as an alternative fuel source for the nervous system (brain). Muscle continues to use fatty acids as a fuel source but decreases its use of ketone bodies, thereby raising the blood concentration of ketone bodies. At the higher concentration of ketone bodies in the blood, the brain can utilize the ketone bodies and does not need as much glucose. Up to 40% of the brain’s energy needs can be met by ketone bodies, but the other 60% still needs to be met by glucose as an energy source. As the brain utilizes ketone bodies the liver can reduce gluconeogenesis, thereby reducing the need for amino acids as precursors and preserving muscle protein. Red blood cells have no mitochondria so they must use glucose only as an energy source (ketone bodies are oxidized in mitochondria). The liver cannot use ketone bodies as it lacks a key enzyme for their degradation, and the heart uses lactate as an energy source, along with fatty acids.
9. **The answer is E.** As blood glucose levels begin to drop, glucagon is released from the pancreas, which stimulates glycogenolysis in the liver. The glucose produced from liver glycogen is used, initially, to maintain blood glucose levels during the early stages of a fast. Gluconeogenesis will kick in later, as this process requires more energy than glycogenolysis, and fatty acid oxidation must be underway before glucose can be produced from lactate, glycerol, and amino acids. Ketone bodies will not be evident after initiating a fast (the levels of ketones will not be significant until 24 to 48 hours after a fast is initiated). Significant protein degradation will not occur until the liver runs out of glycogen, about 24 to 36 hours after the start of the fast (and without protein degradation, urea synthesis will remain normal). The red blood cell will still be metabolizing glucose, so blood lactate levels (the end product of red cell glucose metabolism) will remain relatively constant.
10. **The answer is C.** As a fast increases in length, the liver will begin to produce ketone bodies from the oxidation of fatty acids, obtained from the adipocyte. As the ketone bodies are released from the liver the brain will begin to utilize them, reducing its need for glucose by approximately 40%. This, in turn, reduces the need of the liver to produce glucose by gluconeogenesis (recall, glycogen stores are depleted by 36 hours of the fast), which, in turn, reduces the rate of protein degradation in the muscle. The overall effect is to spare muscle protein for as long as possible.
11. **The answer is A.** As the body transitions from the basal state to the starved state, the liver begins to increase fatty acid oxidation and produce ketone bodies, which are exported to be used as fuel for the nervous system. The liver lacks the enzyme necessary to metabolize ketone bodies, and fatty acids cannot enter the nervous system at an appreciable rate to generate the energy the nervous system needs to function. Urea production is decreased as liver gluconeogenesis decreases, owing to the nervous system using ketone bodies for energy, which partially reduces its need for glucose as an energy source. Muscles can oxidize either fatty acids or ketone bodies as an energy source, but they do not produce ketone bodies.
12. **The answer is F.** As the levels of glucagon increase relative to insulin the liver will be switched to glucose export mode, such that glycogen degradation and gluconeogenesis will be active. Once the glycogen is depleted (after about 30 hours), gluconeogenesis is solely responsible for providing glucose to the blood, so the rate of gluconeogenesis will increase over the first 3 days of a fast. Muscle glycogen synthesis is decreased as insulin is required to transport glucose into the muscle to be stored as glycogen, and insulin levels are low. Triglyceride synthesis, either in the liver or fat cells, only occurs when glucose levels are high (high insulin), which is not the case during the first days of an extended fast.
13. **The answer is C.** Before the weight loss the patient’s BMI was 19.0. The BMI is calculated by dividing the weight in kg by the square of the height (in meters). The patient is 1.8 meters tall, so 1.8 squared is 3.24. Plugging into the equation, $19.0 = (\text{weight})/3.24$, and solving for weight yields a value of 61.56 kg. After weight loss the BMI is 16.7, so $16.7 = (\text{weight})/3.24$, and the weight is 54.10 kg. The weight loss, then, after 3 months is 7.46 kg, or about 16.5 lb.

14. **The answer is C.** The patient has been losing weight for 3 months, most likely owing to insufficient caloric intake. The liver would then switch to exporting glucose (but not fatty acids—the fat cells will be exporting fatty acids under these conditions) and oxidizing fatty acids for energy (the liver will not oxidize glucose because it must export glucose). The muscle is degrading protein to export amino acids to the liver for gluconeogenesis, but the liver is not exporting amino acids—it is using their carbon skeletons to produce glucose to maintain blood glucose levels. The liver will also begin to synthesize ketone bodies as an alternative fuel source for the brain, to spare the degradation of muscle protein and to reduce (although not eliminate) the nervous system's need for glucose as an energy source.
15. **The answer is B.** The low-fat content of the diet means there is very little triglyceride to be digested in the small intestine, such that the intestinal epithelial cells do not have sufficient substrates for chylomicron synthesis, so the release of chylomicrons from the cells after a meal will be reduced as when on a normal diet. Fat-soluble vitamins (such as vitamin A) are absorbed with the fatty acids from the intestinal lumen, and with low levels of fatty acids in the diet the patient runs the risk of becoming deficient in the fat-soluble vitamins (A, E, D, and K; vitamin C is a water-soluble vitamin). The liver is still functioning normally and exporting glucose, so there will not be hypoglycemia in between meals. Despite the high-carbohydrate intake, the caloric intake is too low to maintain the current weight, and weight loss results from the degradation of stored triglycerides to glycerol and fatty acids for use as a fuel for the muscles and liver.

SECTION

II

Chemical and Biologic Foundations of Biochemistry

The discipline of biochemistry developed as chemists began to study the molecules of cells, tissues, and body fluids and physicians began to look for the molecular basis of various diseases. Today, the practice of medicine depends on understanding the roles and interactions of the enormous number of different chemicals that enable our bodies to function. The task is less overwhelming if one knows the properties, nomenclature, and functions of classes of compounds such as carbohydrates and enzymes. This section intends to review some of this information in a context relevant to medicine. Students enter medical school with different scientific backgrounds, and some of the information in this section will therefore be familiar to many students.

The nomenclature used to describe patients may include the name of a class of compounds. For example, a patient with diabetes mellitus, who has hyperglycemia, has hyper (high) concentrations of carbohydrates (glyc) in their blood (emia).

From a biochemist's point of view, most metabolic diseases are caused by enzymes and other proteins that malfunction, and the pharmacologic drugs used to treat these diseases correct that malfunction. For example, individuals with atherosclerosis, who have elevated blood cholesterol levels, are treated with a drug that inhibits an enzyme in the pathway for cholesterol synthesis. Even a bacterial infection can be considered a disease of protein function if one considers the bacterial toxins that are proteins, the enzymes in our cells affected by these toxins, and the proteins involved in the immune response when we try to destroy these bacteria.

We begin by discussing the relationship of metabolic acids and buffers to blood pH in Chapter 4. Chapter 5 focuses on the nomenclature, structure, and some of the properties of the major classes of compounds found in the human body. The structure of a molecule determines its function and its fate, and the common name of a compound can often tell something about its structure.

Proteins are linear chains of amino acids that fold into complex three-dimensional structures. They function in the maintenance of cellular and tissue structure and the transport and movement of molecules. Some proteins are enzymes, which are catalysts that enormously increase the rate of chemical reactions in the body. Chapters 6 and 7 describe the amino acids and their interactions within proteins that provide proteins with a flexible and functional three-dimensional structure. Chapters 8 and 9 describe the properties, functions, and regulation of enzymes.

Proteins and other compounds function within a specialized environment defined by their location in cells or body fluids. Their ability to function is partially dependent on membranes that restrict the free movement of molecules. Chapter 10 includes a brief review of the components of cells, their organization into subcellular organelles, and the manner in which various types of molecules move into cells and between compartments within a cell.

In a complex organism such as a human, different cell types carry out different functions. This specialization of function requires cells to communicate with each other. One of the ways they communicate is through the secretion of chemical messengers that carry a signal to another cell. In Chapter 10, we consider some of the principles of cell signaling and describe some of the chemical messenger systems.

Dianne A. had an elevated blood glucose level of 684 mg/dL. What is the molar concentration of glucose in **Dianne A.**'s blood? (Hint: The molecular weight of glucose [$C_6H_{12}O_6$] is 180 g/mol.)

Both in this book and in medical practice, you will need to interconvert different units used for the weight and size of compounds and for their concentration in blood and other fluids. Table II.1 provides definitions of some of the units used for these interconversions.

TABLE II.1 Common Units Expressed in Equivalent Ways		
1 M	1 MOL/L	MOLECULAR WEIGHT IN G/L
1 mM	1 millimol/L	10^{-3} mol/L
1 μ M	1 micromol/L	10^{-6} mol/L
1 nM	1 nanomol/L	10^{-9} mol/L
1 mL	1 milliliter	10^{-3} L
1 mg%	1 mg/100 mL	10^{-3} g/100 mL
1 mg/dL	1 mg/100 mL	10^{-3} g/100 mL
1 mEq/L	1 milliequivalent/L	mM \times valence of ion
1 kg	1,000 g	2.2 lb
1 cm	10^{-2} m	0.394 in

 Milligrams per deciliter (mg/dL) is the common way clinicians in the United States express blood glucose concentration. A concentration of 684 mg/dL is 684 mg per 100 mL of blood, or 6,480 mg/L, or 6.48 g/L. If 6.84 g/L is divided by 180 g/mol, one obtains a value of 0.038 mol/L, which is 0.038 M or 38 mM. In contrast, normal fasting blood glucose levels are approximately 5 mM.

4

Water, Acids, Bases, and Buffers

Approximately 60% of our body is water. It acts as a solvent for the substances we need, such as K^+ , glucose, adenosine triphosphate (ATP), and proteins. It is important for the transport of molecules and heat. Many of the compounds produced in the body and dissolved in water contain chemical groups that act as acids or bases, releasing or accepting hydrogen ions. The hydrogen ion content and the amount of body water are controlled to maintain a constant environment for the cells called homeostasis (same state) (Fig. 4.1). Significant deviations from a constant environment, such as acidosis or dehydration, may be life-threatening. This chapter describes the role of water in the body and the buffer systems used by the body to protect itself from acids and bases produced from metabolism.

FIGURE 4.1 Maintenance of body pH. The body produces approximately 13 to 22 mol/day of acid from normal metabolism. The body protects itself against this acidity by buffers that maintain a neutral pH and by the expiration of CO₂ through the lungs and by the excretion of NH₄⁺ and other ions through the kidneys.

Water. Water is distributed between intracellular and extracellular compartments, the latter comprising interstitial fluids, blood, and lymph. Because water is a **dipolar molecule** with an uneven distribution of electrons between the hydrogen and oxygen atoms, it forms hydrogen bonds with other polar molecules and acts as a **solvent**.

The pH of Water. Water **dissociates** to a slight extent to form **hydrogen (H⁺)** and hydroxyl (OH⁻) ions. The concentration of hydrogen ions determines the acidity of the solution, which is expressed in terms of **pH**. The pH of a solution is the negative log of its hydrogen ion concentration.

Acids and Bases. An **acid** is a substance that can **release hydrogen ions** (protons), and a **base** is a substance that can **accept hydrogen ions**. When dissolved in water, almost all the molecules of a **strong acid** dissociate and release their hydrogen ions, but only a small percentage of the total molecules of a weak acid dissociate. A **weak acid** has a characteristic **acid dissociation constant, K_a**. The relationship between the pH of a solution, the K_a of an acid, and the extent of its dissociation are given by the **Henderson–Hasselbalch equation**.

Buffers. A buffer is a mixture of an **undissociated acid** and its **conjugate base** (the form of the acid that has lost its proton). It causes a solution to resist changes in pH when either H⁺ or OH⁻ is added. A buffer has its greatest buffering capacity in the pH range near its **pK_a** (the negative log of its K_a). Two factors determine the effectiveness of a buffer: its pK_a relative to the pH of the solution and its concentration.

Metabolic Acids and Bases. Normal metabolism generates CO₂, **metabolic acids** (e.g., **lactic acid** and **ketone bodies**), and **inorganic acids** (e.g., **sulfuric acid**). The major source of acid is CO₂, which reacts with water to produce **carbonic acid**. To maintain the pH of body fluids in a range compatible with life, the body has **buffers** such as **bicarbonate**, **phosphate**, and **hemoglobin** (see Fig. 4.1). Ultimately, **respiratory mechanisms** remove carbonic acid through the **expiration of CO₂**, and the **kidneys excrete acid** as **ammonium ion (NH₄⁺)** and other ions.

THE WAITING ROOM

Dianne (Di) A. is a 26-year-old woman who was diagnosed with type 1 diabetes mellitus at the age of 12 years. She has an absolute insulin deficiency resulting from autoimmune destruction of the β-cells of her pancreas. As a result, she depends on daily injections of insulin to prevent severe elevations of glucose and ketone bodies in her blood. When she could not be aroused from an afternoon nap, her roommate called an ambulance, and **Dianne A.** was brought to the emergency department of the hospital in a coma. Her roommate reported that **Dianne A.** had been feeling nauseated and drowsy and had been vomiting for 24 hours. **Dianne A.** is clinically dehydrated, and her blood pressure is low. Her respirations are deep and rapid, and her pulse rate is rapid. Her breath has the “fruity” odor of acetone.

Blood samples are drawn for measurement of her arterial blood pH, arterial partial pressure of carbon dioxide (Paco₂), serum glucose, and serum bicarbonate (HCO₃⁻). In addition, serum and urine are tested for the presence of ketone bodies, and **Dianne A.** is treated with intravenous normal saline and insulin. The laboratory reports that her blood pH is 7.08 (reference range 7.36 to 7.44) and that ketone bodies are present in both blood and urine. Her blood glucose level is 648 mg/dL (reference range 70 to 100 mg/dL after an overnight fast, and no higher than 200 mg/dL in a casual glucose sample taken without regard to the time of the last meal).

Dennis V., age 3 years, was brought to the emergency department by his grandfather, **Percy V.** While **Dennis**

V. was visiting his grandfather, he climbed up on a chair and took a half-full 500-tablet bottle of 325-mg aspirin (acetylsalicylic acid) tablets from the kitchen counter. **Percy V.** discovered **Dennis V.** with a mouthful of aspirin, which he removed, but he could not tell how many tablets **Dennis V.** had already swallowed. When they arrived at the emergency department, the child appeared bright and alert, but **Dennis V.** was hyperventilating.

I. Water

Water is the solvent of life. It bathes our cells, dissolves and transports compounds in the blood, provides a medium for movement of molecules into and throughout cellular compartments, separates charged molecules, dissipates heat, and participates in chemical reactions. Most compounds in the body, including proteins, must interact with an aqueous medium in order to function. In spite of the variation in the amount of water we ingest each day and produce from metabolism, our body maintains a nearly constant amount of water that is approximately 60% of our body weight (Fig. 4.2).

A. Total body water

B. Extracellular fluid

FIGURE 4.2 Fluid compartments in the body based on an average 70-kg man.

Dianne A. has a ketoacidosis. When the amount of insulin she injects is inadequate, she remains in a condition similar to a fasting state although she ingests food (see Chapters 2 and 3). Her liver continues to metabolize fatty acids to the ketone bodies acetoacetic acid and β -hydroxybutyric acid. These compounds are weak acids that dissociate to produce anions (acetoacetate and β -hydroxybutyrate, respectively) and hydrogen ions, thereby lowering her blood and cellular pH below the normal range. Because the dissociation of the ketone bodies is causing acidosis, it is classified as ketoacidosis.

A. Fluid Compartments in the Body

Total body water is roughly 50% to 60% of body weight in adults and 75% of body weight in children. Because fat has relatively little water associated with it, obese people tend to have a lower percentage of body water than thin people, women tend to have a lower percentage than men, and older people have a lower percentage than younger people.

Approximately 60% of the total body water is intracellular and 40% extracellular (see Fig. 4.2). The extracellular water includes the fluid in plasma (blood after the cells have been removed) and interstitial water (the fluid in the tissue spaces, lying between cells). Transcellular water is a small, specialized portion of extracellular water that includes gastrointestinal secretions, urine, sweat, and fluid that has leaked through capillary walls because of such processes as increased hydrostatic pressure or inflammation.

B. Hydrogen Bonds in Water

The dipolar nature of the water (H_2O) molecule allows it to form hydrogen bonds, a property that is responsible for the role of water as a solvent. In H_2O , the oxygen atom has two unshared electrons that form an electron-dense cloud around it. This cloud lies above and below the plane formed by the water molecule (Fig. 4.3). In the covalent bond formed between the hydrogen and oxygen atoms, the shared electrons are attracted toward the oxygen atom, thus giving the oxygen atom a partial negative charge and the hydrogen atom a partial positive charge. As a result, the oxygen side of the molecule is much more electronegative than the hydrogen side, and the molecule is dipolar.

FIGURE 4.3 Hydrogen bonds between water molecules. The oxygen atoms are shown in black.

M **Blood-gas** analyzers are used to measure pO_2 and pCO_2 . The basic mechanism whereby these analyzers work is through the use of specific gas-permeable membranes. For oxygen, a Clark electrode is used; oxygen diffuses through a membrane specific for oxygen permeability, and once oxygen passes through the membrane it diffuses to the cathode. When oxygen reaches the cathode, electrons are attracted from the anode, thereby reducing the oxygen to water. Because it requires four electrons to reduce molecular oxygen (forming two molecules of water), measurement of the current flow can quantitate the amount of oxygen that has reached the cathode. pCO_2 is determined using a Severinghaus electrode, which consists of an outer gas-permeable membrane, specific for CO_2 , and a bicarbonate buffer within the electrode. Once the CO_2 crosses the membrane, the gas interacts with bicarbonate, altering the equilibrium among CO_2 , carbonic acid, and bicarbonate. This alters the pH in direct proportion to the amount of CO_2 gas that has entered the electrode, and the change in pH can be used to calculate the pCO_2 . Improved manufacturing techniques have allowed microelectrodes, and tiny circuit boards, to be used in these machines, thereby greatly increasing their portability.

Both the hydrogen and oxygen atoms of the water molecule form hydrogen bonds and participate in hydration shells. A hydrogen bond is a weak noncovalent interaction between the hydrogen of one molecule

and the more electronegative atom of an acceptor molecule. The oxygen of water can form hydrogen bonds with two other water molecules so that each water molecule is hydrogen-bonded to approximately four close neighboring water molecules in a fluid three-dimensional lattice (see Fig. 4.3).

1. Water as a Solvent

Polar organic molecules and inorganic salts can readily dissolve in water because water also forms hydrogen bonds and electrostatic interactions with these molecules. Organic molecules containing a high proportion of electronegative atoms (generally oxygen or nitrogen) are soluble in water because these atoms participate in hydrogen bonding with water molecules (Fig. 4.4A). Chloride (Cl^-), bicarbonate (HCO_3^-), and other anions are surrounded by a hydration shell of water molecules arranged with their hydrogen atoms closest to the anion. Similarly, the oxygen atom of water molecules interacts with inorganic cations such as Na^+ and K^+ to surround them with a hydration shell (see Fig. 4.4B).

where water is

FIGURE 4.4 **A.** Hydrogen bonds between water and polar molecules. *R* denotes additional atoms. **B.** Hydration shells surrounding anions and cations.

Although hydrogen bonds are strong enough to dissolve polar molecules in water and to separate charges, they are weak enough to allow the movement of water and solutes. The strength of the hydrogen bond between two water molecules is only approximately 4 kcal, roughly 1/20th of the strength of the covalent O–H bond in the water molecule. Thus, the extensive water lattice is dynamic and has many strained bonds that are continuously breaking and re-forming. The average hydrogen bond between water molecules lasts only about 10 picoseconds (1 picosecond is 10^{-12} seconds), and each water molecule in the hydration shell of an ion stays only 2.4 nanoseconds (1 nanosecond = 10^{-9} seconds). As a result, hydrogen bonds between water molecules and polar solutes continuously dissociate and re-form, thereby permitting solutes to move through water and water to pass through channels in cellular membranes.

2. Water and Thermal Regulation

The structure of water also allows it to resist temperature change. Its heat of fusion is high, so a large drop in temperature is needed to convert liquid water to the solid state of ice. The thermal conductivity of water is also high, thereby facilitating heat dissipation from high energy utilizing areas such as the brain into the blood and the total body water pool. Its heat capacity and heat of vaporization are remarkably high; as liquid water is converted to a gas and evaporates from the skin, we feel a cooling effect. Water responds to the input of heat by decreasing the extent of hydrogen bonding and to cooling by increasing the bonding between water molecules.

C. Electrolytes

Both extracellular fluid (ECF) and intracellular fluid (ICF) contain electrolytes, a general term applied to bicarbonate and inorganic anions and cations. The electrolytes are unevenly distributed between compartments; Na^+ and Cl^- are the major electrolytes in the ECF (plasma and interstitial fluid), and K^+ and phosphates such as HPO_4^{2-} are the major electrolytes in cells (Table 4.1). This distribution is maintained principally by energy-requiring transporters that pump Na^+ out of cells in exchange for K^+ (see Chapter 10).

	ECF ^a (MMOL/L)	ICF (MMOL/L)
Cations		
Na^+	145	12
K^+	4	150
Anions		
Cl^-	105	5
HCO_3^-	25	12
Inorganic phosphate	2	100

ECF, extracellular fluid; ICF, intracellular fluid.

^aThe content of inorganic ions is very similar in plasma and interstitial fluid, the two components of the extracellular fluid.

In the emergency department, **Dianne A.** was rehydrated with intravenous saline, which is a solution of 0.9% NaCl. Why was saline used instead of water?

0.9% NaCl is 0.9 g NaCl/100 mL, equivalent to 9 g/L. NaCl has a molecular weight of 58 g/mol, so the concentration of NaCl in isotonic saline is 0.155 M or 155 mM. If all of the NaCl were dissociated into Na^+ and Cl^- ions, the osmolality would be 310 mOsm/kg water. Because NaCl is not completely dissociated and some of the hydration shells surround undissociated NaCl molecules, the osmolality of isotonic saline is approximately 290 mOsm/kg H_2O . The osmolality of plasma, interstitial fluids, and ICF is also approximately 290 mOsm/kg water, so no large shifts of water or swelling occur when isotonic saline is given intravenously. In some cases, glucose is added to this at a 5% concentration (5 g/100 mL). The glucose provides fuel for the individual. If this is done, the saline solution has the designation of D5, for 5% dextrose.

D. Osmolality and Water Movement

Water distributes between the different fluid compartments according to the concentration of solutes, or osmolality, of each compartment. The osmolality of a fluid is proportional to the total concentration of all dissolved molecules, including ions, organic metabolites, and proteins, and is usually expressed as milliosmoles (mOsm)/kg water. The semipermeable cellular membrane that separates the extracellular and intracellular compartments contains a number of ion channels through which water can move freely but other molecules cannot. Likewise, water can move freely through the capillaries separating the interstitial fluid and the plasma. As a result, water will move from a compartment with a low concentration of solutes (lower osmolality) to one with a higher concentration to achieve an equal osmolality on both sides of the membrane. The force it would take to keep the same amount of water on both sides of the membrane is called the osmotic pressure.

As water is lost from one fluid compartment, it is replaced with water from another compartment to maintain a nearly constant osmolality. The blood contains a high content of dissolved negatively charged proteins and the electrolytes needed to balance these charges. As water is passed from the blood into the urine to balance the excretion of ions, the blood volume is replenished with water from interstitial fluid. When the osmolality of the blood and interstitial fluid is too high, water moves out of the cells. The loss of cellular water also can occur in hyperglycemia because the high concentration of glucose increases the osmolality of the blood.

II. Acids and Bases

Acids are compounds that donate a hydrogen ion (H^+) to a solution, and bases are compounds (such as the OH^- ion) that accept hydrogen ions. Water itself dissociates to a slight extent, generating hydrogen ions (H^+), which are also called protons, and hydroxide ions (OH^-) (Fig. 4.5). The hydrogen ions are extensively hydrated in water to form species such as H_3O^+ , but nevertheless are usually represented as simply H^+ . Water itself is neutral, neither acidic nor basic.

FIGURE 4.5 Dissociation of water.

A. The pH of Water

The extent of dissociation by water molecules into H^+ and OH^- is very slight, and the hydrogen ion concentration of pure water is only 0.0000001 M or 10^{-7} mol/L. The concentration of hydrogen ions in a solution is usually denoted by the term pH, which is the negative \log_{10} of the hydrogen ion concentration expressed in moles per liter (mol/L) (Equation 4.1). Therefore, the pH of pure water is 7.

Equation 4.1. Definition of pH

$$pH = -\log[H^+]$$

The dissociation constant for water, K_d , expresses the relationship between the hydrogen ion concentration $[H^+]$, the hydroxide ion concentration $[OH^-]$, and the concentration of water $[H_2O]$ at equilibrium (Equation 4.2). Because water dissociates to such a small extent, $[H_2O]$ is essentially constant at 55.5 M. Multiplication of the K_d for water (approximately 1.8×10^{-16} M) by 55.5 M gives a value of approximately 10^{-14} (mol/L)², which is called the ion product of water (K_w) (Equation 4.3). Because K_w , the product of $[H^+]$ and $[OH^-]$, is always constant, a decrease of $[H^+]$ must be accompanied by a proportionate increase of $[OH^-]$.

Equation 4.2. Dissociation constant of water

$$K_d = \frac{[H^+][OH^-]}{[H_2O]}$$

Equation 4.3. Ion product of water

$$K_w = [H^+][OH^-] = 1 \times 10^{-14}$$

A pH of 7 is termed neutral because $[H^+]$ and $[OH^-]$ are equal. Acidic solutions have a greater hydrogen ion concentration and a lower hydroxide ion concentration than pure water (pH < 7.0), and basic solutions have a lower hydrogen ion concentration and a greater hydroxide ion concentration (pH > 7.0).

B. Strong and Weak Acids

During metabolism, the body produces a number of acids that increase the hydrogen ion concentration of the blood or other body fluids and tend to lower the pH (Table 4.2). These metabolically important acids can be classified as weak acids or strong acids by their degree of dissociation into a hydrogen ion and a base (the anion component). Inorganic acids such as sulfuric acid (H_2SO_4) and hydrochloric acid (HCl) are strong acids that dissociate completely in solution (Fig. 4.6). Organic acids containing carboxylic acid groups (e.g., the ketone bodies acetoacetic acid and β -hydroxybutyric acid) are weak acids that dissociate to only a limited extent in water. In general, a weak acid (HA), called the conjugate acid, dissociates into a hydrogen ion and an anionic component (A^-), called the conjugate base. The name of an undissociated acid usually ends in “ic acid” (e.g., acetoacetic acid), and the name of the dissociated anionic component ends in “ate” (e.g., acetoacetate).

TABLE 4.2 Acids in the Blood of a Healthy Individual			
ACID	ANION	pK _a	MAJOR SOURCES
Strong acid			
Sulfuric acid (H_2SO_4)	Sulfate (SO_4^{2-})	Completely dissociated	Dietary sulfate and S-containing amino acids
Weak acid			
Carbonic acid (R-COOH)	Bicarbonate (R-COO ⁻)	3.80	CO ₂ from TCA cycle
Lactic acid (R-COOH)	Lactate (R-COO ⁻)	3.73	Anaerobic glycolysis
Pyruvic acid (R-COOH)	Pyruvate (R-COO ⁻)	2.39	Glycolysis
Citric acid (R-3COOH)	Citrate (R-3COO ⁻)	3.13; 4.76; 6.40	TCA cycle and diet (e.g., citrus fruits)
Acetoacetic acid (R-COOH)	Acetoacetate (R-COO ⁻)	3.62	Fatty acid oxidation to ketone bodies
β -Hydroxybutyric acid (R-COOH)	β -Hydroxybutyrate (R-COO ⁻)	4.41	Fatty acid oxidation to ketone bodies
Acetic acid (R-COOH)	Acetate (R-COO ⁻)	4.76	Ethanol metabolism
Dihydrogen phosphate ($H_2PO_4^-$)	Monohydrogen phosphate (HPO_4^{2-})	7.2	Dietary organic phosphates
Ammonium ion (NH_4^+)	Ammonia (NH_3)	9.25	Dietary nitrogen-containing compounds

pK_a, the pH at which 50% dissociation occurs; TCA, tricarboxylic acid.

FIGURE 4.6 Dissociation of acids. Sulfuric acid is a strong acid that dissociates into H^+ ions and sulfate. The ketone bodies acetoacetic acid and β -hydroxybutyric acid are weak acids that partially dissociate into H^+ and their conjugate bases.

 **Dianne A.** has an osmotic diuresis. Because her blood levels of glucose and ketone bodies are so high, these compounds are passing from the blood into the glomerular filtrate in the kidneys and then into the urine. As a consequence of the high osmolality of the glomerular filtrate, much more water is being excreted in the urine than usual. Thus, she has polyuria (increased urine volume). As a result of water lost from the blood into the urine, water passes from inside cells into the interstitial space and the blood, resulting in intracellular dehydration. The dehydrated cells in the brain are unable to carry out their normal functions. As a result, she is in a coma.

The tendency of the acid (HA) to dissociate and donate a hydrogen ion to a solution is denoted by its K_a , the equilibrium constant for dissociation of a weak acid (Equation 4.4). The higher the K_a , the greater is the tendency to dissociate a proton.

Equation 4.4. The K_a of an acid

For the reaction

$$K_a = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]}$$

In the Henderson–Hasselbalch equation, the formula for the dissociation constant of a weak acid is converted to a convenient logarithmic equation (Equation 4.5). The term $\text{p}K_a$ represents the negative log of K_a .

If the pK_a for a weak acid is known, this equation can be used to calculate the ratio of the unprotonated to the protonated form at any pH. From this equation, you can see that a weak acid is 50% dissociated at a pH equal to its pK_a .

 **Dennis V.** has ingested an unknown number of acetylsalicylic acid (aspirin) tablets. Acetylsalicylic acid is rapidly converted to salicylic acid in the body. The initial effect of aspirin is to produce a respiratory alkalosis caused by stimulation of the “metabolic” central respiratory control center in the medulla. This increases the rate of breathing and the expiration of CO_2 . This is followed by a complex metabolic acidosis caused partly by the dissociation of salicylic acid (salicylic acid \leftrightarrow salicylate $^-$ + H^+ , $pK_a = \sim 3.5$).

Acetylsalicylate

Salicylate also interferes with mitochondrial ATP production (acting as an uncoupler, see Chapter 24), resulting in increased generation of CO_2 and accumulation of lactate (owing to stimulation of glycolysis, see Chapter 22) and other organic acids in the blood. Subsequently, salicylate may impair renal function, resulting in the accumulation of strong acids of metabolic origin, such as sulfuric acid and phosphoric acid. Usually, children who ingest toxic amounts of aspirin are acidotic by the time they arrive in the emergency department.

Equation 4.5. The Henderson–Hasselbalch equation

For the weak acid HA,

$$pH = pK_a + \log \frac{[A^-]}{[HA]}$$

Most of the metabolic carboxylic acids have a pK_a between 2 and 5, depending on the other groups on the molecule (see Table 4.2). The pK_a reflects the strength of an acid. Acids with a pK_a of 2 are stronger acids than those with a pK_a of 5 because, at any pH, a greater proportion is dissociated.

 The laboratory reported that **Dianne A.**'s blood pH was 7.08 (reference range = 7.37 to 7.43). What was the $[H^+]$ in her blood compared with the concentration at a normal pH of 7.4?

III. Buffers

Buffers consist of a weak acid and its conjugate base. Buffers allow a solution to resist changes in pH when hydrogen ions or hydroxide ions are added. In Figure 4.7, the pH of a solution of the weak acid acetic acid is graphed as a function of the amount of OH^- that has been added. The OH^- is expressed as equivalents of total acetic acid present in the dissociated and undissociated forms. At the midpoint of this curve, 0.5 equivalents of OH^- have been added and half of the conjugate acid has dissociated, so $[A^-]$ equals $[HA]$. This midpoint is

expressed in the Henderson–Hasselbalch equation as the pK_a , defined as the pH at which 50% dissociation occurs. As you add more OH^- ions and move to the right on the curve, more of the conjugate acid molecules (HA) dissociate to generate H^+ ions, which combine with the added OH^- ions to form water. Consequently, only a small increase in pH results. If you add hydrogen ions to the buffer at its pK_a (moving to the left of the midpoint in Fig. 4.7), conjugate base molecules (A^-) combine with the added hydrogen ions to form HA, and there is almost no fall in pH.

FIGURE 4.7 Titration curve for acetic acid. HA, weak acid; pK_a , the pH at which 50% dissociation occurs.

As can be seen from Figure 4.7, a buffer can only compensate for an influx or removal of hydrogen ions within approximately 1 pH unit of its pK_a . When the pH of a buffered solution changes from the pK_a to one pH unit below the pK_a , the ratio of $[A^-]$ to HA changes from 1:1 to 1:10. If more hydrogen ions were added, the pH would fall rapidly because relatively little conjugate base remains. Likewise, at 1 pH unit above the pK_a of a buffer, relatively little undissociated acid remains. More concentrated buffers are more effective simply because they contain a greater total number of buffer molecules per unit volume that can dissociate or recombine with hydrogen ions.

IV. Metabolic Acids and Buffers

An average rate of metabolic activity produces roughly 22,000 milliequivalents (mEq) of acid per day. If all of this acid were dissolved at one time in unbuffered body fluids, their pH would be <1 . However, the pH of the blood is normally maintained between 7.36 and 7.44, and intracellular pH at approximately 7.1 (between 6.9 and 7.4). The widest range of extracellular pH over which the metabolic functions of the liver, the beating of the heart, and conduction of neural impulses can be maintained is 6.8 to 7.8. Thus, until the acid produced from metabolism can be excreted as CO_2 in expired air and as ions in the urine, it needs to be buffered in the body fluids. The major buffer systems in the body are the bicarbonate–carbonic acid buffer system, which operates principally in ECF; the hemoglobin (Hb) buffer system in red blood cells; the phosphate buffer system in all types of cells; and the protein buffer system of cells and plasma.

A. The Bicarbonate Buffer System

The major source of metabolic acid in the body is the gas CO_2 , produced principally from fuel oxidation in the tricarboxylic acid (TCA) cycle. Under normal metabolic conditions, the body generates more than 13 mol of CO_2 per day (approximately 0.5 to 1 kg). CO_2 dissolves in water and reacts with water to produce carbonic acid, H_2CO_3 , a reaction that is accelerated by the enzyme carbonic anhydrase (Fig. 4.8). Carbonic acid is a weak acid that partially dissociates into H^+ and bicarbonate anion, HCO_3^- .

FIGURE 4.8 The bicarbonate buffer system. $\text{CO}_2(\text{d})$ refers to carbon dioxide dissolved in water and not in the gaseous state.

 The partial pressure of CO_2 (PaCO_2) in **Dianne A.**'s arterial blood was 28 mm Hg (reference range 37 to 43 mm Hg), and her serum bicarbonate level was 8 mEq/L (reference range 24 to 28 mEq/L). Elevated levels of ketone bodies had produced ketoacidosis, and she was exhaling increased amounts of CO_2 by breathing deeply and frequently (Kussmaul breathing) to compensate. Why does this occur? Ketone bodies are weak acids that partially dissociate, increasing H^+ levels in the blood and the interstitial fluid surrounding the "metabolic" respiratory center in the hypothalamus that controls the rate of breathing. A drop in pH elicits an increase in the rate of breathing. Bicarbonate combines with protons, forming H_2CO_3 , thereby lowering bicarbonate levels. The H_2CO_3 is converted to CO_2 and H_2O , which increase the CO_2 concentration, which is exhaled. The increase in CO_2 concentration leads to an increase in the respiratory rate, causing a fall in the partial pressure of arterial CO_2 (PaCO_2). As shown by **Dianne A.**'s low arterial blood pH of 7.08, Kussmaul breathing was unable to fully compensate for the high rate of acidic ketone body production.

Carbonic acid is both the major acid produced by the body and its own buffer. The pK_a of carbonic acid itself is only 3.8, so at the blood pH of 7.4, it is almost completely dissociated and theoretically unable to buffer and generate bicarbonate. However, carbonic acid can be replenished from CO_2 in body fluids and air because the concentration of dissolved CO_2 in body fluids is approximately 400 times greater than that of carbonic acid. As the base is added and H^+ is removed, H_2CO_3 dissociates into hydrogen and bicarbonate ions, and dissolved CO_2 reacts with H_2O to replenish the H_2CO_3 (see Fig. 4.8). Dissolved CO_2 is in equilibrium with the CO_2 in air in the alveoli of the lungs, and thus the availability of CO_2 can be increased or decreased by an adjustment in the rate of breathing and the amount of CO_2 expired. The pK_a for the bicarbonate buffer system in the body thus

combines K_h (the hydration constant for the reaction of water and CO_2 to form H_2CO_3) with the chemical $\text{p}K_a$ to obtain a modified version of the Henderson–Hasselbalch equation (Equation 4.6). To use the terms for blood components measured in the emergency department, the dissolved CO_2 is expressed as a fraction of the partial pressure of CO_2 in arterial blood, Paco_2 . The $\text{p}K_a$ for dissociation of bicarbonate anion (HCO_3^-) into H^+ and carbonate (CO_3^{2+}) is 9.8; therefore, only trace amounts of carbonate exist in body fluids.

Equation 4.6. The Henderson–Hasselbalch equation for the bicarbonate buffer system

$$\text{pH} = \text{p}K_a + \log \frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]}$$

The $\text{p}K_a = 3.5$, so

$$\text{pH} = 3.5 + \log \frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]}$$

$[\text{H}_2\text{CO}_3]$ is best estimated as $[\text{CO}_2]_d/400$, where $[\text{CO}_2]_d$ is the concentration of dissolved CO_2 , so substituting this value for $[\text{H}_2\text{CO}_3]$ we get

$$\text{pH} = 3.5 + \log 400 + \log \frac{[\text{HCO}_3^-]}{[\text{CO}_2]_d}$$

 From inspection, you can tell that her $[\text{H}^+]$ is greater than normal, but <10 times higher. A 10-fold change in $[\text{H}^+]$ changes the pH by 1 unit. For **Dianne A.**, the pH of 7.08 = $-\log[\text{H}^+]$, and therefore her $[\text{H}^+]$ is $1 \times 10^{-7.08}$. To calculate her $[\text{H}^+]$, express -7.08 as $-8 + 0.92$. The antilog to the base 10 of 0.92 is 8.3. Thus, her $[\text{H}^+]$ is 8.3×10^{-8} compared to 4.0×10^{-8} at pH 7.4, or slightly more than double the normal value.

or

$$\text{pH} = 6.1 + \log \frac{[\text{HCO}_3^-]}{[\text{CO}_2]_d}$$

Because only 3% of the gaseous CO_2 is dissolved, $[\text{CO}_2]_d = 0.03 \text{ Paco}_2$, so

$$\text{pH} = 6.1 + \log \frac{[\text{HCO}_3^-]}{0.03 \text{ Paco}_2}$$

The HCO_3^- is expressed as milliequivalents per milliliter (mEq/mL) and Paco_2 as millimeters of mercury (mm Hg).

B. Bicarbonate and Hemoglobin in Red Blood Cells

The bicarbonate buffer system and Hb in red blood cells cooperate in buffering the blood and transporting CO_2 to the lungs. Most of the CO_2 produced from tissue metabolism in the TCA cycle diffuses into the interstitial fluid and the blood plasma and then into red blood cells (Fig. 4.9, circle 1). Although no carbonic anhydrase can be found in blood plasma or interstitial fluid, the red blood cells contain high amounts of this enzyme, and CO_2 is rapidly converted to carbonic acid (H_2CO_3) within these cells (Fig. 4.9, circle 2). As the carbonic acid dissociates (Fig. 4.9, circle 3), the H^+ released is also buffered by combination with Hb (Fig. 4.9, circle 4). The

side chain of the amino acid histidine in Hb has a pK_a of 6.7 and is thus able to accept a proton. The bicarbonate anion is transported out of the red blood cells into the blood in exchange for chloride anions, and thus bicarbonate is relatively high in the plasma (Fig. 4.9, circle 5) (see Table 4.1).

FIGURE 4.9 Buffering systems of the body. CO_2 produced from cellular metabolism is converted to bicarbonate and H^+ in the red blood cells. Within the red blood cells, the H^+ is buffered by hemoglobin (Hb) and phosphate (HPO_4^{2-}) (circles 4 and 6). The bicarbonate is transported into the blood to buffer H^+ generated by the production of other metabolic acids, like the ketone body acetoacetic acid (circle 5). Other proteins (Pr) also serve as intracellular buffers. Numbers refer to the text discussion. TCA, tricarboxylic acid.

As the red blood cells approach the lungs, the direction of the equilibrium reverses. CO_2 is released from the red blood cells, causing more carbonic acid to dissociate into CO_2 and water and more hydrogen ions to combine with bicarbonate. Hb loses some of its hydrogen ions, a feature that allows it to bind oxygen more readily (see Chapter 7). Thus, the bicarbonate buffer system is intimately linked to the delivery of oxygen to tissues.

Bicarbonate and carbonic acid, which diffuse through the capillary wall from the blood into the interstitial fluid, provide a major buffer for both plasma and interstitial fluid. However, blood differs from interstitial fluid in that the blood contains a high content of extracellular proteins, such as albumin, which contribute to its buffering capacity through amino acid side chains that are able to accept and release protons. The protein content of interstitial fluid is too low to serve as an effective buffer.

 Both **Dianne A.** and **Percy V.** were hyperventilating when they arrived at the emergency department: **Dianne A.** in response to her primary metabolic acidosis and **Percy V.** in response to anxiety. Hyperventilation raised blood pH in both cases: In **Dianne A.**'s case it partially countered the acidosis, and in **Percy V.**'s case it produced a respiratory alkalosis (abnormally high arterial blood pH).

C. Intracellular pH

Phosphate anions and proteins are the major buffers involved in maintaining a constant pH of ICFs. The inorganic phosphate anion H_2PO_4^- dissociates to generate H^+ and the conjugate base, HPO_4^{2-} with a pK_a of 7.2 (see Fig. 4.9, circle 6). Thus, phosphate anions play a major role as an intracellular buffer in the red blood cell and in other types of cells, where their concentration is much higher than in blood and interstitial fluid (see Table 4.1, ECF). Organic phosphate anions, such as glucose 6-phosphate and ATP, also act as buffers. ICF contains a high content of proteins that contain histidine and other amino acids that can accept protons, in a fashion similar to hemoglobin (see Fig. 4.9, circle 7).

The transport of hydrogen ions out of the cell is also important for the maintenance of a constant intracellular pH. Metabolism produces a number of other acids in addition to CO_2 . For example, the metabolic acids acetoacetic acid and β -hydroxybutyric acid are produced from fatty acid oxidation to ketone bodies in the liver, and lactic acid is produced by glycolysis in muscle and other tissues. The pK_a for most metabolic carboxylic acids is <5 , so these acids are completely dissociated at the pH of the blood and cellular fluid. Metabolic anions are transported out of the cell together with H^+ (see Fig. 4.9, circle 8). If the cell becomes too

acidic, more H^+ is transported out in exchange for Na^+ ions by a different transporter. If the cell becomes too alkaline, more bicarbonate is transported out in exchange for Cl^- ions.

D. Urinary Hydrogen, Ammonium, and Phosphate Ions

The nonvolatile acid that is produced from body metabolism cannot be excreted as expired CO_2 and is excreted in the urine. Most nonvolatile acid hydrogen ion is excreted as undissociated acid that generally buffers the urinary pH between 5.5 and 7.0. A pH of 5.0 is the minimum urinary pH. The acid secretion includes inorganic acids such as phosphate and ammonium ions, as well as uric acid, dicarboxylic acids, and TCAs such as citric acid (see Table 4.2). One of the major sources of nonvolatile acid in the body is H_2SO_4 . Sulfuric acid is generated from the sulfate-containing compounds ingested in foods and from the metabolism of the sulfur-containing amino acids, cysteine and methionine. It is a strong acid that is dissociated into H^+ and sulfate anion (SO_4^-) in the blood and urine (see Fig. 4.6). Urinary excretion of $H_2PO_4^-$ helps to remove the acid. To maintain metabolic homeostasis, we must excrete the same amount of phosphate in the urine that we ingest with food as phosphate anions or organic phosphates such as phospholipids. Whether the phosphate is present in the urine as $H_2PO_4^-$ or HPO_4^- depends on the urinary pH and the pH of the blood.

Ammonium ions are acids that dissociate to form the conjugate base, ammonia, and hydrogen ions. What is the form present in blood? In urine?

Ammonium ions are major contributors to buffering urinary pH but not blood pH. Ammonia (NH_3) is a base that combines with protons to produce ammonium (NH_4^+) ions ($NH_3 + H^+ \leftrightarrow NH_4^+$), a reaction that occurs with a pK_a of 9.25. Ammonia is produced from amino acid catabolism or absorbed through the intestine and is kept at very low concentrations in the blood because it is toxic to neural tissues. Cells in the kidney generate NH_4^+ and excrete it into the urine in proportion to the acidity (proton concentration) of the blood. As the renal tubular cells transport H^+ into the urine, they return bicarbonate anions to the blood.

E. Hydrochloric Acid

HCl, also called gastric acid, is secreted by parietal cells of the stomach into the stomach lumen, where the strong acidity denatures ingested proteins, so they can be degraded by digestive enzymes. When the stomach contents are released into the lumen of the small intestine, gastric acid is neutralized by bicarbonate secreted from pancreatic cells and by cells in the intestinal lining.

CLINICAL COMMENTS

Dianne A. has type 1 diabetes mellitus. Because the β -cells of her pancreas have a very limited ability to synthesize and secrete insulin, she maintains her insulin level by giving herself several subcutaneous (under the skin) injections of insulin every day. If her blood insulin levels fall too low, she remains in a condition similar to a fasting state although she ingests food (see Chapters 2 and 3). Free fatty acids leave her adipocytes (fat cells) and are converted by the liver to the ketone bodies acetoacetic acid and β -hydroxybutyric acid. These compounds are weak acids that dissociate to produce anions (acetoacetate and β -hydroxybutyrate, respectively) and hydrogen ions, thereby lowering her blood and cellular pH below the normal range. As these acids accumulate in the blood, a metabolic acidosis known as diabetic ketoacidosis (DKA) develops.

Diabetes mellitus is diagnosed by the concentration of plasma glucose (plasma is blood from which the red blood cells have been removed by centrifugation). Because plasma glucose normally increases after a meal, the normal reference ranges and the diagnostic level are defined relative to the time of consumption of food or to consumption of a specified amount of glucose during an oral glucose tolerance test. After an overnight fast, values for the fasting plasma glucose below 100 mg/dL are considered normal; a level above 126 mg/dL defines diabetes mellitus. Fasting plasma glucose values ≥ 100 and < 126 mg/dL define an intermediate condition termed impaired fasting glucose or prediabetes. Normal random plasma glucose levels (random is defined as any time of day without regard to the time since the last meal) should not be > 200 mg/dL. Normal subjects generally do not increase their blood sugar above 140 mg/dL, even after a meal. Thus, a 2-hour postprandial (after a meal or after an oral glucose load) plasma glucose level between 140 and 199 mg/dL defines a condition known as impaired

glucose tolerance, or prediabetes, where a level above 200 mg/dL defines overt diabetes mellitus. Diabetes mellitus is also diagnosed by measuring the hemoglobin A_{1C} (HbA_{1C}) values, which is a measure of glycosylated hemoglobin in the red blood cells. This is a nonenzymatic reaction that is dependent upon glucose concentration, so as the glucose concentration increases, the levels of HbA_{1C} increase. Normal levels of HbA_{1C} are 4% to 5.6% of total hemoglobin, and a value of $\geq 6.5\%$ HbA_{1C} defines diabetes mellitus, whereas values between 5.7% and 6.4% indicate an increased risk for diabetes.

Once DKA develops, until insulin is administered to reverse this trend, several compensatory mechanisms operate to minimize the extent of the acidosis. One of these mechanisms is a stimulation of the respiratory center in the hypothalamus induced by acidosis, which leads to deeper and more frequent respiration (Kussmaul breathing). CO₂ is expired more rapidly than normal, and the blood pH rises toward normal. The results of the laboratory studies performed on **Dianne A.** in the emergency department were consistent with a moderately severe DKA. Her arterial blood pH and serum bicarbonate were low, and ketone bodies were present in her blood and urine (normally, ketone bodies are not present in the urine). In addition, her serum glucose level was 648 mg/dL (reference range 70 to 110 mg/dL fasting and no higher than 200 mg/dL in a random glucose sample). Her hyperglycemia, which induces an osmotic diuresis, contributed to her dehydration and the hyperosmolality of her body fluids.

Treatment was initiated with intravenous saline solutions to replace fluids lost with osmotic diuresis and hyperventilation. The osmotic diuresis resulted from increased urinary water volume required to dilute the large amounts of glucose and ketone bodies excreted in the urine. Hyperventilation increased the water of respiration lost with expired air. A loading dose of regular insulin was given as an intravenous bolus followed by an insulin drip, giving her continuous insulin. The patient's metabolic response to the treatment was monitored closely.

Dennis V. remained alert in the emergency department. While awaiting the report of his initial serum salicylate level, his stomach was lavaged, and several white tablets were found in the stomach aspirate. He was examined repeatedly and showed none of the early symptoms of salicylate toxicity, such as respiratory stimulation, upper-abdominal distress, nausea, or headache.

His serum salicylate level was reported as 92 $\mu\text{g/mL}$ (usual level in an adult on a therapeutic dosage of 4 to 5 g/day is 120 to 350 $\mu\text{g/mL}$, and a level of 800 $\mu\text{g/mL}$ is considered potentially lethal). He was admitted for overnight observation and continued to do well. The serum salicylate level the following morning was 24 $\mu\text{g/mL}$. He was discharged later that day.

The pK_a for dissociation of ammonium ions is 9.25. Thus, the undissociated conjugate acid form, NH₄⁺, predominates at the physiologic pH of 7.4 and urinary pH of 5.5 to 7.0. Ammonia is an unusual conjugate base because it is not an anion.

Percy V. At the emergency department, **Percy V.** complained of light-headedness and “pins and needles” (paresthesias) in his hands and around his lips. These symptoms resulted from an increase in respiratory drive mediated in this case through the “behavioral” rather than the “metabolic” central respiratory control system (as seen in **Dianne A.** when she was in diabetic ketoacidosis). The behavioral system was activated in **Percy V.**'s case by his anxiety over his grandson's potential poisoning. His alveolar hyperventilation caused his PaCO₂ to decrease below the normal range of 37 to 43 mm Hg. The alkalemia caused his neurologic symptoms. After being reassured that his grandson would be fine, **Percy V.** was asked to breathe slowly into a small paper bag placed around his nose and mouth, allowing him to reinhale the CO₂ being exhaled through hyperventilation. Within 20 minutes, his symptoms disappeared.

BIOCHEMICAL COMMENTS

Body Water and Dehydration. Dehydration, or loss of water, occurs when salt and water intake are less than the combined rates of renal plus extrarenal volume loss (Fig. 4.10). In a true hypovolemic state, total body water, functional ECF volume, and ICF volume are decreased. One of the causes of hypovolemia is an intake of water that is inadequate to resupply the daily excretion volume (maintenance of fluid homeostasis). The amount of water lost by the kidneys is determined by the amount of water necessary to dilute the ions, acids, and other solutes excreted. Both urinary solute excretion and water loss in expired air, which amount to almost 400 mL/day, occur during fasting as well as during periods of normal food intake. Thus, people who are lost in the desert or shipwrecked continue to lose water in air and urine, in addition to

their water loss through the skin and sweat glands. Comatose patients and patients who are debilitated and unable to swallow also continue to lose water and become dehydrated. Anorexia (loss of appetite), such as **Percy V.** experienced during his depression (see Chapters 1 and 3), can result in dehydration because food intake is normally a source of fluid. Cerebral injuries that cause a loss of thirst response also can lead to dehydration.

Water gain

Water loss

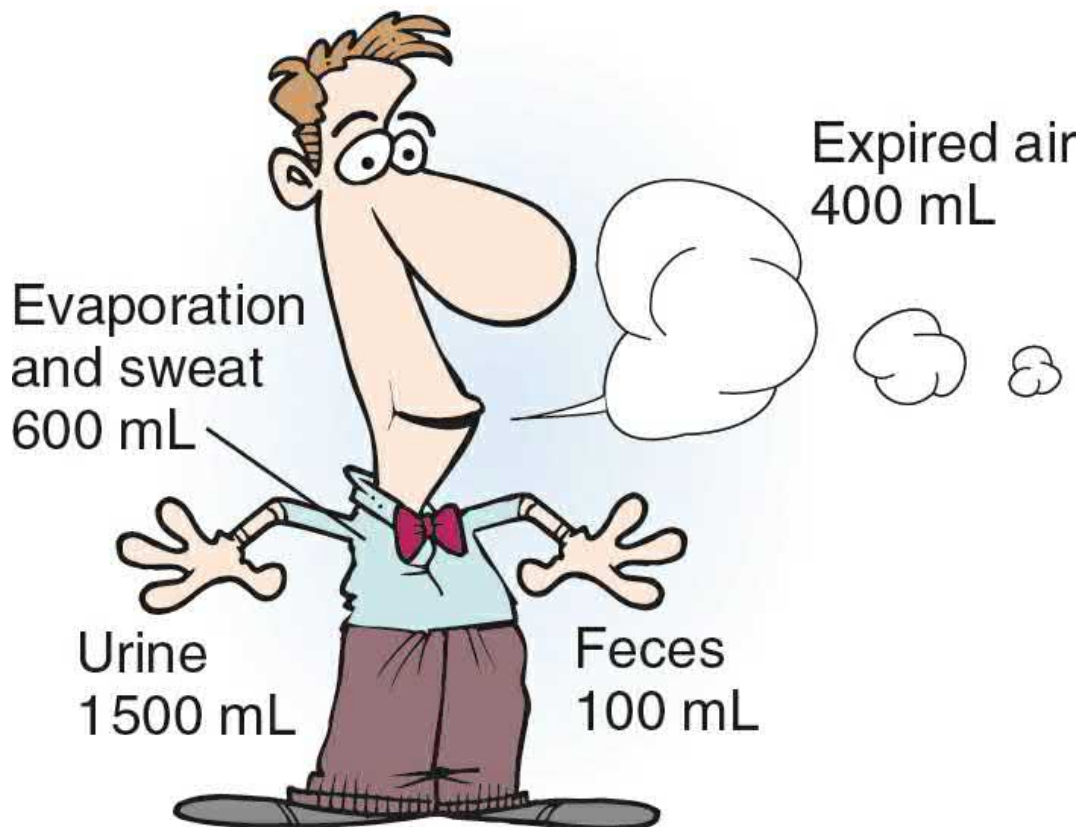

FIGURE 4.10 Body fluid homeostasis (constant body water balance). Intake is influenced by the availability of fluids and food, thirst, hunger, and the ability to swallow. The rates of breathing and evaporation and urinary volume influence water loss. The body adjusts the volume of urinary excretion to compensate for variations in other types of water loss and for variations in intake. The hormones aldosterone and antidiuretic hormone (ADH) help to monitor blood volume and osmolality through mechanisms that regulate thirst as well as sodium and water balance.

Dehydration also can occur secondary to excessive water loss through the kidneys, lungs, and skin. Excessive renal loss could be the result of impaired kidney function or impaired response to the hormones that regulate water balance (e.g., antidiuretic hormone [ADH] and aldosterone). However, in individuals such as **Dianne A.** who have normal kidney function, dehydration can occur as a response to water dilution of the high concentrations of ketone bodies, glucose, and other solutes excreted in the urine (osmotic diuresis). If the urinary water loss is associated with acidosis, hyperventilation occurs, increasing the amount of water lost in expired air. Water loss in expired air (pulmonary water loss) could occur also as a result of a tracheotomy or cerebral injury. An excessive loss of water and electrolytes through the skin can result from extensive burns.

Gastrointestinal water losses also can result in dehydration. We secrete approximately 8 to 10 L of fluid per day into our intestinal lumen. Normally, more than 90% of this fluid is reabsorbed in the intestines. The percentage reabsorbed can be decreased by vomiting, diarrhea, tube drainage of gastric contents, or loss of water into tissues around the gut via bowel fistulas.

Symptoms of mild to moderate dehydration may include increased thirst, dry mouth, drowsiness, decreased urine output of a more concentrated (yellow) urine, headache, dry skin, dizziness, and a reduced ability to generate tears. The symptoms can rapidly progress to severe dehydration that leads to no urine output, inability to walk or stand normally, orthostatic hypotension, rapid heart rate, fever, lethargy or confusion, shock, and even a coma.

KEY CONCEPTS

- ◆ Approximately 60% of our body weight is water.
- ◆ Water is distributed between intracellular and extracellular (interstitial fluids, blood, lymph) compartments.
- ◆ Because water is a dipolar molecule with an uneven distribution of electrons between the hydrogen and oxygen atoms, it forms hydrogen bonds with other polar molecules and acts as a solvent.
- ◆ Many of the compounds produced in the body and dissolved in water contain chemical groups that act as acids or bases, releasing or accepting hydrogen ions.
- ◆ The hydrogen ion content and the amount of body water are controlled to maintain homeostasis, a constant environment for our cells.
- ◆ The pH of a solution is the negative log of its hydrogen ion concentration.
- ◆ Acids release hydrogen ions; bases accept hydrogen ions.
- ◆ Strong acids dissociate completely in water, whereas only a small percentage of the total molecules of a weak acid dissociate.
- ◆ The acid dissociation constant of a weak acid is designated as K_a .
- ◆ The Henderson–Hasselbalch equation defines the relationship between the pH of a solution, the K_a of the acid, and the extent of acid dissociation.
- ◆ A buffer, a mixture of undissociated acid and its conjugate base, resists changes in pH when either H^+ or OH^- is added.
- ◆ Buffers work best within a range of 1 pH unit either above or below the pK_a of the buffer, where the pK_a is the negative log of the K_a .
- ◆ Normal metabolism generates metabolic acids (lactate, ketone bodies), inorganic acids (sulfuric acid, hydrochloric acid), and carbon dioxide.
- ◆ Carbon dioxide reacts with water to form carbonic acid, which will dissociate to form bicarbonate and a proton.
- ◆ Physiologic buffers include bicarbonate, phosphate, and the protein hemoglobin.
- ◆ Diseases discussed in this chapter are described in Table 4.3.

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
Type 1 diabetes	Genetic and environmental	Lack of insulin production leads to type 1 diabetes. Consequences of untreated type 1 diabetes include polydipsia (increased thirst), polyuria (increased urination), and ketoacidosis (elevated levels of ketone bodies in the blood).
Salicylate overdose	Environmental	Complex effects on respiratory center and basic metabolism, causing alterations in acid/base management, among other effects. Leads to impaired renal function.
Hyperventilation	Environmental	Complex effects on respiratory center and acid/base management. Leads to respiratory alkalosis.

REVIEW QUESTIONS—CHAPTER 4

- A patient attempted suicide by ingesting 50 aspirin tablets. This led to a fairly severe metabolic acidosis. A decrease of blood pH from 7.5 to 6.5 would be accompanied by which one of the following changes in ion concentration?
 - A 10-fold increase in hydrogen ion concentration
 - A 10-fold increase in hydroxyl ion concentration
 - An increase in hydrogen ion concentration by a factor of 7.5/6.5
 - A decrease in hydrogen ion concentration by a factor of 6.5/7.5
 - A shift in the concentration of buffer anions, with no change in hydrogen ion concentration
- A medical student is attempting to understand the buffering system of the human body and has set up the following experiment in the laboratory to help with their understanding. Consider a biochemical reaction that is taking place in a 0.1 M buffer. The initial pH is 7.4, and the pK_a of the buffer is 7.2. If, in a final reaction volume of 1.0 mL, 10 μ moles of protons are generated, what would be the final pH of the solution?
 - 7.59
 - 7.25
 - 7.22
 - 7.20
 - 7.15
- A patient with an enteropathy (intestinal disease) produced large amounts of ammonia (NH_3) from bacterial overgrowth in the intestine. The ammonia was absorbed through the intestine into the portal vein and entered the circulation. Which of the following is a likely consequence of his ammonia absorption?
 - A decrease of blood pH
 - Conversion of ammonia to ammonium ion in the blood
 - A decreased concentration of bicarbonate in the blood
 - Kussmaul respiration
 - Increased expiration of CO_2
- Which of the following physiologic/pathologic conditions is most likely to result in an alkalosis, provided the body couldn't fully compensate?
 - Production of lactic acid by muscles during exercise
 - Production of ketone bodies by a patient with diabetes mellitus
 - Repeated vomiting of stomach contents, including HCl
 - Diarrhea with loss of the bicarbonate anions secreted into the intestine
 - An infection resulting in a fever and hypercatabolism
- Laboratory tests on the urine of a patient identified the presence of methylmalonate ($^-OOC-CH(CH_3)-COO^-$). Methylmalonate is best described as which one of the following?
 - A strong acid.
 - The conjugate base of a weak acid.
 - It is 100% dissociated at its pK_a .

- D. It is 50% dissociated at the pH of the blood.
E. It is a major intracellular buffer.
6. A patient with influenza has a fever of 101.8°F orally. The excess heat is dissipated throughout the body via a substance that can be best described by which one of the following?
A. It is a dipolar molecule.
B. It is composed mostly of amino acids.
C. It is a weak acid.
D. It is a weak base.
E. It is composed mostly of carbohydrates.
7. A patient with hypertension is being treated with hydrochlorothiazide, a diuretic medication that can cause some dehydration and major intracellular electrolyte imbalances. Which one of the following electrolytes might be in imbalance under these conditions?
A. Na^+
B. K^+
C. Cl^-
D. HCO_3^-
E. H_2O
8. A patient with panic attacks and hyperventilation is in respiratory alkalosis. The excess hydroxide ions were able to overcome which one of the following buffers that has the greatest buffering capacity in and near to normal blood pH?
A. Carbonic acid
B. Dihydrogen phosphate
C. Ammonium ion
D. Acetoacetic acid
E. Acetic acid
9. A patient is in early diabetic ketoacidosis. Which one of the following would this patient be expected to exhibit upon examination?
A. Excess fluid in the tissues of the lower extremity
B. Increased respiratory rate
C. Low blood glucose
D. Decreased respiratory rate
E. Decreased urine output as an attempt to preserve water
10. A patient with severe anemia (reduced number of red blood cells in circulation) has a decreased capacity to utilize the bicarbonate buffer system to help maintain blood pH in the normal range. Which one of the following statements best describes the reason for this decreased capacity?
A. The total amount of carbonic anhydrase in blood plasma is decreased in anemia.
B. The total amount of carbonic anhydrase in blood plasma is increased in anemia.
C. The total amount of carbonic anhydrase in red blood cells is decreased in anemia.
D. The total amount of carbonic anhydrase in red blood cells is increased in anemia.
E. The total amount of carbonic anhydrase in interstitial fluid is decreased.
F. The total amount of carbonic anhydrase in interstitial fluid is increased.
1. Water is the solvent of life, yet it only dissociates to a small extent. What is the pK_a of water?
A. 0.5
B. 3.5
C. 7.0
D. 10.7
E. 15.7
2. The amino acid glycine has been used as a buffer for a number of biochemical experiments. Glycine contains two ionizable groups, one with a pK_a of 2.34, and the other with a pK_a of 9.60. Glycine would be an effective buffer at which one of the following pH values?
A. 4.0
B. 6.0
C. 8.0
D. 9.0
E. 11.0

3. Consider a buffer that has a free amino group ($X-NH_2$) with a pK_a of 8.5. If the buffer is present at a 0.1 M concentration what percentage of the buffer is in the acid form at pH 8.0?
 - A. 25
 - B. 50
 - C. 60
 - D. 75
 - E. 90
4. The major source of metabolic acid in the body is carbon dioxide owing to its ability to be enzymatically converted to which one of the following?
 - A. Hydrochloric acid
 - B. Sulfuric acid
 - C. Acetoacetic acid
 - D. Carbonic acid
 - E. Butyric acid
5. Histidine is an amino acid with three ionizable groups, one of which has a pK_a of 6.0. This group, when protonated, has a positive charge. If this ionizable group, within a protein, forms an ionic interaction with a negatively charged group, what would you predict would happen to the pK_a of the histidine ionizable group?
 - A. Increase
 - B. Decrease
 - C. Stay the same

ANSWERS TO REVIEW QUESTIONS

1. **The answer is A.** The pH is the negative log of the hydrogen ion concentration, $[H^+]$. Thus, at a pH of 7.5, $[H^+]$ is $10^{-7.5}$; at pH 6.5 it is $10^{-6.5}$. The $[H^+]$ has changed by a factor of $10^{-6.5}/10^{-7.5}$, which is 10^1 or 10. Any decrease of 1 pH unit is a 10-fold increase of $[H^+]$ or a 10-fold decrease of $[OH^-]$. A shift in the concentration of buffer anions has definitely occurred, but the change in pH reflects the increase in hydrogen ion concentration in excess of that absorbed by buffers. A drop of 1 pH unit in metabolic acidosis is a very severe condition.
2. **The answer is C.** In order to solve this problem one first needs to calculate the concentration of the conjugate base and acid of the buffer at pH 7.4. Using the Henderson–Hasselbalch equation, one can calculate that the concentration of the conjugate base is 0.061 M and that of the acid is 0.039 M. At this point the reaction occurs, generating 0.01 M protons (10 μ moles/mL is a concentration of 10 mM or 0.01 M). As the protons are generated, they will combine with the conjugate base, producing the acid. This will change the concentration of the conjugate base to 0.051 M and the concentration of the acid to 0.049 M. Plugging those values into the Henderson–Hasselbalch equation leads to a pH value of 7.22. Recall, if the concentration of the conjugate base equaled the concentration of the acid, the pH would be the pK value (in this case 7.2). Because protons are being generated the pH will drop, not rise, so answer (A) cannot be correct.
3. **The answer is B.** NH_3 is a weak base, which associates with a proton to produce the ammonium ion ($NH_3 + H^+ \rightarrow NH_4^+$), which has a pK_a of 9.5. Thus, at pH 7.4, most of the ammonia will be present as ammonium ions. The absorption of hydrogen ions will tend to increase, not decrease, the pH of the blood (thus, A is incorrect). With the decrease of hydrogen ions, carbonic acid will dissociate to produce more bicarbonate ($H_2CO_3 \rightarrow HCO_3^- + H^+$) and more CO_2 will go toward carbonic acid (thus, C is incorrect). Kussmaul respiration, an increased expiration of CO_2 , occurs under an acidosis, the opposite condition.
4. **The answer is C.** Vomiting expels the strong acid HCl (gastric acid). As cells in the stomach secrete more HCl, they draw on H^+ ions in interstitial fluid and blood, thereby tending to increase blood pH and cause alkalosis. The other conditions tend to produce acidosis (thus, A, B, D, and E are incorrect). Lactic acid is a weak acid secreted into the blood by muscles during exercise. A patient with increased ketone body production can exhibit a fall in pH because the ketone bodies acetoacetate and β -hydroxybutyrate are dissociated acids. As bicarbonate in the intestinal lumen is lost in watery diarrhea, more bicarbonate is secreted by intestinal cells. As intestinal cells produce bicarbonate, more H^+ is also generated ($H_2CO_3 \rightarrow HCO_3^- + H^+$). While the bicarbonate produced by these cells is released into the intestinal lumen, the

protons accumulate in the blood, resulting in acidosis. Hypercatabolism (see E), an increased rate of catabolism, generates additional CO_2 , which produces more acid ($\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{CO}_3 \rightarrow \text{HCO}_3^- + \text{H}^+$).

5. **The answer is B.** Methylmalonic acid contains two carboxylic acid groups and is, therefore, a weak acid. According to the Henderson–Hasselbalch equation, the carboxylic acid groups are 50% dissociated at their pK_a (thus, C is incorrect). Carboxylic acid groups usually have a pK_a between 2 and 5, so this acid would be nearly fully dissociated at a blood pH of 7.4 and cannot buffer intracellularly at neutral pH (thus, D and E are incorrect). (Although you do not need to know anything about methylmalonate to answer this question, methylmalonate is an organic acid generated in patients with a problem in the metabolism of methylmalonyl coenzyme A, such as a deficiency in vitamin B_{12} . Its acidity may contribute to the development of symptoms involving the nervous system. Its appearance in the urine can be classified as organic aciduria).
6. **The answer is A.** Water has high thermal conductivity and is the main transporter of molecules and heat in the body. It is a dipolar molecule (H_2O). It has a neutral pH with the same amount of H^+ and OH^- ions, so it is neither a weak acid nor a weak base. Water is neither a protein nor a carbohydrate although water can transport both proteins and carbohydrates.
7. **The answer is B.** Electrolyte is a general term applied to bicarbonate and inorganic anions and cations. Water is not an electrolyte. The major extracellular electrolytes are Na^+ , Cl^- , and HCO_3^- . The major intracellular electrolytes are K^+ and inorganic phosphate.
8. **The answer is B.** A buffer has its greatest buffering capacity in the pH ranges near its pK_a . Normal blood pH is 7.4. The pK_a of dihydrogen phosphate (H_2PO_4^-) is 7.20. The pK_a of carbonic acid is 3.80. The pK_a of ammonium ion (NH_4^+) is 9.25, whereas that of acetoacetic acid (a ketone body) is 3.62. Acetic acid has a pK_a of 4.76. The pK_a of dihydrogen phosphate is thus the closest to normal blood pH (7.4) and would exhibit the greatest buffering ability at that pH of the buffers listed. This is owing to the other acids and ammonium ion exhibiting a $\text{pK}_a > 1$ pH unit from normal blood and thereby contain relatively little undissociated acid or conjugate base, at that pH, to be an effective buffer.
9. **The answer is B.** Because of the high concentration of ketone bodies (acid) in the blood, the patient would have a lower blood pH and metabolic acidosis. To help compensate for this acidosis, the respiratory rate would increase to “blow off CO_2 .” The decrease in blood CO_2 would increase the formation of carbonic acid from bicarbonate and a proton, thereby reducing the proton concentration and raising the blood pH. Decreasing respiration would do the opposite and increase the proton concentration to further decrease pH and worsen the acidosis. A patient with diabetic ketoacidosis has abnormally high blood glucose and ketone body levels, which greatly increase blood osmolality and leads to water leaving the tissues and entering the blood to help balance the increased osmolality, which results in intracellular dehydration. The kidney normally would decrease urine output in dehydration, but the high osmolality of the glomerular filtrate increases the water content of the filtrate in order to dilute these ions. This movement of water increases urine output, leading to the patient becoming even more dehydrated.
10. **The answer is C.** Carbonic anhydrase is not normally found in blood plasma or interstitial fluid, but the red blood cells contain high amounts of this enzyme, which helps to rapidly convert CO_2 to carbonic acid within the red blood cells. In severe anemia, the number of red blood cells is greatly decreased, so the total amount of carbonic anhydrase available would be decreased, and the bicarbonate buffer system, as well as the hemoglobin buffer system, would be less effective than someone who was not anemic.
11. **The answer is E.** Recall that the K_w , water constant, is equal to the concentration of water (55.5 M) multiplied by the K_a of water. Because $K_w = 1 \times 10^{-14}$, K_a is equal to $(1 \times 10^{-14}/55.5)$, which is 1.8×10^{-16} . The pK_a is defined as $-\log K_a$, so $-\log (1.8 \times 10^{-16})$ is 15.74. With such a high pK_a , water has a very slight dissociation.
12. **The answer is D.** Buffers are most effective plus or minus one pH unit from their pK_a value. Glycine’s two pK_a values are 2.34 and 9.60, so the effective buffering range for glycine is 1.34 to 3.34, and 8.60 to 10.60. Thus, only the answer of pH 9.0 fits within one of those ranges. When buffers are in a pH range outside of one pH unit of their pK_a values, there are insufficient levels of either the conjugate base or the acid for the buffer to absorb either excess protons or hydroxide ions.
13. **The answer is D.** To solve this problem, the Henderson–Hasselbalch equation needs to be utilized. The overall buffer concentration is 0.1 M, so the sum of $[\text{X-NH}_3^+]$ and $[\text{X-NH}_2]$ is 0.1 M. We can let $[\text{X-NH}_3^+]$

(the acid form) = x , and $[X-NH_2]$ then equals $0.1 - x$. The Henderson–Hasselbalch equation then boils down to $8.0 = 8.5 + \log [(0.1 - x)/(x)]$. Solving the equation for x one arrives at .075 M as the concentration of $X-NH_3^+$, which is 75% of the overall buffer. Because the pH (8.0) is less than the pK_a (8.5), one would expect the majority of the buffer to be in the protonated form.

14. **The answer is D.** When carbon dioxide is produced, the enzyme carbonic anhydrase will combine the CO_2 with H_2O to form carbonic acid, which dissociates into a proton and bicarbonate. Hydrochloric acid is produced in the stomach, sulfuric acid in the tissues from sulfur-containing amino acids, and acetoacetic acid and butyric acid are derived from fatty acid metabolism.
15. **The answer is A.** When the histidine ionizable group, which is protonated, is in an ionic interaction with a negatively charged group the protonated form of histidine is stabilized, and it is more difficult to remove the proton from histidine. This results in an apparent increase in the pK_a of the ionizable group (one would need a higher pH in order to remove the proton because of the stabilization of the protonated state by the ionic interaction).

Structures of the Major Compounds of the Body

Our body contains compounds of great structural diversity, ranging from relatively simple sugars and amino acids to enormously complex polymers such as proteins and nucleic acids. Many of these compounds have common structural features related to their names, their solubility in water, the pathways in which they participate, or their physiologic functions. Thus, learning the terminology used to describe individual compounds and classes of compounds can greatly facilitate learning biochemistry.

CH₃CH₂OH ethanol

CH₃OH methanol

The names of chemical groups are often incorporated into the common name of a compound and denote important differences in chemical structure. For example, in the name “ethanol,” the “eth” denotes the ethyl group (CH₃CH₂–), the “ol” denotes the alcohol group (OH), and the “an” denotes the single bonds between the carbon atoms. Methanol contains a methyl group (CH₃) instead of the ethyl group. Methanol (also called wood alcohol) is much more toxic to humans than ethanol, the alcohol in alcoholic beverages. Ingestion of methanol results in visual disturbances, bradycardia (slow heartbeat), coma, and seizures.

In this chapter, we describe the major classes of carbohydrates and lipids and some of the classes of nitrogen-containing compounds. The structures of amino acids, proteins, nucleic acids, and vitamins are covered in more detail in subsequent chapters.

Functional Groups on Molecules. Organic molecules are composed principally of carbon and hydrogen. However, their unique characteristics are related to structures termed functional groups that involve **oxygen, nitrogen, phosphorus, or sulfur**.

Carbohydrates. Carbohydrates, commonly known as sugars, can be classified by their carbonyl group (**aldo-** or **keto sugars**), the number of carbons they contain (e.g., pentoses, hexoses), or the positions of the hydroxyl groups on their asymmetric carbon atoms (**D-** or **L-sugars**, **stereoisomers**, or **epimers**). They can also be categorized according to their substituents (e.g., **amino sugars**), or the number of monosaccharides (such as glucose) joined through **glycosidic bonds** (**disaccharides**, **oligosaccharides**, and **polysaccharides**). **Glycoproteins** and **proteoglycans** have sugars attached to their protein components.

Lipids. Lipids are a group of structurally diverse compounds defined by their **hydrophobicity**; they are not very soluble in water. The major lipids of the human body are the **fatty acids**, which are esterified to **glycerol** to form **triacylglycerols** (triglycerides) or **phosphoacylglycerols** (phosphoglycerides). In the **sphingolipids**, a fatty acid is attached to sphingosine, which is derived from the amino acid serine and another fatty acid. **Glycolipids** contain lipids attached to a sugar hydroxyl group. Specific **polyunsaturated fatty acids** are precursors of **eicosanoids**. The lipid **cholesterol** is a component of membranes and the precursor of other compounds that contain the steroid nucleus, such as the **bile salts** and **steroid hormones**. Cholesterol is one of the compounds synthesized from a five-carbon precursor called the **isoprene** unit.

The ketone bodies synthesized in the liver are β-hydroxybutyrate and acetoacetate. A third ketone body, acetone, is formed by the nonenzymatic decarboxylation of acetoacetate (see Fig. 3.3). Acetone is volatile and accounts for the sweet mousy odor in the breath of patients such as **Dianne A.** when they have ketoacidosis. What functional groups are present in each of these ketone bodies?

Nitrogen-Containing Compounds. Nitrogen in **amino groups** or **heterocyclic ring** structures often carries a positive charge at neutral pH. **Amino acids** contain a carboxyl group, an amino group, and one or more additional carbons. **Purines**, **pyrimidines**, and **pyridines** have heterocyclic nitrogen-

containing ring structures. **Nucleosides** comprise one of these ring structures attached to a sugar. The addition of a phosphate to a nucleoside produces a **nucleotide**.

THE WAITING ROOM

Dianne A. recovered from her bout of diabetic ketoacidosis (DKA) and was discharged from the hospital (see Chapter 4). She has returned for a follow-up visit as an outpatient. She reports that she has been compliant with her recommended diet and that she faithfully gives herself insulin by subcutaneous injection several times daily. She self-monitors her blood glucose levels at least 4 times a day and reports the results to her physician.

Dianne A. had metabolic acidosis resulting from increased hepatic production of ketone bodies. Her initial workup included screening tests for ketone bodies in her urine that employed a paper strip containing nitroprusside, a compound that reacts with keto groups. Her blood glucose was measured with an enzymatic assay that is specific for the sugar D-glucose and will not react with other sugars.

Lotta T. is a 54-year-old woman who came to her physician's office complaining of severe throbbing pain in the right great toe that began 8 hours earlier. The toe has suffered no trauma but appears red and swollen. It is warmer than the surrounding tissue and is exquisitely tender to even light pressure. She is unable to voluntarily flex or extend the joints of the digit, and passive motion of the joints causes great pain.

I. Functional Groups on Biologic Compounds

A. Biologic Compounds

The organic molecules of the body consist principally of carbon, hydrogen, oxygen, nitrogen, sulfur, and phosphorus joined by covalent bonds. The key element is carbon, which forms four covalent bonds with other atoms. Carbon atoms are joined through double or single bonds to form the carbon backbone for structures of varying size and complexity (Fig. 5.1). Groups containing one, two, three, four, and five carbons plus hydrogen are referred to as methyl, ethyl, propionyl, butyl, and pentanyl groups, respectively. If the carbon chain is branched, the prefix “iso” is used. If the compound contains a double bond, “ene” is sometimes incorporated into the name. Carbon structures that are straight or branched with single or double bonds, but do not contain a ring, are called aliphatic.

A**Aliphatic isopentenyl group****B****Aromatic phenyl group**

FIGURE 5.1 Examples of aliphatic and aromatic compounds. **A.** An **isoprene** group, which is an aliphatic group. The “iso-” prefix denotes branching, and the “-ene” denotes a double bond. **B.** A benzene ring (or phenyl group), which is an aromatic group.

β -Hydroxybutyrate and acetoacetate are carboxylates (dissociated carboxylic acids). Acetoacetate and acetone contain keto/ketone groups. Because β -hydroxybutyrate contains an alcohol (hydroxyl) group and not a keto group, the general name of ketone bodies for these compounds is a misnomer.

Carbon-containing rings are found in a number of biologic compounds. One of the most common is the six-membered carbon-containing benzene ring, sometimes called a phenyl group (see Fig. 5.1B). This ring has three double bonds, but the electrons are shared equally by all six carbons and delocalized in planes above and below the ring. Compounds containing the benzene ring, or a similar ring structure with benzene-like properties, are called aromatic.

B. Functional Groups

Biochemical molecules are defined both by their carbon skeleton and by structures called functional groups that usually involve bonds between carbon and oxygen, carbon and nitrogen, carbon and sulfur, or carbon and phosphate groups (Fig. 5.2). In carbon–carbon and carbon–hydrogen bonds, the electrons are shared equally between atoms, and the bonds are nonpolar and relatively unreactive. In carbon–oxygen and carbon–nitrogen bonds, the electrons are shared unequally, and the bonds are polar and more reactive. Thus, the properties of the functional groups usually determine the types of reactions that occur and the physiologic role of the molecule.

FIGURE 5.2 Major types of functional groups found in biochemical compounds of the human body.

Functional group names are often incorporated into the common name of a compound. For example, a **ketone** might have a name that ends in “-one,” such as **acetone**, and the name of a compound that contains a hydroxyl (alcohol or OH group) might end in “-ol” (e.g., **ethanol**). The acyl group is the portion of the molecule that provides the carbonyl ($-\text{C}=\text{O}$) group in an ester or amide linkage. It is denoted in a name by an “-yl” ending. For example, the fat stores of the body are **triacylglycerols**. Three acyl (fatty acid) groups are esterified to **glycerol**, a compound that contains three alcohol groups. In the remainder of this chapter, we will bold the portions of names of compounds that refer to a class of compounds or a structural feature.

1. Oxidized and Reduced Groups

The carbon–carbon and carbon–oxygen groups are described as “oxidized” or “reduced” according to the number of electrons around the carbon atom. Oxidation is the loss of electrons and results in the loss of hydrogen atoms together with one or two electrons or the gain of an oxygen atom or hydroxyl group. Reduction is the gain of electrons and results in the gain of hydrogen atoms or the loss of an oxygen atom. Thus, the carbon becomes progressively more oxidized (and less reduced) as we go from an alcohol to an aldehyde or a ketone to a carboxyl group (see Fig. 5.2). Carbon–carbon double bonds are more oxidized (and less reduced) than carbon–carbon single bonds.

Which compound is **glycerol**, and which is **glyceraldehyde**?

2. Groups That Carry a Charge

Acidic groups contain a proton that can dissociate, usually leaving the remainder of the molecule as an anion with a negative charge (see Chapter 4). In biomolecules, the major anionic substituents are **carboxylate** groups, **phosphate** groups, or **sulfate** groups (the “-ate” suffix denotes a negative charge) (Fig. 5.3). Phosphate groups attached to metabolites are often abbreviated as P with a circle around it, or just as “P,” as in glucose 6-**P**.

Phosphate group

Sulfate group

FIGURE 5.3 Examples of anions formed by dissociation of acidic groups. At physiologic pH, carboxylic acids, phosphoric acid, and sulfuric acid are dissociated into hydrogen ions and negatively charged anions.

Judging from the structures of the ketone bodies shown in Figure 3.3, which compound is more oxidized, β -hydroxybutyrate or

acetoacetate? Which is more reduced?

Compounds that contain nitrogen are usually basic and can acquire a positive charge (Fig. 5.4). Nitrogen has five electrons in its valence shell. If only three of these electrons form covalent bonds with other atoms, the nitrogen has no charge. If the remaining two electrons form a bond with a hydrogen ion or a carbon atom, the nitrogen carries a positive charge. Amines consist of nitrogen attached through single bonds to hydrogen atoms and to one or more carbon atoms. Primary amines, such as dopamine, have one carbon–nitrogen bond. These amines are weak acids with a pK_a of approximately 9 so that at pH 7.4 they carry a positive charge. Secondary, tertiary, and quaternary amines have two, three, and four nitrogen–carbon bonds, respectively (see Fig. 5.4).

Dopamine (a primary amine)

Choline (a quaternary amine)

FIGURE 5.4 Examples of amines. At physiologic pH, many amines carry positive charges.

C. Polarity of Bonds and Partial Charges

Polar bonds are covalent bonds in which the electron cloud is denser around one atom (the atom with the greater electronegativity) than the other. Oxygen is more electronegative than carbon, and a carbon–oxygen bond is therefore polar, with the oxygen atom carrying a partial negative charge and the carbon atom carrying a partial positive charge (Fig. 5.5). In nonpolar carbon–carbon bonds and carbon–hydrogen bonds, the two

electrons in the covalent bond are shared almost equally. Nitrogen, when it has only three covalent bonds, also carries a partial negative charge relative to carbon, and the carbon–nitrogen bond is polarized. Sulfur can carry a slight partial negative charge.

FIGURE 5.5 Partial charges on carbon–oxygen, carbon–nitrogen, and carbon–sulfur bonds.

1. Solubility

Water is a dipolar molecule in which the oxygen atom carries a partial negative charge and the hydrogen atoms carry partial positive charges (see Chapter 4). For molecules to be soluble in water, they must contain charged or polar groups that can associate with the partial positive and negative charges of water. Thus, the solubility of organic molecules in water is determined by both the proportion of polar to nonpolar groups attached to the carbon–hydrogen skeleton and to their relative positions in the molecule. Polar groups or molecules are called hydrophilic (water-loving), and nonpolar groups or molecules are hydrophobic (water-fearing). Sugars such as glucose 6-phosphate, for example, contain so many polar groups (many hydroxyl and one phosphate) that they are very hydrophilic and almost infinitely water-soluble (Fig. 5.6). The water molecules interacting with a polar or ionic compound form a hydration shell around the compound, which includes hydrogen bonds and/or ionic interactions between water and the compound.

Glucose 6-phosphate

FIGURE 5.6 Glucose 6-phosphate, a very polar and water-soluble molecule.

Compounds that have large nonpolar regions are relatively water-insoluble. They tend to cluster together in an aqueous environment and form weak associations through van der Waals interactions and hydrophobic interactions. Hydrophobic compounds are essentially pushed together (the hydrophobic effect) as the water molecules maximize the number of energetically favorable hydrogen bonds they can form with each other in the water lattice. Thus, lipids form droplets or separate layers in an aqueous environment (e.g., vegetable oils in a salad dressing).

2. Reactivity

Another consequence of bond polarity is that atoms that carry a partial (or full) negative charge are attracted to atoms that carry a partial (or full) positive charge and vice versa. These partial or full charges dictate the course of biochemical reactions, which follow the same principles of electrophilic and nucleophilic attacks that are characteristic of organic reactions in general. The partial positive charge on the carboxyl carbon attracts more negatively charged groups and accounts for many of the reactions of carboxylic acids. An ester is formed when a carboxylic acid and an alcohol combine, releasing water (Fig. 5.7). Similarly, a thioester is formed when an acid combines with a sulfhydryl group, and an amide is formed when an acid combines with an amine. Similar reactions result in the formation of a phosphoester from phosphoric acid and an alcohol and in the formation of an anhydride from two acids.

FIGURE 5.7 Formation of esters, thioesters, amides, phosphoesters, and anhydrides.

A Compound A contains three **alcohol** groups and is called **glycerol**. Compound B contains an **aldehyde group** and is called **glyceraldehyde**.

D. Nomenclature

Biochemists use two systems for the identification of the carbons in a chain. In the first system, the carbons in a compound are numbered, starting with the carbon in the most oxidized group (e.g., the carboxyl group). In the second system, the carbons are given Greek letters, starting with the carbon next to the most oxidized group. Hence, the compound shown in Figure 5.8 is known as 3-hydroxybutyrate or β -hydroxybutyrate.

FIGURE 5.8 Two systems for identifying the carbon atoms in a compound. This compound is called 3-hydroxybutyrate or β -hydroxybutyrate.

A Acetoacetate is more oxidized than β -hydroxybutyrate. The carbon in the keto group contains one less hydrogen than the carbon to which the $-\text{OH}$ group is attached. It has lost an electron.

II. Carbohydrates

A. Monosaccharides

Simple monosaccharides consist of a linear chain of three or more carbon atoms, one of which forms a carbonyl group through a double bond with oxygen (Fig. 5.9). The other carbons of an unmodified monosaccharide contain hydroxyl groups, resulting in the general formula for an unmodified sugar of $\text{C}_n\text{H}_{2n}\text{O}_n$. The suffix “-ose” is used in the names of sugars. If the carbonyl group is an aldehyde, the sugar is an aldose; if the carbonyl group is a ketone, the sugar is a ketose. Monosaccharides are also classified according to their number of carbons: sugars containing three, four, five, six, and seven carbons are called trioses, tetroses, pentoses, hexoses, and heptoses, respectively. Fructose is therefore a ketohexose (see Fig. 5.9), and glucose is an aldohexose (see Fig. 5.6).

Ketose

Fructose

FIGURE 5.9 Fructose is a ketohexose.

1. *D*- and *L*-Sugars

A carbon atom containing four different chemical groups forms an asymmetric (or chiral) center (Fig. 5.10A). The groups attached to the asymmetric carbon atom can be arranged to form two different isomers that are mirror images of each other and not superimposable. Monosaccharide stereoisomers are designated *D* or *L* based on whether the position of the hydroxyl group farthest from the carbonyl carbon matches *D*- or *L*-glyceraldehyde (see Fig. 5.10B). Such mirror-image compounds are known as enantiomers. Although a more sophisticated system of nomenclature using the designations (*R*) and (*S*) is generally used to describe the positions of groups on complex molecules such as drugs, the *D* and *L* designations are still used in medicine for describing sugars and amino acids. Because glucose (the major sugar in human blood) and most other sugars in human tissues belong to the *D* series, sugars are assumed to be *D* unless *L* is specifically added to the name.

A**D-Glyceraldehyde****L-Glyceraldehyde****B****D-Glyceraldehyde****D-Glucose**

FIGURE 5.10 A. D- and L-glyceraldehyde. The carbon in the center contains four different substituent groups arranged around it in a tetrahedron. A different arrangement creates an isomer that is a nonsuperimposable mirror image. If you rotate the mirror-image structure so that groups 1 and 2 align, group 3 will be in the position of group 4, and group 4 will be in position 3. **B.** D-glyceraldehyde and D-glucose. These sugars have the same configuration at the asymmetric carbon atom farthest from the carbonyl group. Both belong to the D series. Asymmetric carbons are shown in red.

2. Stereoisomers and Epimers

Stereoisomers have the same chemical formula but differ in the position of the hydroxyl group on one or more of their asymmetric carbons (Fig. 5.11). A sugar with n asymmetric centers has 2^n stereoisomers unless it has a plane of symmetry. Epimers are stereoisomers that differ in the position of the hydroxyl group at only one of their asymmetric carbons. D-Glucose and D-galactose are epimers of each other, differing only at position 4, and can be interconverted in human cells by enzymes called epimerases. D-Mannose and D-glucose are also epimers of each other, differing only at position 2.

FIGURE 5.11 Examples of stereoisomers. These compounds have the same chemical formula ($C_6H_{12}O_6$) but differ in the positions of the hydroxyl groups on their asymmetric carbons (in red).

Are D-mannose and D-galactose stereoisomers? Are they epimers of each other? (See Fig. 5.11.)

3. Ring Structures

Monosaccharides exist in solution mainly as ring structures in which the carbonyl (aldehyde or ketone) group has reacted with a hydroxyl group in the same molecule to form a five- or six-membered ring (Fig. 5.12). The oxygen that was on the hydroxyl group is now part of the ring, and the original carbonyl carbon, which now contains an $-OH$ group, has become the anomeric carbon atom. A hydroxyl group on the anomeric carbon drawn down below the ring is in the α position; drawn up above the ring, it is in the β position. In the actual three-dimensional structure, the ring is not planar but usually takes a “chair” conformation in which the hydroxyl groups are located at a maximal distance from each other.

D-Glucose

α-D-Glucopyranose

D-Fructose

α-D-Fructofuranose

FIGURE 5.12 Pyranose and furanose rings formed from glucose and fructose. The anomeric carbons are highlighted (carbon 1 of glucose and carbon 2 of fructose).

The stereospecificity of D-glucose is still frequently denoted in medicine by the use of its old name, dextrose. A solution used for intravenous infusions in patients is a 5% (5 g/100 mL) solution of dextrose.

In solution, the hydroxyl group on the anomeric carbon spontaneously (nonenzymatically) changes from the α to the β position through a process called mutarotation. When the ring opens, the straight-chain aldehyde or ketone is formed. When the ring closes, the hydroxyl group may be in either the α or the β position (Fig. 5.13). This process occurs more rapidly in the presence of cellular enzymes called mutarotases. However, if the anomeric carbon forms a bond with another molecule, that bond is fixed in the α or β position, and the sugar cannot mutarotate. Enzymes are specific for α or β bonds between sugars and other molecules, and react with

only one type.

FIGURE 5.13 Mutarotation of glucose in solution, with percentages of each form at equilibrium.

They are stereoisomers but not epimers of each other. They have the same chemical formula but differ in the position of two hydroxyl groups.

4. Substituted Sugars

Sugars frequently contain phosphate groups, amino groups, sulfate groups, or *N*-acetyl groups. Most of the free monosaccharides within cells are phosphorylated at their terminal carbons, which prevents their transport out of the cell (see glucose 6-phosphate in Fig. 5.6). Amino sugars such as galactosamine and glucosamine contain an amino group instead of a hydroxyl group on one of the carbon atoms, usually carbon 2 (Fig. 5.14). Frequently, this amino group has been acetylated to form an *N*-acetylated sugar. In complex molecules termed proteoglycans, many of the *N*-acetylated sugars also contain negatively charged sulfate groups attached to a hydroxyl group on the sugar.

N-Acetyl- β -D-glucosamine

FIGURE 5.14 An *N*-acetylated amino sugar. The “*N*” denotes the amino group to which the acetyl group is attached, shown in the colored box.

5. Oxidized and Reduced Sugars

Sugars can be oxidized at the aldehyde carbon to form an acid. Technically, the compound is no longer a sugar, and the ending on its name is changed from “-ose” to “-onic acid” or “-onate” (e.g., **gluconic** acid, Fig. 5.15). If the carbon containing the terminal hydroxyl group is oxidized, the sugar is called a uronic acid (e.g., **glucuronic** acid).

Oxidized Sugars

β -D-Glucuronate

D-Gluconate

Reduced Sugars

D-Sorbitol

Deoxyribose

FIGURE 5.15 Oxidized and reduced sugars. The affected group is shown in the colored box. Glucuronic acid is formed by oxidation of the glucose terminal –OH group. Gluconic acid (D-gluconate) is formed by the oxidation of the glucose aldehyde carbon. Sorbitol, a sugar alcohol, is formed by the reduction of the glucose aldehyde group. Deoxyribose is formed by the reduction of ribose.

If the aldehyde of a sugar is reduced, all of the carbon atoms contain alcohol (hydroxyl) groups, and the sugar is a **polyol** (e.g., **sorbitol**) (see Fig. 5.15). If one of the hydroxyl groups of a sugar is reduced so that the carbon contains only hydrogen, the sugar is a **deoxysugar**, such as the **deoxyribose** in DNA.

Proteoglycans contain many long unbranched polysaccharide chains attached to a core protein. The polysaccharide chains, called **glycosaminoglycans**, are composed of repeating disaccharide units containing oxidized acid sugars (such as glucuronic acid), sulfated sugars, and *N*-acetylated amino sugars. The large number of negative charges causes the glycosaminoglycan chains to radiate out from the protein so that the overall structure resembles a bottle brush. The proteoglycans are essential parts of the extracellular matrix, the aqueous humor of the eye, secretions of mucus-producing cells, and cartilage and are described in further detail in Chapter 47.

B. Glycosides

1. *N*- and *O*-Glycosidic Bonds

The hydroxyl group on the anomeric carbon of a monosaccharide can react with an –OH or an –NH group of another compound to form a **glycosidic bond**. The linkage may be either α or β , depending on the position of the atom attached to the anomeric carbon of the sugar. *N*-Glycosidic bonds are found in **nucleosides** and **nucleotides**. For example, in the adenosine moiety of ATP, the nitrogenous base adenine is linked to the sugar ribose through a β -*N*-glycosidic bond (Fig. 5.16). In contrast, *O*-glycosidic bonds, such as those found in lactose, join sugars to each other or attach sugars to the hydroxyl group of an amino acid on a protein.

FIGURE 5.16 *N*- and *O*-glycosidic bonds. Adenosine triphosphate (ATP) contains a β , *N*-glycosidic bond. Lactose contains an *O*-glycosidic $\beta(1 \rightarrow 4)$ bond. Starch contains α -1,4 and α -1,6 *O*-glycosidic bonds. The glycosidic bonds are shown in red.

2. Disaccharides, Oligosaccharides, and Polysaccharides

A disaccharide contains two monosaccharides joined by an *O*-glycosidic bond. Lactose, which is the sugar in milk, consists of galactose and glucose linked through a $\beta(1 \rightarrow 4)$ bond formed between the β -OH group of the anomeric carbon of galactose and the hydroxyl group on carbon 4 of glucose (see Fig. 5.16). Oligosaccharides contain from 3 to roughly 12 monosaccharides linked together. They are often found attached through *N*- or *O*-glycosidic bonds to proteins to form **glycoproteins** (see Chapter 6). Polysaccharides contain tens to thousands of monosaccharides joined by glycosidic bonds to form linear chains or branched structures. Amylopectin (a form of starch) and glycogen (the storage form of glucose in human cells) are branched polymers of glucosyl residues linked through $\alpha(1 \rightarrow 4)$ and $\alpha(1 \rightarrow 6)$ bonds.

III. Lipids

A. Fatty Acids

Fatty acids are usually straight aliphatic chains with a methyl group at one end (called the ω -carbon) and a carboxyl group at the other end (Fig. 5.17A). Most fatty acids in the human have an even number of carbon atoms, usually between 16 and 20. Saturated fatty acids have single bonds between the carbons in the chain, and unsaturated fatty acids contain one or more double bonds. The most common saturated fatty acids present in the cell are palmitic acid (C16) and stearic acid (C18). Although these two fatty acids are generally called by their common names, shorter fatty acids are often called by the Latin word for the number of carbons, such as octanoic acid (8 carbons) and decanoic acid (10 carbons).

FIGURE 5.17 A. Saturated fatty acids and unsaturated fatty acids. In stearic acid, the saturated fatty acid at the top of the figure, all the atoms are shown. A more common way of depicting the same structure is shown below the numbered structure. The carbons are either numbered starting with the carboxyl group or given Greek letters starting with the carbon next to the carboxyl group. The methyl (or ω) carbon at the end of the chain is always called the ω -carbon, regardless of the chain length. The symbol 18:0 refers to the number of carbon atoms (18) and the number of double bonds (0). In the unsaturated fatty acids shown, not all of the carbons are numbered, but note that the double bonds are *cis* and spaced at three-carbon intervals. Both ω -3 and ω -6 fatty acids are required in the diet. **B.** *cis* and *trans* double bonds in fatty-acid side chains. Note that the *cis* double bond causes the chain to bend.

The melting point of a fatty acid increases with chain length and decreases with the degree of unsaturation. Thus, fatty acids with many double bonds, such as those in vegetable oils, are liquid at room temperature; saturated fatty acids, such as those in butterfat, are solids. Lipids with lower melting points are more fluid at body temperature and contribute to the fluidity of our cellular membranes.

Monounsaturated fatty acids contain one double bond, and polyunsaturated fatty acids contain two or more double bonds (see Fig. 5.17). The position of a double bond is designated by the number of the carbon in the double bond that is closest to the carboxyl group. For example, oleic acid, which contains 18 carbons and a double bond between positions 9 and 10, is designated 18:1, Δ^9 . The number 18 denotes the number of carbon atoms, 1 (one) denotes the number of double bonds, and Δ^9 denotes the position of the double bond between the

9th and 10th carbon atoms. Oleic acid can also be designated 18:1(9), without the Δ . Fatty acids are also classified by the distance of the double bond closest to the ω end (the methyl group at the end farthest from the carboxyl group). Thus, oleic acid is an ω -9 fatty acid, and linolenic acid is an ω -3 fatty acid. Arachidonic acid, a polyunsaturated fatty acid with 20 carbons and 4 double bonds, is an ω -6 fatty acid that is completely described as 20:4, $\Delta^{5,8,11,14}$. The eicosanoids are a group of hormone-like compounds produced by many cells in the body. They are derived from polyunsaturated fatty acids such as arachidonic acid that contain 20 carbons (eicosa) and have 3, 4, or 5 double bonds. The prostaglandins, thromboxanes, and leukotrienes belong to this group of compounds.

The double bonds in most naturally occurring fatty acids are in the *cis* configuration (Fig. 5.17B). The designation *cis* means that the hydrogens are on the same side of the double bond and the acyl chains are on the other side. In *trans* fatty acids, the acyl chains are on opposite sides of the double bond. *Trans* fatty acids are produced by the chemical hydrogenation of polyunsaturated fatty acids in vegetable oils and are not a natural food product.

Palmitoleic acid, oleic acid, and arachidonic acid are the most common unsaturated fatty acids in the cell. Palmitoleic acid is a 16:1, Δ^9 fatty acid. How would you name it an ω fatty acid?

B. Acylglycerols

An **acylglycerol** comprises glycerol with one or more fatty acids (the **acyl** group) attached through ester linkages (Fig. 5.18). Monoacylglycerols, diacylglycerols, and triacylglycerols contain one, two, or three fatty acids esterified to glycerol, respectively. **Triacylglycerols** rarely contain the same fatty acid at all three positions and are therefore called mixed triacylglycerols. Unsaturated fatty acids, when present, are most often esterified to carbon 2. In the three-dimensional configuration of glycerol, carbons 1 and 3 are not identical, and enzymes are specific for one or the other carbon.

Triacyl-*sn*-glycerol

FIGURE 5.18 A triacylglycerol. Note that carbons 1 and 3 of the glycerol moiety are not identical. The broad end of each arrowhead is closer to the reader than the narrow, pointed end.

 *Trans* fatty acids (partially hydrogenated fat) were utilized by restaurants as an oil that had a longer shelf life than polyunsaturated fatty acids. However, the presence of trans fat in food has been linked in some studies to an increased risk of heart disease. These findings, however, have been challenged by the food industry. The Food and Drug Administration (FDA) now mandates the labeling of foods with *trans* fatty-acid content, and the use of *trans* fatty acids in commercial food preparations has been banned in certain localities in the United States.

C. Phosphoacylglycerols

Phosphoacylglycerols contain fatty acids esterified to positions 1 and 2 of glycerol and a phosphate (alone or with a substituent) attached to carbon 3. If only a phosphate group is attached to carbon 3, the compound is **phosphatidic acid** (Fig. 5.19). Phosphatidic acid is a precursor for the synthesis of the other phosphoacylglycerols.

FIGURE 5.19 Phosphoacylglycerols. Phospholipids found in membranes, such as phosphatidylcholine, have a polar group attached to the phosphate.

Phosphatidylcholine is one of the major phosphoacylglycerols found in membranes (see Fig. 5.19). The **amine** is positively charged at neutral pH, and the phosphate is negatively charged. Thus, the molecule is amphipathic: it contains large polar and nonpolar regions. Phosphatidylcholine is also called lecithin. Removal of a fatty acyl group from a phosphoacyl glycerol leads to a lysolipid; for example, removing the fatty acyl group from lecithin forms lysolecithin.

 Palmitoleic acid is an ω -7 fatty acid. It has one double bond between the 9th and 10th carbons. It has 16 carbons, like palmitic acid, so the double bond is at the 7th carbon from the ω end.

D. Sphingolipids

Sphingolipids do not have a glycerol backbone; they are formed from sphingosine (Fig. 5.20). **Sphingosine** is derived from **serine** and a specific fatty acid, palmitate. **Ceramides** are **amides** formed from sphingosine by attaching a fatty acid to the amino group. Various sphingolipids are then formed by attaching different groups to the hydroxyl group on ceramide. As reflected in the names for **cerebrosides** and **gangliosides**, these sphingolipids contain sugars attached to the hydroxyl group of ceramide through glycosidic bonds. They are glycolipids (more specifically, glycosphingolipids). Sphingomyelin, which contains a phosphorylcholine group attached to ceramide, is a component of cell membranes and the myelin sheath around neurons.

The $-NH$ and $-OH$ were contributed by serine. Different groups are added to the hydroxyl group of ceramide to form sphingomyelin, galactocerebrosides, and gangliosides. Gal, galactose; GalNAc, *N*-acetylgalactosamine; Glc, glucose; NANA, *N*-acetylneuraminic acid, also called sialic acid;

E. Steroids

Steroids contain a four-ring structure called the steroid nucleus (Fig. 5.21). Cholesterol is the steroid precursor in human cells from which all of the steroid hormones are synthesized by modifications to the ring or C-20 side chain. Although cholesterol is not very water-soluble, it is converted to amphipathic water-soluble bile salts such as cholic acid. Bile salts line the surfaces of lipid droplets called micelles in the lumen of the intestine, where they keep the droplets emulsified in the aqueous environment.

FIGURE 5.21 Cholesterol and its derivatives. The steroid nucleus is shown in the *green box*. The bile salt, cholic acid, and the steroid hormone 17β -estradiol are derived from cholesterol and contain the steroid ring structure.

Cholesterol is one of the compounds synthesized in the human from branched five-carbon units with one double bond called an isoprenyl unit (see Fig. 5.1A). Isoprenyl units are combined in long chains to form other structures, such as the side chains of coenzyme Q in humans and vitamin A in plants. Isoprene units form polymers to generate geranyl groups (10 carbons) and farnesyl groups (15 carbons) (see Chapter 32). The geranyl and farnesyl groups, owing to their highly hydrophobic nature, are often covalently attached to proteins to allow the proteins to associate with cellular membranes.

What structural features account for the differences in the solubility of cholesterol, estradiol, and cholic acid in the body? (See Fig. 5.21.)

IV. Nitrogen-Containing Compounds

Nitrogen, as described in Section I.B.2, is an electronegative atom with two unshared electrons in its outer valence shell. At neutral pH, the nitrogen in amino groups is usually bonded to four other atoms and carries a positive charge. However, the presence of a nitrogen atom in an organic compound will increase its solubility in water, whether the nitrogen is charged or uncharged.

A. Amino Acids

Amino acids are compounds that contain an amino group and a carboxylic acid group. In proteins, the amino acids are always *L*- α amino acids (the amino group is attached to the α carbon in the *L*-configuration) (Fig. 5.22). These same amino acids also serve as precursors of nitrogen-containing compounds in the body, such as phosphatidylcholine (see Fig. 5.19), and are the basis of most human amino acid metabolism. However, our metabolic reactions occasionally produce an amino acid that has a β or γ amino group, such as the neurotransmitter γ -aminobutyric acid (see Fig. 5.22). However, only *L*- α amino acids are incorporated into proteins. Although *D*-amino acids are not usually incorporated into proteins in living organisms, they serve many other functions in bacteria, such as the synthesis of cross-links in cell walls.

FIGURE 5.22 The structure of the α -amino acid alanine (both the D- and L-configuration), and the γ -amino acid γ -aminobutyrate.

B. Nitrogen-Containing Ring Structures

1. Purines, Pyrimidines, and Pyridines

Nitrogen is also a component of ring structures referred to as heterocyclic rings or nitrogenous bases. The three most common types of nitrogen-containing rings in the body are **purines** (e.g., **adenine**), **pyrimidines** (e.g., **thymine**), and **pyridines** (e.g., the vitamins **nicotinic acid**, also called **niacin**, and **pyridoxine**, also called **vitamin B₆**) (Fig. 5.23). The suffix “-ine” denotes the presence of nitrogen (**amine**) in the ring. The pyrimidine uracil is an exception to this general type of nomenclature. The utility of these nitrogen-containing ring structures lies in the ability of the nitrogen to form hydrogen bonds and to accept and donate electrons while still part of the ring. In contrast, the unsubstituted aromatic benzene ring, in which electrons are distributed equally among all six carbons (see Fig. 5.1), is nonpolar, hydrophobic, and relatively unreactive.

Purines

Guanine (G)

Pyrimidine

Thymine (T)

Pyridine

Nicotinic acid

FIGURE 5.23 The nitrogenous bases.

2. Nucleosides and Nucleotides

Nitrogenous bases form nucleosides and nucleotides. A nucleoside consists of a nitrogenous base joined to a sugar, usually ribose or deoxyribose, through an *N*-glycosidic bond (see Fig. 5.16). If phosphate groups are attached to the sugar, the compound becomes a nucleotide. In the name of the nucleotide adenosine triphosphate (ATP), the addition of the ribose is indicated by the name change from adenine to **adenosine** (for the **glycosidic** bond). Monophosphate, diphosphate, or triphosphate are added to the name to indicate the presence of one, two, or three phosphate groups in the nucleotide. The structures of the nucleotides that serve as precursors of DNA and RNA are discussed in more detail in Section III, Chapter 11.

3. Tautomers

In many of the nitrogen-containing rings, the hydrogen can shift to produce a tautomer, a compound in which the hydrogen and double bonds have changed position (i.e., $-N=C-OH \rightarrow -NH-C=O$) (Fig. 5.24). Tautomers are considered the same compound, and the structure may be represented either way. Generally, one tautomeric form is more reactive than the other. For example, in the two tautomeric forms of uric acid, a proton can dissociate from the enol form to produce urate.

FIGURE 5.24 Tautomers of uric acid. The tautomeric form affects reactivity. The enol form dissociates a proton to form urate.

V. Free Radicals

Radicals are compounds that have a single electron, usually in an outer orbital. Free radicals are radicals that exist independently in a solution or a lipid environment. Although many enzymes generate radicals as intermediates in reactions, these are not usually released into the cell to become free radicals.

Many of the compounds in the body are capable of being converted to free radicals by natural events that remove one of their electrons or by radiation. Radiation, for example, dissociates water into the hydrogen atom and the hydroxyl radical:

In contrast, water normally dissociates into a proton and the negatively charged hydroxyl ion. The hydroxyl radical forms organic radicals by taking one electron (as $H\cdot$) from a compound such as an unsaturated membrane lipid, which then has a single unpaired electron and is a new radical.

A Cholesterol is composed almost entirely of $-CH_2$ groups and is therefore water-insoluble. Estradiol is likewise relatively water-insoluble. However, cholic acid contains a hydrophilic carboxyl group and three hydroxyl groups. As shown by the dashed lines, the three hydroxyl groups all lie on one side of the molecule, thus creating a hydrophilic surface.

Compounds that are radicals may be written with, or without, the radical showing. For example, nitrogen dioxide, a potent, reactive, toxic radical present in smog and cigarette smoke, may be designated in medical and lay literature as NO_2 rather than $NO_2\cdot$. Superoxide, a radical produced in the cell and that is the source of much destruction, is correctly written as the superoxide anion, O_2^- . However, to emphasize its free-radical nature, the same compound is sometimes written as $O_2^-\cdot$. If a compound is designated as a radical in the medical literature, you can be certain that it is a reactive radical, and that its radical nature is important for the pathophysiology under discussion. Reactive oxygen and nitrogen-containing free radicals are discussed in more detail in Chapter 25.

Lotta T. has gouty arthritis (podagra) involving her great right toe. Polarized light microscopy of the fluid aspirated from the joint space showed crystals of monosodium urate phagocytosed by white blood cells. The presence of the relatively insoluble urate crystals within the joint space activates an inflammatory cascade leading to the classic components of joint inflammation (pain, redness, warmth, swelling, and limitation of joint motion). Uric acid is produced from the degradation of purines (adenine and guanine). At a blood pH of 7.4, all of the uric acid has dissociated a proton to form urate, which is not very water-soluble and forms crystals of the Na^+ salt. In the more acidic urine generated by the kidney, the acidic form, uric acid, may precipitate to form kidney stones.

CLINICAL COMMENTS

Dianne A. The severity of clinical signs and symptoms in patients with DKA, such as **Dianne A.**, is correlated directly with the concentration of ketone bodies in the blood. Direct quantitative methods for measuring acetoacetate and β -hydroxybutyrate are not routinely available. As a result, clinicians usually rely on semiquantitative reagent strips (Ketostix) or tablets (Acetest) to estimate the level of acetoacetate in the blood and the urine. The nitroprusside on the strips and in the tablets reacts with acetoacetate and to a lesser degree with acetone (both of which have ketone groups) but does not react with β -hydroxybutyrate (which does not have a ketone group). β -Hydroxybutyrate is the predominant ketone body present in the blood of a patient in DKA, and its concentration could decline at a disproportionately rapid rate compared with that of acetoacetate and acetone. Therefore, tests employing the nitroprusside reaction to monitor the success of therapy in such a patient may be misleading. As a result, clinicians will follow the “anion gap” in the blood, which in DKA represents the increase in ketone bodies.

Free radicals are not just esoteric reactants; they are the agents of cell death and destruction. They are involved in many chronic disease states (e.g., coronary artery disease, diabetes mellitus, arthritis, and emphysema) as well as acute injury (e.g., radiation, strokes, myocardial infarction, and spinal cord injury). Through free-radical defense mechanisms in our cells, we can often restrict the damage attributed to the “normal” aging process.

The anion gap refers to the difference in concentration between routinely measured anions (chloride and bicarbonate) and cations (sodium and potassium) in the blood. Because these cations are in most cases in greater concentration than the measured anions, the difference in value is known as the anion gap. The normal value for the anion gap is 12 (8 to 16). If the anion gap is greater than normal, it is indicative of unknown anions being present in excess, and in the case of type 1 diabetes, most often reflects the production of ketone bodies.

In contrast to the difficulty of ketone body measurements, diabetic patients can self-monitor blood glucose levels at home, thereby markedly decreasing the time and expense of the many blood glucose determinations they need. Capillary blood obtained from a finger prick is placed on the pad of a plastic strip. The strip has been impregnated with an enzyme (usually the bacterial enzyme glucose oxidase) that specifically converts the glucose in the blood to an oxidized sugar (gluconate) and a reduced compound (hydrogen peroxide [H_2O_2]). The H_2O_2 reacts with a dye to produce a color. The intensity of the color, which is directly proportional to the concentration of glucose in the patient’s blood, is read on an instrument called a blood glucose monitor.

The reducing sugar test. The reducing sugar test was used for the detection of sugar in the urine long before specific enzymatic assays for glucose and galactose became available. In this test, the aldehyde group of a sugar is oxidized as it donates electrons to copper; the copper becomes reduced and produces a blue color. In alkaline solution, keto sugars (e.g., fructose) also react in this test because they form tautomers that are aldehydes. Ring structures of sugars also react but only if the ring can open (i.e., it is not attached to another compound through a glycosidic bond). Until a specific test for fructose becomes available, a congenital disease resulting in the presence of fructose in the urine is indicated by a positive reducing sugar test and negative results in the specific enzymatic assays for glucose or galactose.

Lotta T. has acute gouty arthritis (podagra) involving her right great toe. She was treated with colchicine for the acute attack of gout affecting her great right toe. After having two doses of colchicine, the throbbing pain in her toe had abated significantly. The redness and swelling also seemed to have lessened slightly. Colchicine will reduce the effects of the inflammatory response to the urate crystals. Several weeks later, **Lotta T.** was started on allopurinol (150 mg, twice daily) while also taking a daily dose of colchicine. Allopurinol inhibits the enzyme that produces uric acid. Within several days of starting allopurinol therapy, her uric acid levels began to decrease.

BIOCHEMICAL COMMENTS

Chlorinated Aromatic Hydrocarbon Environmental Toxins. As a result of human endeavors, toxic compounds containing chlorinated benzene rings have been widely distributed in the environment. The pesticide DDT (dichlorodiphenyltrichloroethane), the class of chemicals called dioxins, and polychlorinated biphenyls (PCBs) provide examples of chlorinated aromatic hydrocarbons and structurally related compounds that are very hydrophobic and poorly biodegraded (Fig. 5.25). As a consequence of their persistence and lipophilicity, these chemicals are concentrated in the adipose tissue of

fish, fish-eating birds, and carnivorous mammals, including humans.

DDT

Chlorodibenzo-*p*-dioxin

PCB

FIGURE 5.25 Environmental toxins. Dichloro-diphenyl trichloroethane (DDT) is a member of a class of aromatic hydrocarbons that contains two chlorinated benzene (phenyl) rings joined by a chlorinated ethane molecule. Chlorodibenzo-*p*-dioxins (CDDs) are a related class of more than 75 chlorinated hydrocarbons that all contain a dibenzo-*p*-dioxin (DD) molecule comprising two benzene rings joined via two oxygen bridges at adjacent carbons on each of the benzene rings. The compound 2,3,7,8-tetrachlorodibenzo-*p*-dioxin is one of the most toxic and the most extensively studied. Chlorinated dibenzofurans (CDFs) are structurally and toxicologic related. Polychlorinated biphenyls (PCBs) consist of two benzene rings linked by a bond with 2 to 10 of the remaining carbons containing a chlorine atom. There are over 200 different varieties of PCBs.

DDT, a chlorinated biphenyl, was widely used in the United States as an herbicide between the 1940s and 1960s (see Fig. 5.25). Although it has not been used in this country since 1972, the chlorinated benzene rings are resistant to biodegradation, and U.S. soil and water are still contaminated with small amounts. DDT is still used in other parts of the world. Because this highly lipophilic molecule is stored in the fat of animals, organisms accumulate progressively greater amounts of DDT at each successive stage of the food chain. Fish-eating birds, one of the organisms at the top of the food chain, have declined in population because of the effect of DDT on the thickness of their eggshells. DDT is not nearly as toxic in the human, although long-term exposure or exposure to high doses may cause reversible neurologic symptoms, hepatotoxic effects, or cancer.

The accumulation of DDT in adipose tissue may be protective in the human because it decreases the amount of DDT available to pass through nonpolar lipid membranes to reach neurons in the brain or pass through placental membranes to reach the fetus. Eventually, we convert DDT to more polar metabolites that are excreted in the urine. However, some may pass with lipid into the breast milk of nursing mothers.

Dioxins, specifically polychlorinated dibenzo-*p*-dioxins (PCDDs), constitute another class of environmental toxins that are currently of great concern (see Fig. 5.25). They have been measured at what is termed background levels in the blood, adipose tissue, and breast milk of all humans tested. PCDDs are formed as a by-product during the production of other chlorinated compounds and herbicides, and from the chlorine bleaching process used by pulp and paper mills. They are released during the incineration of industrial, municipal, and domestic wastes, and during the combustion of fossil fuels, and are found in cigarette smoke and the exhaust from engines that burn gasoline and diesel fuels. They can also be formed from the combustion of organic matter during forest fires. They enter the atmosphere as particulate matter, are vaporized, and can spread large distances to enter soil and water.

Most of what is known about the toxicity of dioxins in the human come from individuals exposed incidentally or chronically to higher levels (e.g., industrial accidents or presence in areas sprayed with Agent Orange or other herbicides contaminated with dioxins). The lowest-dose effects are probably associated with thymic atrophy and decreased immune response, chloracne and related skin lesions, and neoplasia (cancer). Dioxins can cross into the placenta to cause developmental and reproductive effects, decreased prenatal growth, and prenatal mortality.

PCBs were originally synthesized for use as nonflammable material for cooling and insulating industrial transformers and capacitors. Owing to accidents in the chemical plants producing the PCBs, it became evident that these chemicals can cause adverse health effects in humans. Production of PCBs stopped in the United States in 1979, although they may still be found in enclosed containers for electrical transformers. All of the chlorinated compounds thus far discussed may have as their mechanism of action an alteration of gene expression via binding to the cytoplasmic aryl hydrocarbon receptor (see Section III of this text). PCB exposure has been linked to cancer and disorders of the immune, reproductive, nervous, and endocrine systems.

All of the polychlorinated derivatives are difficult to remove from the environment. One promising approach is to utilize genetically engineered bacteria that can utilize these compounds as a food source and will safely metabolize the toxins. This approach, however, has the drawback of introducing genetically engineered organisms into the environment, which has its own potential problems (see Chapter 17).

As humans at the top of the food chain, we have acquired our background levels of dioxins principally through the consumption of food, primarily meat, dairy products, and fish. Once in the human body, dioxins are stored in human fat and adipose tissue and have an average half-life of approximately 5 to 15 years. They are unreactive, poorly degraded, and not readily converted to more water-soluble compounds that can be excreted in the urine. They are slowly excreted in the bile and feces and together with lipids enter the breast milk of nursing mothers.

KEY CONCEPTS

- ◆ Carbohydrates, commonly known as sugars, can be classified by a number of criteria:
 - ◆ Type of carbonyl group (aldo- or keto sugars)
 - ◆ Number of carbons (pentoses [five carbons], hexoses [six carbons])
 - ◆ Positions of hydroxyl groups on asymmetric carbon atoms (D- or L-configuration, stereoisomers, epimers)
 - ◆ Substituents (amino sugars)
 - ◆ Number of monosaccharides joined through glycosidic bonds (disaccharides, oligosaccharides, polysaccharides)
- ◆ Lipids are structurally diverse compounds that are not very soluble in water (i.e., they are hydrophobic).
 - ◆ The major lipids are fatty acids.
 - ◆ Triacylglycerols (triglycerides) consist of three fatty acids esterified to the carbohydrate glycerol.
 - ◆ Phosphoacylglycerols (phosphoglycerides or phospholipids) are similar to triacylglycerol but contain phosphate in place of a fatty acid.
 - ◆ Sphingolipids are built on sphingosine.
 - ◆ Cholesterol is a component of membranes and a precursor for molecules that contain the steroid nucleus, such as bile salts and steroid hormones.
- ◆ Nitrogen is found in a variety of compounds, in addition to amino sugars.
 - ◆ Amino acids and heterocyclic rings contain nitrogens, which carry a positive charge at neutral pH.
 - ◆ Amino acids contain a carboxyl group, an amino group, and a side chain attached to a central carbon.
 - ◆ Proteins consist of a linear chain of amino acids.
 - ◆ Purines, pyrimidines, and pyridines have heterocyclic nitrogen-containing ring structures.
 - ◆ Nucleosides consist of a heterocyclic ring attached to a sugar.
 - ◆ A nucleoside plus phosphate is a nucleotide.
- ◆ Glycoproteins and proteoglycans have sugars attached to protein components.
- ◆ Diseases discussed in this chapter are summarized in Table 5.1.

TABLE 5.1 Diseases Discussed in Chapter 5

DISORDER OF CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
Gout	Both	May be caused by mutations in specific proteins or by dietary habits. Leads to a buildup of uric acid in the blood and precipitates of urate crystals in the joints.
Type 1 diabetes	Both	Appropriate management of type 1 diabetes requires insulin injections and frequent monitoring of blood glucose levels throughout the day. Without such careful monitoring, ketone bodies may be produced inappropriately.

REVIEW QUESTIONS—CHAPTER 5

Select the single best answer for each of the following questions. Base your answers on your knowledge of nomenclature. You need not recognize any of the structures shown to answer the questions.

1. A component of a “lipid panel” for a patient are triglycerides, which are best described by which one of the following?
 - A. Contains a steroid nucleus
 - B. Three fatty acids esterified to sphingosine
 - C. Three fatty acids esterified to a polyol
 - D. Two fatty acids and a phosphate esterified to a sphingosine
 - E. Two fatty acids and a phosphate esterified to a polyol
2. A patient was admitted to the hospital emergency department in a coma. Laboratory tests found high levels of the compound shown below in her blood:

Based on its structure (and your knowledge of the nomenclature of functional groups), you identify the compound as which one of the following?

- Methanol (wood alcohol)
 - Ethanol (alcohol)
 - Ethylene glycol (antifreeze)
 - β -Hydroxybutyrate (a ketone body)
 - γ -Hydroxybutyrate (the “date rape” drug)
- A patient was diagnosed with a deficiency of the lysosomal enzyme α -glycosidase. The name of the deficient enzyme suggests that it hydrolyzes a glycosidic bond, which is best described as a bond formed via which one of the following?
 - Through multiple hydrogen bonds between two sugar molecules
 - Between the anomeric carbon of a sugar and an O–H (or N) of another molecule
 - Between two anomeric carbons in polysaccharides
 - Internal bond formation between the anomeric carbon of a monosaccharide and its own 5th carbon hydroxyl group
 - Between the carbon containing the aldol or keto group and the α -carbon of the sugar
 - In the congenital disease galactosemia, high concentrations of galactose and galactitol accumulate in the blood. Based on their names, you would expect which one of the following statements to be correct?
 - Galactitol is an aldehyde formed from the keto sugar galactose.
 - Galactitol is the oxidized form of galactose.
 - Galactitol is the sugar alcohol of galactose.
 - Both galactose and galactitol are sugars.
 - Both galactose and galactitol would give a positive reducing sugar test.
 - A patient was diagnosed with one of the types of sphingolipidoses, which are congenital diseases involving the inability to degrade sphingolipids. All sphingolipids have in common which one of the following?
 - A glycerol backbone
 - Ceramide
 - Phosphorylcholine
 - N*-Acetylneuraminic acid (NANA)
 - A steroid ring structure to which sphingosine is attached.
 - In diabetic ketoacidosis, metabolic acidosis results from increased hepatic production of ketone bodies (β -hydroxybutyrate, acetoacetate, and acetone). Which one of the following terms best describes all three of these ketone bodies?
 - Butyl structure
 - Aromatic structure
 - Aliphatic structure
 - Hydroxyl-containing structure
 - Amine-containing structure
 - Omega-3 fatty acids are found in “oily” fish and are considered beneficial for heart health. A food containing which one of the following would fall into this category?
 - cis* $\Delta^{9,12,15}$ C18:3
 - cis* $\Delta^{9,12}$ C18:2
 - cis* $\Delta^{6,9,12}$ C18:3
 - cis* $\Delta^{9,12,15}$ C20:3
 - cis* $\Delta^{6,9}$ C16:2
 - A patient has had viral gastroenteritis for three days and has been unable to keep any oral intake down, such that the patient is now dehydrated. In the emergency department, he is given 2 L of IV D5 0.9% NaCl solution. Which of the following best describes this IV solution?
 - It is hypotonic.
 - It is hypertonic.
 - It contains D-glucose.
 - It contains L-glucose.
 - It contains D-galactose.
 - A patient with hyperlipidemia has been counseled to reduce the saturated fats in his diet, so he has replaced

butter with a butter substitute that he knows is made from a polyunsaturated oil. The manufacturer of this butter substitute has partially hydrogenated this product. Which one of the following is the best description of why this product was partially hydrogenated?

- A. The trans fatty acids produced by commercial hydrogenation are very healthy in humans.
 - B. Hydrogenation reduces the double bonds creating a more saturated product, which is more marketable.
 - C. Hydrogenation makes the product less expensive to produce.
 - D. Hydrogenation reduces the cholesterol content of the oil.
 - E. Hydrogenation increases the cholesterol content of the oil.
0. A researcher is trying to design an antibiotic to kill bacteria but not harm any human cells. Which one of the following theoretically could be utilized for this purpose?
- A. A medication that inhibits reactions using only D-amino acids
 - B. A medication that inhibits reactions using only L-amino acids
 - C. A medication that inhibits reactions using only amino acids containing a β -amino group
 - D. A medication that inhibits reactions using only amino acids containing a γ -amino group
 - E. A medication that only inhibits reactions using only aromatic amino acids.
1. When D-glucose enters cells, it is rapidly phosphorylated to form glucose 6-phosphate. The bond created in this step is best referred to as which one of the following?
- A. An ester linkage
 - B. An amide linkage
 - C. A phosphoester linkage
 - D. A phosphoanhydride linkage
 - E. A thioester linkage

Questions 12 and 13 concern D-erythrose, a 4-carbon aldose sugar.

2. How many asymmetric carbons are present in D-erythrose?
- A. 0
 - B. 1
 - C. 2
 - D. 3
 - E. 4
3. How many potential stereoisomers are there in D-erythrose?
- A. 1
 - B. 2
 - C. 4
 - D. 8
 - E. 16
4. β -D-Glucuronic acid can participate in which one of the following as compared to its precursor, β -D-glucose?
- A. Increased hydrophobicity
 - B. Increased vDW interactions
 - C. Ionic interactions
 - D. Hydrogen bonds
 - E. Increased α -1,6 glycosidic bond formation
5. Defects in glycosphingolipid degradation can lead to a variety of serious diseases. Glycosphingolipids are derived from which of the following?
- A. Glycine, palmitic acid, and carbohydrates
 - B. Serine, palmitic acid, and a steroid
 - C. Glycine, serine, and carbohydrates
 - D. Serine, palmitic acid, and carbohydrates
 - E. Palmitic acid, carbohydrates, and a steroid

ANSWERS TO REVIEW QUESTIONS

1. **The answer is C.** Triglyceride (triacylglycerol) consists of three fatty acids esterified to the polyol glycerol. Phosphoacylglycerols are similar to triacylglycerol but contain phosphate in place of a fatty acid. Cholesterol contains a steroid nucleus. Sphingolipids are built on sphingosine but not triglycerides.
2. **The answer is E.** The compound contains an $-\text{OH}$ group, which should appear in the name as an “-ol” or

a “hydroxyl-” group. All answers fit this criterion. The structure also contains a carboxylate group ($-\text{COO}^-$), which should appear in the name as an “-ate” or “acid.” Only D and E fit this criterion. Counting backward from the carboxylate group (carbon 1), the second carbon is α , the third carbon is β , and the fourth carbon, containing the hydroxyl group, is γ . Thus, the compound is γ -hydroxybutyrate. A, B, and C can also be eliminated because “meth-” denotes a single carbon, “eth-” denotes two carbons, and the “-ene” in ethylene denotes a double bond.

- The answer is B.** The term “glycosidic bond” refers to a *covalent* bond formed between the anomeric carbon of one sugar, when it is in a ring form, and a hydroxyl group or nitrogen of another compound (see Fig. 5.16) (Thus, A, D, and E are incorrect). Disaccharides can be linked through their anomeric carbons but not polysaccharides because there would be no anomeric carbon left to form a link with the next sugar in the chain (thus, C is incorrect).
- The answer is C.** The keto or aldehyde group is necessary for a positive reducing sugar test (a nonspecific test used to identify the presence of sugar in the urine). Because galactitol has had its aldehyde group already reduced to form the alcohol group, it would no longer give a positive result in a reducing sugar test. An “**ol**” in the name denotes the compound is an alcohol (has an $-\text{OH}$ group) and an “**ose**” denotes a sugar. Thus, the alcohol that is derived from galactose is galactitol. All sugars have a keto or aldehyde group, which is reduced when the compound becomes alcohol (a gain of electrons, as indicated by an increase in hydrogen relative to oxygen). Oxidation of the keto or aldehyde group would lead to an acid group being generated, not an alcohol group. Galactose is an aldose sugar, not a keto sugar.
- The answer is B.** Sphingolipids contain a ceramide group, which is sphingosine with an attached fatty acid. They do not contain a glycerol moiety (thus, A is incorrect). However, different sphingolipids have different substituents on the $-\text{CH}_2\text{OH}$ group of ceramide. For example, sphingomyelin contains phosphorylcholine, and gangliosides contain NANA (thus, C and D are incorrect). No known sphingolipids contain a steroid (E).
- The answer is C.** None of these ketone bodies contains a benzene or similar ring (aromatic), so they are all defined as aliphatic. Two of these have four carbons (butyl), but acetone has only three carbons (propyl structure). Only β -hydroxybutyrate contains a hydroxyl group ($-\text{OH}$) and none contain a nitrogen atom or group (amine).
- The answer is A.** The ω -series of fatty acids refers to counting carbons from the ω -end of the fatty acid (usually the methyl carbon end) until a double bond is reached. For the *cis* $\Delta^{9,12,15}$ C18:3 fatty acid, the double bonds are between carbons 9 and 10, 12 and 13, and 15 and 16. If one counts backward from carbon 18, one counts three carbons (18, 17, and 16) before the double bond is reached, indicating that this fatty acid belongs to the ω -3 family. The *cis* $\Delta^{9,12}$ C18:2 fatty acid belongs to the ω -6 group as does the *cis* $\Delta^{6,9,12}$ C18:3 fatty acid. The *cis* $\Delta^{9,12,15}$ C20:3 fatty acid belongs to the ω -5 group, whereas the *cis* $\Delta^{6,9}$ C16:2 fatty acid belongs to the ω -7 group.
- The answer is C.** 0.9% saline is considered “normal” saline (NS) and is isotonic. This is a very common solution in IV fluids used to treat dehydration. D5 refers to 5% dextrose solution or 50 g/L of dextrose given as a means of parenteral nutrition because the patient can’t take oral nutrition. Dextrose is another name for D-glucose. L-Glucose is not commonly found in the human body. The glucose is completely metabolized and does not contribute to tonicity. Galactose is not present in this type of solution.
- The answer is B.** Polyunsaturated fatty acids have a lower melting point than more saturated fats. Butter is a highly saturated fat and is a solid around room temperature. Polyunsaturated fats melt at room temperature. Most consumers don’t want a butter substitute that melts at room temperature, so such a product wouldn’t sell as well as natural butter. Hydrogenation reduces the double bonds in the polyunsaturated fats and makes the product more saturated, which raises the melting point of the oil as well as increasing the shelf life of the product. Hydrogenated oils are less expensive to produce than animal fats, but hydrogenation introduces an extra step in manufacturing and increases costs as compared to not changing the product at all. Unfortunately, commercial hydrogenation creates *trans* double bonds in the fats whereas all naturally occurring unsaturated fatty acids contain double bonds in the *cis* configuration. The presence of *trans* fats in American diets has been linked to the development of cardiovascular disease. Hydrogenation of fatty acids has no link to cholesterol.
- The answer is A.** In human proteins, the amino acids are always L- α -amino acids (in the L-configuration). D-Amino acids are not used for synthesizing proteins in humans but are used to generate products in bacteria. Inhibiting the use of D-amino acids would inhibit bacterial growth but not affect human cell growth. Some human products contain β - and γ -amino groups, so drugs inhibiting their production would

not be beneficial for human use.

11. **The answer is C.** Adding a phosphate to the hydroxyl (an alcohol) on position 6 of glucose creates a phosphoester bond. An amide linkage (answer choice B) would require nitrogen being present, and a thioester linkage (answer choice E) would require a sulfur atom being present. A phosphoanhydride is formed when two acids condense, and glucose contains an alcohol that is condensing with the phosphate. An ester linkage contains a carbonyl group, and in glucose 6-phosphate the carbonyl group is at carbon 1, not carbon 6.
12. **The answer is C.** Carbon 1 of D-erythrose contains an aldehyde, so it is not an asymmetric carbon, and carbon 4 contains a CH_2OH , so it is also not asymmetric. Only carbons 2 and 3 of D-erythrose contain four distinct substituents and are considered asymmetric carbons.
13. **The answer is C.** For carbohydrates, the number of stereoisomers is equal to 2^n , where n is equal to the number of asymmetric carbons. Because there are two asymmetric carbons, there are 2^2 , or 4, possible stereoisomers.
14. **The answer is C.** Glucuronic acid is derived from glucose through the oxidation of the alcohol group on carbon 6 of glucose to a carboxylic acid, which would have a negative charge at neutral pH. The negative charge could participate in ionic interactions with nearby positively charged groups. In glucose, the alcohol at position 6 would be able to participate in hydrogen bonding but not in ionic bond formation. Phosphate groups are highly hydrophilic, not hydrophobic. The van der Waals interactions would be similar between glucose and glucose 6-phosphate. When the six position of glucose has been oxidized to an acid, it can no longer participate in glycosidic bond formation, so there would not be increased α -1,6 glycosidic bond formation with glucuronic acid.
15. **The answer is D.** Glycosphingolipids are composed of sugars (carbohydrates) linked to ceramide. Ceramide is derived from a fatty acid and sphingosine. Sphingosine is derived from serine and palmitic acid. Thus, the best answer is serine, palmitic acid, and carbohydrates. The steroid ring structure is not found in glycosphingolipids, nor is the amino acid glycine a precursor for glycosphingolipid synthesis.

Amino Acids in Proteins

Proteins have many functions in the body. They serve as transporters of hydrophobic compounds in the blood, as cell adhesion molecules that attach cells to each other and to the extracellular matrix, as hormones that carry signals from one group of cells to another, as ion channels through lipid membranes, and as enzymes that increase the rate of biochemical reactions. The unique characteristics of a protein are dictated by its linear sequence of amino acids, termed its **primary structure**. The primary structure of a protein determines how it can fold and how it interacts with other molecules in the cell to perform its function. The primary structures of all of the diverse human proteins are synthesized from 20 amino acids arranged in a linear sequence determined by the genetic code.

The genetic code is the sequence of three bases (nucleotides) in DNA that contains the information for the linear sequence of amino acids in a polypeptide chain (its primary structure). A gene is the portion of DNA that encodes a functional product, such as a polypeptide chain. Mutations, which are changes in the nucleotides in a gene, result in a change in the products of that gene that may be inherited. The inherited disease sickle cell anemia, for example, is caused by a mutation in the gene that encodes one of the subunits of hemoglobin. Hemoglobin is the protein present in red blood cells that reversibly binds O₂ and transports it to tissues. The adult hemoglobin protein comprises four polypeptide chains, 2 α and 2 β . The α and β subunits differ in their primary structure (i.e., they have different sequences of amino acids and are encoded by different genes). Sickle cell anemia is caused by a single-nucleotide mutation in DNA that changes just one amino acid in the hemoglobin β -chains from a glutamic acid to a valine.

General Properties of Amino Acids. Each of the amino acids used for protein synthesis has the same general structure (Fig. 6.1A). It contains a **carboxylic acid group**, an **amino group** attached to the **α -carbon** in an **L-configuration**, a **hydrogen atom**, and a chemical group called a **side chain** that is different for each amino acid. In solution, at physiologic pH, the free amino acids exist as **zwitterions**: ions in which the amino group is positively charged and the carboxylate group is negatively charged (see Fig. 6.1B). In proteins, these amino acids are joined into linear polymers called **polypeptide chains** through **peptide bonds** between the carboxylic acid group of one amino acid and the amino group of the next amino acid.

A**B**

FIGURE 6.1 A. General structure of the amino acids found in proteins. **B.** Dissociation of the α -carboxyl and α -amino groups of amino acids. At physiologic pH (~ 7), a form in which both the α -carboxyl and α -amino groups are charged predominates. Some amino acids also have ionizable groups on their side chains. pK_a , $-\log$ of the acid dissociation constant; R , side chain.

Classification of Amino Acids According to Chemical Properties of the Side Chains. The chemical properties of the side chain determine the types of bonds and interactions each amino acid in a polypeptide chain can make with other molecules. Thus, amino acids are often grouped by polarity of the side chain (**charged**, **nonpolar hydrophobic**, or **uncharged polar**) or by structural features (**aliphatic**, **cyclic**, or **aromatic**). The side chains of the **nonpolar hydrophobic** amino acids (alanine, valine, leucine, isoleucine, phenylalanine, and methionine) cluster together to exclude water in the **hydrophobic effect**. The **uncharged polar** amino acids (serine, threonine, tyrosine, asparagine, and glutamine) participate in **hydrogen bonding**.

Cysteine, which contains a sulfhydryl group, forms **disulfide bonds**. The negatively charged **acidic** amino acids (aspartate and glutamate) form **ionic (electrostatic) bonds** with positively charged molecules, such as the **basic** amino acids (lysine, arginine, and histidine). The charge on the amino acid at a particular pH is determined by the pK_a ($-\log$ of the acid **dissociation constant**) of each group that has a dissociable proton.

Amino Acid Substitutions in the Primary Structure. Mutations in the genetic code result in proteins with an altered **primary structure**. Mutations resulting in single amino acid substitutions can affect the functioning of a protein or can confer an advantage specific to a tissue or a set of circumstances. Many proteins, such as **hemoglobin**, exist in the human population as **polymorphisms** (genetically determined variations in primary structure).

Within the same individual, the primary structure of many proteins varies with the stage of development and is present in **fetal** and **adult isoforms**, such as fetal and adult hemoglobin. The primary structure of some proteins, such as **creatine kinase**, can also vary between tissues (**tissue-specific isozymes**) or between intracellular locations in the same tissue. **Electrophoretic separation** of tissue-specific isozymes has been useful in medicine as a means of identifying the tissue site of injury.

Modified Amino Acids. In addition to the amino acids encoded by DNA that form the primary structure of proteins, many proteins contain specific amino acids that have been modified by **phosphorylation**, **oxidation**, **carboxylation**, or other reactions. When these reactions are enzyme-catalyzed, they are referred to as **posttranslational modifications**.

THE WAITING ROOM

Will S. is a 17-year-old boy who presented to the hospital emergency department with severe pain in his lower back, abdomen, and legs, which began after a 2-day history of nausea and vomiting caused by gastroenteritis. He was diagnosed as having sickle cell disease at age 3 years and has been admitted to the hospital on numerous occasions for similar vaso-occlusive sickle cell crises.

On admission, the patient's hemoglobin level in peripheral venous blood was 7.8 g/dL (reference range, 12 to 16 g/dL). The hematocrit or packed cell volume (the percentage of the total volume of blood made up of red blood cells) was 23.4% (reference range, 41% to 53%). His serum total bilirubin level (a pigment derived from hemoglobin degradation) was 2.3 mg/dL (reference range, 0.2 to 1.0 mg/dL). A radiograph of his abdomen showed radiopaque stones in his gallbladder. With chronic hemolysis (red blood cell destruction), the amount of heme degraded to bilirubin is increased. These stones are the result of the chronic excretion of excessive amounts of bilirubin from the liver into the bile, leading to bilirubinate crystal deposition in the gallbladder lumen.

David K. is a 16-year-old boy who was brought to the hospital by his mother because of the sudden onset of severe pain in his left flank, radiating around his left side toward his pubic area. His urine was reddish-brown in

 color, and a urinalysis showed the presence of many red blood cells. When his urine was acidified with acetic acid, clusters of flat hexagonal transparent crystals of cystine were noted. There was no family history of kidney stone disease.

 **Dianne A.**, who has type 1 diabetes mellitus, has to give herself subcutaneous injections of insulin several times a day to try to mimic what her pancreas would do if she could produce insulin. Insulin was initially purified from animals, and then synthetic human insulin was developed. There is now modified synthetic insulin, which allows the onset of action to be adjusted. She takes long-acting insulin (glargine) once a day, and rapid-acting insulin (lispro) with meals. Her physician will adjust the doses to keep her blood glucose levels controlled.

 The term **calculus** is used to describe any abnormal concretion (concretelike precipitate) of mineral salts. These almost always form within the cavity of a hollow organ, such as the kidney (kidney or renal stones) or the lumen of a duct (e.g., common bile duct stones).

 **Anne J.** is a 54-year-old woman who is 68 in tall and weighs 198 lb. She has a history of high blood pressure and elevated serum cholesterol levels. Following a heated argument with a neighbor, she experienced a “tight pressure-like band of pain” across her chest, associated with shortness of breath, sweating, and a sense of light-headedness.

 The term **angina** describes a crushing or compressive pain. The term **angina pectoris** is used when this pain is located in the center of the chest or pectoral region, often radiating to the neck or arms. The most common mechanism for the latter symptom is a decreased supply of oxygen to the heart muscle caused by atherosclerotic coronary artery disease, which results in obstruction of the vessels that supply arterial blood to cardiac muscle.

After 5 hours of intermittent chest pain, she went to the hospital emergency department, where her electrocardiogram showed changes consistent with acute cardiac ischemia and blood was sent to the laboratory for various tests, including a determination of cardiac troponin T (TnT) levels. She was given medications to treat her acute cardiac ischemia.

I. General Structure of the Amino Acids

Twenty different amino acids are commonly found in proteins. They are all α -amino acids—amino acids in which the amino group is attached to the α -carbon (the carbon atom next to the carboxylate group) (see Fig. 6.1A). The α -carbon has two additional substituents: a hydrogen atom and an additional chemical group called a side chain ($-R$). The side chain is different for each amino acid.

At a physiologic pH of 7.4, the amino group on these amino acids carries a positive charge and the carboxylic acid group is negatively charged (see Fig. 6.1B). The pK_a of the primary carboxylic acid groups for all of the amino acids is approximately 2 (1.8 to 2.4). At pH values much lower than the pK_a (higher hydrogen ion concentrations), all of the carboxylic acid groups are protonated. At the pK_a , 50% of the molecules are dissociated into carboxylate anions and protons, and at a pH of 7.4, over 99% of the molecules are dissociated (see Chapter 4). The pK_a for all of the α -amino groups is approximately 9.5 (8.8 to 11.0), so that at the lower pH of 7.4, most of the amino groups are fully protonated and carry a positive charge. The form of an amino acid that has both a positive and a negative charge is called a **zwitterion**. Because these charged chemical groups can form hydrogen bonds with water molecules, all of these amino acids are water-soluble at physiologic pH.

 Bilirubin is a degradation product of hemoglobin, and its levels are elevated in **Will S.** Bilirubin can be present in serum either conjugated to glucuronic acid (which is determined by the direct measurement) or free (which is very hydrophobic and is determined by the indirect measurement). Measurement of bilirubin in serum is dependent on the reaction of bilirubin with a diazotized sulfonic acid, which generates, after appropriate treatments, a blue azobilirubin. The intensity of the blue color can be determined spectrophotometrically at 600 nm. Total bilirubin is measured in the presence of caffeine-benzoate, which separates the hydrophobic nonconjugated bilirubin from its binding partners. A second measurement is done in the absence of caffeine-benzoate, which will only determine the conjugated, soluble forms of bilirubin (the direct measurement). Unconjugated bilirubin is then calculated by determining the difference in values obtained in the presence and absence of caffeine-benzoate (the indirect measurement). Recently, a transcutaneous device has been developed to determine bilirubin levels in newborns. The instrument is pressed against the infant's forehead, and light at various wavelengths is transmitted through the forehead, generating a reflective multiwavelength spectrum. Analysis of the spectrum allows the instrument to

determine the levels of bilirubin, hemoglobin, and melanin in the infant's skin.

In all of the amino acids but glycine (where the side chain is a hydrogen), the α -carbon is an asymmetric carbon atom that has four different substituents and can exist in either the D- or L-configuration (Fig. 6.2). The amino acids in mammalian proteins are all L-amino acids represented with the amino group to the left if the carboxyl group is at the top of the structure. These same amino acids serve as precursors of nitrogen-containing compounds that are synthesized in the body, and thus human amino acid metabolism is also centered on L-amino acids. The amino acid glycine is neither D nor L because the α -carbon atom contains two hydrogen atoms and is not an asymmetric carbon.

FIGURE 6.2 L- and D-Amino acids. The L-forms are the only ones found in human proteins. Bonds coming out of the paper are shown by *black arrows*; those going in, by *shaded arrows*. The α -amino groups and H atoms come toward the reader, and the α -carboxyl and side chains go away from the reader. The L- and D-forms are mirror images that cannot be superimposed by rotating the molecule. The reference for the L- and D-forms is the stereoisomers of glyceraldehyde (see Fig. 5.10A). *R*, side chain.

The chemical properties of the amino acids give each protein its unique characteristics. Proteins are composed of one or more linear **polypeptide chains** and may contain hundreds of amino acids. The sequence of amino acids, termed the **primary structure**, is determined by the genetic code for the protein. In the polypeptide chains, amino acids are joined through **peptide bonds** between the carboxylic acid of one amino acid and the amino group of the adjacent amino acid (Fig. 6.3, see also Fig. 1.5). Thus, the amino group, the α -carbon, and the carboxyl groups form the peptide backbone, and the side chains of the amino acids extend outward from this backbone. The side chains interact with the peptide backbone of other regions of the chain or with the side chains of other amino acids in the protein to form hydrophobic regions, electrostatic bonds, hydrogen bonds, or disulfide bonds. These interactions dictate the folding pattern of the molecule. The three-dimensional folding of the protein forms distinct regions called **binding sites** that are lined with amino acid side chains that interact specifically with another molecule termed a **ligand** (such as the heme in hemoglobin). Thus, the chemical properties of the side chains determine how the protein folds, how it binds specific ligands, and how it interacts with its environment (such as the aqueous medium of the cytoplasm). Each chain will have a **carboxyl terminal** and an **amino terminal**. The amino terminal is the first amino acid in the chain, which contains a free amino group. The carboxyl terminal is the last amino acid in the chain, which contains a free carboxylate group.

FIGURE 6.3 Peptide bonds. Amino acids in a polypeptide chain are joined through peptide bonds between the carboxyl group of one amino acid and the amino group of the next amino acid in the sequence. *R*, side chain.

II. Classification of Amino Acid Side Chains

In Figure 6.4, the 20 amino acids used for protein synthesis are grouped into different classifications according to the polarity and structural features of the side chains. These groupings can be helpful in describing common functional roles or metabolic pathways of the amino acids. However, some amino acid side chains fit into a number of different classifications and are therefore grouped differently in different textbooks. Two of the characteristics of the side chain that are useful for classification are its pK_a and its hydrophobic index, listed in Table 6.1. The hydrophobic index is a scale used to denote the hydrophobicity of the side chain; the more positive the hydrophobic index, the greater is the tendency to cluster with other nonpolar molecules and exclude water in the hydrophobic effect. These hydrophobic side chains tend to occur in membranes or in the center of a folded protein, where water is excluded. The more negative the hydrophobic index of an amino acid, the more hydrophilic is its side chain.

TABLE 6.1 Properties of the Common Amino Acids

AMINO ACID	PK_{a1}^a (CARBOXYL)	PK_{a2} (AMINO)	PK_{aR} (R GROUP)	HYDROPATHY INDEX ^b
Nonpolar aliphatic				
Glycine	2.4	9.8		-0.4
Proline	2.0	11.0		-1.6
Alanine	2.3	9.7		1.8
Leucine	2.4	9.6		3.8
Valine	2.3	9.6		4.2
Isoleucine	2.4	9.7		4.5
Aromatic				
Phenylalanine	1.8	9.1		2.8
Tyrosine	2.2	9.1	10.5	-1.3
Tryptophan	2.4	9.4		-0.9
Polar uncharged				
Threonine	2.1	9.6	13.6	-0.7
Serine	2.2	9.2	13.6	-0.8
Asparagine	2.0	8.8		-3.5
Glutamine	2.2	9.1		-3.5
Sulfur-containing				
Cysteine	2.0	10.3	8.4	2.5
Methionine	2.3	9.2		1.9
Charged negative				
Aspartate	1.9	9.6	3.9	-3.5
Glutamate	2.2	9.7	4.1	-3.5
Charged positive				
Histidine	1.8	9.3	6.0	-3.2
Lysine	2.2	9.0	10.5	-3.9
Arginine	2.2	9.0	12.5	-4.5
Average	2.2	9.5		

^aWhen these amino acids reside in proteins, the pK_a for the side chains may vary to some extent from the value for the free amino acid, depending on the local environment of the amino acid in the three-dimensional structure of the protein.

^bThe hydrophathy index is a measure of the hydrophobicity of the amino acid (the higher the number, the more hydrophobic). Values based on Kyte J, Doolittle RF. A simple method for displaying the hydrophobic character of a protein. *J Mol Biol.* 1982;157:105-132.

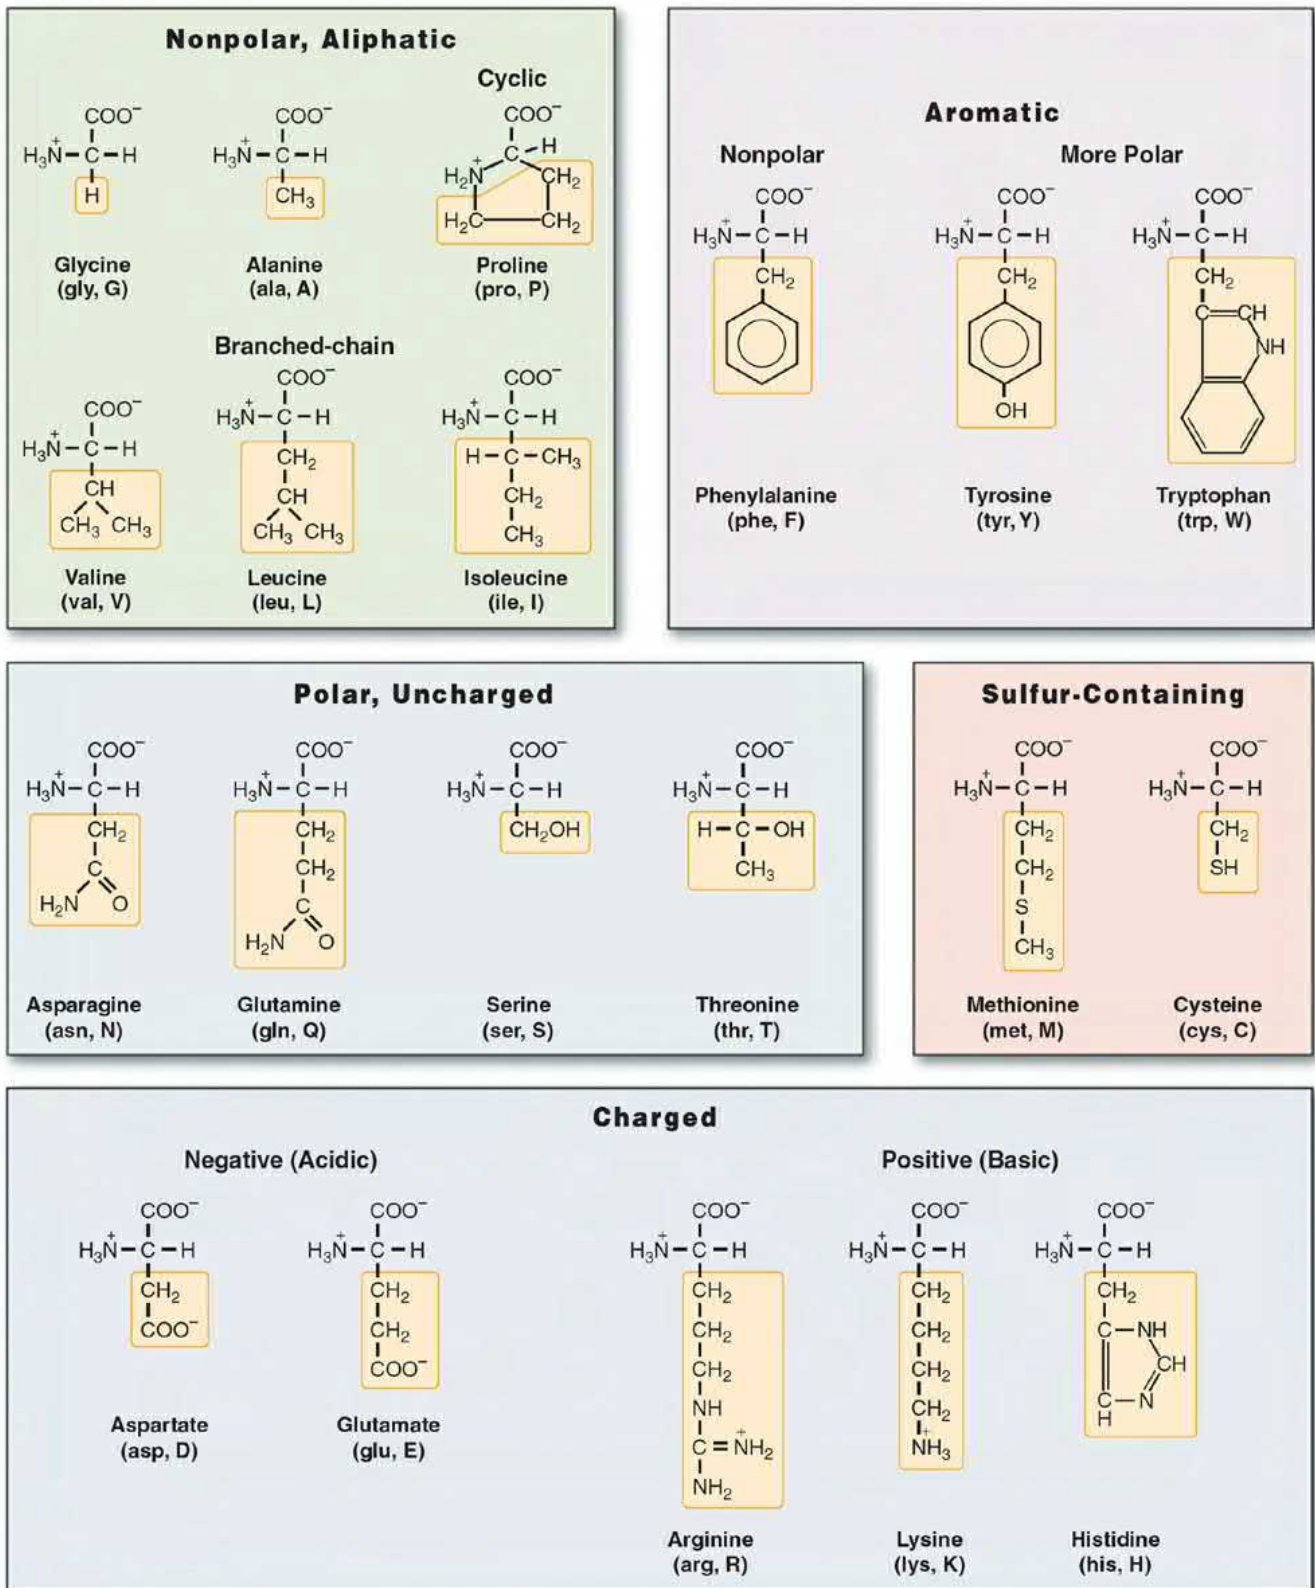

FIGURE 6.4 The side chains of the amino acids. The side chains are *highlighted*. The amino acids are grouped by the polarity and structural features of their side chains. These groupings are not absolute, however. Tyrosine and tryptophan, often listed with the nonpolar amino acids, are more polar than other aromatic amino acids because of their phenolic and indole rings, respectively. The single-letter and three-letter codes are also indicated for each amino acid.

The names of the different amino acids have been given three-letter and one-letter abbreviations (see Fig. 6.4). The three-letter abbreviations use the first two letters in the name plus the third letter of the name or the letter of a characteristic sound, such as “trp” for tryptophan. The one-letter abbreviations use the first letter of

the name of the most frequent amino acid in proteins (such as an “A” for alanine). If the first letter has already been assigned, the letter of a characteristic sound is used (such as an “R” for arginine). Single-letter abbreviations are usually used to denote the amino acids in a polypeptide sequence.

A. Nonpolar, Aliphatic Amino Acids

Glycine is the simplest amino acid, and it does not fit well into any classification because its side chain is just a hydrogen atom. Because the side chain of glycine is so small compared with that of other amino acids, it causes the least amount of steric hindrance in a protein (i.e., it does not significantly impinge on the space occupied by other atoms or chemical groups). Therefore, glycine is often found in bends or in the tightly packed chains of fibrous proteins.

The proteolytic digestive enzyme chymotrypsin cleaves the peptide bonds formed by the carboxyl groups of large, bulky uncharged amino acids. Which amino acids fall into this category?

Alanine and the branched-chain amino acids (valine, leucine, and isoleucine) have bulky, nonpolar, **aliphatic** (open-chain hydrocarbons) side chains and exhibit a high degree of hydrophobicity (see Table 6.1). Electrons are shared equally between the carbon and hydrogen atoms in these side chains, so that they cannot hydrogen bond with water. Within proteins, these amino acid side chains will cluster together to form hydrophobic cores. Their association is also promoted by van der Waals forces between the positively charged nucleus of one atom and the electron cloud of another. This force is effective over short distances when many atoms pack closely together.

The role of proline in amino acid structure differs from those of the nonpolar amino acids. The amino acid proline contains a ring involving its α -carbon and its α -amino group, which are part of the peptide backbone. It is an imino acid. This rigid ring causes a kink in the peptide backbone that prevents it from forming its usual configuration and it will restrict the conformation of the protein at that point.

Chymotrypsin's highest activity is toward peptide bonds formed by the carboxyl groups of aromatic amino acids (phenylalanine, tyrosine, tryptophan). The side chains of these amino acids are all large and uncharged. One of the chymotrypsin isozymes also exhibits activity toward leucine and methionine, which are similar in polarity.

B. Aromatic Amino Acids

The **aromatic** amino acids have been grouped together because they all contain ring structures with similar properties, but their polarities differ a great deal. The aromatic ring is a six-membered carbon–hydrogen ring with three conjugated double bonds (the benzene ring or phenyl group). These hydrogen atoms do not participate in hydrogen bonding. The substituents on this ring determine whether the amino acid side chain engages in polar or hydrophobic interactions. In the amino acid phenylalanine, the ring contains no substituents, and the electrons are shared equally between the carbons in the ring, resulting in a very nonpolar hydrophobic structure in which the rings can stack on each other (Fig. 6.5). In tyrosine, a hydroxyl group on the phenyl ring engages in hydrogen bonds, and the side chain is therefore more polar and more hydrophilic. The more complex ring structure in tryptophan is an indole ring with a nitrogen that can engage in hydrogen bonds. Tryptophan is therefore also more polar than phenylalanine.

Will S. has sickle cell anemia caused by a point mutation in his DNA that changes the sixth amino acid in the β -globin chain of hemoglobin from glutamate to valine. What difference would you expect to find in the chemical bonds formed by these two amino acids?

C. Aliphatic, Polar, Uncharged Amino Acids

Amino acids with side chains that contain an amide group (asparagine and glutamine) or a hydroxyl group (serine and threonine) can be classified as aliphatic, polar, uncharged amino acids. Asparagine and glutamine are amides of the amino acids aspartate and glutamate. The hydroxyl groups and the amide groups in the side chains allow these amino acids to form hydrogen bonds with water, with each other and the peptide backbone, or with other polar compounds in the binding sites of the proteins (see Fig. 6.5). As a consequence of their hydrophilicity, these amino acids are frequently found on the surface of water-soluble globular proteins. Cysteine, which is sometimes included in this class of amino acids, has been separated into the class of sulfur-containing amino acids.

D. Sulfur-Containing Amino Acids

Both cysteine and methionine contain sulfur. The side chain of cysteine contains a sulfhydryl group that has a pK_a of approximately 8.4 for dissociation of its hydrogen, so cysteine is predominantly undissociated and uncharged at the physiologic pH of 7.4. The free cysteine molecule in solution can form a covalent disulfide bond with another cysteine molecule through spontaneous (nonenzymatic) oxidation of their sulfhydryl groups. The resultant amino acid, cystine, is present in blood and tissues, and is not very water-soluble. In proteins, the formation of a cystine disulfide bond between two appropriately positioned cysteine sulfhydryl groups often plays an important role in holding two polypeptide chains or two different regions of a chain together (Fig. 6.6). Methionine, although it contains a sulfur group, is a nonpolar amino acid with a large bulky side chain that is hydrophobic. It does not contain a sulfhydryl group and cannot form disulfide bonds. Its important and central role in metabolism is related to its ability, when appropriately activated, to transfer the methyl group attached to the sulfur atom to other compounds.

E. The Acidic and Basic Amino Acids

The amino acids aspartate and glutamate have carboxylic acid groups that carry a negative charge at physiologic pH (see Fig. 6.4). The basic amino acids histidine, lysine, and arginine have side chains containing nitrogen that can be protonated and positively charged at physiologic and lower pH values. Histidine has a nitrogen-containing imidazole ring for a side chain, lysine has a primary amino group on the ϵ -carbon (from the sequence α , β , γ , δ , ϵ), and arginine has a guanidinium group.

The positive charges on the basic amino acids enables them to form ionic bonds (electrostatic bonds) with negatively charged groups, such as the side chains of acidic amino acids or the phosphate groups of coenzymes (Fig. 6.7). In addition, lysine and arginine side chains often form ionic bonds with negatively charged compounds bound to the protein binding sites, such as the phosphate groups in adenosine triphosphate (ATP). The acidic and basic amino acid side chains also participate in hydrogen bonding and the formation of salt bridges (e.g., the binding of an inorganic ion such as Na^+ between two partially or fully negatively charged groups).

FIGURE 6.7 Electrostatic interaction between the positively charged side chain of lysine and the negatively charged side chain of aspartate.

David K. passed a renal stone shortly after admission, which immediately relieved his pain. Its major component was identified as cystine. Normally, amino acids are filtered by glomerular capillaries into the tubular urine but are almost entirely reabsorbed from this fluid back into the blood via transport proteins in the proximal tubular cells. **David K.** has cystinuria, an inherited amino acid substitution in the transport protein that reabsorbs cystine, arginine, and lysine. Therefore, his urine contained high amounts of these amino acids. Cystine, which is less soluble than other amino acids, precipitates in the urine to form renal stones (calculi).

The charge on these amino acids at physiologic pH is a function of their pK_a for dissociation of protons from the α -carboxylic acid groups, the α -amino groups, and the side chains. The titration curve of histidine illustrates the changes in amino acid structure that occurs as the pH of the solution is changed from <1 to 14 by the addition of hydroxide ions (Fig. 6.8). At low pH, all groups carry protons, amino groups have a positive

charge, and carboxylic acid groups have zero charge. As the pH is increased by the addition of alkali (OH^-), the proton dissociates from the carboxylic acid group, and its charge changes from 0 to -1 with a pK_a of approximately 2, the pH at which 50% of the protons have dissociated.

FIGURE 6.8 Titration curve of histidine. The ionic species that predominates in each region is shown below the graph. pI is the isoelectric point (the pH at which there is no net charge on the molecule). pK_a , $-\log$ of the acid dissociation constant; R, side chain.

The histidine side chain is an imidazole ring with a pK_a of about 6 that changes from a predominantly protonated positively charged ring to an uncharged ring at this pH. The amino group on the α -carbon titrates at a much higher pH (between 9 and 10), and the charge changes from $+1$ to 0 as the pH rises. The pH at which the net charge on the molecules in solution is zero is called the **isoelectric point (pI)**. At this pH, the molecules will not migrate in an electric field toward either a positive pole (cathode) or a negative pole (anode), because the number of negative charges on each molecule is equal to the number of positive charges.

A Glutamate carries a negative charge on its side chain at physiologic pH and thus can engage in ionic bonds or hydrogen bonds with water or other side chains. Valine is a hydrophobic amino acid and therefore tends to interact with other hydrophobic side chains to exclude water.

Amino acid side chains change from uncharged to negatively charged, or positively charged to uncharged as they release protons (Fig. 6.9). The acidic amino acids lose a proton from their carboxylic acid side chains at a pH of roughly 4 and are thus negatively charged at pH 7.4. Cysteine and tyrosine lose protons at their pK_a

(~8.4 and 10.5, respectively), so their side chains are uncharged at physiologic pH. Histidine, lysine, and arginine side chains change from positively charged to neutral at their pK_a . The side chains of the two basic amino acids, arginine and lysine, have pK_a values above 10, so that the positively charged form always predominates at physiologic pH. The side chain of histidine ($pK_a \sim 6.0$) dissociates near physiologic pH, so only a portion of the histidine side chains carry a positive charge (see Fig. 6.8).

	Form that predominates below the pK_a	pK_a	Form that predominates above the pK_a
Aspartate	$\text{---CH}_2\text{---COOH}$	3.9	$\text{---CH}_2\text{---COO}^- + \text{H}^+$
Glutamate	$\text{---CH}_2\text{---CH}_2\text{---COOH}$	4.1	$\text{---CH}_2\text{---CH}_2\text{---COO}^- + \text{H}^+$
Histidine	$\text{---CH}_2\text{---}$ 	6.0	$\text{---CH}_2\text{---}$  $+ \text{H}^+$
Cysteine	$\text{---CH}_2\text{SH}$	8.4	$\text{---CH}_2\text{S}^- + \text{H}^+$
Tyrosine	$\text{---CH}_2\text{---}$ 	10.5	$\text{---CH}_2\text{---}$  $+ \text{H}^+$
Lysine	$\text{---CH}_2\text{---CH}_2\text{---CH}_2\text{---CH}_2\text{---NH}_3^+$	10.5	$\text{---CH}_2\text{---CH}_2\text{---CH}_2\text{---CH}_2\text{---NH}_2 + \text{H}^+$
Arginine	$\text{---CH}_2\text{---CH}_2\text{---CH}_2\text{---NH---C} \begin{matrix} \text{NH}_2 \\ \text{NH}_2 \end{matrix}$	12.5	$\text{---CH}_2\text{---CH}_2\text{---CH}_2\text{---NH---C} \begin{matrix} \text{NH} \\ \text{NH}_2 \end{matrix} + \text{H}^+$

FIGURE 6.9 Dissociation of the side chains of the amino acids. As the pH increases, the charge on the side chain goes from 0 to negative (-) or from positive (+) to 0. The pK_a is the pH at which half the molecules of an amino acid in solution have side chains that are charged. Half are uncharged. pK_a , -log of the acid dissociation constant.

In proteins, only the amino acid side chains, the amino group at the amino terminal, and the carboxyl group at the carboxyl terminal have dissociable protons. All of the other carboxylic acid and amino groups on the α -carbons are joined in peptide bonds that have no dissociable protons. The amino acid side chains might have very different pK_a values than those of the free amino acids if they are involved in hydrogen or ionic bonds with other amino acid side chains. The pK_a of the imidazole group of histidine, for example, is often shifted to a higher value between 6 and 7 so that it adds and releases a proton in the physiologic pH range.

Electrophoresis, a technique used to separate proteins on the basis of charge, has been extremely useful in medicine to identify proteins with different amino acid compositions. The net charge on a protein at a certain pH is a summation of all of the positive and negative charges on all of the ionizable amino acid side chains plus the *N*-terminal amino and *C*-terminal carboxyl groups. Theoretically, the net charge of a protein at any pH could be determined from its amino acid composition by calculating the concentration of positively and negatively charged groups from the Henderson-Hasselbalch equation (see Chapter 4). However, hydrogen bonds and ionic bonds between amino acid side chains in the protein, which can alter pK_a values, make this calculation unrealistic.

Is the substitution of a glutamate for a valine in sickle cell hemoglobin a conservative replacement? What about the substitution of an aspartate for a glutamate?

III. Variations in Primary Structure

The primary structure of a protein is its linear sequence of amino acids. Although almost every amino acid in the primary structure of a protein contributes to its conformation (three-dimensional structure), the primary structure of a protein can vary to some degree between species. Even within the human species, the amino acid sequence of a normal functional protein can vary somewhat among individuals, tissues of the same individual, and the stage of development. These variations in the primary structure of a functional protein are tolerated if they are confined to noncritical regions (called variant regions), if they are conservative substitutions (replace one amino acid with one of similar structure), or if they confer an advantage. If many different amino acid residues are tolerated at a position, the region is called **hypervariable**. In contrast, the regions that form binding sites or are critical for forming a functional three-dimensional structure are usually **invariant** regions that have exactly the same amino acid sequence from individual to individual, tissue to tissue, or species to species.

A. Polymorphism in Protein Structure

Within the human population, the primary structure of a protein may vary slightly among individuals. The variations generally arise from mutations in DNA that are passed to the next generation. The mutations can result from the substitution of one base for another in the DNA sequence of nucleotides (a point mutation), from deletion or insertions of bases into DNA, or from larger changes (see Chapter 12). For many alleles, the variation has a distinct phenotypic consequence that contributes to our individual characteristics, produces an obvious dysfunction (a congenital or inherited disease), or increases susceptibility to certain diseases. A defective protein may differ from the most common allele by as little as a single amino acid that is a nonconservative substitution (replacement of one amino acid with another of a different polarity or very different size) in an invariant region. Such mutations might affect the ability of the protein to carry out its function, catalyze a particular reaction, reach the appropriate site in a cell, or be degraded. For other proteins, the variations appear to have no significance.

For the most part, human chromosomes occur as homologous pairs, with each member of a pair containing the same genetic information. One member of the pair is inherited from the mother and one from the father. Genes are arranged linearly along each chromosome. A genetic locus is a specific position or location on a chromosome. Alleles are alternative versions of a gene at a given locus. For each locus (site), we have two alleles of each gene, one from our mother and one from our father. If both alleles of a gene are identical, the individual is homozygous for this gene; if the alleles are different, the individual is heterozygous for this gene. **Will S.** has two identical alleles for the sickle variant of the β -globin gene that results in substitution of a valine for a glutamate residue at the sixth position of the β -globin chain. He is therefore homozygous for the sickle cell allele and has sickle cell anemia. Individuals with one normal gene and one sickle cell allele are heterozygous. They are carriers of the disease and have sickle cell trait.

Variants of an allele that occur with a significant frequency in the population are referred to as polymorphisms. Thus far in studies of the human genome, almost one-third of the genetic loci appear to be polymorphic. When a particular variation of an allele, or polymorphism, increases in the general population to a frequency of $>1\%$, it is considered stable. The sickle cell allele is an example of a point mutation that is stable in the human population. Its persistence is probably the result of selective pressure for the heterozygous mutant phenotype, which confers some protection against malaria.

B. Tissue and Developmental Variations in Protein Structure

Within the same individual, different **isoforms** or **isozymes** of a protein may be synthesized during different stages of fetal and embryonic development, may be present in different tissues, or may reside in different intracellular locations. Isoforms of a protein all have the same function. If they are isozymes (isoforms of enzymes), they catalyze the same reactions. However, isoforms have somewhat different properties and amino acid structure.

1. Developmental Variation

Hemoglobin isoforms provide an example of variation during development. Hemoglobin (Hb) is expressed as the fetal isozyme HbF during the last trimester of pregnancy until after birth, when it is replaced with HbA. HbF is composed of two hemoglobin α and two hemoglobin γ polypeptide chains, in contrast to the adult hemoglobin, hemoglobin A, which has two α - and two β -chains. During the embryonic stages of development,

chains with a different amino acid composition, the embryonic ϵ - and ζ -chains, are produced. These differences are believed to arise evolutionarily from mutation of a duplicated α gene to produce ζ , and mutation of a duplicate β gene to produce ϵ . The fetal and embryonic forms of hemoglobin have a much higher affinity for O_2 than the adult forms and thus confer an advantage at the low O_2 tensions to which the fetus is exposed. At different stages of development, the globin genes specific for that stage are expressed and translated (this is discussed in more detail in Chapter 42, Section V).

The substitution of a glutamate for a valine is a nonconservative replacement because a negatively charged amino acid is substituted for a hydrophobic branched-chain aliphatic amino acid. However, the substitution of an aspartate for a glutamate is a conservative replacement because the two amino acids have the same polarity and are nearly the same size.

2. Tissue-Specific Isoforms

Proteins that differ somewhat in primary structure and properties from tissue to tissue, but that retain essentially the same function, are called **tissue-specific isoforms** or **isozymes**. The enzyme creatine kinase (CK) is an example of a protein that exists as tissue-specific isozymes, each composed of two subunits with 60% to 72% sequence homology (similarity between sequences). Of the two CKs that bind to the muscle sarcomere, the M form is produced in skeletal muscle and the B polypeptide chains are produced in the brain. The protein is composed of two subunits; therefore, the skeletal muscle produces an MM creatine kinase and the brain produces a BB form. The heart produces both types of chains and therefore forms a heterodimer, MB, as well as the homodimers. Two more CK isozymes are found in mitochondria—a heart mitochondrial CK and the “universal” isoform found in other tissues. In general, most proteins that are present in both the mitochondria and cytosol will be present as different isoforms. The advantage conferred on different tissues by having their own isoform of CK is unknown. However, tissue-specific isozymes such as MB creatine kinase can be useful in diagnosing sites of tissue injury and cell death.

Will S.'s hemoglobin, HbS, is composed of two normal α -chains and two β -globin chains with the sickle cell variant ($\alpha_2\beta_2^S$). The change in amino acid composition from a glutamate to a valine in the β -chain allows sickle hemoglobin to be separated from normal adult hemoglobin (HbA, or $\alpha_2\beta_2^A$) by electrophoresis. In electrophoresis, an aliquot of blood or other solution containing proteins is applied to a support, such as paper or a gel. An electrical field is applied and the proteins migrate a distance toward the anode (negative pole) or cathode (positive pole) depending on their net charge. Because β^S contains one less negative charge than β^A , it will migrate differently in an electric field. Individuals with sickle cell trait are heterozygous and express both HbA and HbS, plus small amounts of HbF (fetal hemoglobin, $\alpha_2\gamma_2$).

In heterozygous individuals with sickle cell trait, the sickle cell allele provides some protection against malaria. Malaria is caused by the parasite *Plasmodium falciparum*, which spends part of its life cycle in red blood cells. The infected red blood cells of individuals with normal hemoglobin (HbA) develop protrusions that attach to the lining of capillaries. This attachment occludes the vessels and prevents oxygen from reaching cells in the affected region, resulting in cell death. In heterozygous individuals, HbS in infected cells aggregates into long fibers that cause the cell to become distorted. These distorted cells containing the malarial parasite are preferentially recognized by the spleen and are rapidly destroyed, thus ending the life of the parasite.

In **Will S.** and other homozygous individuals with sickle cell anemia, the red blood cells sickle more frequently than in heterozygotes, especially under conditions of low oxygen tension (see Chapter 7). The result is a vaso-occlusive crisis in which the sickled cells clog capillaries and prevent oxygen from reaching cells (ischemia), thereby causing pain. The enhanced destruction of the sickled cells by the spleen results in anemia. Consequently, the sickle cell allele is of little advantage to homozygous individuals.

Because heterozygous individuals occur more frequently in a population than homozygous individuals, a selective advantage in a heterozygous state can outweigh a disadvantage in a homozygous state, causing the mutation to become a stable polymorphism in a population. As a consequence, sickle cell anemia occurs more frequently in people who are from or have ancestors from parts of the world where malaria is or was common. This includes sub-Saharan Africa, India, Saudi Arabia, and Mediterranean countries.

The structure of proteins involved in the response to hormones has been studied in greater depth than many other types of proteins, and most of these proteins are present as several tissue-specific isoforms that help different tissues respond differently to the same hormone. One of these proteins present in cell membranes is adenylyl cyclase, an enzyme that catalyzes the synthesis of intracellular 3',5'-cyclic adenosine monophosphate (cAMP) (Fig. 6.10). In human tissues, at least nine different isoforms of adenylyl cyclase are coded by different genes in different tissues. Although they have an overall sequence homology of 50%, the two intracellular regions involved in the synthesis of cAMP are an invariant consensus sequence with a 93% identity. The different isoforms help cells respond differently to the same hormone.

Extracellular side

Intracellular side

FIGURE 6.10 Invariant regions in the isoforms of adenylyl cyclase. The invariant regions are on the cytosolic side of the membrane in the C1 and C2 loops shown in red. These amino acid residues participate in the catalytic function of the enzyme, synthesis of 3',5'-cyclic adenosine monophosphate. The protein also has several helical regions that span the membrane (M_1 and M_2 helices), represented as tubes. An oligosaccharide chain is attached to an extracellular domain. N is the amino terminus. (From Taussig R, Gilman AG. Mammalian membrane-bound adenylyl cyclases. *J Biol Chem.* 1995;270(1):1-4. <https://creativecommons.org/licenses/by/4.0/>)

C. Species Variations in the Primary Structure of Insulin

Species variations in primary structure are also important in medicine, as illustrated by the comparison of human, beef, and pork insulin. **Insulin** is one of the hormones that are highly conserved between species, with very few amino acid substitutions and none in the regions that affect activity. Insulin is a polypeptide hormone of 51 amino acids that is composed of two polypeptide chains (Fig. 6.11). It is synthesized as a single polypeptide chain but is cleaved in three places before secretion to form the C-peptide and the active insulin molecule containing the A and B chains. The folding of the A and B chains into the correct three-dimensional structure is promoted by the presence of one intrachain and two interchain disulfide bonds formed by cysteine residues. The invariant residues consist of the cysteine residues engaged in disulfide bonds and the residues that form the surface of the insulin molecule that binds to the insulin receptor. The amino acid substitutions in bovine and porcine insulin (shown in red in Fig. 6.11) are not in amino acids that affect its activity. Consequently, bovine and pork insulin were used for many years for the treatment of diabetes mellitus. However, even with only a few different amino acids, some patients developed an immune response to these forms of insulin.

FIGURE 6.11 The primary structure of human insulin. The substituted amino acids in bovine (beef) and porcine (pork) insulin are shown in red. Threonine 30 at the carboxyl terminal of the B chain is replaced by alanine in both beef and pork insulin. In beef insulin, threonine 8 on the A chain is also replaced with alanine, and isoleucine 10 with valine. The cysteine residues, which form the disulfide bonds (shown in blue) holding the chains together, are invariant. In the bioengineered insulin Humalog (lispro insulin), the positions of proline at B28 and lysine at B29 are switched. Insulin is synthesized as a longer precursor molecule, proinsulin, which is one polypeptide chain. Proinsulin is converted to insulin by proteolytic cleavage of certain peptide bonds (*squiggly lines* in the figure). The cleavage removes a few amino acids and the 31-amino acid C-peptide that connects the A and B chains. The active insulin molecule thus has two nonidentical chains.

Proteins can also be described as belonging to families and superfamilies. Further discussion of such classifications can be found in the online supplement to this chapter.

A myocardial infarction (heart attack) is caused by an atheromatous obstruction and/or a severe spasm in a coronary artery that prevents the flow of blood to an area of heart muscle distal to the obstruction. Thus, heart cells in this region suffer from a lack of oxygen and blood-borne fuel. Because the cells cannot generate ATP, the membranes become damaged, and enzymes leak from the cells into the blood.

The blood test of choice to determine whether cell damage has occurred is the cardiac troponins level. Creatine kinase (see next paragraph) was originally utilized for this determination, but the introduction of very sensitive assays for troponin led to the recommendation of using troponin measurements to follow the course of heart damage.

Creatine kinase (CK or CPK) assays are still performed to measure skeletal muscle injury. The protein is composed of two subunits, which may be either of the muscle (M) or the brain (B) type. The MB form, containing one M and one B subunit, is found primarily in cardiac muscle.

Although bovine (beef) insulin is identical to human insulin in those amino acid residues essential for activity, the amino acid residues that are in the variable regions can act as antigens and stimulate the formation of antibodies against bovine insulin. Consequently, recombinant DNA techniques have been used for the synthesis of human insulins, such as Humulin (intermediate-acting) or Humalog (rapid acting, also known as lispro) (see Chapter 17 for information on recombinant DNA technology). There are no longer animal-sourced insulins manufactured in the United States.

IV. Modified Amino Acids

After synthesis of a protein has been completed, a few amino acid residues in the primary sequence may be further modified in enzyme-catalyzed reactions that add a chemical group, oxidize, or otherwise modify specific amino acids in the protein. Because protein synthesis occurs by a process known as translation, these changes are called posttranslational modification. More than 100 different posttranslationally modified amino acid residues have been found in human proteins. These modifications change the structure of one or more specific amino acids on a protein in a way that may serve a regulatory function, target or anchor the protein in membranes, enhance a protein's association with other proteins, or target it for degradation (Fig. 6.12). Posttranslational modifications usually occur once the protein has already folded into its three-dimensional

conformation.

Carbohydrate addition

O-glycosylation: OH of ser, thr, tyr,

N-glycosylation: NH_2 of asn

Lipid addition

Palmitoylation: Internal SH of cys

Myristoylation: NH of N-terminal gly

Prenylation: SH of cys

Regulation

Phosphorylation: OH of ser, thr, tyr

Acetylation: NH_2 of lys, N-terminus

ADP-ribosylation: N of arg, gln; S of cys

Modified amino acids

Oxidation: pro, lys

Carboxylation: glu

FIGURE 6.12 Posttranslational modifications of amino acids in proteins. Some of the common amino acid modifications and the sites of attachment are illustrated. The added group is shown in red. Because these modifications are enzyme-catalyzed, only a specific amino acid in the primary sequence is altered. *R-O-* represents additional carbohydrates attached to the first carbohydrate. In *N*-glycosylation, the attached sugar is usually *N*-acetylglucosamine (*N*-Ac). Not all prenylated proteins are modified to contain an *O*-methyl carboxyl terminal.

A number of pathogenic bacteria produce bacterial toxins that are ADP-ribosyltransferases (NAD^+ -glycohydrolases). These enzymes hydrolyze the *N*-glycosidic bond of NAD^+ and transfer the ADP-ribose portion to a specific amino acid residue on a protein in the affected human cell. Cholera AB toxin, a pertussis toxin, and a diphtheria toxin are all ADP-ribosyltransferases.

A. Glycosylation

Glycosylation refers to the addition of carbohydrates to a molecule. In *O*-glycosylation, oligosaccharides (small carbohydrate chains) are bound to serine or threonine residues in proteins by *O*-linkages. In *N*-glycosylation, the carbohydrates are bound by *N*-linkage to the amide nitrogen of asparagine (see Fig. 6.12). *N*-linked oligosaccharides are found attached to cell-surface proteins, where they protect the cell from proteolysis or an immune attack. In contrast, an *O*-glycosidic link is a common way of attaching oligosaccharides to the serine or threonine hydroxyl groups in secreted proteins. The intracellular polysaccharide glycogen is attached to a protein through an *O*-glycosidic linkage to a tyrosine. Adenylyl cyclase is an example of an enzyme that is posttranslationally modified (see Fig. 6.10). It has an oligosaccharide chain attached to the external portion of the protein.

B. Fatty Acylation or Prenylation

The addition of lipids to a molecule is called fatty acylation. Many membrane proteins contain a covalently attached lipid group that interacts hydrophobically with lipids in the membrane. Palmitoyl groups (C16) are often attached to plasma membrane proteins, and the myristoyl group (C14) is often attached to proteins in the lipid membranes of intracellular vesicles (myristoylation, see Fig. 6.12). Prenylation involves the addition of the farnesyl group (C15) or geranylgeranyl groups (C20), which are synthesized from the five-carbon isoprene unit (isopentenyl pyrophosphate, see Fig. 5.1A). These are attached in thioether linkage to a specific cysteine residue of certain membrane proteins, particularly proteins involved in regulation.

The switch in position of amino acids in lispro does not affect the action of this synthetic insulin on cells because it is not in a critical invariant region, but it does affect the ability of insulin to bind zinc. Normally, human insulin is secreted from the pancreas as a zinc hexamer in which six insulin molecules are bound to the zinc atom. When zinc insulin is injected, the binding to zinc slows the absorption from the subcutaneous (under the skin) injection site. Lispro cannot bind zinc to form a hexamer, and thus, it is absorbed much more quickly than other forms of insulin.

C. Regulatory Modifications

Phosphorylation, acetylation, and adenosine diphosphate (ADP)-ribosylation of specific amino acid residues in a polypeptide can alter bonding by that residue and change the activity of the protein (see Fig. 6.12). Phosphorylation of the hydroxyl group on serine, threonine, or tyrosine by a protein kinase (an enzyme that transfers a phosphate group from ATP to a protein) introduces a large, bulky, negatively charged group that can alter the structure and activity of a protein. Some of the isozymes of adenylyl cyclase contain serine residues on the intracellular portion of the protein that can be phosphorylated by a protein kinase. Reversible acetylation occurring on lysine residues of histone proteins in chromatin changes their interaction with the negatively charged phosphate groups of DNA. ADP-ribosylation is the transfer of an ADP-ribose from nicotinamide adenine dinucleotide (NAD^+) to an arginine, glutamine, or a cysteine residue on a target protein in the membrane (primarily in leukocytes, skeletal muscles, brain, and testes). This modification may regulate the activity of these proteins.

D. Other Amino Acid Posttranslational Modifications

A number of other posttranslational modifications of amino acid side chains alter the activity of the protein in the cell (see Fig. 6.12). Carboxylation of the γ -carbon of glutamate (carbon 4) in certain blood-clotting proteins is important for attaching the clot to a surface. Calcium ions mediate this attachment by binding to the two

negatively charged carboxyl groups of γ -glutamate and two additional negatively charged groups provided by phospholipids in the cell membrane. Collagen, an abundant fibrous extracellular protein, contains the oxidized amino acid hydroxyproline. The addition of the hydroxyl group (hydroxylation) to the proline side chain provides an extra polar group that can engage in hydrogen bonding between the polypeptide strands of the fibrous protein and stabilize its structure.

E. Selenocysteine

The unusual amino acid selenocysteine is found in a few enzymes and is required for their activity (Fig. 6.13). Its synthesis is not a posttranslational modification, however, but a modification to serine that occurs while serine is bound to a unique tRNA (see Chapter 14). A selenium atom replaces the hydroxyl group of serine. The selenocysteine is then inserted into the protein as it is being synthesized.

FIGURE 6.13 Selenocysteine.

CLINICAL COMMENTS

Will S. was treated for 3 days with parenteral (not by mouth/digestion) narcotics, intravenous hydration, and nasal inhalation of oxygen for his vaso-occlusive crisis. The diffuse severe pains of sickle cell crises result from occlusion of small vessels in a variety of tissues, thereby causing damage to cells from ischemia (low blood flow) or hypoxia (low levels of oxygen). Vaso-occlusion occurs when sickle hemoglobin (HbS) molecules in red blood cells polymerize in the lumen of capillaries, where the partial pressure of O_2 ($p\text{O}_2$) is low. This polymerization causes the red blood cells to change from a biconcave disc to a sickle shape that cannot deform to pass through the narrow capillary lumen. The cells aggregate in the capillaries and occlude blood flow. In addition, once he recovered from his sickle cell crisis, **Will S.** was treated with hydroxyurea therapy, which increases the production of red blood cells containing fetal hemoglobin. Fetal hemoglobin molecules cannot participate in sickling and can decrease the frequency at which sickle crises occur.

Will S.'s acute symptoms gradually subsided. Patients with sickle cell anemia periodically experience sickle cell crises, and his physician urged him to seek medical help whenever symptoms reappeared. He also counseled him to try to avoid triggers of sickle cell crisis: overexertion, dehydration, extremely cold weather, and exposure to tobacco.

David K. has cystinuria, a relatively rare disorder, with a prevalence that ranges between 1 in 2,500 and 1 in 15,000 births, depending on the population studied. It is a genetically determined disease with a complex recessive mode of inheritance resulting from allelic mutations. These mutations lead to a reduction in the activity of renal tubular cell transport proteins that normally carry cystine

from the tubular lumen into the renal tubular cells. The transport of the basic amino acids (lysine, arginine, and ornithine, an amino acid found in the urea cycle but not in proteins) is also often compromised, and they appear in the urine.

Because cystine is produced by oxidation of cysteine, conservative treatment of cystinuria includes decreasing the amount of cysteine within the body and, therefore, the amount of cystine eventually filtered by the kidneys. Reduction of cysteine levels is accomplished by restricting dietary methionine, which contributes its sulfur to the pathway for cysteine formation. To increase the amount of cystine that remains in solution, the volume of fluid ingested daily is increased. Crystallization of cystine is further prevented by chronically alkalinizing the urine. Finally, drugs may be administered to enhance the conversion of urinary cystine to more soluble compounds. If these conservative measures fail to prevent continued cystine stone formation, existing stones may be removed by a surgical technique that involves sonic fracture of the stones. The fragmented stones may then pass spontaneously or may be more easily extracted surgically because of their smaller size.

Dianne A. takes insulin several times a day. Insulin was initially purified from animals before synthetic human insulin was developed. Humulin (synthetic insulin, Eli Lilly and Company, Indianapolis, Indiana, USA) is mass-produced by recombinant DNA techniques that insert the human DNA sequences for the insulin A and B chains into the *Escherichia coli* or yeast genome (see Chapter 16). The insulin chains that are produced are then extracted from the media and treated to form the appropriate disulfide bonds between the chains.

Her physician then recommended that she take Humalog, an insulin preparation containing lispro, an ultrafast-acting bioengineered insulin analog in which lysine at position B29 has been moved to B28 and proline at B28 has been moved to B29 (hence, lispro, Eli Lilly and Company, Indianapolis, Indiana, USA) (see Fig. 6.11). With lispro, she will be able to time her injections of this rapidly acting insulin minutes before her consumption of carbohydrate-containing meals, rather than having to remember to give herself an insulin injection 1 hour before a meal. She will also take a long-acting insulin shot once a day (Lantus, Sanofi-Aventi, Bridgewater, New Jersey, USA), along with her Humalog shots prior to meals each day.

Anne J. continued to be monitored in the cardiac care unit. The physicians followed the trends of troponin T (TnT) in her blood. Cardiac troponin levels (TnT and TnI) are normally undetectable in the blood; however, after myocardial damage these cardiac markers leak into the blood and can be detected within 2 to 3 hours after the event. The levels will slowly decline over the next 5 to 7 days after the event. This is advantageous when compared to using creatine kinase as a cardiac marker, which takes longer after the event to be detected, and returns to baseline in less time than troponin levels. Creatine kinase elevation could also be because of skeletal muscle exertion. Historically, physicians would also follow the total CK and CK-MB levels, but this has essentially been replaced by following troponin levels.

BIOCHEMICAL COMMENTS

Nucleic Acid, Enzyme, and Protein Databases. Large databases of nucleic acid sequences and protein structure have been assembled to collate data from various laboratories around the world. The National Library of Medicine maintains a Web site, PubMed, which catalogs the medical literature, and a search engine that allows you to search for reference articles by topic or author (www.ncbi.nlm.nih.gov/pubmed). From the menu, you can enter a nucleic acid, protein, or a structure database directly. These databases are linked, so you can type in the name of a protein, such as human hemoglobin chain A, obtain a list of contributors to sequence data, and retrieve a complete amino acid sequence for many proteins. You can link to PubMed to find recent articles about the protein, or you can link to the structure database. A program called Cn3D can be downloaded and utilized from this site that allows you to view three-dimensional versions of the protein structures.

These databases are only a few of more than 1000 biologic databases that have been assembled to collate and exchange biologic information in the areas of DNA, RNA, genomics, gene mapping, and protein structure. The first issue of the *Journal of Nucleic Acid Research* each year provides a description of currently available biologic databases (as of 1/1/2021, 1641 different databases were available). Their goal is to provide information that can relate a particular DNA sequence or mutation to the protein involved, to its function, and to the pathologic consequences of a particular amino acid substitution, by comparing proteins that have similar functional elements.

Two of the very useful databases accessible to scientists are GenBank (www.ncbi.nlm.nih.gov/genbank) and the RCSB (Research Collaboratory for Structural Bioinformatics) protein data bank (www.rcsb.org). GenBank is a nucleic acid sequence database, which is linked to the DNA Data Bank of Japan (DDBJ) and the European Molecular Biology Laboratory (EMBL) database. The three databases exchange information every day, so all are current. GenBank allows for submission of new sequences as well as searches for existing sequences. One can also do a BLAST search (Basic Logical Alignment Search Tool) to compare a nucleic acid sequence of unknown origin with those in the database to detect comparable sequences in existing genes and to garner an understanding of what the gene from which the unknown sequence was obtained may do.

The RCSB protein data bank allows one to search for proteins, to examine the amino acid sequence of the protein (and the nucleic acid sequence which led to the protein sequence; see Section III of this text), and to visualize the protein's structure in a three-dimensional format. One can also search the database with an amino acid sequence from a protein with no known function to determine if other proteins contain similar sequences, which will give clues as to the function of the unknown protein.

The field of bioinformatics is developing new tools for scientists to appropriately mine the large amount of data becoming available through nucleic acid and protein structure databases. Will these databases be of any use to the practicing physician or to the practice-oriented medical student? Very few students will ever want to do protein modeling. However, students and physicians may wish to use the literature search in PubMed as part of their approach to evidence-based medicine. They also may wish to use it to track definitions or fundamental knowledge about particular topics. Thus, biomedical and basic science textbooks are also being linked to PubMed.

KEY CONCEPTS

- ◆ A protein's unique characteristics, including its three-dimensional folded structure, are dictated by its linear sequence of amino acids, termed its primary structure.
- ◆ The primary structures of all of the diverse human proteins are synthesized from 20 amino acids arranged in a linear sequence determined by the genetic code.
- ◆ Each three-base (nucleotide) sequence within the coding region of a gene (the genetic code) specifies which amino acid should be present in a protein. The genetic code is discussed further in Chapter 11.
- ◆ All amino acids contain a central α -carbon joined to a carboxylic acid group, an amino group, a hydrogen, and a side chain, which varies among the 20 different amino acids.
- ◆ At physiologic pH the amino acids are zwitterions; the amino group is positively charged, and the carboxylate is negatively charged.
- ◆ In proteins, amino acids are joined into linear polymers called polypeptide chains via peptide bonds, which are formed between the carboxylic acid of one amino acid and the amino group of the next amino acid.
- ◆ Amino acid side chains can be classified either by polarity (charged, nonpolar hydrophobic, or uncharged polar) or structural features (aliphatic, cyclic, or aromatic).
- ◆ Depending on their side-chain characteristics, certain amino acids cluster together to exclude water (hydrophobic effect), whereas others participate in hydrogen bonding. Cysteine can form disulfide bonds, whereas charged amino acids can form ionic bonds.
- ◆ Amino acids in proteins can be modified by phosphorylation, carboxylation, or other reactions after the protein is synthesized (posttranslational modifications).
- ◆ Alterations in the genetic code may lead to mutations in the protein's primary structure, which can affect the protein's function.
- ◆ Proteins with the same function but different primary structures (isoforms and isozymes) can exist in different tissues or during different phases of development.
- ◆ Diseases discussed in this chapter are summarized in Table 6.2.

TABLE 6.2 Diseases Discussed in Chapter 6

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
Sickle cell anemia	Genetic	Single amino acid replacement at the sixth position of the β -chain of hemoglobin, leading to an E6V alteration (instead of

		glutamic acid at position 6, a valine is in its place)
Cystinuria	Genetic	Inability to appropriately transport cystine, leading to its accumulation in the kidney and the formation of kidney stones
Type 1 diabetes	Both	Understanding the structure of insulin, and how it is absorbed at injection sites, allows various forms of insulin to be synthesized that are either rapidly or slowly absorbed. This provides type 1 diabetic patients with a variety of treatment options.
Myocardial infarction	Both	Primarily environmental factors, which can be exacerbated by genetic conditions. The release of heart-specific isozymes into the circulation is diagnostic for a heart attack.

REVIEW QUESTIONS—CHAPTER 6

- Sickle cell anemia is caused by a single-nucleotide change in DNA that leads to the substitution of one amino acid (E6V) in the β -chain. This one change in the primary sequence leads to the ability of the deoxygenated form of HbS to form polymers. As the polymers grow in size, the shape of the red blood cell is altered to accommodate the chains of hemoglobin. Which one of the following primarily dictates the polymerization of deoxygenated HbS?
 - The peptide backbone
 - Ionic interactions
 - Hydrophobic interactions
 - Hydrogen bonds
 - Peptide bonds
- One of the main sources of nonvolatile acid in the body is sulfuric acid generated from the sulfur-containing compounds in ingested food or from the metabolism of the sulfur-containing amino acids. Which of the following amino acids would lead to sulfuric acid formation?
 - Cysteine and isoleucine
 - Cysteine and alanine
 - Cysteine and methionine
 - Methionine and isoleucine
 - Isoleucine and alanine
- Dianne A.**'s different preparations of insulin contain some insulin complexed with protamine that is absorbed slowly after injection. Protamine is a protein preparation from rainbow trout sperm containing arginine-rich peptides that bind insulin. Which one of the following provides the best explanation for complex formation between protamine and insulin?
 - Arginine is a basic amino acid that binds to negatively charged amino acid side chains in insulin.
 - Arginine is a basic amino acid that binds to the α -carboxylic acid groups at the *N*-terminals of insulin chains.
 - Arginine is a large, bulky hydrophobic amino acid that complexes with leucine and phenylalanine in insulin.
 - Arginine forms disulfide bonds with the cysteine residues that hold the A and B chains together.
 - Arginine has a side chain that forms peptide bonds with the carboxyl terminals of the insulin chains.
- Phosphorylation of proteins is an important component of signal transduction. Protein kinases phosphorylate proteins only at certain hydroxyl groups on amino acid side chains. Which of the following groups of amino acids contain side-chain hydroxyl groups and could be a potential substrate for such a protein kinase?
 - Aspartate, glutamate, and serine
 - Serine, threonine, and tyrosine
 - Threonine, phenylalanine, and arginine
 - Lysine, arginine, and proline
 - Alanine, asparagine, and serine
- A protein's activity is altered when a particular serine side chain is phosphorylated. Which of the following amino acid substitutions at this position could lead to a permanent alteration in normal enzyme activity?
 - S \rightarrow E

- B. S → T
 - C. S → Y
 - D. S → K
 - E. S → L
6. Proteins, which are composed of amino acids, help transport lipids in the bloodstream. These proteins need to be able to cluster with other nonpolar molecules and exclude water. Which of the following would best describe the side chains of these amino acids in the lipid transport proteins?
- A. A more positive hydrophobic index
 - B. A more negative hydrophobic index
 - C. A neutral hydrophobic index
 - D. A pK_a of the primary carboxylic acid group of approximately 2
 - E. A pK_a of the α -amino group of approximately 9.5
7. A patient with high cholesterol begins taking a statin medication and develops myalgias (muscle soreness and aches). The physician orders CK (creatinase kinase) levels to check for muscle damage, a known side effect of statins. Lab results show a higher than normal level of CK-MM. Which one of the following best describes CK-MM?
- A. Heterodimer
 - B. Isozyme
 - C. Produced by the brain
 - D. Produced by the heart
 - E. Produced by the liver
8. All of the amino acids that are used to synthesize human proteins (with the exception of glycine) have which one of the following in common?
- A. An aromatic group
 - B. A hydroxyl group
 - C. An asymmetric carbon in the D-configuration
 - D. An asymmetric carbon in the L-configuration
 - E. An asymmetric β -carbon
- Questions 9 and 10 refer to the following patient.*
A patient with recurrent kidney stones is found to have an inherited amino acid substitution in a transport protein that reabsorbs certain amino acids from the glomerular filtrate so they are not lost in the urine.
9. Which of the following amino acid groups are not reabsorbed from the glomerular filtrate in this disease process?
- A. Cysteine, methionine, and arginine
 - B. Cysteine, methionine, and lysine
 - C. Cysteine, arginine, and lysine
 - D. Methionine, arginine, and lysine
 - E. Methionine, arginine, and histidine
10. Which one of the following amino acids is most responsible for this patient's recurrent kidney stones?
- A. Cysteine
 - B. Methionine
 - C. Arginine
 - D. Lysine
 - E. Histidine
11. A protein loses activity with a V96L mutation. Activity can be restored to the protein by introducing a second mutation, V172A. The most likely possible explanation for this finding is which one of the following?
- A. Substitution of one hydrophilic residue for another restores activity
 - B. The V96L mutation disrupts an ionic interaction stabilizing the protein structure, whereas the V172A mutation allows restoration of the ionic interaction
 - C. The V96L mutation disrupted hydrogen bond stabilization of the structure, whereas the V172A mutation allowed restoration of the hydrogen bond interactions
 - D. The V96L mutation introduced steric hindrance into the structure, whereas the V172A relieved the steric hindrance introduced by the first mutation
 - E. The V96L mutation disrupted a disulfide bond, whereas introducing the V172A mutation allowed the disulfide bond to re-form

2. The enzyme that catalyzes the first step in glycolysis converts glucose to glucose 6-phosphate. The liver form of this enzyme is encoded by a different gene than the muscle form of this enzyme. The different forms of the enzyme can best be described as which one of the following?
 - A. Isomers
 - B. Epimers
 - C. Stereoisomers
 - D. Isozymes
 - E. Mirror images
3. An enzyme has an aspartic acid side chain, which is critical for enzyme activity. The pH optimum of the enzyme is 5.5, and studies have shown that at pH 5.5 this critical aspartic acid side chain is in its protonated state. This can occur due to which one of the following?
 - A. The aspartic acid side chain is in a hydrophobic environment within the protein.
 - B. The aspartic acid side chain is surrounded by K and R amino acid side chains.
 - C. The pK_a for this aspartic acid side chain is reduced by the structure of the enzyme.
 - D. The aspartic acid side chain is stabilized by ionic interactions within the protein.
 - E. The aspartic acid side chain is involved in hydrogen bond formation with L and V side chains.
4. Protein X (156 amino acids long) is normally targeted to the membrane via a posttranslational modification. A variant of X has been studied that lost the ability to be translocated to the membrane, and the protein is instead targeted for degradation within the endoplasmic reticulum. Which of the following mutations could lead to these findings?
 - A. S55L
 - B. N62R
 - C. C153S
 - D. Y154F
 - E. L15V
5. A local hospital is treating a patient with the symptoms of excessive insulin release into the blood. A method to determine if the patient took an insulin overdose would be to measure which one of the following in the patient's blood?
 - A. The A-peptide of insulin
 - B. The B-peptide of insulin
 - C. The C-peptide of insulin
 - D. The levels of zinc ions
 - E. The levels of calcium ions

ANSWERS TO REVIEW QUESTIONS

1. **The answer is C.** In the sickle version of hemoglobin, a valine has replaced a glutamate in the sixth position of the β -chain. In the deoxygenated state, the valine forms hydrophobic interactions with a hydrophobic patch on another sickle hemoglobin molecule, leading to polymerization of the hemoglobin molecules. The primary interaction is not the result of ionic interactions or hydrogen bonding; it is the hydrophobic interactions between molecules that initiate the polymerization. The peptide backbone, along with peptide bonds, can participate in hydrogen bonding but does not play a role in polymerization.
2. **The answer is C.** Cysteine and methionine are the sulfur-containing amino acids. Both isoleucine and alanine are nonpolar hydrophobic amino acids, and neither contains sulfur.
3. **The answer is A.** Arginine is a basic amino acid that has a positively charged side chain at neutral pH. It can, therefore, form tight electrostatic bonds with negatively charged aspartic acid and glutamic acid side chains in insulin. The α -carboxylic acid groups at the *N*-terminals of proteins are bound through peptide bonds (thus, B is incorrect). The arginine side chain is not hydrophobic, and it cannot form disulfide bonds because it has no sulfhydryl group (thus, C and D are incorrect). Its basic group is a guanidinium group that cannot form peptide bonds (thus, answer E is incorrect).
4. **The answer is B.** Only the amino acids serine, threonine, and tyrosine have side-chain hydroxyl groups. As a general rule, serine–threonine protein kinases form one group of protein kinases, and tyrosine protein kinases form another.
5. **The answer is A.** Adding a phosphate group to the serine side chain adds negative charges to the side chain, allowing ionic interactions to develop. These new ionic interactions allow the protein to change

shape and to alter its activity. Substituting a glutamate for the serine adds a negative charge to this location within the protein, which may participate in ionic interactions and lead to a shape change in the protein. None of the other suggested mutations (serine to either threonine [which adds a hydroxyl group, just as serine has], to tyrosine [again, another hydroxyl containing amino acid side chain], to lysine [adding a positive charge rather than a negative charge], or to leucine [a totally hydrophobic side chain]) will lead to the insertion of negative charges at this location in the protein.

6. **The answer is A.** The hydrophobic index is a scale that denotes the hydrophobicity of the side chains. The more positive the hydrophobic index, the greater the hydrophobicity of the side chain. The pK_a of the primary carboxylic acid group for all the amino acids is around 2 and the pK_a of the α -amino groups of all the amino acids is approximately 9.5, but these elements of the protein do not contribute to the protein's hydrophobic nature.
7. **The answer is B.** Proteins that differ somewhat in primary structure from tissue to tissue but retain essentially the same function are called tissue-specific isoforms or isozymes. CK is a classic example of this. Muscle produces the M form, brain the B form, and heart both, leading to an MB form (a heterodimer). Because the protein consists of two subunits, muscle produces CK-MM, a homodimer. By measuring specific isozymes of CK, one can determine if there is skeletal muscle damage (CK-MM) or heart-specific damage (elevated levels of CK-MB).
8. **The answer is D.** Each of the amino acids used for protein synthesis has the same general structure. Each contains a carboxylic acid group, an amino group attached to the α -carbon, a hydrogen atom, and a side chain. When the α -carbon is asymmetric, the configuration about that carbon is in the L-configuration. Glycine is excluded because its side chain is a hydrogen atom, and there is no asymmetric carbon atom in glycine.
9. **The answer is C.** The patient described has cystinuria, an inherited amino acid substitution in the transport protein that reabsorbs cysteine, arginine, and lysine from the glomerular filtrate. Therefore, these amino acids cannot be returned to the blood and the urine contains large amounts of these amino acids.
10. **The answer is A.** Cysteine will be oxidized to form cystine (a dimer of cysteine linked by a disulfide bond). Cystine is less soluble than the other amino acids indicated as answers and precipitates in the kidney, forming renal stones (kidney stones or calculi). Cystine is also found in the urine in elevated amounts, leading to cystinuria.
11. **The answer is D.** The first mutation, V96L, places a bulkier leucine side chain in the protein in place of a valine residue. The leucine is too large to fit at this location in the protein, leading to a conformational change in the protein which reduces its activity. The second mutation, V172A, places a smaller alanine side chain in place of valine, and provides more "space" for the leucine at position 96 to fit within the protein (this explanation requires that V96 and V172 face each other in the same area of the folded protein). By providing more space for the leucine residue, and because both L and A are hydrophobic, as is V, the normal structure of the protein can be maintained. V, L, and A have hydrophobic side chains and cannot participate in ionic bond formation, or hydrogen bond formation. They also do not contain sulfhydryl groups and cannot participate in disulfide bond formation.
12. **The answer is D.** Proteins that catalyze the same reaction, but are encoded by different genes, are known as isoforms or isozymes. The terms isomer, epimer, stereoisomer, and mirror images refer to chemicals (and in particular carbohydrates), but not to proteins.
13. **The answer is A.** The aspartic acid is in an environment that stabilizes the protonated form (and raises the pK_a). This could be one that allows hydrogen bonding of the protonated aspartic acid side chain with hydrogen bond acceptors (but not L or V side chains, which do not participate in hydrogen bonding), or in a hydrophobic environment such that a negative charge would be destabilizing to the structure in that environment. If the aspartate were in an environment surrounded by K and R residues, the pK_a of the aspartic acid group would drop, as the negatively charged form of the side chain would be stabilized by the presence of the positive charges on the K and R side chains.
14. **The answer is C.** Prenylation of cysteine side chains in proteins, near the C-terminus of the protein, will lead to membrane targeting of the protein because of the hydrophobic nature of the prenyl groups. Loss of the cysteine (single-letter code C) residue would lead to an inability to prenylate the protein and an inability to target the protein to the membrane.
15. **The answer is C.** Insulin is synthesized as a large precursor that undergoes proteolytic processing to produce mature insulin (consisting of the A and B chains) and the C-peptide, which is degraded. Taking exogenous insulin (e.g., by shots) does not lead to an elevation of C-peptide levels because recombinant

insulin is not produced with a C chain. Thus, if the patient had high levels of insulin, but very low levels of C-peptide, you would know that the patient was taking insulin by injections. If the levels of C-peptide were comparable to the levels of insulin, then you would suspect a pancreatic tumor that was secreting insulin all of the time.

Structure–Function Relationships in Proteins

A multitude of different proteins can be formed from only 20 common amino acids because these amino acids can be linked together in an enormous variety of sequences determined by the genetic code. The sequence of amino acids, its primary structure, determines the way a protein folds into a unique three-dimensional structure, which is its native conformation. Once it is folded, the three-dimensional structure of a protein forms binding sites for other molecules, thereby dictating the function of the protein in the body. In addition to creating binding sites, a protein must fold in such a way that it is flexible, stable, able to function in the correct site in the cell, and capable of being degraded by cellular enzymes.

Diseases can be caused by changes in protein structure that affect the protein's ability to bind other molecules and carry out its function. They also can be caused by conformational changes in proteins that affect their solubility and degradability. In amyloidosis/AL, immunoglobulin chains form an insoluble protein aggregate called amyloid in organs and tissues. Alzheimer disease and familial amyloid polyneuropathy are neurodegenerative diseases characterized by the deposition of amyloid. Prion diseases result from misfolding and aggregation of a normal cellular protein. Even in sickle cell anemia, the mutation in hemoglobin principally affects the quaternary structure of hemoglobin and its solubility, and not its ability to bind oxygen.

Levels of Protein Structure. Protein structure is described in terms of four different levels: primary, secondary, tertiary, and quaternary (Fig. 7.1). The **primary structure** of a protein is the linear sequence of amino acids in the polypeptide chain. **Secondary structure** consists of local regions of polypeptide chains formed into structures that are stabilized by a repeating pattern of hydrogen bonds, such as the regular structures called α -helices and β -sheets. The **rigidity of the peptide backbone** determines the types of secondary structure that can occur. The **tertiary structure** involves folding of the secondary structural elements into an overall three-dimensional conformation. In **globular proteins** such as **myoglobin**, the tertiary structure generally forms a densely packed **hydrophobic core** with polar amino acid side chains on the outside. Some proteins exhibit **quaternary structure**, the combination of two or more **subunits**, each composed of a polypeptide chain.

FIGURE 7.1 Levels of structure in a protein.

Domains and Folds. The tertiary structure of a globular protein can be made up of structural **domains**, regions of structure that fold independently. Multiple domains can be linked together to form a functional protein. Within a domain, a combination of secondary structural elements forms a fold, such as the **nucleotide-binding fold** or an **actin fold**. Folds are defined by their similarity in a number of different proteins.

Quaternary Structure. Assembly of globular polypeptide subunits into a multisubunit complex can provide the opportunity for **cooperative binding** of ligands (e.g., O_2 binding to hemoglobin), form **binding sites** for complex molecules (e.g., antigen binding to immunoglobulin), and increase **stability** of the protein. The polypeptide chains of **fibrous proteins** such as **collagen** are aligned along an axis, have repeating elements, and are extensively linked to each other through hydrogen and covalent bonds.

Ligand Binding. Proteins form binding sites for specific molecules, called **ligands** (e.g., adenosine triphosphate [ATP] or O_2), or for another protein. The affinity of a binding site for its ligand is characterized quantitatively by an **association** or **affinity constant**, K_a (or its **dissociation constant**, K_d , in which $K_d = 1/K_a$).

Folding of Proteins. The primary structure of a protein dictates the way that it folds into its tertiary structure, which is a **stable conformation** that is identical to the shape of other molecules of the same protein (i.e., its **native conformation**). **Chaperonins** act as templates to overcome the kinetic and thermodynamic barrier to reaching a stable conformation. **Prion proteins** cause neurodegenerative diseases by acting as a template for misfolding. Heat, acid, and other agents cause proteins to **denature**; that is, to unfold or refold and lose their native three-dimensional conformation.

THE WAITING ROOM

Will S., who has sickle cell anemia, was readmitted to the hospital with symptoms indicating that he was

experiencing another sickle cell crisis (see Chapter 6). Sickle cell disease is a result of improper aggregation of hemoglobin within the red blood cell.

Anne J. is a 54-year-old woman who arrived in the hospital 4 days ago, about 5 hours after she began to feel chest pain (see Chapter 6). In the emergency department, the physician drew blood for the measurement of cardiac troponin T subunit (cTN-T). The results from these tests had supported the diagnosis of an acute myocardial infarction (MI), and **Anne J.** was hospitalized.

The simplest test to detect protein in the urine is the use of specific reagent test strips. The strips are coated with tetrabromophenolblue, buffered at pH 3.0. In the presence of protein, the indicator dye is no longer as responsive to changes in pH as in the absence of protein. A yellow color indicates that protein is not detectable; as protein levels increase, the yellow color changes, going to green, then bluish-green. This is a useful qualitative test (which detects primarily serum albumin), but to be more quantitative, different dyes, which react specifically with particular amino acid side chains, are used. Different tests are required to detect the presence of a specific protein in the urine or sera, and these will be discussed in subsequent chapters.

Amy L. is a 62-year-old woman who presented with weakness, fatigue, an enlarged tongue (macroglossia), and edema. She had signs and symptoms of cardiac failure, including electrocardiographic abnormalities. Initial laboratory studies showed a serum creatinine of 1.9 mg/dL (reference range [females], 0.5 to 1.1 mg/dL), indicating mild renal failure. A urinalysis indicated the presence of a moderate proteinuria. She was subsequently diagnosed with amyloidosis/AL secondary to a plasma cell dyscrasia. Amyloidosis is a term that encompasses many diseases that share as a common feature the extracellular deposition of pathologic insoluble fibrillar proteins called **amyloid** in organs and tissues. In **Amy L.**'s disease, amyloidosis/AL, the amyloid is derived from immunoglobulin light chains (AL-5 amyloidosis, light-chain-related), and is the most common form of amyloidosis.

Dianne A. returned to her physician's office for a routine visit to monitor her treatment (see Chapters 4, 5, and 6). Her physician drew blood for an HbA_{1c} (pronounced hemoglobin A-1-c) determination. Her HbA_{1c} was 8.5%, which was above the normal level of <5.6% for a person without diabetes, and of <7.0% for a person with controlled diabetes.

I. General Characteristics of Three-Dimensional Structure

The overall conformation of a protein, the particular position of the amino acid side chains in three-dimensional space, determines the function of the protein.

A. Descriptions of Protein Structure

Proteins are generally grouped into major structural classifications: globular proteins, fibrous proteins, and transmembrane proteins. **Globular proteins** are usually soluble in aqueous medium and resemble irregular balls. The **fibrous proteins** are geometrically linear, arranged around a single axis, and have a repeating unit structure. Another general classification, **transmembrane proteins**, consists of proteins that have one or more regions aligned to cross the lipid membrane (see Fig. 6.10). **DNA-binding proteins**, although a member of the globular protein family, are sometimes classified separately and are considered in Chapter 15.

The structure of proteins is often described according to levels called primary, secondary, tertiary, and quaternary structure (see Fig. 7.1). The **primary structure** is the linear sequence of amino acid residues joined through peptide bonds to form a polypeptide chain. The **secondary structure** refers to recurring structures (such as the regular structure of the α -helix) that form in short localized regions of the polypeptide chain. The overall three-dimensional conformation of a protein is its **tertiary structure**, the summation of its secondary structural elements. The **quaternary structure** is the association of polypeptide subunits in a geometrically specific manner. The forces involved in a protein folding into its final conformation are primarily noncovalent interactions. These interactions include the attraction between positively and negatively charged molecules (ionic interactions), the hydrophobic effect, hydrogen bonding, and van der Waals interactions (the nonspecific attraction between closely packed atoms).

B. Requirements of the Three-Dimensional Structure

The overall three-dimensional structure of a protein must meet certain requirements to enable the protein to function in the cell or extracellular medium of the body. The first requirement is the creation of a binding site that is specific for just one molecule or a group of molecules with similar structural properties. The specific binding sites of a protein usually define its role. The three-dimensional structure must also exhibit the degrees of flexibility and rigidity appropriate to its specific function. Some rigidity is essential for the creation of binding sites and for a stable structure (i.e., a protein that is excessively flexible would have the potential to be dysfunctional). However, flexibility and mobility in structure enables the protein to fold as it is synthesized and to adapt as it binds other proteins and small molecules. The three-dimensional structure must have an external surface that is appropriate for its environment (e.g., cytoplasmic proteins need to keep polar amino acids on the surface to remain soluble in an aqueous environment). In addition, the conformation must also be stable, with little tendency to undergo refolding into a form that cannot fulfill its function or that precipitates in the cell. Finally, the protein must have a structure that can be degraded when it is damaged or no longer needed in the cell.

II. The Three-Dimensional Structure of the Peptide Backbone

The amino acids in a polypeptide chain are joined sequentially by peptide bonds between the carboxyl group of one amino acid and the amide group of the next amino acid in the sequence (Fig. 7.2). Usually, the peptide bond assumes a *trans* configuration in which successive α -carbons and their R groups are located on opposite sides of the peptide bond.

FIGURE 7.2 The peptide backbone. Because of the resonance nature of the peptide bond, the C and N of the peptide bonds form a series of rigid planes. Rotation within allowed torsion angles can occur around the bonds attached to the α -carbon. The side chains are *trans* to each other and alternate above and below the peptide chain. The actual peptide bond is a hybrid

between the resonance forms shown, resulting in a partial negative charge on the carbonyl oxygen, a partial positive charge on the nitrogen, and partial double-bond characteristic for the peptide bond itself.

The polypeptide backbone can bend in a very restricted way. The peptide bond itself is a hybrid of two **resonance structures**, one of which has double-bond characteristic, so that the carboxyl and amide groups that form the bond must remain planar (see Fig. 7.2). However, rotation within certain allowed angles (torsion angles) can occur around the bond between the α -carbon and the α -amino group and around the bond between the α -carbon and the carbonyl group. This rotation is subject to steric constraints that maximize the distance between atoms in the different amino acid side chains and prohibit torsion (rotation) angles that place the side-chain atoms too close to each other. These folding constraints, which depend on the specific amino acids present, limit the secondary and tertiary structures that can be formed from the polypeptide chain.

III. Secondary Structure

Regions within polypeptide chains form recurring, localized structures known as **secondary structures**. The two regular secondary structures called the **α -helix** and the **β -sheet** contain repeating elements formed by hydrogen bonding between atoms of the peptide bonds. Other regions of the polypeptide chain form nonregular, nonrepetitive secondary structures such as loops and coils.

A. The α -Helix

The α -helix is a common secondary structural element of globular proteins, membrane-spanning domains, and DNA-binding proteins. It has a rigid, stable conformation that maximizes hydrogen bonding while staying within the allowed rotation angles of the polypeptide backbone. The peptide backbone of the α -helix is formed by hydrogen bonds between each carbonyl oxygen atom and the amide hydrogen (N–H) of an amino acid residue located four residues farther down the chain (Fig. 7.3). Thus, each peptide bond is connected by hydrogen bonds to the peptide bond four amino acid residues ahead of it and four amino acid residues behind it in the amino acid sequence. The core of the helix is tightly packed, thereby maximizing association energies between atoms. The *trans* side chains of the amino acids project backward and outward from the helix, thereby avoiding steric hindrance with the polypeptide backbone and with each other (Fig. 7.4). The amino acid proline, because of its ring structure, cannot form the necessary bond angles to fit within an α -helix. Thus, proline is known as a “helix breaker” and is not found in the middle of α -helical regions of proteins, but can be found at the first or second position of an α -helical region.

FIGURE 7.3 The α -helix. Each oxygen atom of a carbonyl group of a peptide bond forms a hydrogen bond (indicated by the *black dots*) with the hydrogen atom attached to a nitrogen atom in a peptide bond four amino acids further along the chain. The result is a highly compact and rigid structure.

FIGURE 7.4 A view down the axis of an α -helix. The side chains (R) jut out from the helix. Steric hindrance occurs if they come within their van der Waals radii of each other, and a stable helix cannot form.

B. β -Sheets

β -Sheets are a second type of regular secondary structure that maximizes hydrogen bonding between the peptide backbones while maintaining the allowed torsion angles. In β -sheets, the hydrogen bonding usually occurs between regions of separate neighboring polypeptide strands aligned parallel to each other (Fig. 7.5A). Thus, the carbonyl oxygen of one peptide bond is hydrogen-bonded to the amide hydrogen of a peptide bond on an adjacent strand. This pattern contrasts with the α -helix, in which the peptide backbone hydrogen bonds are located within the same strand. Optimal hydrogen bonding occurs when the sheet is bent (pleated) to form β -pleated sheets.

FIGURE 7.5 **A.** A β -pleated sheet. In this case, the chains are oriented in opposite directions (antiparallel). The *large arrows* show the direction of the carboxy terminals. The amino acid side chains (R) in one strand are *trans* to each other and alternate above and below the plane of the sheet, which can have a hydrophobic face and a polar face that engages in hydrogen bonding. **B.** Hydrogen-bonding pattern with parallel β -strands.

The β -pleated sheet is described as parallel if the polypeptide strands run in the same direction (as defined by their amino and carboxyl terminals) and antiparallel if they run in opposite directions. Antiparallel strands are often the same polypeptide chain folded back on itself, with simple hairpin turns or long runs of polypeptide chain connecting the strands. The amino acid side chains of each polypeptide strand alternate between extending above and below the plane of the β -sheet (see Fig. 7.5). Parallel sheets tend to have hydrophobic residues on both sides of the sheets; antiparallel sheets usually have a hydrophobic side and a hydrophilic side. Frequently, sheets twist in one direction.

The hydrogen-bonding pattern is slightly different depending on whether one examines a parallel or antiparallel β -sheet (see Fig. 7.5B). In an antiparallel sheet, the atoms involved in hydrogen bonding are directly opposite to each other; in a parallel β -sheet, the atoms involved in the hydrogen bonding are slightly skewed from one another, such that one amino acid is hydrogen-bonded to two others in the opposite strand. Because the hydrogen bonds are at an angle in the parallel β -sheets the bonds are weaker than in an antiparallel β -sheet.

A renal biopsy used in the diagnosis of **Amy L.**'s disease showed amorphous deposits in the glomeruli. When stained with Congo red dye, these deposits appeared red with ordinary light microscopy and exhibited apple-green fluorescence when viewed in polarized light. This staining is characteristic of the amyloid fibril structure, which is composed of repeated β -sheets aligned orthogonally (perpendicular) to the axis of the fiber.

A number of diseases involve deposition of a characteristic amyloid fiber. However, in each of these diseases, the amyloid is derived from a different protein that has changed its conformation (three-dimensional structure) to that of the amyloid repeated β -sheet structure. Once amyloid deposition begins, it seems to proceed rapidly, as if the fibril itself were promoting formation and deposition of more fibrils (a phenomenon called “seeding”). The different clinical presentations in each of these diseases results from differences in the function of the native protein and the site of amyloid deposition.

C. Nonrepetitive Secondary Structures

α -Helices and β -pleated sheets are patterns of regular structure with a repeating element—the ordered formation of hydrogen bonds. In contrast, bends, loops, and turns are nonregular secondary structures that do

not have a repeating element of hydrogen bond formation. They are characterized by an abrupt change of direction and are often found on the protein surface. For example, β -turns are short regions that usually involve four successive amino acid residues. They often connect strands of antiparallel β -sheets (Fig. 7.6). The surface of large globular proteins usually has at least one omega loop: a structure with a neck like the capital Greek letter omega (Ω).

FIGURE 7.6 β -Turn. The four amino acid residues that form the β -turn (also called a *hairpin loop*) are held together by hydrogen bonds, which make this an extremely stable structure. The $C\alpha$ carbons of the amino acids are *numbered* in the figure.

D. Patterns of Secondary Structure

Figure 7.7 is a three-dimensional drawing of a globular domain in the soluble enzyme lactate dehydrogenase (LDH). It illustrates the combination of secondary structural elements to form patterns. This LDH domain is typical of globular proteins, which average approximately 31% α -helical structure and approximately 28% β -pleated sheets (with a wide range of variation). The helices of globular domains have an average span of approximately 12 residues, corresponding to approximately three to four helical turns, although many are much

longer. The β -sheets, represented in diagrams by an *arrow* for each strand, are an average of six residues long and six strands wide (2 to 15 strands). Like the β -sheet in the LDH domain, they generally twist to the right rather than lie flat (see Fig. 7.7). Most globular domains, such as this LDH domain, also contain motifs. Motifs are relatively small arrangements of secondary structure that are recognized in many different proteins. For example, certain of the β -strands are connected with α -helices to form the $\beta\alpha\beta$ structural motif.

Lactate dehydrogenase domain 1

FIGURE 7.7 Ribbon drawing showing the arrangement of secondary structures into a three-dimensional pattern in domain 1 of lactate dehydrogenase. The individual polypeptide strands in the six-stranded β -sheet are shown with *arrows*. Different strands are connected by helices and by nonrepetitive structures (turns, coils, and loops). This domain is the nucleotide-binding fold. Nicotinamide adenine dinucleotide (NAD^+) is bound to a site created by the helices (*upper left of figure, in green*). (Modified from Richardson JS. The anatomy and taxonomy of protein structure. *Adv Protein Chem.* 1981;34:167–339. Reprinted with permission from Jane S. Richardson.)

The remaining polypeptide segments connecting the helices and β -sheets are said to have a coil or loop conformation (see Fig. 7.7). Although some of the connecting segments recognized in many proteins have been given names (like the Ω -loops), other segments such as those in this LDH domain appear disordered or irregular. These nonregular regions, generally called **coils**, should never be referred to as “random coils.” They are neither truly disordered nor random; they are stabilized through specific hydrogen bonds dictated by the primary sequence of the protein and do not vary from one molecule of the protein to another of the same protein.

The nonregular coils, loops, and other segments are usually more flexible than the relatively rigid helices and β -pleated sheets. They often form hinge regions that allow segments of the polypeptide chain to move as a compound binds or to move as the protein folds around another molecule.

IV. Tertiary Structure

The tertiary structure of a protein is the pattern of the secondary structural elements folding into a three-dimensional conformation, as shown for the LDH domain in Figure 7.7. The three-dimensional structure is flexible and dynamic, with rapidly fluctuating movement in the exact positions of amino acid side chains and domains. These fluctuating movements take place without unfolding of the protein. They allow ions and water to diffuse through the structure and provide alternative conformations for ligand binding. As illustrated with examples later in this chapter, this three-dimensional structure is designed to serve all aspects of the protein’s function. It creates specific and flexible binding sites for **ligands** (the compounds that bind), illustrated with actin and myoglobin. The tertiary structure also maintains residues on the surface appropriate for the protein’s cellular location, polar residues for cytosolic proteins, and hydrophobic residues for transmembrane proteins (illustrated with the β_2 -adrenergic receptor). Flexibility is one of the most important features of protein structure. The forces that maintain tertiary structure are hydrogen bonds, ionic bonds, van der Waals interactions, the hydrophobic effect, and disulfide bond formation.

A. Domains in the Tertiary Structure

The tertiary structure of large complex proteins is often described in terms of physically independent regions called **structural domains**. You can usually identify domains from visual examination of a three-dimensional figure of a protein, such as the three-dimensional figure of G-actin shown in Figure 7.8. Each domain is formed from a continuous sequence of amino acids in the polypeptide chain that are folded into a three-dimensional structure independently of the rest of the protein, and two domains are connected through a simpler structure such as a loop (e.g., the hinge region of Fig. 7.8). The structural features of each domain can be discussed independently of another domain in the same protein, and the structural features of one domain may not match that of other domains in the same protein.

FIGURE 7.8 G-actin. Adenosine triphosphate (ATP) (in *black*) binds in the center of the cleft. The two domains that form the cleft are further subdivided into subdomains 1 through 4. The overall structure is found in many ATP-binding proteins and is called the actin fold. The conformations of the regions shown in *green* are nearly superimposable among the proteins that contain the actin fold. The *arrows* represent regions of β -sheet, whereas the coils represent α -helical regions of the protein. (From Kabsch W, Holmes KC. The actin fold. *FASEB J.* 1995;9(2):167–174. © FASEB. Reprinted by permission of John Wiley & Sons, Inc.)

B. Folds in Globular Proteins

Folds are relatively large patterns of three-dimensional structure that have been recognized in many proteins, including proteins from different branches of the phylogenetic tree. Over 1,000 folds have now been recognized, and it is predicted that there are only a few thousand different folds for all the proteins that have ever existed. A characteristic activity is associated with each fold, such as adenosine triphosphate (ATP)

binding and hydrolysis (the actin fold, see Fig. 7.8) or NAD⁺ (oxidized nicotinamide adenine dinucleotide) binding (the nucleotide-binding fold, see Fig. 7.7).

C. The Solubility of Globular Proteins in an Aqueous Environment

Most globular proteins are soluble in the cell. In general, the core of a globular domain has a high content of amino acids with nonpolar side chains (valine, leucine, isoleucine, methionine, and phenylalanine), out of contact with the aqueous medium (the hydrophobic effect). This hydrophobic core is densely packed to maximize attractive van der Waals forces, which exert themselves over short distances. The charged polar amino acid side chains (arginine, histidine, lysine, aspartate, and glutamic acid) are generally located on the surface of the protein, where they form ion pairs (salt bridges, ionic interactions) or are in contact with aqueous solvent. Charged side chains often bind inorganic ions (e.g., K⁺, PO₄³⁻, or Cl⁻) to decrease repulsion between like charges. When charged amino acids are located on the interior, they are generally involved in forming specific binding sites. The polar uncharged amino acid side chains of serine, threonine, asparagine, glutamine, tyrosine, and tryptophan are also usually found on the surface of the protein, but they may occur in the interior, hydrogen-bonded to other side chains. Cysteine disulfide bonds (the bond formed by two cysteine sulfhydryl groups) are sometimes involved in the formation of tertiary structure, where they add stability to the protein. However, their formation in soluble globular proteins is infrequent.

D. Tertiary Structure of Transmembrane Proteins

Transmembrane proteins, such as the β_2 -adrenergic receptor, contain membrane-spanning domains and intra- and extracellular domains on either side of the membrane (Fig. 7.9). Many ion-channel proteins, transport proteins, neurotransmitter receptors, and hormone receptors contain similar membrane-spanning segments that are α -helices with hydrophobic residues exposed to the lipid bilayer. These rigid helices are connected by loops containing hydrophilic amino acid side chains that extend into the aqueous medium on both sides of the membrane. In the β_2 -adrenergic receptor, the helices clump together so that the extracellular loops form a surface that acts as a binding site for the hormone adrenaline (epinephrine)—our fight-or-flight hormone. The binding site is sometimes referred to as a **binding domain** (a functional domain), even though it is not formed from a continuous segment of the polypeptide chain. Once adrenaline binds to the receptor, a conformational change in the arrangement of rigid helical structures is transmitted to the intracellular domains that form a binding site for another signaling protein, a heterotrimeric G-protein (a guanosine triphosphate [GTP]-binding protein composed of three different subunits, which is described further in Chapter 10). Thus, receptors require both rigidity and flexibility to transmit signals across the cell membrane.

FIGURE 7.9 β_2 -Adrenergic receptor. The receptor has seven α -helical domains that span the membrane and is therefore a member of the heptahelical class of receptors. **A.** The transmembrane domains are drawn in an extended form. The amino terminus (residues 1 through 34) extends out of the membrane and has branched high-mannose oligosaccharides linked through *N*-glycosidic bonds to the amide of asparagine. Part of the receptor is anchored in the lipid plasma membrane by a palmitoyl group (shown as a *squiggle*) that forms a thioester with the $-SH$ residue of a cysteine. The $-COOH$ terminus, which extends into the cytoplasm, has a number of serine and threonine phosphorylation sites (shown as *red circles*). **B.** The seven transmembrane helices (shown as *tubes*) form a cylindrical structure. Loops connecting helices form the hormone-binding site on the external side of the plasma membrane, and a binding site for a G-protein is on the intracellular side.

As discussed in Chapter 6, transmembrane proteins usually have a number of posttranslational modifications that provide additional chemical groups to fulfill requirements of the three-dimensional structure. As shown in Fig. 7.9 (and see Fig. 6.13), the amino terminus of the β_2 -adrenergic receptor (residues 1 to 34) extends out of the membrane and has branched high-mannose oligosaccharides linked through *N*-glycosidic bonds to the amide of asparagine. Part of the receptor is anchored in the lipid plasma membrane by a palmitoyl group that forms a thioester with the $-SH$ residue of a cysteine. The carboxyl terminus, which extends into the cytoplasm, has a number of serine and threonine phosphorylation sites (shown as *red circles*) that regulate receptor activity.

V. Quaternary Structure

The quaternary structure of a protein refers to the association of individual polypeptide chain subunits in a geometrically and stoichiometrically specific manner. Many proteins function in the cell as dimers, tetramers, or oligomers, proteins in which two, four, or more subunits, respectively, have combined to make one functional protein. The subunits of a particular protein always combine in the same number and in the same way, because the binding between the subunits is dictated by the tertiary structure, which is dictated by the primary structure, which is determined by the genetic code.

A number of different terms are used to describe subunit structure. The prefix **homo-** or **hetero-** is used to describe identical or different subunits, respectively, of two, three, or four subunit proteins (e.g., heterotrimeric G-proteins have three different subunits). A **protomer** is the unit structure composed of nonidentical subunits. For example, adult hemoglobin consists of two α - and two β -chains and is a tetramer ($\alpha_2\beta_2$). One α - β pair can be considered a protomer. In contrast, F-actin is an **oligomer**, a multisubunit protein composed of identical G-actin subunits. **Multimer** is sometimes used as a more generic term to designate a complex with many subunits of more than one type.

The contact regions between the subunits of globular proteins resemble the interior of a single-subunit protein; they contain closely packed nonpolar side chains, hydrogen bonds involving the polypeptide backbones and their side chains, and occasional ionic bonds or salt bridges. The subunits of globular proteins are very rarely held together by interchain disulfide bonds and never by other covalent bonds. In contrast, fibrous and other structural proteins may be extensively linked to other proteins through covalent bonds.

Insulin is composed of two nonidentical polypeptide chains attached to each other through disulfide bonds between the chains (see Chapter 6, Fig. 6.11). The subunits of globular proteins are generally not held together by disulfide bonds, but regions of the same chain may be connected by disulfide bonds that form as the chain folds. Insulin actually fits this generalization because it is synthesized as a single polypeptide chain, which forms the disulfide bonds. Subsequently, a proteolytic enzyme in secretory vesicles clips the polypeptide chain into two nonidentical subunits. Generally, each subunit of most protomers and oligomers is synthesized as a separate polypeptide chain. In fibrous proteins, which have a regular, sometimes repeating sequence of amino acids, inter- and intrachain covalent binding serves different functions. In collagen, for example, extensive interchain binding provides great tensile strength. Collagen is discussed in more detail in Chapter 47.

Assembly into a multisubunit structure increases the stability of a protein. The increase in size increases the number of possible interactions between amino acid residues and therefore makes it more difficult for a protein to unfold and refold. As a result, many soluble proteins are composed of two or four identical or nearly identical subunits with an average size of approximately 200 amino acids. The forming of multisubunit proteins also aids in the function of the protein.

A multisubunit structure has many advantages besides increased stability. It may enable the protein to exhibit cooperativity between subunits in binding ligands (illustrated later with hemoglobin) or to form binding sites with a high affinity for large molecules (illustrated with antigen binding to the immunoglobulin molecule, IgG). An additional advantage of a multisubunit structure is that the different subunits can have different activities and cooperate in a common function. Examples of enzymes that have regulatory subunits or exist as

multiprotein complexes are provided in Chapter 9.

VI. Quantitation of Ligand Binding

In the examples of tertiary structure we have discussed, the folding of a protein created a three-dimensional binding site for a ligand (NAD⁺ for the LDH domain 1, ATP for G-actin, or adrenaline for the β_2 -adrenergic receptor). The binding affinity of a protein for a ligand is described quantitatively by its **association constant**, K_a , which is the equilibrium constant for the binding reaction of a ligand (L) with a protein (P) (Equation 7.1).

Equation 7.1. The association constant, K_a for a binding site on a protein.

Consider a reaction in which a ligand (L) binds to a protein (P) to form a ligand–protein complex (LP) with a rate constant of k_1 . LP dissociates with a rate constant of k_2 :

then,

$$K_{\text{eq}} = \frac{k_1}{k_2} = \frac{[LP]}{[L][P]} = K_a = \frac{1}{K_d}$$

Two different ligands (A and B) bind to the same receptor on the cell surface. The K_d for ligand A is 10^{-7} M and for ligand B it is 10^{-9} M. Which ligand has the higher affinity for the receptor?

The equilibrium constant, K_{eq} , is equal to the association constant (K_a) or $1/K_d$, the dissociation constant. Unless otherwise given, the concentrations of L, P, and LP are expressed as mol/L, and K_a has the units of $(\text{mol/L})^{-1}$.

K_a is equal to the rate constant (k_1) for association of the ligand with its binding site divided by the rate constant (k_2) for dissociation of the ligand–protein complex (LP). K_d , the **dissociation constant** for ligand–protein binding, is the reciprocal of K_a . The tighter the binding of the ligand to the protein, the higher is the K_a and the lower is the K_d . The K_a is useful for comparing proteins produced by different alleles or for describing the affinity of a receptor for different drugs.

VII. Structure–Function Relationships in Myoglobin and Hemoglobin

Myoglobin and hemoglobin are two oxygen-binding proteins with a very similar primary structure (Fig. 7.10). However, myoglobin is a globular protein composed of a single polypeptide chain that has one oxygen-binding site. Hemoglobin is a tetramer composed of two different types of subunits (2 α - and 2 β -polypeptide chains, referred to as **two $\alpha\beta$ -protomers**). Each subunit has a strong sequence homology to myoglobin and contains an oxygen-binding site. A comparison between myoglobin and hemoglobin illustrates some of the advantages of a multisubunit quaternary structure.

FIGURE 7.10 Myoglobin and hemoglobin. Myoglobin (**A**) consists of a single polypeptide chain, which is similar in structure to the α - and β -subunits of hemoglobin (**B**). In all of the subunits, heme is tightly bound in a hydrophobic binding pocket. **C** displays the quaternary structure of hemoglobin (which consists of two α - and two β -chains). (**C**: Adapted from Zubay GL. *Biochemistry*, 4th ed. William C. Brown Communications Inc.; 1998, Fig. 6.12.)

The tetrameric structure of hemoglobin facilitates saturation with O_2 in the lungs and release of O_2 as it travels through the capillary beds (Fig. 7.11). When the amount of oxygen bound to myoglobin or hemoglobin is plotted against the partial pressure of oxygen (pO_2), a hyperbolic curve is obtained for myoglobin, whereas that for hemoglobin is sigmoidal. These curves show that when the pO_2 is high, as in the lungs, both myoglobin and hemoglobin are saturated with oxygen. However, at the lower levels of pO_2 in oxygen-using tissues, hemoglobin cannot bind oxygen as well as myoglobin (i.e., its percent saturation is much lower). Myoglobin, which is present in heart and skeletal muscle, can bind the O_2 released by hemoglobin, which it stores to meet the demands of contraction. As O_2 is used in the muscle cell for generation of ATP during contraction, it is released from myoglobin and picked up by cytochrome oxidase, a heme-containing enzyme in the electron transport chain that has an even higher affinity for oxygen than myoglobin.

FIGURE 7.11 Oxygen saturation curves for myoglobin and hemoglobin. Note that the curve for myoglobin is hyperbolic, whereas that for hemoglobin is sigmoidal. The effect of the tetrameric structure is to inhibit O₂ binding at low O₂ concentrations. P₅₀ is the partial pressure of O₂ (pO₂) at which the protein is half-saturated with O₂. P₅₀ for myoglobin is 2.8 torr and that for hemoglobin is 26 torr, where 1 torr is equal to 1 mm Hg.

 Myoglobin is readily released from skeletal muscle or cardiac tissue when the cell is damaged. It has a low molecular weight, 17,000 Da, and is not complexed to other proteins in the cell. (Da is the abbreviation for the Dalton, which is a unit of mass approximately equal to one H atom. Thus, a molecular weight of 17,000 Da is equal to approximately 17,000 g/mol.) Large injuries to skeletal muscle that result from physical crushing or lack of ATP production result in cellular swelling and the release of myoglobin and other proteins into the blood. Myoglobin passes into the urine (myoglobinuria) and turns the urine red because the heme (which is red) remains covalently attached to the protein. During an acute MI, myoglobin is one of the first proteins released into the blood from damaged cardiac tissue; however, the amount released is not high enough to cause myoglobinuria. Laboratory measurements of serum myoglobin were used in the past for early diagnosis in patients such as **Anne J**. Because myoglobin is not present in skeletal muscle and the heart as tissue-specific isozymes, and the amount released from the heart is much smaller than the amount that can be released from a large skeletal muscle injury, myoglobin measurements are not specific for an MI. Because of the lack of specificity in myoglobin measurements, the cardiac marker of choice for detection of MIs is the heart isozyme of the troponins (I and/or T).

A. Oxygen Binding and Heme

The tertiary structure of myoglobin consists of eight α -helices connected by short coils, a structure that is known as the **globin fold** (see Fig. 7.10). This structure is unusual for a globular protein in that it has no β -sheets. The helices create a hydrophobic O_2 -binding pocket containing tightly bound **heme** with an iron atom (ferrous, Fe^{2+}) in its center.

Heme consists of a planar porphyrin ring composed of four pyrrole rings linked by methenyl bridges that lie with their nitrogen atoms in the center, binding a Fe^{2+} atom (Fig. 7.12). Negatively charged propionate groups on the porphyrin ring interact with arginine and histidine side chains from the hemoglobin, and the hydrophobic methyl and vinyl groups that extend out from the porphyrin ring interact with hydrophobic amino acid side chains from hemoglobin, positioning the heme group within the protein. Altogether, there are about 16 different interactions between myoglobin amino acids and different groups in the porphyrin ring.

FIGURE 7.12 Heme. The Fe^{2+} is bound to four nitrogen atoms in the center of the heme porphyrin ring. Methyl (M, $-CH_3$), vinyl (V, $-CH = CH_2$), and propionate (P, $-CH_2CH_2COO^-$) side chains extend out from the four pyrrole rings that comprise the porphyrin ring.

Organic ligands that are tightly bound to proteins, such as the heme of myoglobin, are called **prosthetic groups**. A protein with its attached prosthetic group is called a **holoprotein**; without the prosthetic group, it is called an **apoprotein**. The tightly bound prosthetic group is an intrinsic part of the protein and does not dissociate until the protein is degraded.

A The K_a (association constant) is equal to the reciprocal of the dissociation constant (K_d). The K_a for ligand A is 10^7 M^{-1} , whereas for ligand B it is 10^9 M^{-1} . Ligand B has the higher affinity for the receptor, by 100 fold as compared to ligand A.

Within the binding pocket of myoglobin and hemoglobin, O_2 binds directly to the Fe^{2+} atom on one side of the planar porphyrin ring (Fig. 7.13A). The Fe^{2+} atom is able to chelate (binds to) six different ligands; four of the ligand positions are in a plane and taken by the central nitrogens in the planar porphyrin ring. There are two ligand positions perpendicular to this plane. One of these positions is taken by the nitrogen atom on a histidine, called the **proximal histidine**, which extends down from a myoglobin or hemoglobin α -helix. The other position is taken by O_2 , CO (carbon monoxide), or remains empty.

FIGURE 7.13 **A.** Oxygen binding to the Fe^{2+} of heme in hemoglobin. A histidine residue called the proximal histidine binds to the Fe^{2+} on one side of the porphyrin ring and slightly pulls the Fe^{2+} out of the plane of the ring; O_2 binds to Fe^{2+} on the other side. **B.** O_2 binding causes a conformational change that pulls the Fe^{2+} back into the plane of the ring. As the proximal histidine moves, it moves the helix (the F-helix) that contains it.

B Sickle cell anemia is really a disease caused by an abnormal quaternary structure. The painful vaso-occlusive crises experienced by **Will S.** are caused by the polymerization of sickle cell hemoglobin (HbS) molecules into long fibers that distort the shape of the red blood cells into sickle cells. The substitution of a hydrophobic valine for a glutamate in the β_2 -chain of hemoglobin creates a knob on the surface of deoxygenated hemoglobin that fits into a hydrophobic binding pocket on the β_1 -subunit of a different hemoglobin molecule. A third hemoglobin molecule, which binds to the first and second hemoglobin molecules through aligned polar interactions, binds a fourth hemoglobin molecule through its valine knob. Thus, the polymerization continues until long fibers are formed.

Polymerization of the hemoglobin molecules is highly dependent on the concentration of HbS and is promoted by the conformation of the deoxygenated molecules. At 100% oxygen saturation, even high concentrations of HbS will not polymerize. A red blood cell spends the longest amount of time at the lower oxygen concentrations of the venous capillary bed, where polymerization is most likely initiated.

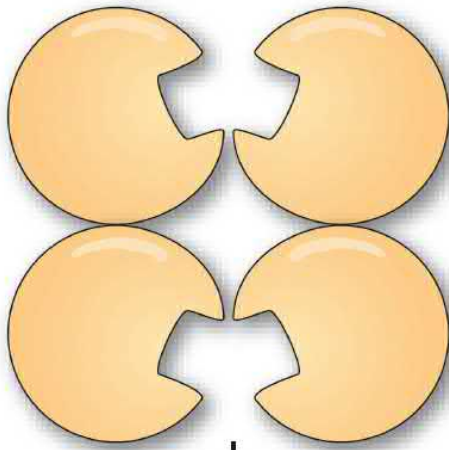

The proximal histidine of myoglobin and hemoglobin is sterically repelled by the heme porphyrin ring. Thus, when the histidine binds to the Fe^{2+} in the middle of the ring, it pulls the Fe^{2+} above the plane of the ring (see Fig. 7.13A). When oxygen binds on the other side of the ring, it pulls the Fe^{2+} back into the plane of the ring (see Fig. 7.13B). The pull of O_2 binding moves the proximal histidine toward the porphyrin ring, which moves the helix containing the proximal histidine. This conformational change has no effect on the function of myoglobin. However, in hemoglobin, the movement of one helix leads to the movement of other helices in that subunit, including one in a corner of the subunit that is in contact with a different subunit through ionic interactions (salt bridges). The loss of these salt bridges then induces conformational changes in all other subunits, and all four subunits may change in a concerted manner from their original conformation to a new

conformation (see Biochemical Comments).

B. Cooperativity of O₂ Binding in Hemoglobin

The cooperativity in oxygen binding in hemoglobin comes from conformational changes in tertiary structure that takes place when O₂ binds (Fig. 7.14). The conformational change of hemoglobin is usually described as changing from a T (tense) state with low affinity for O₂ to an R (relaxed) state with a high affinity for O₂. Breaking the salt bridges in the contacts between subunits is an energy-requiring process, and consequently, the binding rate for the first oxygen is very low. When the next oxygen binds, many of the hemoglobin molecules containing one O₂ will already have all four subunits in the R state, and therefore the rate of binding is much higher. With two O₂ molecules bound, an even higher percentage of the hemoglobin molecules will have all four subunits in the R state. This phenomenon, known as positive cooperativity, is responsible for the sigmoidal oxygen saturation curve of hemoglobin (see Fig. 7.11).

T state

R state

R state

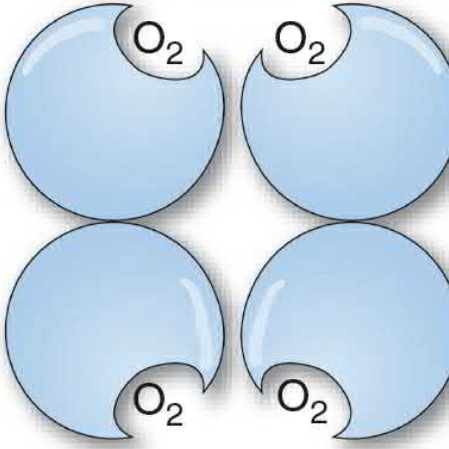

FIGURE 7.14 Equilibria for binding of O₂ molecules to hemoglobin according to the concerted model of Monod, Wyman, and Changeux. Hemoglobin exists in two alternate conformations: the *T* (tense) state with a low affinity for O₂ and the *R* (relaxed) state with a higher affinity. In the *T* subunits, the binding sites are hindered, and in the *R* state the binding sites are open. Each successive addition of O₂ shifts the equilibrium further toward the *R* state. Because the conformation of all the subunits can change when O₂ binds to one subunit, oxygen binding is said to follow the concerted model. Most of the molecules change to the *R* state when two O₂ molecules have bound.

C. Agents That Affect Oxygen Binding

The major agents that affect oxygen binding to hemoglobin are shown in Figure 7.15.

- ① Hydrogen ions
- ② 2,3-Bisphosphoglycerate
- ③ Covalent binding of CO₂

FIGURE 7.15 Agents that affect oxygen binding by hemoglobin. Binding of hydrogen ions, 2,3-bisphosphoglycerate, and carbon dioxide to hemoglobin decrease its affinity for oxygen.

1. 2,3-Bisphosphoglycerate

2,3-Bisphosphoglycerate (2,3-BPG) is formed in red blood cells from the glycolytic intermediate 1,3-bisphosphoglycerate (see Chapters 22 and 42). 2,3-BPG binds to hemoglobin in the central cavity formed by the four subunits, increasing the energy required for the conformational changes that facilitate the binding of oxygen. Thus, 2,3-BPG lowers the affinity of hemoglobin for oxygen. Therefore, oxygen is less readily bound (i.e., is more readily released in tissues) when hemoglobin has bound 2,3-BPG. Red blood cells can modulate oxygen affinity for hemoglobin by altering the rate of synthesis or degradation of 2,3-BPG.

2. Proton Binding (Bohr Effect)

The binding of protons by hemoglobin lowers its affinity for oxygen (Fig. 7.16), contributing to a phenomenon known as the **Bohr effect** (Fig. 7.17). The pH of the blood decreases as it enters the tissues (and the proton concentration rises) because the CO₂ produced by metabolism is converted to carbonic acid by the reaction catalyzed by carbonic anhydrase in red blood cells. Dissociation of carbonic acid produces protons that react with several amino acid residues in hemoglobin, causing conformational changes that promote the release of oxygen.

FIGURE 7.16 Effect of pH on oxygen saturation curves. As the pH decreases, the affinity of hemoglobin for oxygen decreases, producing the Bohr effect.

FIGURE 7.17 Effect of H^+ on oxygen binding by hemoglobin (Hb). **A.** In the tissues, CO_2 is released. In the red blood cell, this CO_2 forms carbonic acid, which releases protons. The protons bind to Hb, causing it to release oxygen to the tissues. **B.** In the lungs, the reactions are reversed. O_2 binds to protonated Hb, causing the release of protons. They bind to bicarbonate (HCO_3^-), forming carbonic acid, which is cleaved to water and CO_2 , which is exhaled. RBC, red blood cells.

In the lungs, this process is reversed. Oxygen binds to hemoglobin (because of high oxygen concentration in the lung), causing a release of protons, which combine with bicarbonate to form carbonic acid. This decrease of protons causes the pH of the blood to rise. Carbonic anhydrase cleaves the carbonic acid to H_2O and CO_2 , and the CO_2 is exhaled. Thus, in tissues in which the pH of the blood is low because of the CO_2 produced by metabolism, oxygen is released from hemoglobin. In the lungs, where the pH of the blood is higher because CO_2 is being exhaled, oxygen binds to hemoglobin.

C. Carbon Dioxide

Although most of the CO_2 produced by metabolism in the tissues is carried to the lungs as bicarbonate, some of the CO_2 is covalently bound to hemoglobin (Fig. 7.18). In the tissues, CO_2 forms carbamate adducts with the *N*-terminal amino groups of the β -chains of deoxyhemoglobin and stabilizes the deoxy conformation. In the lungs, where the pO_2 is high, oxygen binds to hemoglobin and thus bound CO_2 is released.

FIGURE 7.18 Binding of CO_2 to hemoglobin. CO_2 forms carbamates with the *N*-terminal amino groups of the β -chain of hemoglobin (Hb). Approximately 15% of the CO_2 in blood is carried to the lungs bound to Hb. The reaction releases protons, which contribute to the Bohr effect. The overall effect is the stabilization of the deoxy form of hemoglobin.

Amy L.'s serum protein electrophoresis indicated the presence of a sharp narrow peak or homogeneous "spike" in the characteristic γ -globulin zone known as an M-protein (monoclonal protein) component. A narrow peak or spike in

electrophoresis, which separates proteins according to charge distribution of the side chains, suggests an elevation of proteins with a similar or identical structure. Subsequently, it was shown that **Amy L.**'s immunoglobulin M-component was composed of a single homogeneous type of immunoglobulin (just one amino acid sequence in the *N*-terminal variable region). Thus, the M-protein was produced by a single clone of antibody-secreting cells (cells that all arose from proliferation of one cell) in the bone marrow (called plasma cell dyscrasia).

In amyloidosis/AL, amyloid is formed from degradation products of the λ - or κ -light chains that deposit most frequently in the ECM of the kidney and the heart but also may deposit in the tongue. In other types of amyloidosis, the amyloid arises from other proteins and deposits in a characteristic organ. For example, the amyloid associated with chronic inflammatory conditions, such as rheumatoid arthritis, is derived from the serum protein called serum amyloid A that is produced by the liver in response to inflammation. It deposits most frequently in the kidney.

The treatment of AL is multifactorial and only partially successful. Initially, alkylating agents were used to reduce the synthesis of immunoglobulin light chains by plasma cells but were found to be too toxic for routine use. The most efficacious approach involves the use of stem cell transplantation in concert with melphalan (an antineoplastic agent). If the patient is not a candidate for transplantation, then melphalan and bortezomib (antineoplastic agents) and dexamethasone (a steroid) can be used.

Renal transplantation and cardiac transplantation have been performed in patients with renal and cardiac amyloidosis, respectively, with some success.

VIII. Structure–Function Relationships in Immunoglobulins

The immunoglobulins (or antibodies) are one line of defense against invasion of the body by foreign organisms. In this capacity, they function by binding to ligands called **antigens** on the invading organisms, thereby initiating the process by which these organisms are inactivated or destroyed.

All immunoglobulins have a similar structure; each antibody molecule contains two identical small polypeptide chains (the light or L chains) and two identical large polypeptide chains (the heavy or H chains) (Fig. 7.19). The chains are joined to each other by disulfide bonds.

A Schematic drawing

B Space-filling model

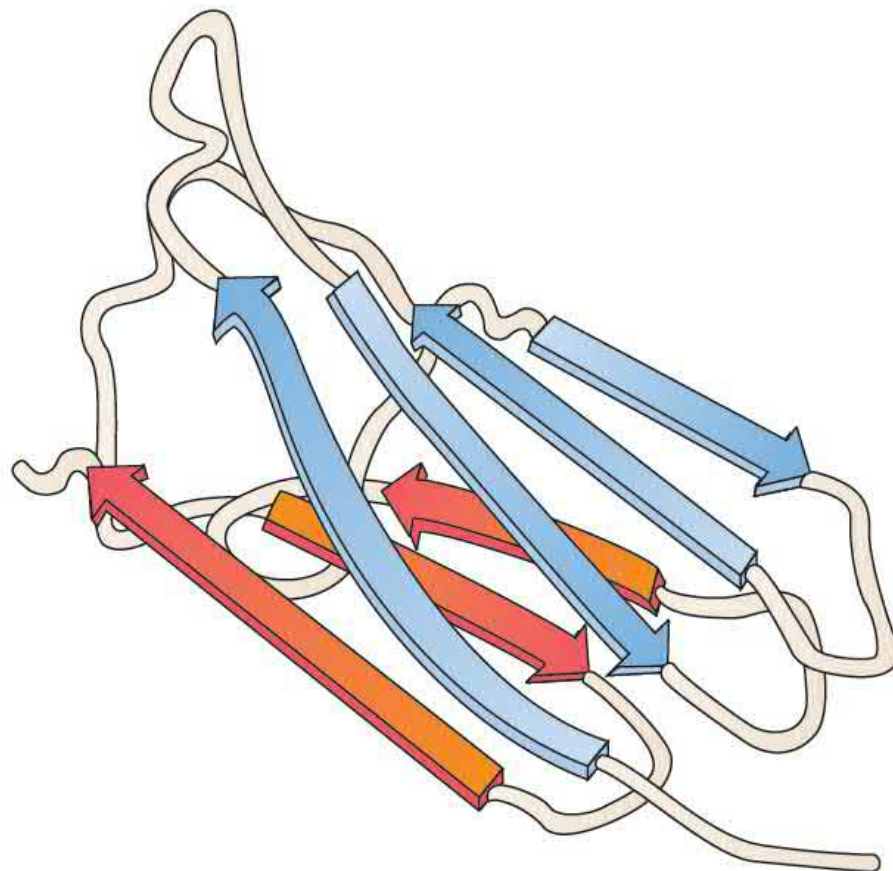

FIGURE 7.19 Structure of immunoglobulins. **A.** Each IgG molecule contains two light (L) and two heavy (H) chains joined by disulfide bonds. Each light chain contains two domains, a variable domain (V_L) and a region of constant amino acid sequence (C_L). Each heavy chain has four domains: one variable domain (V_H) and three constant domains (C_H). The conformation of the constant domain contains the β -sheets that are called the immunoglobulin fold. The variable domains are specific for the antigen that is bound, whereas the constant regions are the same for all antibody molecules of a given class. Carbohydrate ($-CHO$) is bound as indicated within the constant region of the heavy chains. The hinge region allows flexibility when the molecule binds antigen. **B.** In the space-filling model, the light chains are light in color and the heavy chains are two different

shades of orange. (Modified from Silverton EW, Navia MA, Davies DR, et al. Three-dimensional structure of an intact human immunoglobulin. *Proc Natl Acad Sci U S A*. 1977;74(11):5142. Reprinted with permission from Dr. Manuel A. Navia.)

The body has five major classes of immunoglobulins. The most abundant immunoglobulins in human blood are the γ -globulins, which belong to the IgG class. The γ -globulins have approximately 220 amino acids in their light chains and 440 in their heavy chains. Like most serum proteins, they have attached oligosaccharides that participate in targeting the protein for clearance from the blood. Both the light and heavy chains consist of domains known as the **immunoglobulin fold**, which is a collapsed number of β -sheets, known as a **β -barrel** (Fig. 7.20).

V_L domain

C_L domain

FIGURE 7.20 Structure of the V_L and C_L domains of IgG. Layers of antiparallel β -sheets are stacked in these domains, which have been referred to as collapsed β -barrels (one can envision a hollow space between the β -sheets, which define the barrel). The antigen binds between the V_H and V_L immunoglobulin folds, and *not* in the barrel. The C_L domain is also called the immunoglobulin fold. (Top modified from Richardson JS. The anatomy and taxonomy of protein structure. *Adv Protein Chem.* 1981;34:167–339. Reprinted with permission from Jane S. Richardson; Bottom reprinted in part with permission from Edmundson AB, Ely KR, Abola EE, et al. Rational allomerism and divergent evolution of domains in immunoglobulin light chains. *Biochemistry.* 1975;14:3954. © 1975. American Chemical Society.)

Both the light and heavy chains contain regions termed **variable** (V) and **constant** (C) regions. The variable regions of the L and H chains (V_L and V_H , respectively) interact to produce a single antigen-binding site at each branch of the Y-shaped molecule. Each population (clone) of B-cells produces an antibody with a different amino acid composition in the variable region that is complementary to the structure of the antigen that elicits the response. The K_d of antibodies for their specific antigens is extremely small and varies from approximately 10^{-7} to 10^{-11} M. The antigen thus binds very tightly with almost no tendency to dissociate and can be removed from circulation as the antigen–antibody complex is ingested by macrophages. The constant domains that form the Fc part of the antibody are important for binding of the antigen–antibody complex to phagocytic cells for clearance and for other aspects of the immune response.

The tight binding affinity of immunoglobulins for their specific antigen makes them useful for the measurement of small amounts of other compounds in various radioimmunoassays. The principle of the radioimmunoassay is that the immunoglobulin will specifically bind the compound being measured, and an additional component of the system that is labeled with a radioactive or fluorescent chemical will bind the immunoglobulin. The complex is then separated from the solution and the bound radioactivity or fluorescence measured. The Tn-T used to track **Anne J.**'s MI is measured with a type of radioimmunoassay. Radioimmunoassays are also useful for measuring the small amounts of hormones present in the blood for diagnosis of endocrine diseases.

IX. Protein Folding

Although the peptide bonds in a protein are rigid, flexibility around the other bonds in the peptide backbone allow an enormous number of possible conformations for each protein. However, every molecule of the same protein folds into the same stable three-dimensional structure. This shape is known as the **native conformation**.

A. Primary Structure Determines Folding

The primary structure of a protein determines its three-dimensional conformation. More specifically, the sequence of amino acid side chains dictates the fold pattern of the three-dimensional structure and the assembly of subunits into quaternary structure. Proteins become denatured when they lose their overall structure. However, under certain conditions, denatured proteins can refold into their native conformation, regaining their original function. This indicates that the primary structure essentially specifies the folding pattern. In some cases, proteins are assisted in folding by heat-shock proteins (some of which are also called **chaperonins**), which use the energy provided by ATP hydrolysis to assist in the folding process (Fig. 7.21).

FIGURE 7.21 Role of heat-shock proteins in folding. **A.** The Hsp 70 family of proteins prevent folding of the nascent chain and promote unfolding. The ATPase domain of the protein has the actin fold. This figure depicts the synthesis of protein from ribosomes bound to mRNA in the cytoplasm (see Chapter 14). **B.** The Hsp 60 class of protein has a barrel shape into which the protein fits. It acts as a template, binding and rebinding portions of the unfolded protein until folding is completed. It hydrolyzes many (adenosine triphosphate) ATP bonds (generating adenosine diphosphate [ADP]) to provide energy for the process.

Treatment of mature insulin (see Fig. 6.12) with denaturing agents, followed by renaturation, does not restore mature insulin activity (a result distinct from that which occurred when the experiment was done with ribonuclease). Why does renaturation of denatured mature insulin not result in restoration of biological activity?

A *cis–trans* isomerase and a **protein disulfide isomerase** also participate in folding. The *cis–trans* isomerase converts a *trans* peptide bond preceding a proline into the *cis* conformation, which is well-suited for making hairpin turns. The disulfide isomerase breaks and reforms disulfide bonds between the –SH groups of two cysteine residues in transient structures formed during the folding process. After the protein has folded, cysteine–SH groups in close contact with the tertiary structure can react to form the final disulfide bonds.

It is important to note that there is very little difference in the energy state of the native conformation and a number of other stable conformations that a protein might assume. This enables the protein to have the flexibility to change conformation when modifiers are bound to the protein, which enables a protein’s activity to be regulated (similar to 2,3-BPG binding to hemoglobin and stabilizing the deoxy form of hemoglobin).

B. Fibrous Proteins—Collagen

Collagen, a family of fibrous proteins, is produced by a variety of cell types but principally by fibroblasts (cells found in interstitial connective tissue), muscle cells, and epithelial cells. Type I collagen, or collagen(I), the most abundant protein in mammals, is a fibrous protein that is the major component of connective tissue. It is found in the extracellular matrix (ECM, see Chapter 47) of loose connective tissue, bone, tendons, skin, blood vessels, and the cornea of the eye. Collagen(I) contains about 33% glycine and 21% proline and hydroxyproline. Hydroxyproline is an amino acid produced by posttranslational modification of peptidyl proline residues.

Procollagen(I), the precursor of collagen(I), is a triple helix composed of three polypeptide (pro- α) chains that are twisted around each other, forming a ropelike structure (Fig. 7.22). Polymerization of collagen(I) molecules forms collagen fibrils, which provide great tensile strength to connective tissues. The individual polypeptide chains each contain approximately 1,000 amino acid residues. The three polypeptide chains of the triple helix are linked by interchain hydrogen bonds. Each turn of the triple helix contains three amino acid residues, such that every third amino acid is in close contact with the other two strands in the center of the structure. Only glycine, which lacks a side chain, can fit in this position, and indeed, every third amino acid residue of collagen is glycine. Thus, collagen is a polymer of (Gly-X-Y) repeats, where Y is frequently proline or hydroxyproline and X is any other amino acid found in collagen.

FIGURE 7.22 The triple helix of collagen. Glycines are present in the three chains where they come into close contact with each other (arrows).

Recall, the primary structure of a protein dictates the folding pattern of the protein. The primary structure of mature insulin is

A different than that of its precursor, preproinsulin. Proinsulin forms the three-dimensional structure, and then the C-peptide is removed from the protein by proteolytic cleavage, thereby altering the primary structure of the protein. This change in primary structure (the loss of the C-peptide) does not allow the denatured mature insulin to refold into an active conformation.

Procollagen(I) is an example of a protein that undergoes extensive posttranslational modifications. Hydroxylation reactions produce hydroxyproline residues from proline residues and hydroxylysine from lysine residues. These reactions occur after the protein has been synthesized (Fig. 7.23) and require vitamin C (ascorbic acid) as a cofactor of the enzymes prolyl hydroxylase and lysyl hydroxylase. Hydroxyproline residues are involved in hydrogen bond formation that helps to stabilize the collagen fibril, whereas hydroxylysine residues are the sites of attachment of disaccharide moieties (galactose–glucose). The role of carbohydrates in collagen structure is still controversial. In the absence of vitamin C (scurvy), the melting temperature of collagen drops from 42°C to 24°C because of the loss of intermolecular hydrogen bond formation, which is in turn caused by the lack of hydroxyproline residues.

FIGURE 7.23 Hydroxylation of proline and lysine residues in collagen. Proline and lysine residues within the collagen chains are hydroxylated by reactions that require vitamin C.

The side chains of lysine residues also may be oxidized to form the aldehyde allysine. These aldehyde residues produce covalent cross-links between collagen molecules to further stabilize the collagen fibril (Fig. 7.24). An allysine residue on one collagen molecule reacts with the amino group of a lysine residue on another molecule, forming a covalent Schiff base (a nitrogen–carbon double bond) that is converted to more stable covalent cross-links. Aldol condensation also may occur between two allysine residues, which forms the structure lysinonorleucine.

FIGURE 7.24 Formation of cross-links in collagen. **A.** Lysine residues are oxidized to allysine (an aldehyde). Allysine may react with an unmodified lysine residue to form a Schiff base (**B**), or two allysine residues may undergo an aldol condensation (**C**) to form lysinonorleucine.

The synthesis and secretion of collagen, as well as its multiple types, is further discussed in Chapter 47.

C. Protein Denaturation

A protein's quaternary, tertiary, and secondary structures can be destroyed by a number of processes, and when this occurs, the protein is considered to be denatured. Denaturation can occur by a variety of means.

1. Denaturation through Nonenzymatic Modification of Proteins

Amino acids on proteins can undergo a wide range of chemical modifications that are not catalyzed by enzymes, such as nonenzymatic glycation or oxidation. Such modifications may lead to a loss of function and denaturation of the protein, sometimes to a form that cannot be degraded in the cell. In nonenzymatic glycation, glucose that is present in blood, or in interstitial or intracellular fluid, binds to an exposed amino group on a protein (Fig. 7.25). The two-step process forms an irreversibly glycated protein. Proteins that turn over very slowly in the body, such as collagen or hemoglobin, exist with a significant fraction present in the glycated form. Because the reaction is nonenzymatic, the rate of glycation is proportionate to the concentration of glucose present, and individuals with hyperglycemia have much higher levels of glycated proteins than individuals with normal blood glucose levels. Collagen and other glycated proteins in tissues are further modified by nonenzymatic oxidation and form additional cross-links. The net result is the formation of large protein aggregates referred to as **advanced glycation end products (AGEs)**. AGE is a particularly meaningful acronym because AGEs accumulate with age, even in individuals with normal blood glucose levels.

Glucose

Amadori rearrangement

FIGURE 7.25 Nonenzymatic glycation of hemoglobin. (Hb). Glucose forms a Schiff base with the *N*-terminal amino group of the protein, which rearranges to form a stable glycated product. Similar nonenzymatic glycation reactions occur on other proteins. Four minor components of adult hemoglobin (HbA) result from posttranslational, nonenzymatic glycation of different amino acid residues (HbA_{1a1}, HbA_{1a2}, HbA_{1b1}, and HbA_{1c}). In HbA_{1c}, the fraction that is usually measured, the glycation occurs on an *N*-terminal valine.

2. Protein Denaturation by Temperature, pH, and Solvent

Proteins can be denatured by changes of pH, temperature, or solvent that disrupt ionic, hydrogen, and hydrophobic bonds. At a low pH, ionic bonds and hydrogen bonds formed by carboxylate groups would be disrupted; at a very alkaline pH, hydrogen and ionic bonds formed by the basic amino acids would be disrupted. Thus, the pH of the body must be maintained within a range compatible with three-dimensional structure.

Dianne A.'s physician used her glycated hemoglobin levels, specifically the HbA_{1c} fraction, to determine the control of her blood glucose and whether she had sustained hyperglycemia over a long period of time. The rate of irreversible nonenzymatic glycation of hemoglobin and other proteins is directly proportional to the glucose concentration to which they are exposed over the last 4 months (the life span of the red blood cell). The danger of sustained hyperglycemia is that, over time, many proteins become glycated and subsequently oxidized, affecting their solubility and ability to function. The glycation of collagen in the heart, for example, is believed to result in a cardiomyopathy in patients with chronic uncontrolled diabetes mellitus. In contrast, glycation of hemoglobin has little effect on its function.

Physiologically, proteins are denatured by the gastric juice of the stomach, which has a pH of 1 to 2. Although this pH cannot break peptide bonds, disruption of the native conformation makes the protein a better substrate for digestive enzymes. Temperature increases vibrational and rotational energies in the bonds, thereby affecting the energy balance that goes into making a stable three-dimensional conformation. Thermal denaturation is often illustrated by the process of cooking an egg. With heat, the protein albumin converts from its native translucent state to a denatured white precipitate. Protein precipitates can sometimes be dissolved by amphipathic agents such as urea, guanidine HCl, or sodium dodecylsulfate (SDS) that form extensive hydrogen bonds and hydrophobic interactions with the protein.

Hydrophobic molecules can also denature proteins by disturbing hydrophobic interactions in the protein. For example, long-chain fatty acids can inhibit many enzyme-catalyzed reactions by binding nonspecifically to hydrophobic pockets in proteins and disrupting hydrophobic interactions. Thus, long-chain fatty acids and other highly hydrophobic molecules have their own binding proteins in the cell.

3. Protein Misfolding and Prions

Prion proteins are believed to cause a neurodegenerative disease by acting as a template to misfold other cellular prion proteins into a form that cannot be degraded. The word “prion” stands for proteinaceous infectious agent. The prion diseases may be acquired either through infection (mad cow disease) or from sporadic (majority of cases) or inherited mutations (e.g., familial Creutzfeldt-Jakob disease [CJD]). Although the infectious prion diseases represent <1% of human cases, their link to mad cow disease in the United Kingdom (new variant CJD), to cadaveric human growth-hormone use in the United States and France (iatrogenic or “doctor-induced” CJD), and to ritualistic cannibalism in the Fore tribespeople of Papua New Guinea (Kuru) have received the most publicity.

Prion diseases are categorized as transmissible spongiform encephalopathies, which are neurodegenerative diseases characterized by spongiform degeneration and astrocytic gliosis in the central nervous system. Frequently, protein aggregates and amyloid plaques are seen. These aggregates are resistant to proteolytic degradation.

The prion protein is normally found in the brain and is encoded by a gene that is a normal component of the human genome. The disease-causing form of the prion protein has the same amino acid composition but is folded into a different conformation that aggregates into multimeric protein complexes resistant to proteolytic degradation (Fig. 7.26). The normal conformation of the prion protein has been designated PrP^c and the disease-causing form as PrP^{Sc} (sc for the prion disease scrapies in sheep). Although PrP^{Sc} and PrP^c have the same amino acid composition, the PrP^{Sc} conformer is substantially enriched in β -sheet structure compared with the normal PrP^c conformer, which has little or no β -sheet structure and is approximately 40% α -helix. This difference favors the aggregation of PrP^{Sc} into multimeric complexes. These two conformations presumably have similar energy levels. Fortunately, spontaneous refolding of PrP proteins into the PrP^{Sc} conformation is

prevented by a large activation energy barrier that makes this conversion extremely slow. Thus, very few molecules of PrP^{Sc} are normally formed during a lifetime.

FIGURE 7.26 The conformation of PrP^c (normal) and PrP^{Sc} (disease form). **A.** The prion proteins have two domains, an N-terminal region that binds four Cu²⁺ per chain and a C-terminal region. **B.** In PrP^c, the C-terminal regions contain three substantial helices and two three-residue β -strands joined by two to three hydrogen bonds (approximately 40% α -helix and almost no β -sheet structure). It exists as a monomer. In PrP^{Sc}, the C-terminal region is folded into an extensive β -sheet. The overall structure is approximately 40% to 50% β -sheet and 20% to 30% α -helices. This conformation promotes aggregation.

The infectious disease occurs with the ingestion of PrP^{Sc} dimers in which the prion protein is already folded into the high β -structure. These PrP^{Sc} proteins are thought to act as a template to lower the activation energy barrier for the conformational change, causing native proteins to refold into the PrP^{Sc} conformation much more rapidly (much like the role of chaperonins). The refolding initiates a cascade as each new PrP^{Sc} formed acts as a template for the refolding of other molecules. As the number of PrP^{Sc} molecules increases in the cell, they aggregate into a multimeric assembly that is resistant to proteolytic digestion. Once an aggregate begins to form, the concentration of free PrP^{Sc} decreases, thereby shifting the equilibrium between PrP and PrP^{Sc} to produce more PrP^{Sc}. This leads to further aggregate formation through the shift in equilibrium.

 Familial prion diseases are caused by point mutations in the gene encoding the Pr protein (point mutations are changes in one base in the DNA nucleotide sequence). The diseases have a variety of names related to the different mutations and the clinical syndrome (e.g., Gertsmann-Straussler-Scheinker disease and familial Creutzfeldt-Jakob disease [fCJD]). fCJD arises from an inherited mutation and has an autosomal dominant pedigree. It typically presents in the fourth decade of life. The mutation lowers the energy required for the protein to fold into the PrP^{Sc} conformation; thus, the conversion occurs more readily. It is estimated that the rate of generating prion disease by refolding of PrP^c in the normal cell is about 3,000 to 4,000 years. Lowering of the activation energy for refolding by mutation presumably decreases this time to the observed 30- to 40-year prodromal period. Sporadic CJD may arise from somatic cell mutation or rare spontaneous refoldings that initiate a cascade of refolding into the PrP^{Sc} conformation. The sporadic form of the disease accounts for 85% of all cases of CJD.

Will S. continues to experience severe low-back and lower-extremity pain for many hours after admission. Diffuse pains of sickle cell crises are believed to result from occlusion of small vessels in a variety of tissues, thereby depriving cells of oxygen and cause ischemic or anoxic damage to the tissues. In a **sickle cell crisis**, long hemoglobin polymers form, causing the red blood cells to become distorted and change from a biconcave disc to an irregular shape, such as a sickle (for which the disease was named) or a stellate structure (Fig. 7.27). The aggregating Hb polymers damage the red blood cell membrane and promote aggregation of membrane proteins, leading to increased permeability of the red blood cell, and dehydration. Surface charge and antigens of red blood cells are carried on the transmembrane proteins glycophorin and band 3 (the erythrocyte anion-exchange channel, see Chapter 10). Hemoglobin S binds tightly to the cytoplasmic portion of band 3, contributing to further polymer aggregation and uneven distribution of negative charge on the sickle cell surface. As a result, the affected cells adhere to endothelial cells in capillaries, occluding the vessel and decreasing blood flow to the distal tissues. The subsequent hypoxia in these tissues causes cellular damage, severe ischemic pain, and even death.

FIGURE 7.27 Sickled red blood cells occlude a blood vessel, causing hypoxia (low O_2 in cells) and necrosis (cell death).

The sickled cells are sequestered and destroyed mainly by phagocytic cells, particularly those in the spleen. An anemia results as the number of circulating red blood cells decreases and bilirubin levels rise in the blood as hemoglobin is degraded.

After a few days of treatment, **Will S.**'s crisis was resolved. In the future, should he suffer a cerebrovascular accident (stroke) as a consequence of sickle cell disease causing damage to one of the large cerebral arteries or have recurrent life-threatening episodes of generalized vaso-occlusion in microvessels, a course of long-term maintenance blood transfusions to prevent cerebrovascular accidents may be indicated. Iron chelation would likely have to accompany such a program to prevent or delay the development of iron overload. Although survival for individuals with this disease has improved for those with access to comprehensive care and they often live into their sixth decade, overall survival is still reduced. Death usually results from infection, renal failure, and/or cardiopulmonary disease.

Troponin is a heterotrimeric protein involved in the regulation of striated and cardiac muscle contraction. Most troponin in the cell is bound to the actin–tropomyosin complex in the muscle fibril. The three subunits of troponin consist of troponin C, troponin T, and troponin I, each with a specific function in the regulatory process. Troponin T and troponin I exist as different isoforms in cardiac and skeletal muscle (sequences with a different amino acid composition), thus allowing the development of specific antibodies against each form. As a consequence, either cardiac troponin T or cardiac troponin I may be rapidly measured in blood samples by immunoassay with a high degree of specificity.

Anne J.'s diagnosis of an acute MI was partly based on measurements of cTN-T (the cardiac isozyme of troponin T, a subunit of the regulatory protein troponin). Early diagnosis is critical for a decision on the type of therapeutic intervention to be used. Serum cardiac troponin T is a highly specific marker of myocardial injury. It is typically detected in an acute MI within 2 to 3 hours after onset of symptoms, is positive in most cases within 8 hours, and approaches 100% sensitivity at 10 to 12 hours. It remains elevated for 5 to 7 days.

She stayed in the hospital until she had recovered from her catheterization and was stable on her medication. She was discharged on a low-fat diet and medications for her heart disease and was asked to participate in the hospital's cardiac rehabilitation program for patients recovering from a recent heart attack. Her physician scheduled her for regular examinations.

Amy L. has amyloidosis/AL, which is characterized by deposition of amyloid fibers derived principally from the variable region of λ - or κ -immunoglobulin light chains. Increased amounts of the fragments of the light chains called **Bence-Jones** proteins appeared in her urine. Fibril deposition in the ECM of her kidney glomeruli has resulted in mild renal failure. Deposition of amyloid in the ECM of her heart muscle resulted in thickened heart muscle seen on an echocardiogram. In addition to other signs of right-sided heart failure, she had peripheral edema. The loss of weight may have been caused by infiltrations of amyloid in the gastrointestinal tract or by constipation and diarrhea resulting from involvement of the autonomic nervous system. Treatment may be directed against the plasma cell proliferation and against the symptomatic results of organ dysfunction and is only partially successful. The most effective approach involves the use of stem cell transplantation in concert with melphalan (an antineoplastic agent). If the patient is not a candidate for transplantation, then melphalan and bortezomib (another antineoplastic agent) with dexamethasone (a steroid) can be used. Renal transplantation and cardiac transplantation have been performed in patients with renal and cardiac amyloidosis, respectively, with some success.

During **Amy L.**'s evaluation, she developed a cardiac arrhythmia that was refractory to treatment. The extensive amyloid deposits in her heart had disrupted the flow of electrical impulses in the conduction system of the heart, ultimately resulting in cardiac arrest. On autopsy, amyloid deposits were found within the heart, tongue, liver, adipose tissue, and every organ examined except the central nervous system, which had been protected by the blood–brain barrier.

Dianne A.'s HbA_{1c} of 8.5% was above the normal level of <5.6% of total hemoglobin. Glycation is a nonenzymatic reaction that occurs with a rate directly proportionate to the concentration of glucose in the blood. In the normal range of blood glucose concentrations (approximately 80 to 140 mg/dL, depending on time after a meal), up to 5.6% of the hemoglobin is glycated to form HbA_{1c}. Hemoglobin turns over in the blood as red blood cells are phagocytosed and their hemoglobin degraded and new red blood cells enter the blood from the bone marrow. The average life span of a red blood cell is 120 days. Thus, the extent of hemoglobin glycation is a direct reflection of the average serum glucose concentration to which the cell has been exposed over its 120-day life span. Her elevated HbA_{1c} indicates that her average

blood glucose level has been elevated over the preceding 3 to 4 months. An increase of her insulin dosage would decrease her hyperglycemia and, over time, decrease her HbA_{1c} level as well.

BIOCHEMICAL COMMENTS

The Basics of Hemoglobin Cooperativity. Using X-ray diffraction to study both the oxygenated and deoxygenated forms of hemoglobin, it is now possible to describe the change in conformation at the molecular level when oxygen binds to hemoglobin. We will present a simplistic approach here, looking at interactions that the β -subunit experiences, and having oxygen bind initially to one of the two β -subunits in the hemoglobin tetramer. All of the subunits of hemoglobin contain eight helices, labeled A through H, with A representing the helix at the amino-terminal end. The deoxygenated form of hemoglobin is stabilized by the following interactions, which are also depicted in Figure 7.28:

A. No oxygen

B. Plus oxygen

FIGURE 7.28 Molecular changes that occur when oxygen binds to hemoglobin. See the text for details. **A.** Interactions in the absence of oxygen. **B.** The loss of stabilizing interactions when oxygen binds.

1. Asp 94 (of the F-helix of the β -chain), through its carboxylate side chain, forms a salt bridge (ionic interaction) with the charged imidazole group of his 146, which is the carboxy-terminal amino acid in the β -chain. Part of the Bohr effect is realized through this interaction, because as the pH is reduced, the

probability that His 146 is protonated is increased.

2. The carbonyl carbon of Val 98 forms a hydrogen bond with the tyrosine hydroxyl group at position 145 (the next-to-last amino acid in the β -chain). The effect of these first two interactions is to position helices F and H in close proximity to each other.
3. The free carboxylate group of His 146 (of the β -chain) forms a salt bridge with the ϵ -amino group of the side chain of Lys 40 of the corresponding α -chain. This salt bridge allows communication between these two subunits and places the β -chain H helix close to the α -subunit.

In the β -chain, the proximal His 92 (the eighth amino acid of the F-helix, F8) forms a coordinate covalent bond with the iron in heme, and in so doing, pulls the iron slightly out of the plane of the heme ring. These interactions are all occurring in the deoxygenated state.

So what happens when oxygen binds to a β -subunit? Oxygen binds to the iron in a bent conformation. The binding event triggers the movement of the iron into the plane of the heme ring. Because the iron is also covalently linked to histidine F8, the entire F-helix, and the FG corner (where the F and G helices meet), also move.

1. Asp 94 is in the F-helix. As it is moved (because of the movement of the F-helix), it can no longer form a salt bridge with the imidazole of His 146, which weakens the interactions between the F and H helices.
2. Valine 98 is in the FG corner of the β -subunit, so as that moves, the hydrogen bond formed between Val 98 and Tyr 145 (at the end of the H helix) is also broken.
3. Due in part to the loss of interactions between the F and H helices, the H helix moves and, in so doing, breaks the ionic interaction between His 146 and Lys 40 of the α -subunit. This, along with the steric hindrance of the heme ring and Val 98, leads to a rotation of one $\alpha\beta$ -dimer relative to the other $\alpha\beta$ -dimer and will allow oxygen to bind more readily to the other subunits. The rotation of dimers also forces 2,3-BPG to leave its binding site on hemoglobin, which will favor oxygen binding.

The disruption of the bonds listed above have to occur for oxygen to bind. This is why it takes a high concentration of oxygen to get the first oxygen bound to hemoglobin. At low oxygen levels, the oxygen can dissociate from the iron, which allows the T form to re-form and allow the salt bridges and hydrogen bonds, which stabilize the deoxygenated form, to re-form. If the oxygen concentration is high, such that the iron is continuously occupied with oxygen, the events described above are more likely to occur, and the oxygenation of hemoglobin will occur.

KEY CONCEPTS

- ◆ There are four levels of protein structure:
 - ◆ The primary structure (linear sequence of amino acids within the protein)
 - ◆ The secondary structure (a regular, repeating pattern of hydrogen bonds that stabilize a particular structure)
 - ◆ The tertiary structure (the folding of the secondary structure elements into a three-dimensional conformation)
 - ◆ The quaternary structure (the association of subunits within a protein)
- ◆ The primary structure of a protein determines the way a protein folds into a unique three-dimensional structure called its **native conformation**.
- ◆ When globular proteins fold, the tertiary structure generally forms a densely packed hydrophobic core with polar amino acid side chains on the outside, facing the aqueous environment.
- ◆ The tertiary structure of a protein consists of structural domains, which may be similar between different proteins, and performs similar functions for the different proteins.
- ◆ Certain structural domains are binding sites for specific molecules, called a **ligand**, or for other proteins.
- ◆ The affinity of a binding site for its ligand is quantitatively characterized by an association or affinity constant, K_a (or dissociation constant, K_d).
- ◆ Protein denaturation is the loss of tertiary (and/or secondary) structure within a protein, which can be caused by heat, acid, or other agents that interfere with hydrogen bonding and usually causes a decrease in solubility (precipitation).
- ◆ Diseases discussed in this chapter are summarized in Table 7.1.

TABLE 7.1 Diseases Discussed in Chapter 7

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
Myocardial infarction	Both	Specific heart proteins analyzed include cardiac troponin-T (c-Tn-T, cardiac specific isozyme). Creatine kinase MB and myoglobin are also elevated after a heart attack but are less specific markers, whereas c-Tn-T is the most specific marker for evidence of heart muscle damage.
Amyloidosis	Both	A generic name for the extracellular deposition of pathological insoluble proteins, called amyloid, which are located in organs and tissues. In this chapter, the amyloid is derived from the immunoglobulin light chain. In this disorder, the amyloid will accumulate in the kidney and heart, leading to renal and cardiac-related symptoms.
Sickle cell disease	Genetic	Hemoglobin S polymerization under deoxygenated conditions because of hydrophobic interactions caused by the valine in position 6 of the β -chain, instead of glutamic acid. This leads to alterations in red blood cell shape, which causes occluded capillaries. The lack of blood flow through the capillaries will lead to hypoxia and tissue damage, which generates some of the pain endured during a sickle cell crisis.
Diabetes, types 1 and 2	Both	The use of glycated hemoglobin (HbA1c) to determine glycemic control in the diabetic patient. HbA1c is generated by the nonenzymatic glycation of hemoglobin. The extent of this reaction is dependent on the glucose levels in the circulation. The higher the blood glucose levels, the greater the extent of glycation.
Prion diseases	Both	Protein aggregation diseases because of altered tertiary structure for proteins with the same, or slightly altered, primary structure. The aggregates that form precipitate in the brain, leading to eventual neural degeneration and loss of function

REVIEW QUESTIONS—CHAPTER 7

- One theory of amyloid fibril formation is that sections of α -helical structure are converted to β -sheets. Such regions of the amyloid proteins would most likely lack which one of the following amino acids?
 - Cysteine
 - Methionine
 - Proline
 - Leucine
 - Isoleucine
- In order for lipid-based hormones such as testosterone or estrogen to be transported in the bloodstream, they are bound to and transported by water-soluble proteins. In order to be water-soluble, the transporting protein contains which one of the following amino acids on its surface in contact with aqueous blood?
 - Valine
 - Arginine
 - Leucine
 - Isoleucine
 - Phenylalanine
- A patient has wheezing and shortness of breath, which are his typical asthma symptoms, so he takes a “rescue inhalant,” which is a β_2 -adrenergic receptor agonist. The active ingredient of the inhalant relaxes the smooth muscle of the bronchi and allows him to breathe more normally. The receptor to which the agonist binds can be best described by which one of the following?
 - A globular protein
 - A transmembrane protein
 - A protein containing a nucleotide-binding fold
 - An exclusively β -pleated sheet protein
 - A protein containing an actin fold
- Autopsies of patients with Alzheimer disease show protein aggregates called **neurofibrillary tangles** and **neuritic plaques** in various regions of the brain. These plaques exhibit the characteristic staining of

amyloid. Which of the following structural features is the most likely characteristic of at least one protein in these plaques?

- A. A high content of β -pleated sheet structure
 - B. A high content of α -helical structure
 - C. A high content of random coils
 - D. Disulfide bond cross-links between polypeptide chains
 - E. A low-energy native conformation
5. While studying a novel pathway in a remote species of bacteria, you discover a new globular protein that phosphorylates a substrate, using ATP as the phosphate donor. This protein most likely contains which one of the following structures?
- A. An actin fold
 - B. An immunoglobulin fold
 - C. A nucleotide-binding fold
 - D. A globin fold
 - E. A β -barrel
6. β_2 -Adrenergic agonists used as treatments for acute asthmatic attacks were formulated to have a higher affinity for the β_2 -adrenergic receptor than epinephrine. Which one of the following would be true of the β_2 -agonist as compared to epinephrine?
- A. The K_a of the agonist is higher than that of adrenaline.
 - B. The K_a of the agonist is lower than that of adrenaline.
 - C. The K_a of the agonist is the same as adrenaline.
 - D. The K_d of the agonist is higher than that of adrenaline.
 - E. The K_d of the agonist is equal to adrenaline.
7. A patient is exposed to hepatitis A and as a preventative measure is given hepatitis A immune globulin to prevent the patient from contracting the disease. The vaccine is an IgG immunoglobulin specific for coat proteins of the hepatitis A virus. The target of the immunoglobulin binds to which of the following locations in the immunoglobulin? Choose the one best answer.
- A. A site consisting of the constant regions of the heavy chains
 - B. A site consisting of the constant regions of the light chains
 - C. A site consisting of the variable regions of the light chains
 - D. A site consisting of the variable regions of the heavy chains
 - E. A site consisting of variable regions of both the light and heavy chains
8. Each IgG molecule (like hepatitis A immunoglobulin) contains two light and two heavy chains, which can be separated by the loss of which one of the following types of interactions?
- A. Hydrogen bonds
 - B. Disulfide bonds
 - C. Ionic bonds
 - D. Van der Waals interactions
 - E. The hydrophobic effect
9. A patient with type 1 diabetes was able to lower her HbA1c value from 8.2% to 5.9%. This occurred because of a reduction of which one of the following processes?
- A. Enzymatic oxidation
 - B. Nonenzymatic oxidation
 - C. Enzymatic glycosylation
 - D. Nonenzymatic glycation
 - E. Enzymatic reduction
 - F. Nonenzymatic reduction
10. In amyloidosis, α -helices may form alternative β -sheets of amyloid fibrils. The α -helices in these proteins can be characterized by which one of the following?
- A. They all have the same primary structure.
 - B. They are formed principally by hydrogen bonds between a carbonyl oxygen atom in one peptide bond and the amide hydrogen from a different peptide bond.
 - C. They are formed principally by hydrogen bonds between a carbonyl atom in one peptide bond and the hydrogen atoms on the side chain of another amino acid.
 - D. They are formed by hydrogen bonding between two adjacent amino acids in the primary sequence.

E. They require a high content of proline and glycine.

1. The classic experiment to demonstrate that primary structure determines secondary and tertiary structure, as well as overall protein folding, was performed by Anfinsen and colleagues in 1973. In this experiment, the enzyme ribonuclease was denatured such that the protein lost all enzymatic activity, and then renatured, at which point it was shown that the protein recovered its enzymatic activity. Such an experiment would have failed if mature insulin were selected as the protein to denature due to which one of the following?
 - A. Insulin lacks disulfide bonds.
 - B. The tertiary structure of insulin exists in several forms.
 - C. The primary structure of insulin has been altered after initial protein folding.
 - D. Secondary structures cannot reform after denaturation.
 - E. Insulin is an exception to the rule, as the quaternary structure of insulin determines overall folding.
2. Working muscle generates carbon dioxide and lactic acid, both of which can reduce the local pH in the tissue. Red blood cells, as they enter the capillaries in the muscle, will release oxygen from hemoglobin because of which of the following? Choose the one best answer.

	Reduced Oxygen Concentration in the Muscle	Reduced 2,3-Bisphosphoglycerate Levels in the Muscle	An Increased Proton Concentration	An Increased Carbon Dioxide Concentration
A	Yes	No	Yes	No
B	Yes	Yes	No	No
C	Yes	No	Yes	Yes
D	No	Yes	No	Yes
E	No	No	Yes	No
F	No	Yes	No	Yes

3. Given the structure of the peptide bond below, around which bonds does free rotation allow the structural domains to be generated during folding?

- A. Bond A only
 - B. Bond B only
 - C. Bond C only
 - D. Bonds A and B
 - E. Bonds B and C
 - F. Bonds A and C
 - G. All three bonds
4. The forces responsible for initiating and maintaining secondary and tertiary structures have which one of the following in common?
- A. Van der Waals interactions
 - B. Electrostatic interactions
 - C. Disulfide bonds
 - D. The hydrophobic effect
 - E. Hydrogen bonds
5. Consider a single subunit globular protein that binds a ligand with a K_d of 10^{-6} M in its native state. However, in response to a certain extracellular signal, two serine residues on the protein become phosphorylated, and the phosphorylated protein now binds the ligand with a K_d of 10^{-9} M. Such a change in binding affinity can occur due to which one of the following?
- A. The ligand is negatively charged and now has a reduced affinity for the protein.
 - B. The ligand is positively charged and now has a reduced affinity for the protein.
 - C. The secondary structure is altered because of the ability to now form ionic interactions.
 - D. The tertiary structure is altered because of the ability to now form ionic interactions.
 - E. The quaternary structure is altered because of the ability to now form ionic interactions.

ANSWERS TO REVIEW QUESTIONS

1. **The answer is C.** In the α -helix, the oxygen atom of a carbonyl group forms a hydrogen bond with the nitrogen atom four amino acids farther along the chain. Because proline's nitrogen is part of its cyclic structure, when proline is in a peptide bond, its nitrogen group lacks a proton and cannot form a hydrogen bond with the appropriate carbonyl oxygen atom. The bond angles within the proline ring are also incompatible with α -helix formation, such that proline is known as a "helix breaker." None of the other amino acids listed has their nitrogen in a cyclic structure, so all can form the bond angles and hydrogen bonds necessary for an α -helix.
2. **The answer is B.** Arginine is a charged polar amino acid and water-soluble, whereas the others listed are

nonpolar and hydrophobic and are not expected to be on the surface of a protein exposed to an aqueous environment.

3. **The answer is B.** The β_2 -adrenergic receptor is a transmembrane protein that contains seven membrane-spanning domains and intracellular and extracellular domains on either side of the membrane. It is composed primarily of α -helices but not β -sheets. It does not contain an actin fold and is neither a globular protein nor a protein containing a nucleotide-binding fold. The receptor is coupled to a GTP-binding protein (a G-protein), which does bind GTP or guanosine diphosphate (GDP). The receptor itself, however, does not bind nucleotides.
4. **The answer is A.** The characteristic staining of amyloid arises from fibrils of β -pleated sheet structure perpendicular to the axis of the fiber (thus, B, C, and D are incorrect). The native conformation of a protein is generally the most stable and lowest-energy conformation, and the lower its energy state, the more readily a protein folds into its native conformation and the less likely it will assume the insoluble β -pleated sheet structure of amyloid (thus, E is incorrect).
5. **The answer is A.** The protein hydrolyzes ATP, which is a characteristic of the actin fold. None of the other folds described will hydrolyze ATP.
6. **The answer is A.** The binding affinity is described quantitatively by its association constant, K_a . The higher the K_a , the higher the affinity. Because K_d is the reciprocal of K_a ($1/K_a$), the higher the affinity, the lower the K_d . Because the β -agonist has a higher affinity than adrenaline, its K_a would be higher and its K_d would be lower than that of adrenaline.
7. **The answer is E.** The variable regions of the light and heavy chains interact to produce a single antigen-specific binding site (in this case, for the hepatitis A virus) at each branch of the Y-shaped immunoglobulin. The constant regions are not involved with specific immunity. The variable regions are physically separated such that they are not able to interact with each other (variable L with variable L or variable H with variable H). The variable region of a light chain is immediately adjacent to the variable region of a heavy chain and they interact to form a single binding site.
8. **The answer is B.** Each IgG molecule contains two light and two heavy chains joined by disulfide bonds. Reduction of the disulfide bonds will lead to the separation of the light and heavy chains.
9. **The answer is D.** In nonenzymatic glycation, glucose present in blood binds to amino acids on hemoglobin forming an irreversible glycated protein through the lifetime of that red blood cell. Because the reaction is nonenzymatic, the rate of glycation is proportional to the concentration of the glucose present. Patients with consistently high blood glucose will have a high HbA1c, a marker of poor diabetic control. Oxidation and/or reduction is not involved with the formation of HbA1c.
10. **The answer is B.** The regular repeating structure of an α -helix is possible because it is formed by hydrogen bonds within the peptide backbone of a single strand. Thus, α -helices can be formed from a variety of primary structures. However, proline cannot accommodate the bends for an α -helix because the atoms involved in the peptide backbone are part of a ring structure and glycine cannot provide the space-filling required for a stable structure.
11. **The answer is C.** Insulin is synthesized as a propeptide and undergoes proteolytic processing to form mature insulin. A C-peptide is removed, leaving an A and B peptide, which are connected by disulfide bonds. The loss of the C-peptide has disrupted the primary sequence, which was necessary for the folding of proinsulin, so denaturing mature insulin, and then renaturing it, will not result in the formation of active insulin due to the alteration in primary sequence. The mature structure of insulin only exists in one form, and different secondary elements can reform after denaturation and renaturation of mature insulin.
12. **The answer is C.** Hemoglobin will release oxygen at lower oxygen concentrations (such as the muscle vs. the lungs), and both protons and carbon dioxide stabilize the deoxygenated form of hemoglobin, such that hemoglobin will release oxygen into the tissues. 2,3-Bisphosphoglycerate (2,3-BPG) will also stabilize the deoxygenated form of hemoglobin, so reducing 2,3-BPG levels will reduce oxygen delivery to the tissues.
13. **The answer is F.** The peptide bond (where arrow B is pointing) has double-bond characteristics and there is no rotation about that bond. Thus, only the bonds designated as A and C have free rotation, and if one knew all such bond angles in a protein, the structure of the protein could be predicted.
14. **The answer is E.** Secondary structure is defined as a regular repeating pattern of hydrogen bond formation. There are no other forces involved in secondary structure, so the only force in common between secondary and tertiary structure is hydrogen bonds. The other forces listed are all involved in tertiary and quaternary structure.
15. **The answer is D.** When the protein is phosphorylated, the tertiary structure of the protein can be altered

due to the phosphoserine side chains now being able to form ionic interactions with arginine or lysine side chains, whereas previously the serine hydroxyl group could only hydrogen bond with other regions of the protein. The change in tertiary structure has enhanced ligand binding by a factor of 10^3 , as the association constant ($1/K_d$) is now 10^9 , as compared to 10^6 prior to phosphorylation. As the protein is a single-chain globular protein, it does not exhibit quaternary structure.

Enzymes as Catalysts

Enzymes are proteins that act as **catalysts**, which are compounds that increase the rate of chemical reactions (Fig. 8.1). Enzyme catalysts bind reactants (substrates), convert them to products, and release the products. Although enzymes may be modified during their participation in this reaction sequence, they return to their original form at the end. In addition to increasing the speed of reactions, enzymes provide a means for regulating the rate of metabolic pathways in the body. This chapter describes the properties of enzymes that allow them to function as catalysts. The next chapter explains the mechanisms of enzyme regulation.

**After 1 year
in the absence of enzyme**

**After 1 second
with one molecule of enzyme**

FIGURE 8.1 Catalytic power of enzymes. Many enzymes increase the rate of a chemical reaction by a factor of 10^{11} or higher. To appreciate an increase in reaction rate by this order of magnitude, consider a room-sized box of golf balls that “react” by releasing energy and turning brown. The 12 ft × 12 ft × 8 ft box contains 380,000 golf balls. If the rate of the reaction in the absence of enzyme were 100 golf balls per year, the presence of 1 molecule of enzyme would turn the entire box of golf balls brown in 1 second (assuming a 10^{11} increase in reaction rate).

Enzyme-Binding Sites. An enzyme binds the **substrates** of the reaction and converts them to **products**. The substrates are bound to specific **substrate-binding sites** on the enzyme through interactions with the amino acid residues of the enzyme. The spatial geometry required for all the interactions between the substrate and the enzyme makes each enzyme **selective for its substrates** and ensures that only **specific products** are formed.

Active Catalytic Sites. The substrate-binding sites overlap in the **active catalytic site** of the enzyme, the region of the enzyme where the reaction occurs. Within the catalytic site, **functional groups** provided by **coenzymes**, **tightly bound metals**, and, of course, **amino acid residues** of the enzyme, participate in catalysis.

Activation Energy and the Transition State. The functional groups in the catalytic site of the enzyme activate the substrate and decrease the energy needed to form the high-energy intermediate stage of the reaction known as the **transition-state complex**. Some of the catalytic strategies employed by enzymes, such as **general acid–base catalysis**, formation of **covalent intermediates**, and **stabilization of the transition state**, are illustrated by **chymotrypsin**.

pH and Temperature Profiles. Enzymes have a functional pH range determined by the pK_a of the functional groups in the active site and the interactions required for three-dimensional structure. Increases of temperature, which do not lead to protein denaturation, increase the reaction rate.

Mechanism-Based Inhibitors. The effectiveness of many **drugs** and **toxins** depends on their ability to inhibit an enzyme. The strongest inhibitors are **covalent inhibitors**, which are compounds that form covalent bonds with a reactive group in the enzyme active site, or **transition-state analogs** that mimic the transition-state complex.

Enzyme Names. Most enzyme names end in “-ase.” Enzymes usually have both a common name and a systematic classification that includes a name and an Enzyme Commission (EC) number.

THE WAITING ROOM

A year after recovering from salicylate poisoning (see Chapter 4), **Dennis V.** was playing in his grandfather’s basement. **Dennis V.** drank an unknown amount of the insecticide malathion, which is sometimes used for killing fruit flies and other insects (Fig. 8.2). Sometime later, when he was not feeling well, he told his grandfather what he had done. His grandfather retrieved the bottle and rushed **Dennis V.** to the emergency room of the local hospital. On the way, **Dennis V.** vomited repeatedly and complained of abdominal cramps. At the hospital, he began salivating and had an uncontrollable defecation.

Malathion

Parathion

Sarin

FIGURE 8.2 Organophosphorus compounds. Malathion and parathion are organophosphorus insecticides. Nausea, coma, convulsions, respiratory failure, and death have resulted from the use of parathion by farmers who have gotten it on their skin. Malathion is similar in structure to parathion but is not nearly as toxic. The nerve gas sarin, another organophosphorus compound, was used in a terrorist attack in a subway in Japan.

In the emergency room, physicians passed a nasogastric tube for stomach lavage, started intravenous fluids, and recorded vital signs. **Dennis V.**'s pulse rate was 48 beats/minute (slow), and his blood pressure was 75/42 mm Hg (low). The physicians noted involuntary twitching of the muscles in his extremities.

Lotta T. was diagnosed with acute gouty arthritis involving her right great toe (see Chapter 5). The presence of insoluble urate crystals within the joint space confirmed the diagnosis. Several weeks after her acute gout attack subsided, she was started on allopurinol therapy in an oral dose of 150 mg twice per day, while continuing a daily dose of colchicine. Allopurinol therapy is effective because the drug inhibits the activity of a specific enzyme.

Al M., a 44-year-old male who has suffered from alcohol use disorder for the past 5 years, has a markedly diminished appetite for food. One weekend, he became unusually irritable and confused after drinking two 750 ml bottles of vodka and eating very little. His landlady convinced him to visit his doctor. Physical examination indicated a heart rate of 104 beats/minute. His blood pressure was slightly low, and he was in early congestive heart failure. He was poorly oriented to time, place, and person.

I. The Enzyme-Catalyzed Reaction

Enzymes, in general, provide speed, specificity, and regulatory control to reactions in the body. Enzymes are usually proteins that act as catalysts, which are compounds that increase the rate of chemical reactions. Enzyme-catalyzed reactions have three basic steps:

1. Binding of substrate (a reactant): $E + S \leftrightarrow ES$
2. Conversion of bound substrate to bound product: $ES \leftrightarrow EP$
3. Release of product: $EP \leftrightarrow E + P$

An enzyme binds the substrates of the reaction it catalyzes and brings them together at the right orientation to react. The enzyme then participates in the making and breaking of bonds required for product formation, releases the products, and returns to its original state once the reaction is completed.

Enzymes do not invent new reactions; they simply make reactions occur faster. The catalytic power of an enzyme (the rate of the catalyzed reaction divided by the rate of the uncatalyzed reaction) is usually in the range of 10^6 to 10^{14} . Without the catalytic power of enzymes, reactions such as those involved in nerve conduction, heart contraction, and digestion of food would occur too slowly for life to exist.

Most, if not all, of the tissues and organs in the body are adversely affected by chronic ingestion of excessive amounts of alcohol, including the liver, pancreas, heart, reproductive organs, central nervous system, and the fetus. Some of the effects of alcohol ingestion, such as the psychotropic effects on the brain or inhibition of vitamin transport, are direct effects caused by ethanol itself. However, many of the acute and chronic pathophysiologic effects of alcohol relate to the pathways of ethanol metabolism (see Chapter 33).

Each enzyme usually catalyzes a specific biochemical reaction. The ability of an enzyme to select just one substrate and distinguish this substrate from a group of very similar compounds is referred to as **specificity** (Fig. 8.3). The enzyme converts this substrate to just one product. The specificity as well as the speed of enzyme-catalyzed reactions result from the unique sequence of specific amino acids that form the three-dimensional structure of the enzyme.

FIGURE 8.3 Reaction catalyzed by glucokinase, an example of enzyme reaction specificity. Glucokinase catalyzes the transfer of a phosphate (P) from adenosine triphosphate (ATP) to carbon 6 of glucose. It cannot rapidly transfer a phosphate from other nucleotides to glucose, or from ATP to closely related sugars such as galactose, or from ATP to any other carbon on glucose. The only products formed are glucose 6-phosphate and adenosine diphosphate (ADP).

A. The Active Site

To catalyze a chemical reaction, the enzyme forms an enzyme–substrate complex in its active catalytic site (Fig. 8.4). The **active site** is usually a cleft or crevice in the enzyme formed by one or more regions of the polypeptide chain. Within the active site, cofactors and functional groups from the polypeptide chain participate in transforming the bound substrate molecules into products.

FIGURE 8.4 Reaction in the enzyme active catalytic site. **A.** The enzyme contains an active catalytic site, shown in *dark red*, with a region or domain where the substrate binds. The active site also may contain cofactors—nonprotein components that assist in catalysis. **B.** The substrate forms bonds with amino acid residues in the substrate-binding site. Substrate binding induces a conformational change in the active site. **C.** Functional groups of amino acid residues and cofactors in the active site participate in forming the transition-state complex, which is stabilized by additional noncovalent bonds with the enzyme, shown in *red*. **D:** Because the products of the reaction dissociate, the enzyme returns to its original conformation.

Initially, the substrate molecules bind to their substrate-binding sites, also called the **substrate-recognition sites** (see Fig. 8.4B). The three-dimensional arrangement of binding sites in a crevice of the enzyme allows the reacting portions of the substrates to approach each other from the appropriate angles. The proximity of the bound substrate molecules and their precise orientation toward each other contribute to the catalytic power of the enzyme.

The active site also contains functional groups that participate directly in the reaction (see Fig. 8.4C). The functional groups are donated by the polypeptide chain, or by bound cofactors (metals or complex organic molecules called coenzymes). As the substrate binds, it induces conformational changes in the enzyme that promote further interactions between the substrate molecules and the enzyme functional groups. (For example, a coenzyme might form a covalent intermediate with the substrate, or an amino acid side chain might abstract a proton from the reacting substrate.) The activated substrates and the enzyme form a **transition-state complex**, an unstable high-energy complex with a strained electronic configuration that is intermediate between substrate and product. Additional bonds with the enzyme stabilize the transition-state complex and decrease the energy required for its formation.

The transition-state complex decomposes to products, which dissociate from the enzyme (see Fig. 8.4D). The enzyme generally returns to its original form. The free enzyme then binds another set of substrates and repeats the process.

B. Substrate-Binding Sites

Enzyme specificity (the enzyme's ability to react with just one substrate) results from the three-dimensional

arrangement of specific amino acid residues in the enzyme that form binding sites for the substrates and activate the substrates during the course of the reaction. The “lock-and-key” and the “induced-fit” models for substrate binding describe two aspects of the binding interaction between the enzyme and substrate.

1. Lock-and-Key Model for Substrate Binding

The substrate-binding site contains amino acid residues arranged in a complementary three-dimensional surface that “recognizes” the substrate and binds it through multiple hydrophobic interactions, electrostatic interactions, or hydrogen bonds. The amino acid residues that bind the substrate can come from very different parts of the linear amino acid sequence of the enzyme, as seen in glucokinase. The binding of compounds with a structure that differs from the substrate even to a small degree may be prevented by steric hindrance and charge repulsion. In the lock-and-key model, the complementarity between the substrate and its binding site is compared to that of a key fitting into a rigid lock.

2. Induced-Fit Model for Substrate Binding

Complementarity between the substrate and the binding site is only part of the picture. As the substrate binds, enzymes undergo a conformational change (“induced fit”) that repositions the side chains of the amino acids in the active site and increases the number of binding interactions (see Fig. 8.4). The induced-fit model for substrate binding recognizes that the substrate-binding site is not a rigid “lock” but rather a dynamic surface created by the flexible overall three-dimensional structure of the enzyme.

The function of the conformational change induced by substrate binding, the induced fit, is usually to reposition functional groups in the active site in a way that promotes the reaction, improves the binding site of a cosubstrate, or activates an adjacent subunit through cooperativity. For example, consider the large conformational changes that occur in the actin fold of glucokinase when glucose binds. First, the substrate glucose binds in a manner resembling a lock and key (Fig. 8.5). As glucose binds, the induced fit results. The induced fit involves changes in the conformation of the whole enzyme that close the cleft of the fold, thereby improving the binding site for adenosine triphosphate (ATP), and excluding water (which might interfere with the reaction) from the active site (Fig. 8.6). Thus, the multiple interactions between the substrate and the enzyme in the catalytic site serve both for substrate recognition and for initiating the next stage of the reaction, formation of the transition-state complex.

FIGURE 8.5 Glucose-binding site in glucokinase. **A.** Glucose, shown in *red*, is held in its binding site by multiple hydrogen bonds between each hydroxyl group and polar amino acids from different regions of the enzyme amino acid sequence in the actin fold (see Chapter 7). The position of the amino acid residue in the linear sequence is given by its number. The multiple interactions enable glucose to induce large conformational changes in the enzyme (induced fit). (Modified from Pilkis SJ, Weber IT, Harrison RW, et al. Glucokinase: structural analysis of a protein involved in susceptibility to diabetes. *J Biol Chem.* 1994;269(35):21925–21928. <https://creativecommons.org/licenses/by/4.0/>) **B.** Enzyme specificity is illustrated by the comparison of galactose and glucose. Galactose differs from glucose only in the position of the –OH group shown in *red*. However, it is not phosphorylated at a significant rate by the enzyme. Cells therefore require a separate galactokinase for the metabolism of galactose.

A

D-glucose

B

FIGURE 8.6 Conformational change resulting from the binding of glucose to hexokinase. (The figure is actually yeast hexokinase, which is more similar to human glucokinase than it is to the other human hexokinase isozymes.) The *shaded* and *unshaded* areas show the two domains (four subdomains) that form the actin fold with its adenosine triphosphate (ATP)-binding cleft. **A.** Free enzyme. **B.** With glucose bound, the cleft closes, forming the ATP-binding site. The closure of the cleft when glucose binds to hexokinase (or human glucokinase) is one of the largest “induced fits” known. (Reprinted from Bennett WS Jr, Steitz TA. Structure of a complex between yeast hexokinase A and glucose: II. Detailed comparisons of conformation and active site configuration with the native hexokinase B monomer and dimer. *J Mol Biol.* 1980;140(2):211–230. © 1980 Elsevier. With permission.)

C. The Transition-State Complex

In order for a reaction to occur, the substrates undergoing the reaction need to be activated. If the energy levels of a substrate are plotted as the substrate is progressively converted to product, the curve will show a maximum energy level that is higher than that of either the substrate or the product (Fig. 8.7). This high energy level occurs at the transition state. For some enzyme-catalyzed reactions, the transition state is a condition in which bonds in the substrate are maximally strained. For other enzyme-catalyzed reactions, the electronic configuration of the substrate becomes very strained and unstable as it enters the transition state. The highest energy level corresponds to the most unstable substrate configuration, and the condition in which the changing substrate molecule is most tightly bound to participating functional groups in the enzyme. The difference in energy between the substrate and the transition-state complex is called the **activation energy**.

FIGURE 8.7 Energy diagram showing the energy levels of the substrates as they progress toward products in the absence of enzyme. The substrates must pass through the high-energy transition state during the reaction. Although a favorable loss of energy occurs during the reaction, the rate of the reaction is slowed by the energy barrier to forming the transition state. The energy barrier is referred to as the activation energy.

According to transition-state theory, the overall rate of the reaction is determined by the number of molecules acquiring the activation energy necessary to form the transition-state complex. Enzymes increase the rate of the reaction by decreasing this activation energy. They use various catalytic strategies, such as electronic

stabilization of the transition-state complex or acid–base catalysis, to obtain this decrease.

Once the transition-state complex is formed, it can collapse back to substrates or decompose to form products. The enzyme does not change the initial energy level of the substrates or the final energy level of the products.

Because the transition-state complex binds more tightly to the enzyme than does the substrate, compounds that resemble its electronic and three-dimensional surface (**transition-state analogs**) are more potent inhibitors of an enzyme than are substrate analogs. Consequently, a drug developed as a transition-state analog would be highly specific for the enzyme it is designed to inhibit. However, transition-state analogs are highly unstable when they are not bound to the enzyme and would have great difficulty making it from the digestive tract or injection site to the site of action. Some of the approaches in drug design that are being used to deal with the instability problem include designing drugs that are almost transition-state analogs but have a stable modification; designing a prodrug that is converted to a transition-state analog at the site of action; and using the transition-state analog to design a complementary antibody.

If the structure of a transition state can be modeled, it can be used as an antigen for the production of **abzymes** (catalytic antibodies). These antibodies have an arrangement of amino acid side chains in their variable regions that is similar to the active site of the enzyme in the transition state. Consequently, they can act as artificial enzymes. For example, abzymes have been developed against analogs of the transition-state complex of cocaine esterase, the enzyme that degrades cocaine in the body. These abzymes have esterase activity, and monthly injections of the abzyme drug can be used to rapidly destroy cocaine in the blood, thereby decreasing the dependence of addicted individuals. (See Chapter 7 for antibody structure.)

II. Strategies for Catalysis

There are five major strategies used by enzymes to enable catalysis: general acid–base catalysis, covalent catalysis, metal-ion catalysis, catalysis by approximation, and cofactor catalysis. Some enzymes will use a combination of these strategies.

A. General Acid–Base Catalysis

In general acid–base catalysis, a functional group on the protein either donates a proton (acid catalysis) or accepts a proton (general base catalysis) during the course of the reaction. An example of general acid–base catalysis is seen in the mechanism of chymotrypsin (see the online Catalytic Mechanism of Chymotrypsin material). During the course of this reaction, histidine 57 acts as a general base catalyst and accepts a proton from serine 195, activating the serine to act as a nucleophile. Later on in the reaction sequence, the protonated histidine 57 acts as a general acid catalyst and donates a proton to a product leaving the reaction.

Catalytic mechanism of chymotrypsin

B. Covalent Catalysis

In covalent catalysis, the substrate is covalently linked during the course of the reaction to an amino acid side chain at the active site of the enzyme. Chymotrypsin (a protease, an enzyme which breaks peptide bonds) also exhibits covalent catalysis. Once histidine 57 activates serine 195 by removing its proton from the hydroxyl group on the side chain, the negatively charged oxyanion attacks the carbonyl group of the peptide bond to be cleaved by the enzyme, forming a covalent bond and tetrahedral intermediate. The substrate stays covalently linked to the enzyme through the course of the reaction.

C. Metal-Ion Catalysis

Many enzymes contain required metal ions to allow catalysis to occur. In the case of carbonic anhydrase, an enzyme-bound zinc at the active site binds and orients water appropriately so it can participate in the reaction. In the absence of the active-site zinc, the reaction occurs very slowly, if at all.

D. Catalysis by Approximation

Catalysis by approximation refers to the enzyme forcing (through the formation of hydrogen bonds and ionic interactions between the enzyme and substrate) substrates to bind in a manner that places reactive groups in the

appropriate orientation so a reaction can take place. Nucleoside monophosphate kinases use this type of mechanism to transfer a phosphate from a nucleoside triphosphate to a nucleoside monophosphate, producing two nucleoside diphosphates.

 In the stomach, gastric acid decreases the pH to 1 to 2 to denature proteins through disruption of ionic interactions and hydrogen bonding. The protease in the stomach, pepsin, is a member of the aspartate protease superfamily, enzymes that use two aspartate residues in the active site for acid–base catalysis of the peptide bond. Why can they not use histidine like chymotrypsin?

E. Cofactor Catalysis

In cofactor catalysis, a required cofactor for an enzyme usually forms a covalent bond with the substrate during the course of the reaction. Enzymes involved in amino acid metabolism use pyridoxal phosphate (derived from vitamin B₆) to form a covalent bond during the course of the reaction.

III. Functional Groups in Catalysis

The catalytic strategies as described in the previous section to increase the reaction rate are common to many enzymes. A variety of functional groups are employed by different enzymes to carry out these catalytic strategies. Some enzymes, such as chymotrypsin, rely on amino acid residues within the active site. Other enzymes increase their repertoire by employing cofactors (nonprotein compounds that participate in the catalytic process) to provide a functional group with the right size, shape, and properties. They are generally divided into three categories: coenzymes (such as pyridoxal phosphate), metal ions (e.g., Fe²⁺, Mg²⁺, or Zn²⁺), and metallocoenzymes (similar to the Fe²⁺-heme in hemoglobin, see Chapter 7).

A. Functional Groups on Amino Acid Side Chains

Almost all of the polar amino acids participate directly in catalysis in one or more enzymes (Table 8.1). Serine, cysteine, lysine, and histidine can participate in covalent catalysis. Histidine, because it has a pK_a that can donate and accept a proton at neutral pH, often participates in acid–base catalysis. Most of the polar amino acid side chains are nucleophilic and participate in nucleophilic catalysis by stabilizing more positively charged groups that develop during the reaction.

TABLE 8.1 Some Functional Groups in the Active Site	
FUNCTION OF AMINO ACID	ENZYME EXAMPLE
<i>Covalent intermediates</i>	
Cysteine–SH	Glyceraldehyde 3–phosphate dehydrogenase
Serine–OH	Acetylcholinesterase, chymotrypsin
Lysine–NH ₂	Aldolase
Histidine–NH	Phosphoglucomutase
<i>Acid–base catalysis</i>	
Histidine–NH	Chymotrypsin
Aspartate–COOH	Pepsin
<i>Stabilization of anion formed during the reaction</i>	
Peptide backbone–NH	Chymotrypsin
Arginine–NH	Carboxypeptidase A
Serine–OH	Alcohol dehydrogenase

 Because most vitamins function as coenzymes, the symptoms of vitamin deficiencies reflect the loss of specific enzyme activities that depend on the coenzyme form of the vitamin. Thus, drugs and toxins that inhibit proteins required for coenzyme synthesis (e.g., vitamin transport proteins or biosynthetic enzymes) can cause the symptoms of a vitamin deficiency. This type of deficiency is called a functional deficiency, whereas an inadequate intake is called a dietary deficiency.

Most coenzymes are tightly bound to their enzymes and do not dissociate during the course of the reaction. However, a functional or dietary vitamin deficiency that decreases the level of a coenzyme will result in the presence of the apoenzyme in

cells (an enzyme devoid of cofactor).

Ethanol is an “antivitamin” that decreases the cellular content of almost every coenzyme. For example, ethanol inhibits the absorption of thiamin, and acetaldehyde produced from ethanol oxidation displaces pyridoxal phosphate from its protein-binding sites, thereby accelerating its degradation.

B. Coenzymes in Catalysis

Coenzymes (cofactors) are complex nonprotein organic molecules that participate in catalysis by providing functional groups, much like the amino acid side chains. In the human, they are usually (but not always) synthesized from vitamins. Each coenzyme is involved in catalyzing a specific type of reaction for a class of substrates with certain structural features. Coenzymes can be divided into two general classes: activation-transfer coenzymes and oxidation–reduction coenzymes.

Although coenzymes look as though they should be able to catalyze reactions autonomously (on their own), they have almost no catalytic power when not bound to the enzyme. Why?

1. Activation-Transfer Coenzymes

Activation-transfer coenzymes usually participate directly in catalysis by forming a covalent bond with a portion of the substrate; the tightly held substrate moiety is then activated for transfer, addition of water, or some other reaction. The portion of the coenzyme that forms a covalent bond with the substrate is its functional group. A separate portion of the coenzyme binds tightly to the enzyme. In general, coenzymes are nonprotein organic cofactors that participate in reactions. They may be covalently bound to enzymes (e.g., biotin), noncovalently bound such that they dissociate from the enzyme under cofactor deficiency conditions (e.g., thiamin), or become incorporated into a product of the reaction (e.g., coenzyme A [CoA], which is derived from pantothenic acid). Cofactors that are covalently or very tightly bound to nonenzyme proteins are usually called **prosthetic groups**. A prosthetic group, such as the heme in hemoglobin, usually does not dissociate from a protein until the protein is degraded.

To participate in general acid–base catalysis, the amino acid side chain must be able to extract a proton at one stage of the reaction and donate it back at another. Histidine (pK_a 6.0) would be protonated at this low pH and could not extract a proton from a potential nucleophile. However, aspartic acid, with a pK_a of about 2 can release protons at a pH of 2. The two aspartates work together to activate water through the removal of a proton to form the hydroxyl nucleophile.

Thiamin pyrophosphate (TPP) provides a good illustration of the manner in which coenzymes participate in catalysis (Fig. 8.8). It is synthesized in human cells from the vitamin thiamin by the addition of a pyrophosphate. This pyrophosphate provides negatively charged oxygen atoms that chelate Mg^{2+} , which then binds tightly to the enzyme. The functional group that extends into the active site is the reactive carbon atom with a dissociable proton (see Fig. 8.8). In all of the enzymes that use TPP, this reactive thiamin carbon forms a covalent bond with a substrate keto group while cleaving the adjacent carbon–carbon bond. However, each thiamin-containing enzyme catalyzes the cleavage of a different substrate (or group of substrates with very closely related structures).

FIGURE 8.8 The role of the functional group of thiamin pyrophosphate (TPP; the reactive carbon shown in *red*) in formation of a covalent intermediate. **A.** A base on the enzyme (*enzB*) abstracts a proton from thiamin, creating a carbanion (general acid–base catalysis). **B.** The carbanion is a strong nucleophile and attacks the partially positively charged keto group on the substrate. **C.** A covalent intermediate is formed, which, after decarboxylation, is stabilized by resonance forms. The uncharged intermediate is the stabilized transition-state complex.

In order for a substrate to react with a coenzyme, it must collide with a coenzyme at exactly the right angle. The probability of the substrate and coenzyme in free solution colliding in exactly the right place at the exactly right angle is very small. In addition to providing this proximity and orientation, enzymes contribute in other ways, such as activating the coenzyme by extracting a proton (e.g., TPP and CoA) or polarizing the substrate to make it more susceptible to nucleophilic attack.

Coenzymes have very little activity in the absence of the enzyme and very little specificity. The enzyme provides specificity, proximity, and orientation in the substrate recognition site, as well as other functional groups for stabilization of the transition state, acid–base catalysis, and so on. For example, thiamin is made into a better nucleophilic attacking group by a basic amino acid residue in the enzyme that removes the dissociable proton (EnzB in Fig. 8.8), thereby generating a negatively charged thiamin carbon anion. Later in the reaction, the enzyme returns the proton.

CoA, biotin, and pyridoxal phosphate are also activation-transfer coenzymes synthesized from vitamins. CoA (CoASH), which is synthesized from the vitamin pantothenate, contains an adenosine 3',5'-bisphosphate that binds reversibly, but tightly, to a site on an enzyme (Fig. 8.9A). Its functional group, a sulfhydryl group at the other end of the molecule, is a nucleophile that always attacks carbonyl groups and forms acyl thioesters (in fact, the “A” in CoA stands for the *acyl* group that becomes attached). Most coenzymes, such as functional groups on the enzyme amino acids, are regenerated during the course of the reaction. However, CoASH and a few of the oxidation–reduction coenzymes are transformed during the reaction into products that dissociate from the enzyme at the end of the reaction (e.g., CoASH is converted to an acyl CoA derivative, and nicotinamide adenine dinucleotide (NAD⁺) is reduced to NADH). These dissociating coenzymes are nonetheless classified as coenzymes rather than substrates because they are common to so many reactions, the original form is regenerated by subsequent reactions in a metabolic pathway, they are synthesized from vitamins, and the amount of coenzyme in the cell is nearly constant.

A. CoASH

B. Biotin

C. Pyridoxal phosphate (PLP)

FIGURE 8.9 Activation-transfer coenzymes. **A.** Coenzyme A (CoA or CoASH) and phosphopantetheine are synthesized from the vitamin pantothenate (pantothenic acid). The active sulfhydryl group, shown in *red*, binds to acyl groups (e.g., acetyl, succinyl, or fatty acyl) to form thioesters. **B.** Biotin activates and transfers CO₂ to compounds in carboxylation reactions. The reactive N is shown in *red*. Biotin is covalently attached to a lysine residue in the carboxylase enzyme. **C:** Reactive sites of pyridoxal phosphate. The functional group of pyridoxal phosphate (PLP) is a reactive aldehyde (shown in the *yellow box*) that forms a covalent intermediate with amino groups of amino acids (a Schiff base). The positively charged pyridine ring is a strong electron-withdrawing group that can pull electrons into it (electrophilic catalysis).

Many people with alcohol use disorder, like **Al M.**, develop thiamin deficiency because alcohol inhibits the transport of thiamin through the intestinal mucosal cells. In the body, thiamin is converted to TPP. TPP acts as a coenzyme in the decarboxylation of α -keto acids such as pyruvate and α -ketoglutarate (see Fig. 8.9) and in the use of pentose phosphates in the pentose phosphate pathway. As a result of thiamin deficiency, the oxidation of α -keto acids is impaired. Dysfunction occurs in the central and peripheral nervous system, the cardiovascular system, and other organs, which require a large amount of energy.

Biotin, which does not contain a phosphate group, is covalently bonded to a lysine in enzymes called **carboxylases** (see Fig. 8.9B). Its functional group is a nitrogen atom that covalently binds a CO₂ group in an energy-requiring reaction. This bound CO₂ group is activated for addition to another molecule. In the human, biotin functions only in carboxylation reactions.

Pyridoxal phosphate is synthesized from the vitamin pyridoxine, which is also called vitamin B₆ (see Fig. 8.9C). The reactive aldehyde group usually functions in enzyme-catalyzed reactions by forming a covalent bond with the amino groups on amino acids. The positively charged ring nitrogen withdraws electrons from a bond in the bound amino acid, resulting in cleavage of that bond. The enzyme participates by removing protons from the substrate and by keeping the amino acid and the pyridoxal group in a single plane to facilitate shuttling of electrons.

These coenzymes illustrate three features all activation-transfer coenzymes have in common: (1) a specific chemical group involved in binding to the enzyme, (2) a separate and different functional or reactive group that participates directly in the catalysis of one type of reaction by forming a covalent bond with the substrate, and (3) dependence on the enzyme for additional specificity of substrate and additional catalytic power.

2. Oxidation–Reduction Coenzymes

Oxidation–reduction coenzymes are involved in oxidation–reduction reactions catalyzed by enzymes categorized as **oxidoreductases**. When a compound is oxidized, it loses electrons. As a result, the oxidized carbon has fewer H atoms or gains an O atom. The reduction of a compound is the gain of electrons, which shows in its structure as the gain of H, or loss of O. Some coenzymes, such as NAD⁺ and flavin adenine dinucleotide (FAD), can transfer electrons together with hydrogen and have unique roles in the generation of ATP from the oxidation of fuels. Other oxidation–reduction coenzymes work with metals to transfer single electrons to oxygen. Vitamin E and vitamin C (ascorbic acid) are oxidation–reduction coenzymes that can act as antioxidants and protect against oxygen free-radical injury. The different functions of oxidation–reduction coenzymes in metabolic pathways are explained in Chapters 20 through 24. A subclass of oxidoreductases is given the name **dehydrogenases** because they transfer hydrogen (hydrogen atoms or hydride ions) from the substrate to an electron-accepting coenzyme, such as NAD⁺.

Oxidation–reduction coenzymes follow the same principles as activation-transfer coenzymes, except that they do not form covalent bonds with the substrate. Each coenzyme has a unique functional group that accepts and donates electrons and is specific for the form of electrons it transfers (e.g., hydride ions, hydrogen atoms, oxygen). A different portion of the coenzyme binds the enzyme. Like activation-transfer coenzymes, oxidation–reduction coenzymes are not good catalysts without participation from amino acid side chains on the enzyme.

The enzyme lactate dehydrogenase, which catalyzes the transfer of electrons from lactate to NAD⁺, illustrates these principles (Fig. 8.10). In the oxidation of lactate to pyruvate, lactate loses two electrons as a hydride ion, and a proton (H⁺) is released. NAD⁺, which accepts the hydride ion, is reduced to NADH. The carbon atom with the keto group in pyruvate is at a higher oxidation state than in lactate because both of the electrons in bonds between carbon and oxygen are counted as belonging to oxygen, whereas the two electrons in the carbon–hydrogen bond are shared equally between carbon and hydrogen.

FIGURE 8.10 The coenzyme nicotinamide adenine dinucleotide (NAD^+) accepting a hydride ion, shown in red, from lactate. NAD^+ -dependent dehydrogenases catalyze the transfer of a hydride ion (H^-) from a carbon to NAD^+ in oxidation reactions such as the oxidation of alcohols to ketones or aldehydes to acids. The positively charged pyridine ring nitrogen of NAD^+ increases the electrophilicity of the carbon opposite it in the ring. This carbon then accepts the negatively charged hydride ion. The proton from the alcohol group is released into water. NADP^+ functions by the same mechanism, but it is usually involved in pathways of reductive synthesis.

In humans, most of ingested ethanol is oxidized to acetaldehyde in the liver by ADH:

ADH is active as a dimer, with an active site containing zinc present in each subunit. The human has at least seven genes that encode isozymes of ADH, each with a slightly different range of specificities for the alcohols it oxidizes.

The acetaldehyde produced from ethanol is highly reactive, toxic, and immunogenic. In **Al M.** and other patients with chronic alcohol use disorder, acetaldehyde is responsible for much of the liver injury associated with this addiction.

The coenzyme NAD^+ is synthesized from the vitamin niacin (which forms the nicotinamide ring), and from ATP (which contributes an adenosine monophosphate [AMP]). The adenosine diphosphate (ADP) portion of the molecule binds tightly to the enzyme and causes conformational changes in the enzyme. The functional group of NAD^+ is the carbon on the nicotinamide ring opposite the positively charged nitrogen. This carbon

atom accepts the hydride ion (a hydrogen atom that has two electrons) transferred from a specific carbon atom on the substrate. The H^+ from the substrate alcohol ($-\text{OH}$) group then dissociates, and a keto group ($\text{C}=\text{O}$) is formed. One of the roles of the enzyme is to contribute a histidine nitrogen that can bind the dissociable proton on lactate, thereby making it easier for NAD^+ to pull off the other hydrogen with both electrons. Finally, NADH dissociates from the enzyme.

C. Metal Ions in Catalysis (See Also Section II.C)

Metal ions, which have a positive charge, contribute to the catalytic process by acting as **electrophiles** (electron-attracting groups). They assist in binding of the substrate, or they stabilize developing anions in the reaction. They can also accept and donate electrons in oxidation–reduction reactions.

 In the clinical laboratory, ethanol (in serum) is usually analyzed by coupling its oxidation to the formation of NADH using the enzyme ADH. NAD^+ has a low extinction coefficient at 340 nm; NADH has a much higher one. Thus, the increase in absorbance at 340 nm that occurs during the reaction indicates how much NADH was produced, which is directly proportional to the ethanol concentration in the serum. These reactions have been fully automated for the clinical lab.

The ability of certain metals to bind multiple ligands in their coordination sphere enables them to participate in binding substrates or coenzymes to enzymes. For example, Mg^{2+} plays a role in the binding of the negatively charged phosphate groups of TPP to anionic or basic amino acids in the enzyme (see Fig. 8.8). The phosphate groups of ATP are usually bound to enzymes through Mg^{2+} chelation.

The metals of some enzymes bind anionic substrates or intermediates of the reaction to alter their charge distribution, thereby contributing to catalytic power. The enzyme alcohol dehydrogenase, which transfers electrons from ethanol to NAD^+ to generate acetaldehyde and NADH , illustrates this role (Fig. 8.11). In the active site of alcohol dehydrogenase, an activated serine pulls a proton off the ethanol $-\text{OH}$ group, leaving a negative charge on the oxygen that is stabilized by zinc. This electronic configuration allows the transfer of a hydride ion to NAD^+ . Zinc is essentially fulfilling the same function in alcohol dehydrogenase that histidine fulfills in lactate dehydrogenase.

FIGURE 8.11 Liver alcohol dehydrogenase (ADH) catalyzes the oxidation of ethanol (shown in red) to acetaldehyde. The active site of liver ADH contains a bound zinc atom, and a serine side chain –OH, and a histidine nitrogen that participate in the reaction. The histidine pulls an H⁺ off the active-site serine, which pulls the H⁺ off of the substrate –OH group, leaving the oxygen with a negative charge that is stabilized by zinc.

D. Noncatalytic Roles of Cofactors

Cofactors sometimes play a noncatalytic structural role in certain enzymes, binding different regions of the enzyme together to form the tertiary structure. They also can serve as substrates that are cleaved during the reaction.

IV. Optimal pH and Temperature

If the activity of most enzymes is plotted as a function of the pH of the reaction, an increase of reaction rate is

usually observed as the pH goes from a very acidic level to the physiologic range; a decrease of reaction rate occurs as the pH goes from the physiologic range to a very basic range (Fig. 8.12). The reason for the increased activity as the pH is raised to physiologic levels usually reflects the ionization of specific functional groups in the active site (or in the substrate) by the increase of pH, and the more general formation of hydrogen bonds important for the overall conformation of the enzyme. The loss of activity on the basic side usually reflects the inappropriate ionization of amino acid residues in the enzyme.

FIGURE 8.12 pH profile of an enzyme. The rate of the reaction increases as the pH increases from 6 to 7.4. The exact shape of the curve depends on the protonation state of active-site amino acid residues or on the hydrogen bonding required for maintenance of three-dimensional structure in the enzyme. For the enzyme shown in the figure, the increase of reaction rate corresponds to deprotonation of the active-site histidine. At a pH >8.5, deprotonation of an amino-terminal $-\text{NH}_3^+$ alters the conformation at the active site and the activity decreases. Other enzymes might have a lower pH maximum, a broader peak, or retain their activity in the basic side of the curve.

Most human enzymes function optimally at a temperature of around 37°C . An increase of temperature from 0°C to 37°C increases the rate of the reaction by increasing the vibrational energy of the substrates. The maximum activity for most human enzymes occurs near 37°C because denaturation (loss of secondary and tertiary structure) occurs at higher temperatures.

V. Mechanism-Based Inhibitors

Inhibitors are compounds that decrease the rate of an enzymatic reaction. Mechanism-based inhibitors mimic or participate in an intermediate step of the catalytic reaction. The term includes transition-state analogs (see Section I.C) and compounds that can react irreversibly with functional groups in the active site.

A. Covalent Inhibitors

Covalent inhibitors form covalent or extremely tight bonds with functional groups in the active catalytic site. These functional groups are activated by their interactions with other amino acid residues and are therefore far more likely to be targeted by drugs and toxins than amino acid residues outside the active site.

The lethal compound diisopropylphosphofluoridate (diisopropylfluorophosphate [DFP]) is an organophosphorus compound that served as a prototype for the development of the nerve gas sarin and other organophosphorus toxins, such as the insecticides malathion and parathion (Fig. 8.13). DFP exerts its toxic effect by forming a covalent intermediate in the active site of acetylcholinesterase, thereby preventing the enzyme from degrading the neurotransmitter acetylcholine. Once the covalent bond is formed, the inhibition by DFP is essentially irreversible and activity can only be recovered as new enzyme is synthesized. DFP also inhibits many other enzymes that use serine for hydrolytic cleavage, but the inhibition is not as lethal.

A. Normal reaction of acetylcholinesterase

B. Reaction with organophosphorus inhibitors

FIGURE 8.13 **A.** Acetylcholinesterase normally catalyzes inactivation of the neurotransmitter acetylcholine in a hydrolysis reaction. The active-site serine forms a covalent intermediate with a portion of the substrate during the course of the reaction. **B.** Diisopropyl phosphofluoridate (DFP), the ancestor of current organophosphorus nerve gases and pesticides, inactivates acetylcholinesterase by forming a covalent complex with the active-site serine that cannot be hydrolyzed by water. The result is that the enzyme (*Enz*) cannot carry out its normal reaction, and acetylcholine accumulates.

Aspirin (acetylsalicylic acid) provides an example of a pharmacologic drug that exerts its effect through the covalent acetylation of an active-site serine in the enzyme prostaglandin endoperoxide synthase (cyclooxygenase). Aspirin resembles a portion of the prostaglandin precursor that is a physiologic substrate for the enzyme.

B. Transition-State Analogs and Compounds That Resemble Intermediate Stages of the Reaction

Transition-state analogs are extremely potent and specific inhibitors of enzymes because they bind so much more tightly to the enzyme than do substrates or products. Drugs cannot be designed that precisely mimic the transition state because of its highly unstable structure. However, substrates undergo progressive changes in their overall electrostatic structure during the formation of a transition-state complex, and effective drugs often resemble an intermediate stage of the reaction more closely than they resemble the substrate. Medical literature often refers to such compounds as substrate analogs, even though they bind more tightly than substrates.

 The symptoms experienced by **Dennis V.** resulted from inhibition of acetylcholinesterase. Acetylcholinesterase cleaves the neurotransmitter acetylcholine to acetate and choline in the postsynaptic terminal, thereby terminating the transmission of the neural signal (see Fig. 8.13). Malathion is metabolized in the liver to a toxic derivative (malaoxon) that

binds to the active-site serine in acetylcholinesterase and other enzymes, an action similar to that of DFP. As a result, acetylcholine accumulates and overstimulates the autonomic nervous system (the involuntary nervous system, including the heart, blood vessels, and glands), thereby accounting for **Dennis V.**'s vomiting, abdominal cramps, salivation, and sweating. Acetylcholine is also a neurotransmitter for the somatic motor nervous system, where its accumulation resulted in his involuntary muscle twitching (muscle fasciculations).

1. Penicillin

The antibiotic penicillin is a transition-state analog that binds very tightly to glycopeptidyl transferase, an enzyme required by bacteria for synthesis of the cell wall (Fig. 8.14). Glycopeptidyl transferase catalyzes a partial reaction with penicillin that covalently attaches penicillin to its own active-site serine. The reaction is favored by the strong resemblance between the peptide bond in the β -lactam ring of penicillin and the transition-state complex of the natural transpeptidation reaction. Active-site inhibitors like penicillin that undergo partial reaction to form irreversible inhibitors in the active site are sometimes termed "suicide inhibitors."

Penicillin

Strained
peptide bond

Glycopeptide
transpeptidase

FIGURE 8.14 The antibiotic penicillin inhibits the bacterial enzyme glycopeptide transpeptidase. The transpeptidase is a serine protease involved in cross-linking components of bacterial cell walls and is essential for bacterial growth and survival. It normally cleaves the peptide bond between two D-alanine residues in a polypeptide. Penicillin contains a strained peptide bond within the β -lactam ring that resembles the transition state of the normal cleavage reaction, and thus, penicillin binds very readily in the enzyme active site. As the bacterial enzyme attempts to cleave this penicillin peptide bond, penicillin becomes irreversibly covalently attached to the enzyme's active-site serine, thereby inactivating the enzyme.

2. Allopurinol

Allopurinol, a drug used to treat gout, decreases urate production by inhibiting xanthine oxidase. This inhibition provides an example of an enzyme that commits suicide by converting a drug to a transition-state analog. The normal physiologic function of xanthine oxidase is the oxidation of hypoxanthine to xanthine and xanthine to uric acid (urate) in the pathway for degradation of purines (Fig. 8.15). The enzyme contains a molybdenum–sulfide (Mo-S) complex that binds the substrates and transfers the electrons required for the oxidation reactions. Xanthine oxidase oxidizes the drug allopurinol to oxypurinol, a compound that binds very tightly to a Mo-S complex in the active site. As a result, the enzyme has committed suicide and is unable to carry out its normal function, the generation of uric acid (urate).

FIGURE 8.15 Allopurinol is a suicide inhibitor of xanthine oxidase. **A.** Xanthine oxidase catalyzes the oxidation of hypoxanthine to xanthine, and xanthine to uric acid (urate) in the pathway for degradation of purine nucleotides. **B.** The oxidations are performed by a molybdenum–oxo–sulfide coordination complex in the active site that complexes with the group being oxidized. Oxygen is donated from water. The enzyme (enz) can work either as an oxidase (O_2 accepts the 2e^- and is reduced to H_2O_2) or as a dehydrogenase (NAD^+ accepts the 2e^- and is reduced to NADH .) The figure only indicates that 2e^- are generated during the course of the reaction. **C.** Xanthine oxidase is able to perform the first oxidation step and convert allopurinol to alloxanthine (oxypurinol). As a result, the enzyme has committed suicide; the oxypurinol remains bound in the molybdenum coordination sphere, where it prevents the next step of the reaction. The portion of the purine ring in *green* indicates the major structural difference between hypoxanthine, xanthine, and allopurinol.

Lotta T. is being treated with allopurinol for gout, which is caused by an accumulation of sodium urate crystals in joints and joint fluid, particularly in the ankle and great toe. Allopurinol is a suicide inhibitor of the enzyme xanthine oxidase,

which is involved in the degradation of purine nucleotides AMP and guanosine monophosphate (GMP) to uric acid (urate). Although both hypoxanthine and xanthine levels increase in the presence of allopurinol, neither compound forms crystals nor precipitates at this concentration. They are excreted in the urine.

C. Heavy Metals

Heavy-metal toxicity is caused by tight binding of a metal such as mercury (Hg), lead (Pb), aluminum (Al), or iron (Fe) to a functional group in an enzyme. Heavy metals are relatively nonspecific for the enzymes they inhibit, particularly if the metal is associated with high dose toxicity. Mercury, for example, binds to so many enzymes, often at reactive sulfhydryl groups in the active site, that it has been difficult to determine which of the inhibited enzymes is responsible for mercury toxicity. Lead provides an example of a metal that inhibits through replacing the normal functional metal in an enzyme, such as calcium, iron, or zinc. Its developmental and neurologic toxicity may be caused by its ability to replace Ca^{2+} in two regulatory proteins important in the central nervous system and other tissues— Ca^{2+} -calmodulin and protein kinase C.

CLINICAL COMMENTS

Dennis V. survived his malathion intoxication because he had ingested only a small amount of the chemical, vomited shortly after the agent was ingested, and was treated rapidly in the emergency room. Lethal doses of oral malathion are estimated at 1 g/kg of body weight for humans, although the correlation between dose and severity of toxicity is poor. Once it has been ingested, the liver converts malathion to the toxic reactive compound, malaoxon, by replacing the sulfur with an oxygen (Fig. 8.16). Malaoxon then binds to the active site of acetylcholinesterase and reacts to form the covalent intermediate. Unlike the complex formed between DFP and acetylcholinesterase, this initial acyl enzyme intermediate is reversible. However, with time, the enzyme-inhibitor complex “ages” (dealkylation of the inhibitor and enzyme modification) to form an irreversible complex.

FIGURE 8.16 The liver converts malathion to malaoxon by replacing a sulfur with an oxygen. Malaoxon will interact with acetylcholinesterase, inhibiting the enzyme. The initial inhibition is reversible with pralidoxime, but if not treated in time, the enzyme-inhibitor complex becomes resistant to oxime treatment.

Emergency department physicians used intravenous atropine, an anticholinergic (antimuscarinic) agent, to antagonize the action of the excessive amounts of acetylcholine accumulating in cholinergic receptors throughout **Dennis V.**'s body. They also used the drug pralidoxime (an oxime) to reactivate the acetylcholinesterase before aged complexes formed. Although this therapy has not been shown to be consistently effective in clinical trials, it is still used.

After several days of intravenous therapy, the signs and symptoms of acetylcholine excess abated, and therapy was slowly withdrawn. **Dennis V.** made an uneventful recovery.

Lotta T. Within several days of starting allopurinol therapy, her serum uric acid level began to fall. Several weeks later, the level in her blood was normal. In order to prevent an acute attack of gouty arthritis, she was continued on a daily dose of colchicine when she was started on the allopurinol (see Chapter 10).

At low concentrations of ethanol, liver ADH is the major route of ethanol oxidation to form acetaldehyde, a highly toxic chemical. Acetaldehyde not only damages the liver but it can also enter the blood and potentially damage the heart and other tissues. At low ethanol intakes, much of the acetaldehyde produced is safely oxidized to acetate in the liver by aldehyde dehydrogenases.

Al M. was admitted to the hospital and intravenous thiamin was initiated at a dose of 100 mg/day (compared with the Recommended Dietary Allowance [RDA] of 1.4 mg/day), although even higher doses are sometimes used and are safe. His congestive heart failure was believed to be the result, in part, of the cardiomyopathy (heart muscle dysfunction) of acute thiamin deficiency known as beriberi heart disease. The cardiac and peripheral nerve dysfunction that results from this nutritional deficiency usually responds to thiamin replacement. However, an alcoholic cardiomyopathy can also occur in well-nourished patients with adequate thiamin levels. Exactly how ethanol, or its toxic metabolite acetaldehyde, causes alcoholic cardiomyopathy in the absence of thiamin deficiency is not completely understood.

BIOCHEMICAL COMMENTS

Basic Reactions and Classes of Enzymes. In the following chapters, students will be introduced to a wide variety of reaction pathways and enzyme names. Although it may seem that the number of reactions is infinite, many of these reactions are similar and occur frequently in different pathways. Recognition of the type of reaction can aid in remembering the pathways and enzyme names, thereby reducing the amount of memorization required. You may wish to use this section for reference as you go through your first biochemical pathways.

The Enzyme Commission (EC) has divided the basic reaction types and the enzymes catalyzing them into six broad numbered classes: (1) oxidoreductases, (2) transferases, (3) hydrolases, (4) lyases, (5) isomerases, and (6) ligases. Each broad class of enzymes includes subsets of enzymes with a systematic name and a common name (e.g., dehydrogenases and kinases). For example, glucokinase (common name) has the systematic name ATP:D-hexose 6-phosphotransferase, and its EC number is EC 2.7.1.2. The first “2” refers to the general class (transferase) of enzyme, followed by a period. The “7” refers to the specific number of subclasses within the transferase family of enzymes (in this case, the class that transfers a phosphate). The “1” denotes transfer to an alcohol receptor; and the final “2” yields a specific enzyme number for glucokinase.

Oxidoreductases. Oxidation–reduction reactions are very common in biochemical pathways and are catalyzed by a broad class of enzymes called oxidoreductases. Whenever an oxidation–reduction reaction occurs, at least one substrate gains electrons and becomes reduced, and another substrate loses electrons and becomes oxidized. One subset of reactions is catalyzed by dehydrogenases, which accept and donate electrons in the form of hydride ions (H^-) or hydrogen atoms. Usually an electron-transferring coenzyme, such as NAD^+/NADH , acts as an electron donor or acceptor (e.g., see Figs. 8.10 and 8.11).

In another subset of reactions, O_2 donates either one or both of its oxygen atoms to an acceptor (e.g., see xanthine oxidase, Fig. 8.15). When this occurs, O_2 becomes reduced and an electron donor is oxidized. Enzymes participating in reactions with O_2 are called hydroxylases and oxidases when one oxygen atom is incorporated into a substrate and the other oxygen atom into water, or both atoms are incorporated into water. They are called oxygenases when both atoms of oxygen are incorporated into the acceptor. Most hydroxylases and oxidases require metal ions, such as Fe^{2+} , for electron transfer.

Transferases. Transferases catalyze group transfer reactions—the transfer of a functional group from one molecule to another. If the transferred group is a high-energy phosphate (as shown in Fig. 8.3), the enzyme is a kinase; if the transferred group is a carbohydrate residue, the enzyme is a glycosyltransferase; if it is a fatty acyl group, the enzyme is an acyltransferase. A common feature of these reactions is that the group being transferred exists as a good leaving group on the donor molecule.

Another subset of group transfer reactions consists of transaminations (Fig. 8.17A). In this type of reaction, the nitrogen group from an amino acid is donated to an α -keto acid, forming a new amino acid and the α -keto acid corresponding to the donor amino acid. Enzymes that catalyze this last type of reaction are called transaminases or aminotransferases. The coenzyme pyridoxal phosphate is required for all transaminases (see Fig. 8.9C).

A. Group Transfer

B. Lyase

C. Isomerase

FIGURE 8.17 **A.** An example of a group transfer reaction—a transamination. Pyridoxal phosphate (PLP) on aspartate aminotransferase transfers an amino group from aspartate to the α -keto acid (α -ketoglutarate) to form a new amino acid (glutamate). The enzyme was formerly called glutamate-oxaloacetate transaminase. **B.** An example of a lyase. Aldolases catalyze carbon–carbon bond cleavage in reactions that are usually reversible. In glycolysis, the enzyme fructose 1,6-bisphosphate aldolase cleaves a carbon–carbon bond in fructose 1,6-bisphosphate. Aldolases have a lysine ϵ -amino group in the active site that participates in the reaction. **C.** An example of an isomerase. Isomerases rearrange atoms within a molecule. In the pathway of glycolysis, triose phosphate isomerase converts dihydroxyacetone phosphate to glyceraldehyde 3-phosphate by rearranging hydrogen atoms. No other substrates or products of the reaction exist.

When the physiologically important aspect of the reaction is the compound synthesized, the transferase may be called a synthase. For example, the enzyme commonly called glycogen synthase transfers a glucosyl residue from uridine diphosphate (UDP)-glucose to the end of a glycogen molecule. Its systematic name is UDP-glucose-glycogen glycosyltransferase.

Hydrolases. In hydrolysis reactions, C–O, C–N, or C–S bonds are cleaved by the addition of H_2O in the form of OH^- and H^+ to the atoms forming the bond. The enzyme class names specify the group being cleaved (e.g., the enzyme commonly named chymotrypsin is a protease, a hydrolase that cleaves peptide bonds in proteins).

Lyases. The lyase class of enzymes consists of a diverse group of enzymes that cleave C–C, C–O, and C–N bonds by means other than hydrolysis or oxidation. Some of the enzymes that catalyze C–C bond cleavage are called aldolases, decarboxylases (when carbon dioxide is released from a substrate), and thiolases (when the sulfur-containing nucleophile of cysteine or CoASH is used to break a carbon–carbon bond) (see Fig. 8.17B). The structures amenable to carbon–carbon bond cleavage usually require a carbonyl carbon that can act as an electron sink to stabilize the carbanion formed transiently when the carbon–carbon bond breaks.

This broad class of enzymes also includes dehydratases and many synthases. Dehydratases remove the elements of water from two adjacent carbon–carbon bonds to form a double bond. Certain enzymes in this group, such as certain group transferases, are commonly called synthases when the physiologically important direction of the reaction favors the formation of a carbon–carbon bond (e.g., citrate synthase).

Isomerases. Many biochemical reactions simply rearrange the existing atoms of a molecule; that is, create isomers of the starting material (see Fig. 8.17C). Enzymes that rearrange the bond structure of a compound are called isomerases, whereas enzymes that catalyze movement of a phosphate from one atom to another are called mutases.

Ligases. Ligases synthesize C–C, C–S, C–O, and C–N bonds in reactions coupled to the cleavage of a high-energy phosphate bond in ATP or another nucleotide. Carboxylases, for example, add CO_2 to another compound in a reaction that requires ATP cleavage to provide energy (see Fig. 8.9B). Most carboxylases require the coenzyme biotin. Other ligases are named synthetases (e.g., fatty acyl CoA synthetase). Synthetases differ from the synthases mentioned under “Lyases” and “Group Transferases” in that synthetases derive the energy for new bond formation from cleavage of high-energy phosphate bonds, and synthases use a different source of energy.

KEY CONCEPTS

- ◆ Enzymes are proteins that act as catalysts—molecules that can accelerate the rate of a reaction.
- ◆ Enzymes are specific for various substrates because of the selective nature of the binding sites on the enzyme.
- ◆ The catalytic (active) site is the portion of the enzyme molecule at which the reaction occurs.
- ◆ Enzymes accelerate reaction rates by decreasing the amount of energy required to reach a high-energy intermediate stage of the reaction, known as the transition-state complex. This is referred to as lowering the energy of activation.
- ◆ Enzymes use functional groups at the active site, provided by coenzymes, metals, or amino acid residues, to perform catalysis.
- ◆ Enzymes use general acid–base catalysis, formation of covalent intermediates, metal ions, cofactor catalysis, and transition-state stabilization as various mechanisms to accelerate reaction rates.
- ◆ Many drugs and toxins act by inhibiting enzymes.

- ◆ Enzymes can be regulated to control reaction rates through a variety of mechanisms.
- ◆ Diseases discussed in this chapter are summarized in Table 8.2.

TABLE 8.2 Diseases Discussed in Chapter 8

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
Malathion poisoning	Environmental	Inhibition of acetylcholinesterase at neuromuscular junctions. This leads to acetylcholine accumulation at the junction, and overstimulation of the autonomic nervous system.
Gout	Both	Accumulation of uric acid in blood, leading to precipitation in joints, accompanied by severe pain and discomfort.
Thiamin deficiency (beriberi heart disease)	Environmental	Leads to lack of energy production because of reduced activity of key enzymes and can lead to disease in the nervous system (Wernicke's encephalopathy/Wernicke-Korsakoff syndrome) and cardiovascular system (beriberi heart disease). It is most often brought about by alcohol use disorder, as manifest by a poor diet, and by ethanol inhibition of thiamin transport through the intestinal mucosa.

REVIEW QUESTIONS—CHAPTER 8

The following questions below cover material from Chapters 6 and 7 as well as Chapter 8 (including Biochemical Comments).

- A patient was born with a mutation in an enzyme that severely affected its ability to bind an activation-transfer coenzyme. As a consequence, which one of the following is most likely to occur?
 - The enzyme will be unable to bind the substrate of the reaction.
 - The enzyme will be unable to form the transition-state complex.
 - The enzyme will normally use a different activation-transfer coenzyme.
 - The enzyme will normally substitute the functional group of an active-site amino acid residue for the coenzyme.
 - The reaction may be carried out by the free coenzyme, provided the diet carries an adequate amount of its vitamin precursor.
- An individual had a disease-causing mutation in glucokinase in which a proline was substituted for a leucine on a surface helix far from the active site but within the hinge region of the actin fold. This mutation would be expected to have which one of the following effects?
 - It would have no effect on the rate of the reaction because it is not in the active site.
 - It would have no effect on the rate of the reaction because proline and leucine are both nonpolar amino acids.
 - It would have no effect on the number of substrate molecules reaching the transition state.
 - It would probably affect the binding of ATP or a subsequent step in the reaction sequence.
 - It would probably cause the reaction to proceed through an alternate mechanism.
- Lysozyme is an important component of the human innate immune system. Lysozyme is an enzyme that cleaves glycosidic linkages in bacterial cell walls. The pH optimum of the purified enzyme is 5.2. There are two acidic residues at the active site of lysozyme (E35 and D52) that are required for enzyme activity. The pK_a of E35 is 5.9, whereas the pK_a of D52 is 4.5. What are the primary ionization states of these two residues at the pH optimum of the enzyme?
 - E35 is protonated; D52 is ionized.
 - E35 is protonated; D52 is protonated.
 - E35 is ionized; D52 is protonated.
 - E25 is ionized; D52 is ionized.
 - This cannot be determined from the information provided.

Questions 4 and 5 refer to the following reaction:

UDP-glucose is a key intermediate in carbohydrate metabolism and serves as a precursor for glycogen synthesis and glycosylation of lipids and protein.

4. The type of reaction shown fits into which one of the following classifications?
 - A. Group transfer
 - B. Isomerization
 - C. Carbon-carbon bond breaking
 - D. Carbon-carbon bond formation
 - E. Oxidation-reduction
5. The type of enzyme that catalyzes this reaction is which one of the following?
 - A. Kinase
 - B. Dehydrogenase
 - C. Glycosyltransferase
 - D. Transaminase
 - E. Isomerase
6. A patient has accidentally ingested the insecticide malathion, leading to symptoms of an overstimulated autonomic nervous system. Which one of the following best describes malathion in this context?
 - A. Enzyme
 - B. Coenzyme
 - C. Inhibitor
 - D. Cofactor
 - E. Coactivator
7. Penicillin is an antibiotic used to treat certain infections. It is a transition-state analog and suicide inhibitor. The use of penicillin affects which one of the following in susceptible targets?
 - A. Enzyme
 - B. Coenzyme
 - C. Inhibitor
 - D. Cofactor
 - E. Coactivator

- A. Viral cell wall
 - B. Bacterial cell wall
 - C. Viral nucleus
 - D. Bacterial nucleus
 - E. Protozoan nucleus
8. Vitamins can act as coenzymes that participate in catalysis by providing functional groups. Therefore, vitamin deficiencies reflect the loss of specific enzyme activities that depend on those coenzymes. Coenzymes are best described by which one of the following?
- A. In humans, they are always synthesized from vitamins.
 - B. They are proteins.
 - C. They participate in only one reaction, like enzymes.
 - D. They are complex, nonprotein organic molecules.
 - E. They are all carbohydrates.

Questions 9 and 10 are linked.

9. Many individuals with chronic alcohol abuse disorder develop thiamin deficiency because of a poor diet and an inability to absorb thiamin from the intestine in the presence of ethanol. Which one of the following cofactors, synthesized from a vitamin, or a vitamin itself, exhibits a mechanism of action similar to thiamin?
- A. NAD^+
 - B. FAD
 - C. Ascorbic acid
 - D. γ -Tocopherol
 - E. CoA
10. Which one of the following vitamins is the precursor for the correct answer to the previous question?
- A. Pantothenate
 - B. Niacin
 - C. Pyridoxine (vitamin B_6)
 - D. Folate
 - E. Biotin
1. A patient with glaucoma has been prescribed acetazolamide, a carbonic anhydrase inhibitor. Which one of the following would also lead to a loss of carbonic anhydrase activity?
- A. Reduce ATP binding to the enzyme
 - B. Reduce NAD^+ binding to the enzyme
 - C. Remove the magnesium from the enzyme
 - D. Remove the zinc from the enzyme
 - E. Increase the concentration of carbon dioxide
2. A histidine residue is required at the active site of serine proteases for the enzyme to be active. The role of the histidine is as a general base catalyst. If the pK_a of this histidine residue is 6.2, at which pH would the enzyme exhibit maximal activity, assuming the rate-limiting step of the enzyme was because of the role of histidine as a general base catalyst?
- A. 5.2
 - B. 5.7
 - C. 6.2
 - D. 6.7
 - E. 7.2
3. Maple syrup urine disease is due to a mutation in the enzyme branched-chain α -keto acid dehydrogenase, an enzyme that requires TPP along with a number of other cofactors. Some patients who have maple syrup urine disease are responsive to pharmacologic doses of thiamin. The basis for this treatment is that the mutation within the enzyme led to which one of the following?
- A. Increased the hydrophobicity of the active site
 - B. Increased the affinity of the enzyme for the amino acid substrates
 - C. Decreased the affinity of the enzyme for the amino acid substrates
 - D. Increased the affinity of the enzyme for thiamin
 - E. Decreased the affinity of the enzyme for thiamin
4. A patient with a deficiency in pyruvate carboxylase, an enzyme that is covalently linked to biotin in order to catalyze its reaction, is not improved when given pharmacologic doses of biotin. This is most likely a

- noneffective treatment owing to which one of the following?
- Dietary biotin cannot be modified to the active form of biotin.
 - The excess biotin blocks substrate binding to the enzyme.
 - The biotin-binding site on the enzyme is altered and can no longer bind biotin.
 - The mutated pyruvate carboxylase binds biotin too tightly such that it cannot react with the substrate.
 - Carbon dioxide, the substrate for carboxylations, reacts with the excess biotin before the biotin can bind to the enzyme.
5. Many drugs work by targeting specific enzymes for inhibition. A major difference between a suicide enzyme inhibitor and a covalent enzyme inhibitor is which one of the following?
- A suicide inhibitor forms a covalent bond with the enzyme, whereas a covalent inhibitor forms a bond with the substrate.
 - A suicide inhibitor is also a substrate for the enzyme, whereas a covalent inhibitor is not.
 - A covalent inhibitor is a substrate for the enzyme, whereas a suicide inhibitor is not.
 - A suicide inhibitor binds to a site outside the active site, whereas a covalent inhibitor binds at the active site.
 - A covalent inhibitor binds to a site outside the active site, whereas a suicide inhibitor binds at the active site.

ANSWERS TO REVIEW QUESTIONS

- The answer is B.** In most reactions, the substrate binds to the enzyme before its reaction with the coenzyme occurs. Thus, the substrate may bind, but it cannot react with the coenzyme to form the transition-state complex. Each coenzyme carries out a single type of reaction, so no other coenzyme can substitute (thus, C is incorrect). The three-dimensional geometry of the reaction is so specific that functional groups on amino acid side chains cannot substitute (thus, D is incorrect). Free coenzymes are not very reactive because amino acid side chains in the active site are required to activate the coenzyme or the reactants (thus, E is incorrect). However, increasing the supply of vitamins to increase the amount of coenzyme bound to the enzyme can sometimes help.
- The answer is D.** The patient was diagnosed with maturity-onset diabetes of the young (MODY) caused by this mutation. In glucokinase, binding of glucose normally causes a huge conformational change in the actin fold that creates the binding site for ATP. Although proline and leucine are both nonpolar amino acids, B is incorrect—proline creates kinks in helices and thus would be expected to disturb the large conformational change required (see Chapter 7). In general, binding of the first substrate to an enzyme creates conformational changes that increases the binding of the second substrate or brings functional groups into position for further steps in the reaction. Thus, a mutation need not be in the active site to impair the reaction, and A is incorrect. It would probably take more energy to fold the enzyme into the form required for the transition-state complex, and fewer molecules would acquire the energy necessary (thus, C is incorrect). The active site lacks the functional groups required for an alternate mechanism (thus, E is incorrect).
- The answer is A.** When the pK_a of an ionizable group is below the pH value, the group will be deprotonated. When the pK_a of an ionizable group is above the pH value, the group will be protonated. Thus, at pH 5.2, glutamate 35 (with a pK_a of 5.9, which is >5.2) will remain protonated, and aspartate 52 (with a pK_a of 4.5, which is <5.2) will be ionized (because the side chain carries a negative charge when deprotonated). Therefore, E35 is protonated and D52 is ionized. There is sufficient information presented to answer this question.
- The answer is A.** The glucose residue from UDP-glucose is being transferred to the alcohol group of another compound. In isomerization reactions, groups are transferred within the same molecule (thus, B is incorrect). There is no cleavage or synthesis of carbon–carbon bonds (thus, C and D are incorrect). Oxidation–reduction has not occurred because no hydrogens or oxygen atoms have been removed or added in the conversion of substrate to product.
- The answer is C.** Transfer of a carbohydrate residue from one molecule to another is a glycosyltransferase reaction. Kinases transfer phosphate groups, dehydrogenases transfer electrons as hydrogen atoms or hydride ions, transaminases transfer amino groups, and isomerases transfer atoms within the same molecule.

6. **The answer is C.** Malathion is a covalent inhibitor and forms an extremely tight bond with the active site of acetylcholinesterase (the enzyme) preventing its function. It does not help the enzyme as a coenzyme would and does not assist catalysis as a cofactor would.
7. **The answer is B.** Penicillin irreversibly binds to glycopeptidyl transferase, an enzyme required by bacteria for synthesis of the cell wall. Neither bacteria nor viruses have nuclei. Viruses have no cell wall. Protozoans have a nucleus but no cell wall. The enzyme inhibited is for cell wall synthesis and is only in bacteria. This is why penicillin is not useful in treating a viral or protozoan infection.
8. **The answer is D.** Most, but not all, coenzymes in humans are synthesized from vitamins. They are neither proteins nor carbohydrates, but are complex organic molecules. They assist in the catalysis of a type of reaction, not just one reaction (coenzymes can associate with a number of different enzymes).
9. **The answer is E.** Thiamin acts via an activation-transfer mechanism, as does CoA. All the other listed coenzymes are of the oxidation-reduction group (tocopherol is vitamin E, niacin is part of NAD^+ , riboflavin part of FAD, and ascorbic acid is vitamin C).
10. **The answer is A.** CoA, an activation-transfer coenzyme, is synthesized from the vitamin pantothenate. NAD^+ is synthesized from niacin and pyridoxal phosphate from vitamin B_6 . Folate and biotin are themselves vitamins.
11. **The answer is D.** Carbonic anhydrase is complexed with zinc at the active site. The role of the zinc is to orient water such that it can be deprotonated by an active-site histidine, and the hydroxyl ion generated then attacks carbon dioxide to generate bicarbonate. The enzyme does not require ATP or NAD^+ for activity, nor does it bind magnesium. Increasing the carbon dioxide concentration will enable the reaction to go faster and would not lead to a loss of activity.
12. **The answer is E.** In order for the histidine to act as a general base, it must be deprotonated so it can accept a proton from the active-site serine. With a pK_a of 6.2, at pH values below 6.2, the histidine will be >50% protonated, whereas at a pH of >6.2, the histidine will be >50% deprotonated. Maximal deprotonation will occur at pH 7.2, which would allow the enzyme to work at a faster rate than at pH 6.7.
13. **The answer is E.** The mutation is most likely in the thiamin binding site and has reduced the affinity of the enzyme for thiamin. This could be overcome by greatly increasing the levels of thiamin available to bind to the enzyme. Thiamin is a hydrophilic molecule, so the active site would not become more hydrophobic to allow thiamin to overcome the mutation. The affinity of the substrates is not altered by thiamin binding to the enzyme.
14. **The answer is C.** The enzyme is mutated in the biotin-binding site and the enzyme cannot covalently attach biotin because of reduced biotin binding to the enzyme. The lack of the cofactor leads to reduced activity of the enzyme. Free biotin will not react with carbon dioxide, and an enzyme with a higher affinity for biotin would still be able to catalyze the carboxylation reaction. Biotin binds to a site on the enzyme that is distinct from the substrate-binding site and would not be acting as a competitive inhibitor of enzyme activity.
15. **The answer is B.** A suicide inhibitor is a substrate analog that is acted upon by the enzyme to create a molecule, which then strongly inhibits enzyme activity. A covalent inhibitor is a compound that forms a covalent bond with the active site of the enzyme without the enzyme altering the structure of the inhibitor. Neither type of inhibitor will form a bond with the substrate.

Regulation of Enzymes

In the human body, thousands of diverse enzymes are regulated to fulfill their individual functions without waste of dietary components. Thus, with changes in our physiologic state, time of eating, environment, diet, or age, the rates of some enzymes must increase and those of others decrease. In this chapter, we describe the mechanisms for regulating enzyme activity and the strategies employed to regulate the metabolic pathways in which they reside.

Regulation Matches Function. Changes in the rate of a metabolic pathway occur because at least one enzyme in that pathway, the regulatory enzyme, has been activated or inhibited, or the amount of enzyme has increased or decreased. Regulatory enzymes usually catalyze the rate-limiting, or slowest, step in the pathway, so that increasing or decreasing their rate changes the rate of the entire pathway (Fig. 9.1). The mechanisms used to regulate the rate-limiting enzyme in a pathway reflect the function of the pathway.

Rate-limiting enzyme

FIGURE 9.1 The flux of substrates down a metabolic pathway is analogous to cars traveling down a highway. The rate-limiting enzyme is the portion of the highway that is narrowed to one lane by a highway barrier. This single portion of the highway limits the rate at which cars can arrive at their final destination miles later. Cars will back up before the barrier (similar to the increase in concentration of a precursor when a rate-limiting enzyme is inhibited). Some cars may exit and take an alternate route (similar to precursors entering another metabolic pathway). Moving the barrier just a little to open an additional lane is like activating a rate-limiting enzyme: It increases flow through the entire length of the pathway.

Substrate Concentration. The rate of all enzymes depends on substrate concentration. Enzymes exhibit **saturation kinetics**; their rate increases with increasing substrate concentration $[S]$, but it reaches a maximum velocity (V_{\max}) when the enzyme is saturated with substrate. For many enzymes, the **Michaelis–Menten equation** describes the relationship between v_i (the initial velocity of a reaction), $[S]$, V_{\max} , and the K_m (the substrate concentration at which $v_i = \frac{1}{2}V_{\max}$).

Reversible Inhibition. Enzymes are reversibly inhibited by **structural analogs** and **products**. These inhibitors are classified as **competitive**, **noncompetitive**, or **uncompetitive**, depending on their effect on formation of the **enzyme–substrate complex**.

Allosteric Enzymes. **Allosteric activators** or **inhibitors** are compounds that bind at sites other than the active catalytic site and regulate the enzyme through **conformational changes** that affect the catalytic site.

Covalent Modification. Enzyme activity may also be regulated by a covalent modification, such as **phosphorylation** of a serine, threonine, or tyrosine residue by a **protein kinase**.

Protein–Protein Interactions. Enzyme activity can be modulated through the reversible binding of a **modulator protein**, such as **Ca²⁺–calmodulin**. **Monomeric G-proteins** (guanosine triphosphate [GTP]–binding proteins) activate target proteins through reversible binding.

Zymogen Cleavage. Some enzymes are synthesized as inactive precursors, called **zymogens**, that are activated by **proteolysis** (e.g., the digestive enzyme chymotrypsin).

Changes in Enzyme Concentration. The concentration of an enzyme can be regulated by changes in the rate of enzyme synthesis (e.g., induction of gene transcription) or the rate of degradation.

Regulation of Metabolic Pathways. The regulatory mechanisms for the rate-limiting enzyme of a pathway always reflect the **function of the pathway in a particular tissue**. In **feedback regulation**, the end product of a pathway directly or indirectly controls its own rate of synthesis; in **feed-forward regulation**, the substrate controls the rate of the pathway. **Biosynthetic** and **degradative** pathways are controlled through different but **complementary regulation**. Pathways are also regulated through **compartmentation** of enzymes unique to specific pathways.

M When **Al M.** was stopped by police, he was required to take a Breathalyzer test. The Breathalyzer analyzes ethanol levels in expired air (assuming a ratio of 1 part ethanol in expired air to 2,100 parts ethanol in the blood). Once the sample enters the Breathalyzer, it is mixed with sulfuric acid, silver nitrate, and potassium dichromate. If ethanol is present, it will react with the potassium dichromate to form potassium sulfate, chromium sulfate, acetic acid, and water. Potassium dichromate generates a reddish-brown color, whereas chromium sulfate is light green. In the Breathalyzer device, the reacted sample is compared to a nonreacted sample, and the difference in light absorption (because of the different colors) is converted to an electrical current. The extent of current generated will lead to a determination of blood alcohol level (i.e., if there is no ethanol in the sample, no current will be generated). Other forms of gaseous ethanol determination use infrared spectroscopy or a fuel cell.

THE WAITING ROOM

Al M. is a 44-year-old man who has suffered from alcohol use disorder for the past 5 years. He was recently admitted to the hospital for congestive heart failure (see Chapter 8). After being released from the hospital, he

continued to drink. One night he arrived at a friend's house at 7:00 P.M. Between his arrival and 11:00 P.M., he drank four beers and five martinis (for a total ethanol consumption of 9.5 oz). His friends encouraged him to stay an additional hour to try and sober up. Nevertheless, he ran his car off the road on his way home. He was taken to the emergency department of the local hospital and arrested for driving under the influence of alcohol. His blood alcohol concentration at the time of his arrest was 240 mg/dL, compared with the legal limit of ethanol for driving of 80 mg/dL (0.08% blood alcohol).

Ann R., a 23-year-old woman, 5 ft 7 in tall, is being treated for anorexia nervosa (see Chapters 1 through 3). She has been gaining weight and is now back to 99 lb from a low of 85 lb. Her blood glucose is within the low normal range (fasting blood glucose of 72 mg/dL, compared with a normal range of 70 to 100 mg/dL). She complains to her physician that she feels tired when she jogs, and she is concerned that the “extra weight” she has gained is slowing her down. Regulation of various metabolic pathways is critical as she gains weight and strives to restore normal activity levels.

I. General Overview

Although the regulation of metabolic pathways is an exceedingly complex subject, dealt with in most of the subsequent chapters of this text, a number of common themes are involved. Physiologic regulation of a metabolic pathway depends on the ability to alter flux through the pathway by activating the enzyme catalyzing the rate-limiting step in the pathway (see Fig. 9.1). The type of regulation employed always reflects the function of the pathway and the need for that pathway in a particular tissue or cell type. Pathways that produce a necessary product are usually feedback-regulated through a mechanism that involves concentration of product (e.g., allosteric inhibition or induction/repression of enzyme synthesis), either directly or indirectly. The concentration of the product signals when enough of the product has been synthesized. Storage and toxic disposal pathways are usually regulated directly or indirectly through a feed-forward mechanism that reflects the availability of precursor. Regulatory enzymes are often tissue-specific isozymes whose properties reflect the different functions of a pathway in particular tissues. Pathways are also regulated through compartmentation, the collection of enzymes with a common function within a particular organelle or at a specific site in the cell.

Al M. was not able to clear his blood ethanol rapidly enough to stay within the legal limit for driving. Ethanol is cleared from the blood at about 0.5 oz/hr (15 mg/dL/hr). Liver metabolism accounts for more than 90% of ethanol clearance from the blood. The major route of ethanol metabolism in the liver is the enzyme liver ADH, which oxidizes ethanol to acetaldehyde with generation of NADH.

The multienzyme complex MEOS, which is also called **cytochrome P450-2E1**, provides an additional route for ethanol oxidation to acetaldehyde in the liver and is used when ethanol levels are elevated.

The mechanisms employed to regulate enzymes have been organized into three general categories: regulation by compounds that bind reversibly in the active site (including the dependence of velocity on substrate concentration and product levels), regulation by changing the conformation of the active site (including allosteric regulators, covalent modification, protein–protein interactions, and zymogen cleavage), and regulation by changing the concentration of enzyme (enzyme synthesis and degradation). We will generally be using the pathways of fuel oxidation to illustrate the role of various mechanisms of enzyme regulation in metabolic pathways (see Chapters 1 through 3 for a general overview of these pathways).

II. Regulation by Substrate and Product Concentration

A. Velocity and Substrate Concentration

The velocity (rate of formation of product per unit time) of all enzymes is dependent on the concentration of substrate. This dependence is reflected in conditions such as starvation, in which a number of pathways are deprived of substrate. In contrast, storage pathways (e.g., glucose conversion to glycogen in the liver) and toxic-waste disposal pathways (e.g., the urea cycle, which prevents NH_3 toxicity by converting NH_3 to urea) are normally regulated to speed up when more substrate is available. In the following sections, we use the **Michaelis–Menten equation** to describe the response of an enzyme to changes in substrate concentration, and we use glucokinase (GK) to illustrate the role of substrate supply in regulation of enzyme activity.

One of the fuels used for jogging by **Ann R.**'s skeletal muscles is glucose, which is converted to glucose 6-P by the enzyme HK and GK. Glucose 6-P is metabolized in the pathway of glycolysis to generate ATP. This pathway is feedback-regulated, so that as her muscles use ATP, the rate of glycolysis will increase to generate more ATP.

When she is resting, her muscles and liver will convert glucose 6-P to glycogen (a fuel storage pathway, shown in red). Glycogen synthesis is feed-forward-regulated by the supply of glucose and by insulin and other hormones that signal glucose availability. Glycogenolysis (glycogen degradation) is activated during exercise to supply additional glucose 6-P for glycolysis. Unless **Ann R.** consumes sufficient calories, her glycogen stores will not be replenished after exercise, and she will tire easily.

1. The Michaelis–Menten Equation

The equations of enzyme kinetics provide a quantitative way of describing the dependence of enzyme rate on substrate concentration. The simplest of these equations, the Michaelis–Menten equation, relates the initial velocity (v_i) to the concentration of substrate $[S]$ (the brackets denote concentration) and the two parameters K_m and V_{max} (Equation 9.1). The V_{max} of the enzyme is the maximal velocity that can be achieved at an infinite concentration of substrate, and the K_m of the enzyme for a substrate is the concentration of substrate required to reach $\frac{1}{2}V_{max}$. The Michaelis–Menten model of enzyme kinetics applies to a simple reaction in which the enzyme and substrate form an enzyme–substrate complex (ES) that can dissociate back to the free enzyme and

substrate. The initial velocity of product formation, v_i , is proportional to the concentration of enzyme–substrate complexes [ES]. As substrate concentration is increased, the concentration of ES complexes increases, and the reaction rate increases proportionately. The total amount of enzyme present is represented by E_t .

Equation 9.1. The Michaelis–Menten equation:

For the reaction

the Michaelis–Menten equation is given by

$$v_i = \frac{V_{\max} [S]}{K_m + [S]}$$

where $K_m = (k_2 + k_3)/k_1$

and $V_{\max} = k_3 [E_t]$

The graph of the Michaelis–Menten equation (v_i as a function of substrate concentration) is a rectangular hyperbola that approaches a finite limit, V_{\max} , as the fraction of total enzyme present as ES complex increases (Fig. 9.2). At a hypothetical infinitely high substrate concentration, all of the enzyme molecules contain bound substrate, and the reaction rate is at V_{\max} . The approach to the finite limit of V_{\max} is called **saturation kinetics**, because velocity cannot increase any further once the enzyme is saturated with substrate. Saturation kinetics is a characteristic property of all rate processes that depend on the binding of a compound to a protein.

FIGURE 9.2 A graph of the Michaelis–Menten equation. V_{\max} (solid red line) is the initial velocity extrapolated to infinite $[S]$. K_m (dotted red line) is the concentration of S at which $v_i = V_{\max}/2$.

The K_m of the enzyme for a substrate is defined as the concentration of substrate at which v_i equals $\frac{1}{2}V_{\max}$. The velocity of an enzyme is most sensitive to changes in substrate concentration over a concentration range below its K_m (see Fig. 9.2). As an example, at substrate concentrations less than one-tenth of the K_m , a doubling of substrate concentration nearly doubles the velocity of the reaction; at substrate concentrations 10 times the K_m , doubling the substrate concentration has little effect on the velocity.

The K_m of an enzyme for a substrate is related to the dissociation constant, K_d , which is the rate of substrate release divided by the rate of substrate binding (k_2/k_1). For example, a genetic mutation that decreases the rate of substrate binding to the enzyme decreases the affinity of the enzyme for the substrate and increases the K_d and K_m of the enzyme for that substrate. The higher the K_m , the higher is the substrate concentration required to reach $\frac{1}{2}V_{\max}$.

Patients with MODY have a rare genetic form of diabetes mellitus in which the amount of insulin being secreted from the pancreas is too low, resulting in hyperglycemia. There are several forms of the disease, all caused by a different mutation in a single gene, leading to dysfunction in various proteins. One of the mutations in the gene for pancreatic GK (a closely related isozyme of liver GK) affects its kinetic properties (K_m or V_{\max}). GK is part of the mechanism that controls release of insulin from the pancreas. Decreased GK activity results in lower insulin secretion for a given blood glucose level.

2. The Lineweaver–Burk Transformation

The K_m and V_{max} for an enzyme can be visually determined from a plot of $1/v_i$ versus $1/S$ called a **Lineweaver–Burk** or a **double-reciprocal** plot. The reciprocal of both sides of the Michaelis–Menten equation generates an equation that has the form of a straight line, $y = mx + b$ (Fig. 9.3). K_m and V_{max} are equal to the reciprocals of the intercepts on the abscissa and ordinate, respectively. Although double-reciprocal plots are often used to illustrate certain features of enzyme reactions, they are not used directly for the determination of K_m and V_{max} values by researchers.

$$\frac{1}{v_i} = \frac{K_m}{V_{max}} \left(\frac{1}{[S]} \right) + \frac{1}{V_{max}}$$

FIGURE 9.3 The Lineweaver–Burk transformation (shown in the *green box*) for the Michaelis–Menten equation converts it to a straight line of the form $y = mx + b$. When $[S]$ is infinite, $1/[S] = 0$, and the line crosses the ordinate (y -axis) at $1/v = 1/V_{max}$. The slope of the line is K_m/V_{max} . Where the line intersects the abscissa (x -axis), $1/[S] = -1/K_m$.

3. Hexokinase Isozymes Have Different K_m Values for Glucose

A comparison between the isozymes of hexokinase (HK) found in red blood cells and in the liver illustrates the significance of the K_m of an enzyme for its substrate. HK catalyzes the first step in glucose metabolism in most cells—the transfer of a phosphate from adenosine triphosphate (ATP) to glucose to form glucose 6-phosphate (glucose 6-P). Glucose 6-P may then be metabolized in glycolysis, which generates energy in the form of ATP, or it can be converted to glycogen, a storage polymer of glucose. Hexokinase I, the isozyme in red blood cells (erythrocytes), has a K_m for glucose of approximately 0.05 mM (Fig. 9.4). The isozyme of HK called **glucokinase** (GK), which is found in the liver and pancreas, has a much higher K_m of approximately 5 to 6

mM. The red blood cell is totally dependent on glucose metabolism to meet its needs for ATP. At the low K_m of the erythrocyte HK, blood glucose could fall drastically below its normal fasting level of approximately 5 mM, and the red blood cell could still phosphorylate glucose at rates near V_{max} . The liver, however, stores large amounts of “excess” glucose as glycogen or converts it to fat. Because GK has a K_m of approximately 5 mM, the rate of glucose phosphorylation in the liver will tend to increase as blood glucose increases after a high-carbohydrate meal and decrease as blood glucose levels fall. The high K_m of hepatic GK thus promotes the storage of glucose as liver glycogen or as fat, but only when glucose is in excess supply.

FIGURE 9.4 A comparison between hexokinase I and GK. The initial velocity (v_i) as a fraction of maximum velocity (V_{max}) is graphed as a function of glucose concentration. The plot for GK (*heavy blue line*) is slightly sigmoidal (S-shaped), possibly because the rate of an intermediate step in the reaction is so slow that the enzyme does not follow Michaelis–Menten kinetics. The *dashed blue line* has been derived from the Michaelis–Menten equation fitted to the data for concentrations of glucose >5 mM. For S-shaped curves, the concentration of substrate required to reach $\frac{1}{2}V_{max}$, or half-saturation, is sometimes called the $S_{0.5}$ or $K_{0.5}$ rather than K_m . At $v_i/V_{max} = 0.5$, for GK, the K_m is 5 mM and the $S_{0.5}$ is 6.7 mM. GK, glucokinase.

 As **Ann R.** eats a high-carbohydrate meal, her blood glucose will rise to approximately 20 mM in the portal vein, and much of the glucose from her carbohydrate meal will enter the liver. How will the activity of GK in the liver change as glucose is increased from 4 to 20 mM? (Hint: Calculate v_i as a fraction of V_{max} for both conditions, using a K_m for glucose of 5 mM and the Michaelis–Menten equation.)

4. Velocity and Enzyme Concentration

The rate of a reaction is directly proportional to the concentration of enzyme; if you double the amount of enzyme, you will double the amount of product produced per minute, whether you are at low or at saturating

concentrations of substrate. This important relationship between velocity and enzyme concentration is not immediately apparent in the Michaelis–Menten equation because the concentration of total enzyme present (E_t) has been incorporated into the term V_{\max} (i.e., V_{\max} is equal to the rate constant $k_3 \times E_t$). However, V_{\max} is most often expressed as product produced per minute per milligram of enzyme and is meant to reflect a property of the enzyme that is not dependent on its concentration.

5. Multisubstrate Reactions

Most enzymes have more than one substrate, and the substrate-binding sites overlap in the catalytic (active) site. When an enzyme has more than one substrate, the sequence of substrate binding and product release affect the rate equation. As a consequence, an apparent value of K_m ($K_{m,app}$) depends on the concentration of cosubstrate or product present.

6. Rates of Enzyme-Catalyzed Reactions in the Cell

Equations for the initial velocity of an enzyme-catalyzed reaction, such as the Michaelis–Menten equation, can provide useful parameters for describing or comparing enzymes. However, many multisubstrate enzymes, such as GK, have kinetic patterns that do not fit the Michaelis–Menten model (or do so under nonphysiologic conditions). The Michaelis–Menten model is also inapplicable to enzymes present in a higher concentration than their substrates. Nonetheless, the term K_m is still used for these enzymes to describe the approximate concentration of substrate at which velocity equals $\frac{1}{2}V_{\max}$.

The liver ADH that is most active in oxidizing ethanol has a very low K_m for ethanol, approximately 0.04 mM, and is at >99% of its V_{\max} at the legal limit of blood alcohol concentration for driving (80 mg/dL or ~17 mM). In contrast, the MEOS isozyme that is most active toward ethanol has a K_m of approximately 11 mM. Thus, MEOS makes a greater contribution to ethanol oxidation and clearance from the blood at higher ethanol levels than at lower ones. Liver damage, such as cirrhosis, results partly from toxic by-products of ethanol oxidation generated by MEOS. **Al M.**, who has a blood alcohol level of 240 mg/dL (~52 mM), is drinking enough to potentially cause liver damage, as well as his car accident and arrest for driving under the influence of alcohol. The various isozymes and polymorphisms of ADH and MEOS are discussed in more detail in Chapter 33.

B. Reversible Inhibition within the Active Site

One of the ways of altering enzyme activity is through compounds binding in the active site. If these compounds are not part of the normal reaction, they inhibit the enzyme. An **inhibitor** of an enzyme is defined as a compound that decreases the velocity of the reaction by binding to the enzyme. It is a **reversible inhibitor** if it is not covalently bound to the enzyme and can dissociate at a significant rate. Reversible inhibitors are generally classified as competitive, noncompetitive, or uncompetitive with respect to their relationship to a substrate of the enzyme. In most reactions, the products of the reaction are reversible inhibitors of the enzyme producing them.

GK, which has a high K_m for glucose, phosphorylates glucose to glucose 6-P about twice as fast after a carbohydrate meal as during fasting. Substitute the values for S and K_m into the Michaelis–Menten equation. The initial velocity will be $0.44 \times V_{\max}$ when blood glucose is at 4 mM and about $0.80 \times V_{\max}$ when blood glucose is at 20 mM. In the liver, glucose 6-P is a precursor for both glycogen and fat synthesis. Thus, these storage pathways are partially regulated through a direct effect of substrate supply. They are also partially regulated through an increase of insulin and a decrease of glucagon, two hormones that signal the supply of dietary fuel.

1. Competitive Inhibition

A **competitive inhibitor** “competes” with a substrate for binding at the enzyme’s substrate-recognition site and therefore is usually a close structural analog of the substrate (Fig. 9.5A). An increase of substrate concentration can overcome competitive inhibition; when the substrate concentration is increased to a sufficiently high level, the substrate-binding sites are occupied by substrate, and inhibitor molecules cannot bind. Competitive inhibitors, therefore, increase the apparent K_m of the enzyme ($K_{m,app}$) because they raise the concentration of substrate necessary to saturate the enzyme. They have no effect on V_{\max} .

A Reaction

Substrates both bind

CI is competitive with respect to A

B Reaction

Substrates both bind

NI is noncompetitive with respect to A

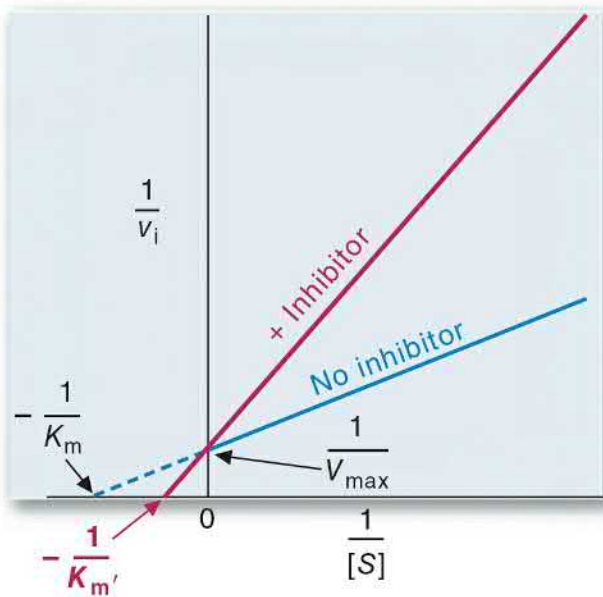

FIGURE 9.5 **A.** Competitive inhibition with respect to substrate A. A and B are substrates for the reaction that forms the enzyme–substrate complex (E–AB). The enzyme has separate binding sites for each substrate, which overlap in the active site. The CI competes for the binding site of A, the substrate it most closely resembles. **B.** NI is a noncompetitive inhibitor with respect to substrate A. A can still bind to its binding site in the presence of NI. However, NI is competitive with respect to B because it binds to the B-binding site. In contrast, an inhibitor that is uncompetitive with respect to A might also resemble B, but it could only bind to the B site after A is bound. CI, competitive inhibitor, NI, noncompetitive inhibitor.

2. Noncompetitive and Uncompetitive Inhibition

If an inhibitor does not compete with a substrate for its binding site, the inhibitor is either a **noncompetitive** or an **uncompetitive inhibitor** with respect to that particular substrate (see Fig. 9.5B). Uncompetitive inhibition is almost never encountered in medicine and will not be discussed further. To illustrate noncompetitive inhibition, consider a multisubstrate reaction in which substrates A and B react in the presence of an enzyme to form a product. An inhibitor (NI) that is a structural analog of substrate B would fit into substrate B’s binding site, but the inhibitor would be a noncompetitive inhibitor with regard to the other substrate, substrate A. An increase of A will not prevent the inhibitor from binding to substrate B’s binding site. The inhibitor, in effect, lowers the concentration of the active enzyme and therefore changes the V_{\max} of the enzyme. If the inhibitor has absolutely no effect on the binding of substrate A, it will not change the K_m for A (a pure noncompetitive inhibitor).

Lineweaver–Burk plots provide a good illustration of competitive inhibition and pure noncompetitive inhibition (Fig. 9.6). In competitive inhibition, plots of $1/v_i$ versus $1/[S]$ at a series of inhibitor concentrations intersect on the y-axis. Thus, at infinite substrate concentration, or $1/[S] = 0$, there is no effect of the inhibitor. In pure noncompetitive inhibition, the inhibitor decreases the velocity even when $[S]$ has been extrapolated to an infinite concentration. However, if the inhibitor has no effect on the binding of the substrate, the K_m is the same for every concentration of inhibitor, and the lines intersect on the x-axis.

A. Competitive inhibition

B. Pure noncompetitive inhibition

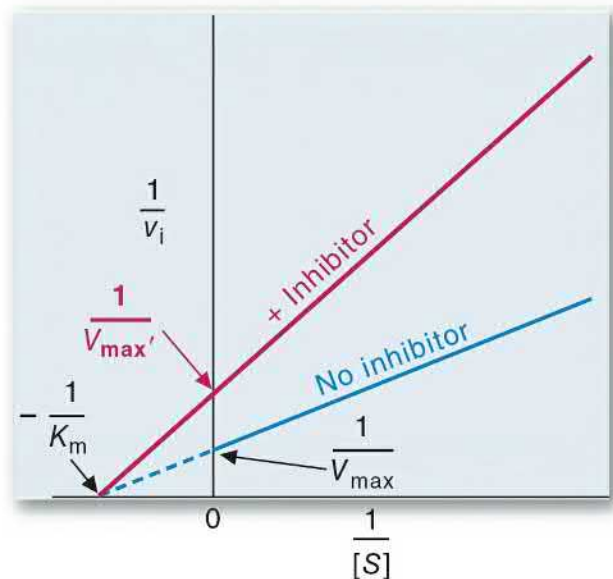

FIGURE 9.6 Lineweaver–Burk plots of competitive and pure noncompetitive inhibition. **A.** $1/v_i$ versus $1/[S]$ in the presence of a competitive inhibitor. The competitive inhibitor alters the intersection on the x-axis. The new intersection is $1/K_{m,app}$ (also called $1/K_m'$). A competitive inhibitor does not affect V_{\max} . **B.** $1/v_i$ versus $1/[S]$ in the presence of a pure noncompetitive inhibitor. The noncompetitive inhibitor alters the intersection on the y-axis, $1/V_{\max,app}$ or $1/V_{\max}'$, but does not affect $1/K_m$. A pure noncompetitive inhibitor binds to E and ES with the same affinity. If the inhibitor has different affinities for E and ES, the lines will intersect to either side of the y-axis, and the noncompetitive inhibitor will change both the K_m' and the V_{\max}' . I, inhibitor.

inhibitor; P , product; S , substrate; v_i , initial velocity; V_{\max} , maximal velocity.

Some of **AI M.**'s problems have arisen from product inhibition of liver ADH by NADH. As ethanol is oxidized in liver cells, NAD^+ is reduced to NADH and the NADH/NAD^+ ratio rises. NADH is an inhibitor of ADH, competitive with respect to NAD^+ , so the increased NADH/NAD^+ ratio slows the rate of ethanol oxidation and ethanol clearance from the blood.

NADH is also a product inhibitor of enzymes in the pathway that oxidizes fatty acids. Consequently, these fatty acids accumulate in the liver, eventually contributing to the alcoholic fatty liver.

Some inhibitors, such as metals, might not bind at either substrate-recognition site. In this case, the inhibitor would be noncompetitive with respect to both substrates.

3. Simple Product Inhibition in Metabolic Pathways

All products are reversible inhibitors of the enzymes that produce them and may be competitive or noncompetitive relative to a particular substrate. **Simple product inhibition**, a decrease in the rate of an enzyme caused by the accumulation of its own product, plays an important role in metabolic pathways. It prevents one enzyme in a sequence of reactions from generating a product faster than it can be used by the next enzyme in that sequence. As an example, product inhibition of HK by glucose 6-P conserves blood glucose for tissues that need it. Tissues take up glucose from the blood and phosphorylate it to glucose 6-P, which can then enter a number of different pathways (including glycolysis and glycogen synthesis). As these pathways become more active, glucose 6-P concentration decreases, and the rate of HK increases. When these pathways are less active, glucose 6-P concentration increases, HK is inhibited, and glucose remains in the blood for other tissues to use.

III. Regulation through Conformational Changes

In substrate response and product inhibition, the rate of the enzyme is affected principally by the binding of a substrate or a product within the catalytic site. Most rate-limiting enzymes are also controlled through regulatory mechanisms that change the conformation of the enzyme in a way that affects the catalytic site. These regulatory mechanisms include (1) allosteric activation and inhibition, (2) phosphorylation or other covalent modification, (3) protein–protein interactions between regulatory and catalytic subunits or between two proteins, and (4) proteolytic cleavage. These types of regulation can rapidly change an enzyme from an inactive form to a fully active conformation.

In the following sections, we describe the general characteristics of these regulatory mechanisms and illustrate the first three with glycogen phosphorylase, glycogen phosphorylase kinase, and protein kinase A.

A. Conformational Changes in Allosteric Enzymes

Allosteric activators and **inhibitors (allosteric effectors)** are compounds that bind to the **allosteric site** (a site separate from the catalytic site) and cause a conformational change that affects the affinity of the enzyme for the substrate. Usually, an allosteric enzyme has multiple interacting subunits that can exist in active and inactive conformations, and the allosteric effector promotes or hinders conversion from one conformation to another.

1. Cooperativity in Substrate Binding to Allosteric Enzymes

Allosteric enzymes usually contain two or more subunits and exhibit positive cooperativity; the binding of substrate to one subunit facilitates the binding of substrate to another subunit (Fig. 9.7). The first substrate molecule has difficulty in binding to the enzyme because all of the subunits are in the conformation with a low affinity for substrate (the taut “T” conformation) (see oxygen binding to hemoglobin in Chapter 7, Section VII.B). The first substrate molecule to bind changes its own subunit and at least one adjacent subunit to the high-affinity conformation (the relaxed “R” state.) In the example of the tetramer hemoglobin, discussed in Chapter 7, the change in one subunit facilitated changes in all four subunits, and the molecule generally changed to the new conformation in a concerted fashion. However, most allosteric enzymes follow a more stepwise (sequential) progression through intermediate stages (see Fig. 9.7).

FIGURE 9.7 A sequential model for an allosteric enzyme. The sequential model is actually the preferred path from the T_0 (taut, with 0 substrate, S, bound) low-affinity conformation to the R_4 (relaxed, with four substrate molecules bound) conformation, taken from an array of all possible equilibrium conformations that differ by the conformation of only one subunit. The final result is a stepwise path in which intermediate conformations exist, and subunits may change conformations independently, depending on their geometric relationship to the subunits already containing bound substrate.

2. Allosteric Activators and Inhibitors

Allosteric enzymes bind activators at the allosteric site, a site physically separate from the catalytic site. The binding of an allosteric activator changes the conformation of the catalytic site in a way that increases the affinity of the enzyme for the substrate.

In general, activators of allosteric enzymes bind more tightly to the high-affinity R state of the enzyme than the T state (i.e., the allosteric site is open only in the R enzyme) (Fig. 9.8). Thus, the activators increase the amount of enzyme in the active state, thereby facilitating substrate binding in their own and other subunits. In contrast, allosteric inhibitors bind more tightly to the T state, so either substrate concentration or activator concentration must be increased to overcome the effects of the allosteric inhibitor.

A model of an allosteric enzyme

FIGURE 9.8 Activators and inhibitors of an allosteric enzyme (simplified model). This enzyme has two identical subunits, each containing three binding sites: one for the substrate (S), one for the allosteric activator (*green triangle*), and one for the allosteric inhibitor (*two-pronged red shape*). The enzyme has two conformations, a relaxed active conformation (R) and an inactive conformation (T). The activator binds only to its activator site when the enzyme is in the R configuration. The inhibitor-binding site is open only when the enzyme is in the T state. A plot of velocity (v_i/V_{max}) versus substrate concentration reveals that binding of the substrate at its binding site stabilizes the active conformation so that the second substrate binds more readily, resulting in an S (sigmoidal)-shaped curve. The graph of v_i/V_{max} becomes hyperbolic in the presence of activator (which stabilizes the high-affinity R form), and more sigmoidal with a higher $S_{0.5}$ in the presence of inhibitor (which stabilizes the low-affinity form).

In the absence of activator, a plot of velocity versus substrate concentration for an allosteric enzyme usually results in a sigmoid or S-shaped curve (rather than the rectangular hyperbola of Michaelis–Menten enzymes) as the successive binding of substrate molecules activates additional subunits (see Fig. 9.8). In plots of velocity versus substrate concentration, the effect of an allosteric activator generally makes the sigmoidal S-shaped

curve more like the rectangular hyperbola, with a substantial decrease in the $S_{0.5}$ (K_m) of the enzyme, because the activator changes all of the subunits to the high-affinity state. These allosteric effectors alter the K_m but not the V_{max} of the enzyme. An allosteric inhibitor makes it more difficult for substrate or activators to convert the subunits to the most active conformation, and therefore, inhibitors generally shift the curve to the right, either increasing the $S_{0.5}$ alone or increasing it together with a decrease in the V_{max} .

Some of the rate-limiting enzymes in the pathways of fuel oxidation (e.g., muscle glycogen phosphorylase in glycogenolysis, phosphofructokinase-1 in glycolysis, and isocitrate dehydrogenase in the tricarboxylic acid [TCA] cycle) are allosteric enzymes regulated by changes in the concentration of adenosine diphosphate (ADP) or adenosine monophosphate (AMP), which are allosteric activators. The function of fuel oxidation pathways is the generation of ATP. When the concentration of ATP in a muscle cell begins to decrease, ADP and AMP increase; ADP activates isocitrate dehydrogenase, and AMP activates glycogen phosphorylase (in muscle) and phosphofructokinase-1. The response is very fast, and small changes in the concentration of activator can cause large changes in the rate of the reaction.

3. Allosteric Enzymes in Metabolic Pathways

Regulation of enzymes by allosteric effectors provides several advantages over other methods of regulation. Allosteric inhibitors usually have a much stronger effect on enzyme velocity than competitive and noncompetitive inhibitors in the active catalytic site. Because allosteric effectors do not occupy the catalytic site, they may function as activators. Thus, allosteric enzymes are not limited to regulation through inhibition. Furthermore, the allosteric effector need not bear any resemblance to substrate or product of the enzyme. Finally, the effect of an allosteric effector is rapid, occurring as soon as its concentration changes in the cell. These features of allosteric enzymes are often essential for feedback regulation of metabolic pathways by end products of the pathway or by signal molecules that coordinate multiple pathways.

B. Conformational Changes from Covalent Modification

1. Phosphorylation

The activity of many enzymes is regulated through **phosphorylation** by a **protein kinase** or **dephosphorylation** by a **protein phosphatase** (Fig. 9.9). Serine/threonine protein kinases transfer a phosphate from ATP to the hydroxyl group of a specific serine (and sometimes threonine) on the target enzyme; tyrosine kinases transfer a phosphate to the hydroxyl group of a specific tyrosine residue. Phosphate is a bulky, negatively charged residue that interacts with other nearby amino acid residues of the protein to create a conformational change at the catalytic site. The conformational change is caused by alterations in ionic interactions and/or hydrogen bond patterns resulting from the presence of the phosphate group. The conformational change makes certain enzymes more active and other enzymes less active. The effect is reversed by a specific protein phosphatase that removes the phosphate by hydrolysis.

Protein with serine side chain

Phosphorylated protein

FIGURE 9.9 Protein kinases and protein phosphatases. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

2. Muscle Glycogen Phosphorylase

Muscle glycogen phosphorylase, the rate-limiting enzyme in the pathway of glycogen degradation, degrades glycogen to glucose 1-phosphate. It is regulated by the allosteric activator AMP, which increases in the cell as ATP is used for muscular contraction (Fig. 9.10). Thus, a rapid increase in the rate of glycogen degradation to glucose 1-phosphate is achieved when an increase of AMP signals that more fuel is needed for ATP generation in the glycolytic pathway.

FIGURE 9.10 Activation of muscle glycogen phosphorylase by AMP and by phosphorylation. Muscle glycogen phosphorylase is composed of two identical subunits. The substrate-binding sites in the active catalytic site are denoted by S. AMP binds to the allosteric site, a site separate from the active catalytic site. Glycogen phosphorylase kinase can transfer a phosphate from ATP to one serine residue in each subunit. Either phosphorylation or binding of AMP causes a change in the active site that increases the activity of the enzyme. The first event at one subunit facilitates the subsequent events that convert the enzyme to the fully active form. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate.

Glycogen phosphorylase also can be activated through phosphorylation by glycogen phosphorylase kinase. Either phosphorylation or AMP binding can change the enzyme to a fully active conformation. The phosphate is removed by protein phosphatase-1. Glycogen phosphorylase kinase links the activation of muscle glycogen phosphorylase to changes in the level of the hormone adrenaline (epinephrine) in the blood. It is regulated through phosphorylation by protein kinase A and by activation of Ca^{2+} -calmodulin (a modulator protein) during contraction.

3. Protein Kinase A

Some protein kinases, called **dedicated protein kinases**, are tightly bound to a single protein and regulate only the protein to which they are tightly bound. However, other protein kinases and protein phosphatases simultaneously regulate a number of rate-limiting enzymes in a cell to achieve a coordinated response. For example, **protein kinase A**, a serine/threonine protein kinase, phosphorylates a number of enzymes that regulate different metabolic pathways. One of these enzymes is glycogen phosphorylase (see Fig. 9.10).

When **Ann R.** begins to jog, AMP activates her muscle glycogen phosphorylase, which degrades glycogen to glucose 1-phosphate. This compound is converted to glucose 6-P, which feeds into the glycolytic pathway to generate ATP for muscle contraction. As she continues to jog, her adrenaline (epinephrine) levels rise, producing the signal that activates glycogen phosphorylase kinase. This enzyme phosphorylates glycogen phosphorylase, causing it to remain active, even as AMP levels may drop (see Fig. 9.10).

Protein kinase A provides a means for hormones to control metabolic pathways. Epinephrine and many other hormones increase the intracellular concentration of the allosteric regulator 3',5'-cyclic AMP (cAMP), which is referred to as a **hormonal second messenger** (Fig. 9.11A). cAMP binds to regulatory subunits of protein kinase A, which dissociate and release the activated catalytic subunits (see Fig. 9.11B). Dissociation of inhibitory regulatory subunits is a common theme in enzyme regulation. The active catalytic subunits

phosphorylate glycogen phosphorylase kinase and other enzymes at serine and threonine residues.

A**B Inactive protein kinase A****Active protein kinase A**

FIGURE 9.11 A. Structure of cAMP. The phosphate group is attached to hydroxyl groups on both the third (3') and fifth (5') carbons of ribose, forming a cyclic molecule. **B.** Protein kinase A. When the regulatory subunits (R) of protein kinase A bind the allosteric activator, cAMP, they dissociate from the enzyme, thereby releasing active catalytic subunits (C). cAMP, 3',5'-cyclic adenosine monophosphate.

In the example shown in Figure 9.10, epinephrine indirectly increases cAMP, which activates protein kinase A, which phosphorylates and activates glycogen phosphorylase kinase, which phosphorylates and activates glycogen phosphorylase. The sequence of events in which one kinase phosphorylates another kinase is called a **phosphorylation cascade**. Because each stage of the phosphorylation cascade is associated with one enzyme molecule activating many enzyme molecules, the initial activating event is greatly amplified.

4. Other Covalent Modifications

A number of proteins are modified covalently by the addition of groups such as acetyl, ADP-ribose, or lipid moieties (see Chapter 6). These modifications may activate or inhibit the enzyme directly. However, they also may modify the ability of the enzyme to interact with other proteins or to reach its correct location in the cell.

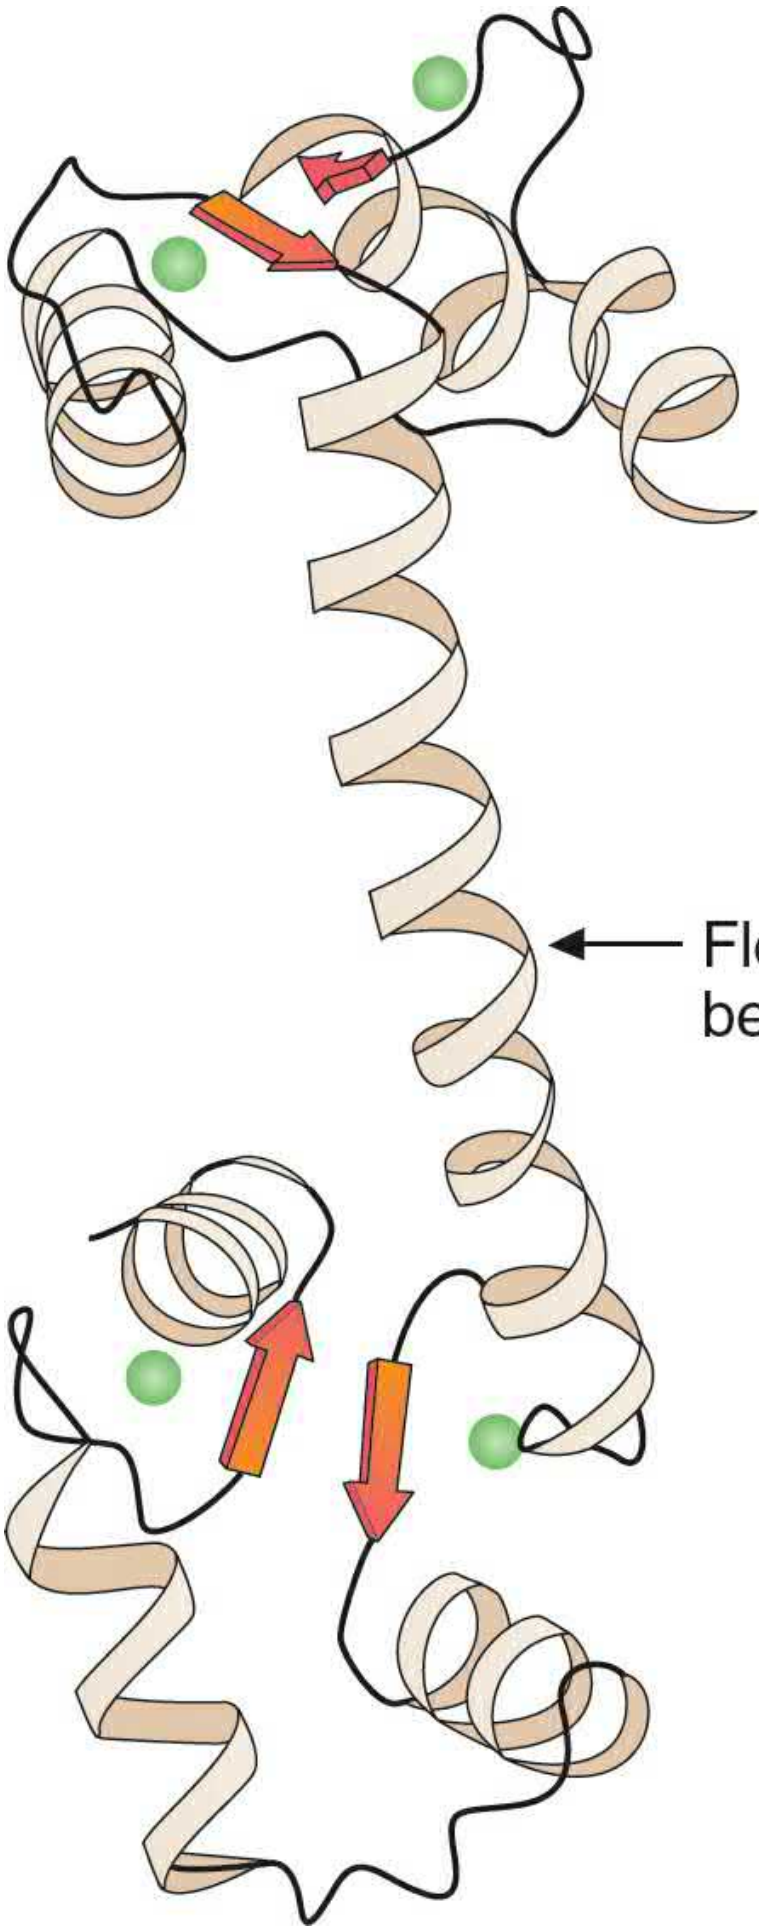

C. Conformational Changes Regulated by Protein–Protein Interactions

Changes in the conformation of the active site can also be regulated by direct protein–protein interaction. This type of regulation is illustrated by Ca^{2+} –calmodulin and small (monomeric) G-proteins.

1. The Calcium–Calmodulin Family of Modulator Proteins

Modulator proteins bind to other proteins and regulate their activity by causing a conformational change at the catalytic site or by blocking the catalytic site (steric hindrance). They are protein allosteric effectors that can either activate or inhibit the enzyme or protein to which they bind.

Ca^{2+} –calmodulin is an example of a dissociable modulator protein that binds to several different proteins and regulates their function in either a positive or negative manner. It also exists in the cytosol and functions as a Ca^{2+} -binding protein (Fig. 9.12). The center of the symmetric molecule is a hinge region that bends as Ca^{2+} –calmodulin folds over the protein it is regulating.

Flexible region
between domains

FIGURE 9.12 Calcium–calmodulin has four binding sites for calcium (shown in *green*). Each calcium forms a multiligand coordination sphere by simultaneously binding several amino acid residues on calmodulin. Thus, calmodulin can create large conformational changes in proteins to which it is bound when calcium binds. Calmodulin has a flexible region in the middle connecting the two domains.

One of the enzymes activated by Ca^{2+} –calmodulin is muscle glycogen phosphorylase kinase (see Fig. 9.10), which is also activated by protein kinase A. When a neural impulse triggers Ca^{2+} release from the sarcoplasmic reticulum, Ca^{2+} binds to the calmodulin subunit of muscle glycogen phosphorylase kinase, which undergoes a conformational change. This conformational change leads to the activation of glycogen phosphorylase kinase, which then phosphorylates glycogen phosphorylase, ultimately increasing the synthesis of ATP to supply energy for muscle contraction. Simultaneously, Ca^{2+} binds to troponin C, a member of the Ca^{2+} –calmodulin superfamily that serves as a nondissociable regulatory subunit of troponin, a regulator of muscle contraction. Calcium binding to troponin prepares the muscle for contraction. Thus, the supply of energy for contraction is activated simultaneously with the contraction machinery.

2. G-proteins

The masters of regulation through reversible protein association in the cell are the **monomeric G-proteins**, small single-subunit proteins that bind and hydrolyze GTP. GTP is a purine nucleotide that, like ATP, contains high-energy phosphoanhydride bonds that release energy when hydrolyzed. When G-proteins bind GTP, their conformation changes so that they can bind to a target protein, which is then either activated or inhibited in carrying out its function (Fig. 9.13, Step 1).

Active G-protein

FIGURE 9.13 Monomeric G-proteins. Step 1: When GTP is bound, the conformation of the G-protein allows it to bind target proteins, which are then activated (as shown), or inhibited. Step 2: The G-protein hydrolyzes a phosphate from GTP to form GDP, which changes the G-protein conformation and causes it to dissociate from the target protein. Step 3: GDP is exchanged for GTP, which reactivates the G-protein. GDP, guanosine diphosphate; GTP, guanosine triphosphate.

G-proteins are said to possess an internal clock because they are GTPases that slowly hydrolyze their own bound GTP to guanosine diphosphate (GDP) and phosphate. As they hydrolyze GTP, their conformation changes and the complex they have formed with the target protein disassembles (see Fig. 9.13, Step 2). The bound GDP on the inactive G-protein is eventually replaced by GTP, and the process can begin again (see Fig. 9.13, Step 3).

The activity of many G-proteins is regulated by accessory proteins (GAPs [GTPase-activating proteins], GEFs [guanine nucleotide exchange factors], and GDIs [GDP dissociation inhibitors]), which may, in turn, be regulated by allosteric effectors. GAPs increase the rate of GTP hydrolysis by the G-protein, and therefore the rate of dissociation of the G-protein–target protein complex (see Fig. 9.13, Step 2). When a GEF protein binds to a G-protein, it increases the rate of GTP exchange for a bound GDP, and therefore activates the G-protein (see Fig. 9.13, Step 3). GDI proteins bind to the GDP–G-protein complex and inhibit dissociation of GDP, thereby keeping the G-protein inactive.

The Ras superfamily of small G-proteins is divided into five families: Ras, Rho, Arf, Rab, and Ran. These monomeric G-proteins play major roles in the regulation of cell growth, morphogenesis, cell motility, axonal guidance, cytokinesis, and trafficking through the Golgi, nucleus, and endosomes. They are generally bound to a lipid membrane through a lipid anchor, such as a myristoyl group or farnesyl group, and regulate the assembly and activity of protein complexes at these sites. The functions of some of these G-proteins will be discussed further in Chapter 10.

D. Proteolytic Cleavage

Although many enzymes undergo some cleavage during synthesis, others enter lysosomes, secretory vesicles, or are synthesized as proenzymes, which are precursor proteins that must undergo proteolytic cleavage to become fully functional. Unlike most other forms of regulation, proteolytic cleavage is irreversible.

The precursor proteins of proteases (enzymes that cleave specific peptide bonds) are called **zymogens**. To denote the inactive zymogen form of an enzyme, the name is modified by addition of the suffix “-ogen” or the prefix “pro-.” The synthesis of zymogens as inactive precursors prevents them from cleaving proteins prematurely at their sites of synthesis or secretion. Chymotrypsinogen, for example, is stored in vesicles within pancreatic cells until secreted into ducts leading to the intestinal lumen. In the digestive tract, chymotrypsinogen is converted to chymotrypsin by the proteolytic enzyme trypsin, which cleaves off a small peptide from the *N*-terminal region (and two internal peptides). This cleavage activates chymotrypsin by causing a conformational change in the spacing of amino acid residues around the binding site for the denatured protein substrate and around the catalytic site.

Most of the proteases involved in blood clotting are zymogens, such as fibrinogen and prothrombin, which circulate in blood in the inactive form. They are cleaved to the active form (fibrin and thrombin, respectively) by other proteases, which have been activated by their attachment to the site of injury in a blood vessel wall. Thus, clots form at the site of injury and not randomly in the circulation (see Chapter 43).

IV. Regulation through Changes in Amount of Enzyme

Tissues continuously adjust the rate at which proteins are synthesized to vary the amount of different enzymes present. The expression for V_{\max} in the Michaelis–Menten equation incorporates the concept that the rate of a reaction is proportional to the amount of enzyme present. Thus, the maximal capacity of a tissue can change with increased protein synthesis or with increased protein degradation.

A. Regulated Enzyme Synthesis

Protein synthesis begins with the process of gene transcription, transcribing the genetic code for that protein from DNA into messenger RNA. The code in messenger RNA is then translated into the primary amino acid sequence of the protein. Generally, the rate of enzyme synthesis is regulated by increasing or decreasing the rate of gene transcription, processes that are generally referred to as **induction** (increase) and **repression**

(decrease). However, the rate of enzyme synthesis is sometimes regulated through stabilization of the messenger RNA. (These processes are covered in Section III of this text.) Compared with the more immediate types of regulation discussed previously, regulation by means of induction/repression of enzyme synthesis is usually slow in humans, occurring over hours to days.

B. Regulated Protein Degradation

The content of an enzyme in the cell can be altered through selective regulated degradation as well as through regulated synthesis. For example, during fasting or infective stress, protein degradation in skeletal muscle is activated to increase the supply of amino acids in the blood for gluconeogenesis or for the synthesis of antibodies and other components of the immune response. Under these conditions, synthesis of ubiquitin, a protein that targets proteins for degradation in proteosomes, is increased by the steroid hormone cortisol. Although all proteins in the cell can be degraded with a characteristic half-life within lysosomes, protein degradation via two specialized systems, proteosomes and caspases, is highly selective and regulated. Protein degradation is discussed in more detail in Chapter 35.

V. Regulation of Metabolic Pathways

The different means of regulating enzyme activity described earlier are used to control metabolic pathways, cellular events, and physiologic processes to match the body's requirements. Although there are hundreds of metabolic pathways in the body, there are a few common themes or principles that are involved in their regulation. The overriding principle is that regulation of a pathway matches its **function**.

 The maximal capacity of MEOS (cytochrome P450-2E1) is increased in the liver with continued ingestion of ethanol through a mechanism involving induction of gene transcription. Thus, **Al M.** has a higher capacity to oxidize ethanol to acetaldehyde than a naive drinker (a person not previously subjected to alcohol). Nevertheless, the persistence of his elevated blood alcohol level shows that he has saturated his capacity for ethanol oxidation (i.e., the enzyme is always running at V_{max}). Once his enzymes are operating near V_{max} , any additional ethanol he drinks will not appreciably increase the rate of ethanol clearance from his blood.

A. Principles of Pathway Regulation

Metabolic pathways are a series of sequential reactions in which the product of one reaction is the substrate of the next reaction (Fig. 9.14). Each step or reaction is usually catalyzed by a separate enzyme. The enzymes of a pathway have a common function—conversion of substrate to the final end products of the pathway. A pathway also may have a branch point at which an intermediate becomes the precursor for another pathway.

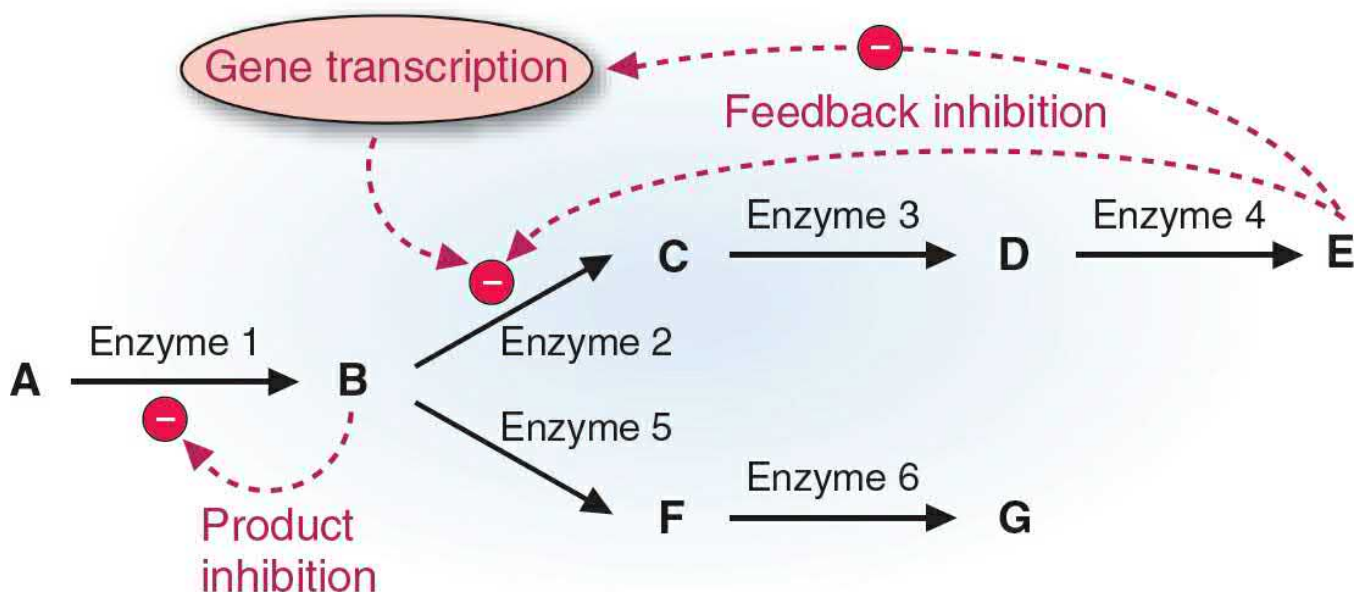

FIGURE 9.14 A common pattern for feedback inhibition of metabolic pathways. The *letters* represent compounds formed from different enzymes in the reaction pathway. Compound B is at a metabolic branch point: It can go down one pathway to E or

down an alternate pathway to G. The end product of the pathway, E, might control its own synthesis by allosterically inhibiting enzyme 2, the first committed step of the pathway, or by inhibiting transcription of the gene for enzyme 2. As a result of the feedback inhibition, B accumulates and more B enters the pathway for conversion to G, which could be a storage pathway or a disposal pathway. In this hypothetical pathway, B is a product inhibitor of enzyme 1, competitive with respect to A. Precursor A might induce the synthesis of enzyme 1, which would allow more A to go to G.

1. Role of the Rate-Limiting Step in Regulation

Pathways are principally regulated at one key enzyme, the regulatory enzyme, which catalyzes the rate-limiting step in the pathway. This is the slowest step and is usually not readily reversible. Thus, changes in the rate-limiting step can influence flux through the rest of the pathway (see Fig. 9.1). The rate-limiting step is usually the first committed step in a pathway or a reaction that is related to or influenced by the first committed step. Additional regulated enzymes occur after each metabolic branchpoint to direct flow into the branch (e.g., in Fig. 9.14, feedback inhibition of enzyme 2 results in accumulation of B, which enzyme 5 then uses for synthesis of compound G). Inhibition of the rate-limiting enzyme in a pathway usually leads to accumulation of the pathway precursor.

When **Ann R.** jogs, the increased use of ATP for muscle contraction results in an increase of AMP, which allosterically activates both the key enzyme phosphofructokinase-1, the rate-limiting enzyme of glycolysis, and muscle glycogen phosphorylase, the rate-limiting enzyme of glycogenolysis. These pathways both provide for a means to increase ATP production. This is an example of feedback regulation by the ATP/AMP ratio. Unfortunately, **Ann R.**'s low caloric consumption has not allowed feed-forward activation of the rate-limiting enzymes in her fuel storage pathways, and she has very low glycogen stores. Consequently, she has inadequate fuel stores to support the increased energy demands of exercise.

2. Feedback Regulation

Feedback regulation refers to a situation in which the end product of a pathway controls its own rate of synthesis (see Fig. 9.14). Feedback regulation usually involves allosteric regulation of the rate-limiting enzyme by the end product of a pathway (or a compound that reflects changes in the concentration of the end product). The end product of a pathway may also control its own synthesis by inducing or repressing the gene for transcription of the rate-limiting enzyme in the pathway. This type of regulation is much slower to respond to changing conditions than allosteric regulation.

3. Feed-Forward Regulation

Certain pathways, such as those involved in the disposal of toxic compounds, are feed-forward-regulated. **Feed-forward regulation** may occur through an increased supply of substrate to an enzyme with a high K_m , allosteric activation of a rate-limiting enzyme through a compound related to substrate supply, substrate-related induction of gene transcription (e.g., induction of cytochrome P450-2E1 by ethanol), or increased concentration of a hormone that stimulates a storage pathway by controlling enzyme phosphorylation state.

4. Tissue Isozymes of Regulatory Proteins

The human body is composed of a number of different cell types that perform specific functions unique to that cell type and synthesize only the proteins consistent with their functions. Because regulation matches function, regulatory enzymes of pathways usually exist as tissue-specific isozymes with somewhat different regulatory properties unique to their function in different cell types. For example, HK and GK are tissue-specific isozymes with different kinetic properties. These different isozymes arose through gene duplication. GK, the low-affinity enzyme found in liver, is a single-polypeptide chain with a molecular weight of 55 kDa that contains one active catalytic site. The HKs found in erythrocytes, skeletal muscles, and most other tissues are 110 kDa and are essentially two mutated GK molecules synthesized as one polypeptide chain. However, only one catalytic site is functional. All of the tissue-specific HKs except GK have a K_m for glucose that is <0.2 mM.

5. Counterregulation of Opposing Pathways

A pathway for the synthesis of a compound usually has one or more enzymatic steps that differ from the pathway for degradation of that compound. A biosynthetic pathway can therefore have a different regulatory enzyme than the opposing degradative pathway, and one pathway can be activated, whereas the other is inhibited (e.g., glycogen synthesis is activated, whereas glycogen degradation is inhibited).

6. Substrate Channeling through Compartmentation

In the cell, compartmentation of enzymes into multienzyme complexes or organelles provides a means of regulation, either because the compartment provides unique conditions or because it limits or channels access of the enzymes to substrates. Enzymes or pathways with a common function are often assembled into organelles. For example, enzymes of the TCA cycle are all located within the mitochondrion. The enzymes catalyze sequential reactions, and the product of one reaction is the substrate for the next reaction. The concentration of the pathway intermediates remains much higher within the mitochondrion than in the surrounding cellular cytoplasm.

Another type of compartmentation involves the assembly of enzymes that catalyze sequential reactions into multienzyme complexes so that intermediates of the pathway can be transferred directly from the active site on one enzyme to the active site on another enzyme, thereby preventing loss of energy and information. One example of this is the microsomal ethanol oxidizing system (MEOS), which is composed of two different subunits with different enzyme activities. One subunit transfers electrons from reduced nicotinamide adenine dinucleotide phosphate (NADPH) to a cytochrome Fe-heme group on the second subunit, which then transfers the electrons to O_2 .

7. Levels of Complexity

You may have noticed by now that regulation of metabolic pathways in humans is exceedingly complex; this might be called the **second principle of metabolic regulation**. As you study different pathways in subsequent chapters, it may help to develop diagrams such as Fig. 9.14 to keep track of the function and rationale behind different regulatory interactions.

CLINICAL COMMENTS

Al M. In the emergency department, **Al M.** was evaluated for head injuries. From the physical examination and blood alcohol levels, it was determined that his mental state resulted from his alcohol consumption. Although his chronic ethanol consumption had increased his level of MEOS (and, therefore, the rate of ethanol oxidation in his liver), his excessive drinking resulted in a blood alcohol level higher than the legal limit of 80 mg/dL. He suffered bruises and contusions but was otherwise uninjured. He left in the custody of the police officer and his driving license was suspended.

Ann R.'s physician explains that she had inadequate fuel stores for her exercise program. To jog, her muscles require an increased rate of fuel oxidation to generate the ATP for muscle contraction. The fuels used by muscles for exercise include glucose from muscle glycogen, fatty acids from adipose tissue triacylglycerols, and blood glucose supplied by liver glycogen. These fuel stores were depleted during her prolonged bout of starvation. In addition, starvation resulted in the loss of muscle mass as muscle protein was degraded to supply amino acids for other processes, including gluconeogenesis (the synthesis of glucose from amino acids and other noncarbohydrate precursors). Therefore, **Ann R.** will need to increase her caloric consumption to rebuild her fuel stores. Her physician helps her calculate the additional amount of calories her jogging program will need, and they discussed which foods she will eat to meet these increased caloric requirements. He also helps her visualize the increase of weight as an increase in strength.

The hormones epinephrine (released during stress and exercise) and glucagon (released during fasting) activate the synthesis of cAMP in a number of tissues. cAMP activates protein kinase A. Because protein kinase A is able to phosphorylate key regulatory enzymes in many pathways, these pathways can be regulated coordinately. In muscle, for example, glycogen degradation is activated, whereas glycogen synthesis is inhibited. At the same time, fatty-acid release from adipose tissue is activated to provide more fuel for muscle. The regulation of glycolysis, glycogen metabolism, and other pathways of metabolism is much more complex than we have illustrated here and is discussed in many subsequent chapters of this text.

BIOCHEMICAL COMMENTS

The catalytic rate constant, k_{cat} , and fractional occupancy of an enzyme can be determined from the derivation of the Michaelis–Menten equation. Enzymes will typically, at maximal velocity, convert substrate to product as

fast as the reaction can proceed. But how fast is that? Every enzyme has its own unique **turnover number**—that is, the number of reactions the enzyme can catalyze per unit time (i.e., reactions per second). For example, the turnover number of carbonic anhydrase is about 4×10^5 reactions per second, whereas for the enzyme lysozyme the turnover number is 0.5 reactions per second (it takes 2 seconds to complete one reaction).

One can estimate the turnover number, or catalytic constant, from the rate constant k_3 in equation 1. Recall that $v = k_3[ES]$; at maximal velocity, all of the enzyme is in the ES form, so $ES = E_t$, where E_t is the total enzyme concentration. Thus, $V_{\max} = k_3E_t$. If the concentration of enzyme is known, and the maximal velocity at that concentration of enzyme, then k_3 (the catalytic constant) can be calculated. The turnover number of an enzyme is dependent on the enzymes structure and the rate at which it can bind substrate and approach and allow the transition state of the reaction to form.

Michaelis–Menten kinetics can also allow one to determine the fractional occupancy of an enzyme at any given reaction velocity. The fraction of an enzyme, E , with bound substrate, S , can be represented as f_{ES} . f_{ES} is equal to the velocity in the presence of S divided by the maximal velocity of the reaction:

$$f_{ES} = (v)/(V_{\max}) \quad \text{(equation 1)}$$

Recall that the velocity of a reaction is equal to the following:

$$v = (V_{\max})([S])/([S] + K_m) \quad \text{(equation 2)}$$

If one substitutes the value of v in equation 2 for v in equation 1, one obtains:

$$f_{ES} = (V_{\max})([S])/(V_{\max})([S] + K_m) \quad \text{(equation 3)}$$

If one cancels out the V_{\max} in the numerator and denominator of equation 3, one obtains:

$$f_{ES} = [S]/([S] + K_m)$$

Thus, when $[S] = K_m$, $f_{ES} = 1/2$. Knowing the concentration of substrate, and the K_m value, one can determine what percentage of enzyme has bound substrate at that time.

KEY CONCEPTS

- ◆ Enzyme activity is regulated to reflect the physiologic state of the organism.
- ◆ The rate of an enzyme-catalyzed reaction is dependent on substrate concentration and can be represented mathematically by the Michaelis–Menten equation.
- ◆ The Lineweaver–Burk transformation of the Michaelis–Menten equation allows a rapid differentiation between competitive and noncompetitive inhibitors of enzyme activity.
- ◆ Allosteric activators or inhibitors are compounds that bind at sites other than the active catalytic site and regulate the enzyme through conformational changes that affect the catalytic site.
- ◆ Several different mechanisms are available to regulate enzyme activity. These include the following:
 - ◆ Feedback inhibition, which often occurs at the first committed step of a metabolic pathway
 - ◆ Covalent modification of an amino acid residue (or residues) within the protein
 - ◆ Interactions with modulator proteins, which, when bound to the enzyme, alter the conformation of the enzyme and hence activity
 - ◆ Altering the primary structure of the protein via proteolysis
 - ◆ Increasing or decreasing the amount of enzyme available in the cell via alterations in the rate of synthesis or degradation of the enzyme
- ◆ Metabolic pathways are frequently regulated at the slowest, or rate-limiting, step of the pathway.
- ◆ Diseases discussed in this chapter are summarized in Table 9.1.

TABLE 9.1 Diseases Discussed in Chapter 9

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
-----------------------	--------------------------	----------

Alcohol use disorder	Both	Both ADH and the microsomal ethanol oxidizing system are active in detoxifying ethanol. High NADH can inhibit ADH, allowing toxic metabolites to accumulate.
Anorexia nervosa	Both	Effects of malnutrition on energy production were discussed.
Maturity-onset diabetes of the young	Genetic	Mutations in various proteins can lead to this form of diabetes, which is manifest by hyperglycemia, but without other complications associated with either type 1 or 2 diabetes. Specifically, mutations in pancreatic glucokinase were discussed.

ADH, alcohol dehydrogenase.

REVIEW QUESTIONS—CHAPTER 9

- Salivary amylase is an enzyme that digests dietary starch. Assume that salivary amylase follows Michaelis–Menten kinetics. Which one of the following best describes a characteristic feature of salivary amylase?
 - The enzyme velocity is at one-half the maximal rate when 100% of the enzyme molecules contain bound substrate.
 - The enzyme velocity is at one-half the maximal rate when 50% of the enzyme molecules contain bound substrate.
 - The enzyme velocity is at its maximal rate when 50% of the enzyme molecules contain bound substrate.
 - The enzyme velocity is at its maximal rate when all of the substrate molecules in solution are bound by the enzyme.
 - The velocity of the reaction is independent of the concentration of enzyme.
- The pancreatic GK of a patient with maturity-onset diabetes of the young (MODY) had a mutation replacing a leucine with a proline. The result was that the K_m for glucose was decreased from a normal value of 6 mM to a value of 2.2 mM, and the V_{max} was changed from 93 U/mg protein to 0.2 U/mg protein. Which one of the following best describes the patient's GK compared with the normal enzyme?
 - The patient's enzyme requires a lower concentration of glucose to reach $\frac{1}{2}V_{max}$.
 - The patient's enzyme is faster than the normal enzyme at concentrations of glucose <2.2 mM.
 - The patient's enzyme is faster than the normal enzyme at concentrations of glucose >2.2 mM.
 - At near-saturating glucose concentration, the patient would need 90 to 100 times more enzyme than normal to achieve normal rates of glucose phosphorylation.
 - As blood glucose levels increase after a meal from a fasting value of 5 to 10 mM, the rate of the patient's enzyme will increase more than the rate of the normal enzyme.
- Methanol (CH_3OH) is converted by alcohol dehydrogenases (ADH) to formaldehyde (CH_2O), a compound that is highly toxic to humans. Patients who have ingested toxic levels of methanol are sometimes treated with ethanol ($\text{CH}_3\text{CH}_2\text{OH}$) to inhibit methanol oxidation by ADH. Which one of the following statements provides the best rationale for this treatment?
 - Ethanol is a structural analog of methanol and might therefore be an effective noncompetitive inhibitor.
 - Ethanol is a structural analog of methanol that can be expected to compete with methanol for its binding site on the enzyme.
 - Ethanol can be expected to alter the V_{max} of ADH for the oxidation of methanol to formaldehyde.
 - Ethanol is an effective inhibitor of methanol oxidation regardless of the concentration of methanol.
 - Ethanol can be expected to inhibit the enzyme by binding to the formaldehyde-binding site on the enzyme, even though it cannot bind at the substrate-binding site for methanol.
- A runner's muscles use glucose as a source of energy. Muscle contains glycogen stores that are degraded into glucose 1-phosphate via glycogen phosphorylase, which is an allosteric enzyme. Assume that an allosteric enzyme has the following kinetic properties: a V_{max} of 25 U/mg enzyme and a $K_{m,app}$ of 1.0 mM. These kinetic parameters were then measured in the presence of an allosteric activator. Which one of the

following would best describe the findings of that experiment?

- A. A V_{\max} of 25 U/mg enzyme and a $K_{m,app}$ of 0.2 mM
 - B. A V_{\max} of 15 U/mg enzyme with a $K_{m,app}$ of 2.0 mM
 - C. A V_{\max} of 25 U/mg enzyme with a $K_{m,app}$ of 2.0 mM
 - D. A V_{\max} of 50 U/mg enzyme with a $K_{m,app}$ of 5.0 mM
 - E. A V_{\max} of 50 U/mg enzyme with a $K_{m,app}$ of 10.0 mM
5. A rate-limiting enzyme catalyzes the first step in the conversion of a toxic metabolite to a urinary excretion product. Which of the following mechanisms for regulating this enzyme would provide the most protection to the body?
- A. The product of the pathway should be an allosteric inhibitor of the rate-limiting enzyme.
 - B. The product of the pathway should act through gene transcription to decrease synthesis of the enzyme.
 - C. The toxin should act through gene transcription to increase synthesis of the enzyme.
 - D. The enzyme should have a high K_m for the toxin.
 - E. The toxin allosterically activates the last enzyme in the pathway.
6. In thyroid hormone production, thyrotropin-releasing hormone (TRH) from the hypothalamus stimulates thyroid-stimulating hormone (TSH) release from the anterior pituitary, which stimulates the thyroid to produce thyroid hormones (triiodothyronine [T_3] and thyroxine [T_4]). Normal or high levels of thyroid hormone then suppress release of TRH. Which of the following best describes the regulation of this pathway?
- A. Complementary regulation
 - B. Feedback regulation
 - C. Compartmentation
 - D. Feed-forward regulation
 - E. Negative regulation
7. A patient with alcoholic liver disease has profound mental status changes caused by a buildup of ammonia (NH_4^+) and is suffering from hepatic encephalopathy. The conversion of NH_4^+ to urea is an example of which one of the following types of pathway regulation?
- A. Complimentary
 - B. Feedback
 - C. Compartmentation
 - D. Feed-forward
 - E. Negative
8. Pathway regulation can occur via the expression of tissue-specific isozymes. Glucose metabolism differs in the red blood cell and liver in that the red blood cells need to metabolize glucose, whereas the liver prefers to store glucose. The first step of glucose metabolism requires either GK (liver) or hexokinase I (red blood cell), which are isozymes. Which one of the following best describes these different isozymes and their K_m for glucose?
- A. The K_m of hexokinase I is higher than the K_m of GK.
 - B. The K_m of hexokinase I is lower than the K_m of GK.
 - C. The K_m of hexokinase I is the same as the K_m of GK.
 - D. Hexokinase I is found in liver.
 - E. GK is found in red blood cells.

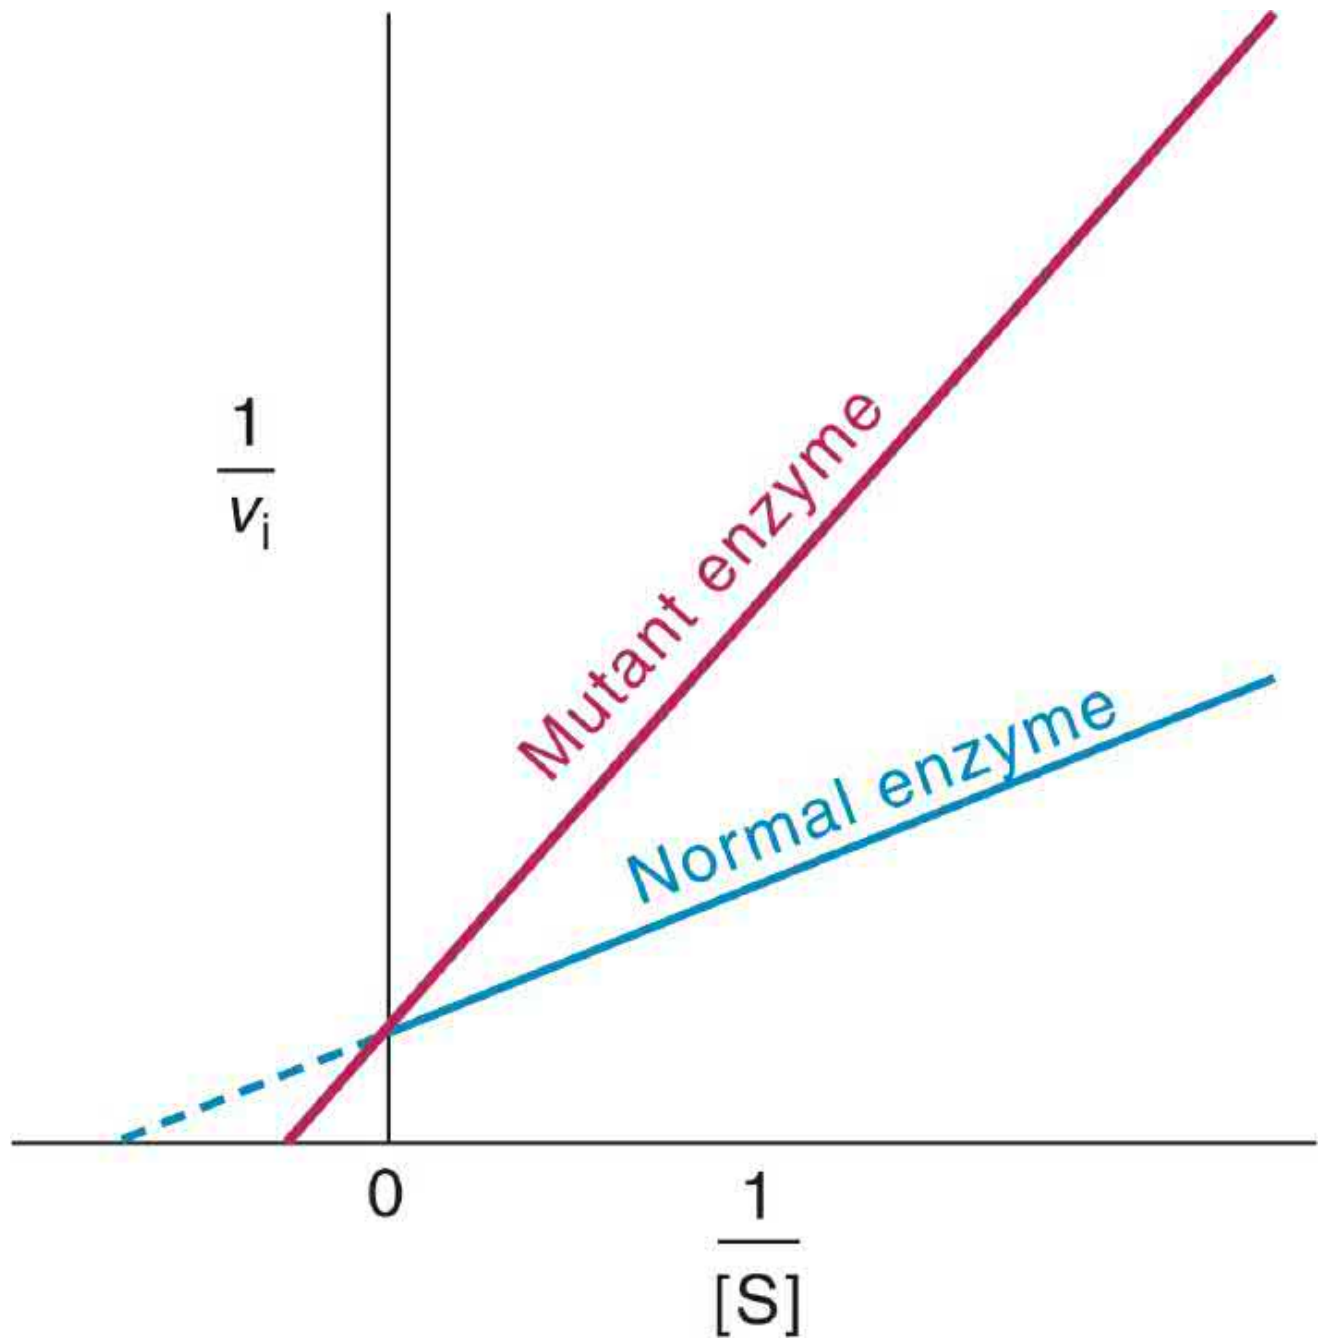

Questions 9 and 10 are linked.

9. An antibiotic is developed that is a close structural analog of a substrate of an enzyme that participates in cell wall synthesis in bacteria. This binding of the antibiotic reduces overall enzyme activity, but such activity can be restored if more substrate is added. The binding of the antibiotic to the enzyme is not via a covalent bond, nor does the enzyme alter the structure of the antibiotic. Which one of the following would best describe this antibiotic?
- A. It is a suicide inhibitor.
 - B. It is an irreversible inhibitor.
 - C. It is a competitive inhibitor.
 - D. It is a noncompetitive inhibitor.
 - E. It is an uncompetitive inhibitor.
10. Which one of the following is true for the inhibitor described in the previous question?

- A. It increases the apparent K_m of the enzyme.
 - B. It decreases the apparent K_m of the enzyme.
 - C. It has no effect on the apparent K_m of the enzyme.
 - D. It increases the V_{max} of the enzyme.
 - E. It decreases the V_{max} of the enzyme.
1. A liver cell line has been isolated that has a variant small GTP-binding protein (G-protein), which lacks GTPase activity. The target of this small G-protein is the enzyme phospholipase C, which, when activated by binding to the G-protein, hydrolyzes phosphatidyl inositol bisphosphate into diacylglycerol (DAG) and inositol trisphosphate (IP_3). Which one of the following would be expected to occur in the cell line when the variant G-protein binds GTP?
- A. Continual increased cellular levels of phosphatidyl inositol bisphosphate
 - B. Continual decreased cellular levels of DAG
 - C. Continual increased levels of IP_3
 - D. Continual decreased levels of IP_3
 - E. Continual inactivation of phospholipase C

Questions 12 and 13 are linked.

2. Consider an enzyme, at a concentration of $1.0 \mu M$, in the presence of substrate (at a concentration of 1.0 mM). The velocity of the enzyme-catalyzed reaction under these conditions is 5.0 mM product formed per minute. What is the maximal velocity of the enzyme at this concentration of enzyme, if the K_m of the enzyme is 2.0 mM ?
- A. 1.0 mM product formed per minute
 - B. 5 mM product formed per minute
 - C. 10 mM product formed per minute
 - D. 15 mM product formed per minute
 - E. 20 mM product formed per minute
3. Considering the enzyme described in question 12, what is the turnover number of the enzyme (k_{cat}) in terms of reactions catalyzed per minute?
- A. 1.5
 - B. 15
 - C. 150
 - D. 1500
 - E. 15,000
4. A key metabolic enzyme is regulated by reversible phosphorylation of a serine side chain on the protein. In the absence of phosphorylation, the serine side chain forms noncovalent interactions with the side chains of glutamine and tyrosine. After phosphorylation, the phosphoserine residue on the protein can form a noncovalent interaction with which one of the following amino acid side chains?
- A. Val
 - B. Phe
 - C. Asp
 - D. Arg
 - E. Leu
5. A variant enzyme was found in a liver cell line, which catalyzed the reaction of $A \rightarrow B$. Enzyme kinetics were done with the wild-type and mutant enzymes, and the following results were obtained. Which one of the following statements is correct in terms of the kinetic properties of these enzymes?

- A. The variant enzyme has a higher V_{\max} than the normal enzyme.
- B. The variant enzyme has a lower V_{\max} than the normal enzyme.
- C. The variant enzyme has a higher K_m than the normal enzyme.
- D. The variant enzyme has a lower K_m than the normal enzyme.
- E. The variant enzyme has the same kinetic properties as the normal enzyme.

ANSWERS TO REVIEW QUESTIONS

1. **The answer is B.** The rate of an enzyme-catalyzed reaction is directly proportional to the percentage of enzyme molecules that contain bound substrate. Thus, it is at 50% of its maximal rate when 50% of the molecules contain bound substrate (thus, A, C, and D are incorrect). The rate of the reaction is directly proportional to the amount of enzyme present, which is incorporated into the term V_{\max} (where $V_{\max} = k[\text{total enzyme}]$) (thus, E is incorrect).
2. **The answer is A.** The patient's enzyme has a lower K_m than the normal enzyme and therefore requires a

lower glucose concentration to reach $\frac{1}{2}V_{\max}$. Thus, the mutation may have increased the affinity of the enzyme for glucose, but it has greatly decreased the subsequent steps of the reaction leading to formation of the transition-state complex, and thus V_{\max} is much slower. The difference in V_{\max} is so great that the patient's enzyme is much slower whether you are above or below its K_m for glucose. You can test this by substituting 2 mM glucose and 4 mM glucose into the Michaelis–Menten equation, $v = V_{\max} S / (K_m + S)$ for the patient's enzyme and for the normal enzyme. The values are 0.0095 and 0.0129 for the patient's enzyme versus 23.2 and 37.2 for the normal enzyme, respectively (thus, B and C are incorrect). At near-saturating glucose concentrations, both enzymes will be near V_{\max} , which is equal to k_{cat} times the enzyme concentration. Thus, it will take nearly 500 times as much of the patient's enzyme to achieve the normal rate ($93 \div 0.2$), and so C is incorrect. E is incorrect because rates change most as you decrease substrate concentration below the K_m . Thus, the enzyme with the highest K_m will show the largest changes in rate.

3. **The answer is B.** Ethanol has a structure very similar to methanol (a structural analog) and thus can be expected to compete with methanol at its substrate-binding site. This inhibition is competitive with respect to methanol, and, therefore, V_{\max} for methanol will not be altered and ethanol inhibition can be overcome by high concentrations of methanol (thus, A, C, and D are incorrect). E is illogical because the substrate methanol stays in the same binding site as it is converted to its product, formaldehyde.
4. **The answer is A.** Allosteric activators will shift the sigmoidal kinetic curve for the enzyme to the left, thereby reducing the $K_{m,\text{app}}$ (so $\frac{1}{2}V_{\max}$ will be reached at a lower substrate concentration) without affecting the maximal velocity (although in some cases V_{\max} can also be increased). Allosteric inhibitors will shift the curve to the right, increasing the $K_{m,\text{app}}$ and sometimes also decreasing the V_{\max} .
5. **The answer is C.** The most effective regulation should be a feed-forward type of regulation in which the toxin activates the pathway. One of the most common ways this occurs is through the toxin acting to increase the amount of enzyme by increasing transcription of its gene. A and B describe mechanisms of feedback regulation, in which the end product of the pathway decreases its own rate of synthesis and are, therefore, incorrect. D is incorrect because a high K_m for the toxin might prevent the enzyme from working effectively at low toxin concentrations, although it would allow the enzyme to respond to increases of toxin concentration. It would do little good for the toxin to allosterically activate any enzyme but the rate-limiting enzyme (thus, E is incorrect).
6. **The answer is B.** In feedback regulation, the end product (thyroid hormone) directly controls its own rate of synthesis by suppressing the release of earlier stimulating hormones. This is called a feedback loop. Feed-forward mechanisms reflect the availability of a precursor to activate a downstream step of a pathway, such as with toxin disposal pathways (only activated when toxin is present, and the rate of toxin removal increases as the level of toxin increases). Compartmentation is a collection of enzymes within a specific compartment of the cell (e.g., cytoplasm, peroxisome, lysosome, mitochondria). Although negative regulation refers to an inhibitor of an enzyme, the best answer to this question is feedback regulation, as the end product of the pathway is the effector that is regulating the pathway. Complementary regulation refers to a number of factors acting similarly (complementing each other) in regulating a pathway, which is not the case in this example.
7. **The answer is D.** Ammonia is a toxin and needs to be removed from the body by converting it to urea. If no ammonia is present, the pathway does not function. When arginine is present (a component of the cycle that generates urea), the disposal pathway becomes functional, and the higher the concentration of arginine, the faster the pathway—a great example of feed-forward regulation. Urea does not feedback to slow production of more urea. The enzymes of the urea cycle are not compartmentalized (they actually exist in both the mitochondria and cytoplasm).
8. **The answer is B.** Red blood cells rely solely on glucose for energy needs and must have an isoenzyme with a much lower K_m (hexokinase I), so that at even low levels of substrate (glucose), glucose can still be phosphorylated at rates near the V_{\max} to allow the red blood cell (RBC) to survive. With a K_m near the normal fasting level of blood glucose, liver GK can convert elevated levels of glucose (after a meal) into glycogen, a glucose storage molecule.
9. **The answer is C.** Because the antibiotic is not covalently bound to the enzyme, it is a reversible inhibitor. The antibiotic is not a suicide inhibitor because the enzyme does not alter the structure of the antibiotic. Because adding excess substrate can overcome the effects of the inhibitor, the inhibitor is acting in a competitive manner, competing with substrate for binding to the active site of the enzyme. Excess substrate cannot overcome the effects of a noncompetitive inhibitor. Uncompetitive or anticompetitive

inhibitors bind to the complex formed between the enzymes and substrate and are not overcome by adding excess substrate.

10. **The answer is A.** A competitive inhibitor increases the apparent K_m of the enzyme because it raises the concentration of substrate necessary to saturate the enzyme. They have no effect on V_{max} . In the example of the antibiotic, a higher dose of the antibiotic would be expected to be more effective (up to maximal saturation of the enzyme). Noncompetitive inhibitors change V_{max} with no effect on K_m of the substrate.
11. **The answer is C.** The small G-protein is activated by binding GTP, and when activated stimulates phospholipase C activity such that the levels of DAG and IP_3 increase. The G-protein cannot be inactivated if its GTPase activity is inactive, so there will be a continual increase in the levels of DAG and IP_3 . The level of substrate, phosphatidyl inositol bisphosphate, will decrease, while phospholipase C will remain active for extended periods of time.
12. **The answer is D.** One can determine the maximal velocity using the Michaelis–Menten equation. The velocity (v) is equal to the expression $((V_{max}[S])/([S] + K_m))$. The question indicates that $v = 5.0$ mM product formed per minute, $[S] = 1.0$ mM, and the $K_m = 2.0$ mM. Plugging in the numbers in the equation and solving for V_{max} , one arrives at 15 mM product formed per minute.
13. **The answer is E.** The formula for calculating the turnover number (or k_{cat}) is $V_{max} = k_{cat} E_t$, where E_t is the total enzyme concentration. It is stated in the previous question that E_t is $1 \mu\text{M}$ (10^{-6} M, or 10^{-3} mM), and the V_{max} is 15 mM product formed per minute. Using these numbers in the equation, 15 mM product formed per minute = $(k_{cat})(10^{-3} \text{ mM})$, and solving for k_{cat} yields a value of 15,000 reactions per minute.
14. **The answer is D.** When the serine side chain on the protein is phosphorylated, the side chain now contains a negative charge and can form an ionic interaction with a positively charged side chain, such as the side chain of arginine. The side chains of valine, phenylalanine, and leucine are all hydrophobic and will not interact with a charged side chain. The side chain of aspartic acid is negatively charged and would repel the negatively charged phosphoserine side chain.
15. **The answer is C.** The variant enzyme has a higher K_m than the normal enzyme as the K_m is determined from the Lineweaver–Burk plot by the x -axis intercept. Because the mutant enzyme line intercepts the x -axis at a smaller value than the normal enzyme, the K_m must be larger for the mutant enzyme as the x -axis is the reciprocal of the value. The y -intercept represents the V_{max} , and both lines intercept the y -axis at the same point, indicating the V_{max} is the same for both enzymes.

Cell Structure and Signaling by Chemical Messengers

The basic unit of a living organism is the cell. In humans, each tissue is composed of a variety of cell types, which mostly differ from those cell types in other tissues. The diversity of cell types dictates the function of the tissue and organs in which they reside, and each cell type has unique structural features that reflect its role. In spite of their diversity in structure, human cell types have certain architectural features in common, such as the plasma membrane, membranes around the nucleus and organelles, and a cytoskeleton (Fig. 10.1). In this chapter, we review common features of cell structure, the functions of organelles, the transport systems for compounds into cells and between organelles, and signaling by chemical messengers.

FIGURE 10.1 Common components of human cells.

Plasma membrane. The cell membrane consists of a **lipid bilayer** that serves as a selective barrier; it restricts the entry and exit of compounds. Within the plasma membrane, different **integral**

membrane proteins facilitate the **transport** of compounds by **energy-requiring active transport**, **facilitated diffusion**, or by forming **pores** or **gated channels**. The plasma membrane is supported by a **membrane skeleton** composed of proteins.

Organelles and Cytoplasmic Membrane Systems. Most organelles within the cell are compartments surrounded by a membrane system that restricts exchange of compounds and information with other compartments (see Fig. 10.1). In general, each organelle has unique functions that are served by the enzymes and other compounds it contains. **Lysosomes** contain **hydrolytic enzymes** that degrade proteins and other large molecules. The **nucleus** contains the genetic material and carries out **DNA replication** and **transcription** of **DNA**. The transcription of DNA generates mRNA, which binds to **ribosomes** in the cytosol to initiate protein synthesis. For certain proteins, the ribosomes become attached to a complex membrane system called the **endoplasmic reticulum**; for other proteins, synthesis is completed on ribosomes that remain in the cytoplasm. The **endoplasmic reticulum** is also involved in lipid synthesis and transport of molecules to the Golgi. The **Golgi** forms vesicles for transport of molecules to the plasma membrane and other membrane systems, and for secretion. **Mitochondria** are organelles committed to **fuel oxidation** and **ATP generation**. **Peroxisomes** contain many enzymes that use or produce **hydrogen peroxide**. The **cytosol** is the intracellular compartment free of organelles and membrane systems.

Cytoskeleton. The **cytoskeleton** is a flexible fibrous protein support system that maintains the geometry of the cell, fixes the position of organelles, and allows movement of compounds within the cell. The cytoskeleton, with signals from the plasma membrane, also facilitates movement of the cell itself. It is composed primarily of **actin microfilaments**, **intermediate filaments**, **tubulin microtubules**, and their attached proteins.

Within a complex organism such as the human, the different organs, tissues, and cell types have developed specialized functions. Yet each cell must contribute in an integrated way as the body grows, differentiates, and adapts to changing conditions. Such integration requires communication that is carried out by chemical messengers traveling through the blood, or from one cell to another, by direct contact of cells with the extracellular matrix or by direct contact of one cell with another. The eventual goal of such signals is to change actions carried out in target cells by intracellular proteins (metabolic enzymes, gene regulatory proteins, ion channels, or cytoskeletal proteins).

Chemical Messengers. Chemical messengers (also called signaling molecules) transmit messages between cells. They are **secreted** from one cell in **response to a specific stimulus** and **travel to a target cell**, where they **bind to a specific receptor** and **elicit a response** (Fig. 10.2). In the nervous system, these chemical messengers are called **neurotransmitters**; in the **endocrine system**, they are called **hormones**; and in **the immune system**, they are called **cytokines**. Additional chemical messengers include **retinoids**, **eicosanoids**, and **growth factors**. Depending on the distance between the secreting and target cells, chemical messengers can be classified as **endocrine** (travel in the blood), **paracrine** (travel between nearby cells), **juxtacrine** (cell–cell contact-dependent signaling), or **autocrine** (act on the same cell that produces the message).

FIGURE 10.2 General features of chemical messengers. 1. Secretion of chemical message. 2. Binding of message to cell surface receptor. 3. Diffusion of a hydrophobic message across the plasma membrane and binding to an intracellular receptor.

Receptors and Signal Transduction. Receptors are proteins that contain a binding site specific for

a chemical messenger and an effector site involved in transmitting the message (see Fig. 10.2). The effector site may interact with another protein or with DNA. They may be either **plasma membrane receptors** (which span the plasma membrane and contain an extracellular binding domain for the messenger) or **intracellular binding proteins** (for messengers able to diffuse into the cell) (see Fig. 10.2). Most plasma membrane receptors fall into the categories of **ion-channel receptors**, **tyrosine kinase receptors**, **tyrosine kinase-associated receptors**, **serine-threonine kinase receptors**, or **G-protein coupled (heptahelical) receptors** (proteins with seven α -helices spanning the membrane). When a chemical messenger binds to a receptor, the signal it is carrying must be converted into an intracellular response. This conversion is called **signal transduction**.

Signal Transduction for Intracellular Receptors. Most intracellular receptors are **gene-specific transcription factors**, proteins that bind to DNA and regulate the transcription of certain genes. (Gene transcription is the process of copying the genetic code from DNA to RNA and is discussed further in Chapter 13.)

Signal Transduction for Plasma Membrane Receptors. Mechanisms of signal transduction that follow the binding of signaling molecules to plasma membrane receptors include phosphorylation of receptors at tyrosine residues (**receptor tyrosine kinase** activity), conformational changes in **signal transducer proteins** (e.g., proteins with **SH2** domains, the **monomeric G-proteins like Ras**, or **heterotrimeric G-proteins**), or increases in the levels of **intracellular second messengers**. Second messengers are nonprotein molecules that are generated inside the cell in response to hormone binding and that continue transmission of the message. Examples include 3',5'-cyclic AMP (**cAMP**), inositol trisphosphate (**IP₃**), and diacylglycerol (**DAG**).

Signaling often requires a rapid response and rapid termination of the message, which may be achieved by internalization of the receptor, by degradation of the receptor itself, by degradation of the messenger or second messenger, the conversion of GTP to GDP on GTP-dependent signaling molecules, deactivation of signal transduction kinases by phosphatases, or other means.

THE WAITING ROOM

Al M. had been drinking heavily when he drove his car off the road and was taken to the hospital emergency department (see Chapters 8 and 9). Although he suffered only minor injuries, his driving license was suspended.

Vibrio cholerae epidemics are rare in the United States. However, these bacteria grow well under the alkaline conditions found in seawater and attach to chitin in shellfish. Thus, sporadic cases occur in the southeast United States associated with the ingestion of contaminated shellfish.

Two years after **Dennis V.** recovered from his malathion poisoning, he visited his grandfather, **Percy V.** took **Dennis V.** with him to a picnic at the shore, where they ate steamed crabs. Early the next morning, **Dennis V.** experienced episodes of profuse watery diarrhea and vomiting. **Percy V.** rushed him to the hospital emergency department. **Dennis V.**'s hands and feet were cold, he appeared severely dehydrated, and he was approaching hypovolemic shock (a severe drop in blood pressure). He was diagnosed with cholera, caused by the bacteria *Vibrio cholerae*. **Dennis V.** was placed on intravenous rehydration therapy, followed by oral rehydration therapy with high glucose and sodium (Na^+) containing fluids and given antibiotics. In his intestinal mucosal cells, the cholera toxin A subunit indirectly activated the cystic fibrosis transmembrane conductance regulator (CFTR) channel, resulting in the secretion of chloride and sodium ions into his intestinal lumen. Ion secretion was followed by loss of water, resulting in vomiting and watery diarrhea.

Uric acid levels in blood or urine can be determined enzymatically through use of the enzyme uricase, which converts uric acid (plus oxygen) to allantoin and hydrogen peroxide. Uricase is found in lower primates but not in humans. Uric

acid has a strong light absorbance at 293 nm, which allantoin does not. Therefore, measurement of the decrease in absorbance at 293 nm after treating an unknown sample with uricase can allow the determination of uric acid levels. As the presence of proteins can reduce the sensitivity of this method, an alternative method is to determine the amount of hydrogen peroxide formed during the course of the reaction. In most cases, the enzymes peroxidase or catalase are utilized and the enzymatic products are coupled to a chemical indicator reaction (a color change). One can determine the extent of color change during the reaction, which is proportional to the hydrogen peroxide produced, which is proportional to the concentration of uric acid in the sample.

Before **Lotta T.** was treated with allopurinol for prevention of a gouty attack (see Chapter 8), her physician-administered colchicine (acetyl trimethyl colchicinic acid) for the acute attack of gout affecting her great toe. After taking two doses of colchicine divided over 1 hour (1.2 mg for the first dose, followed 1 hour later by 0.6 mg), the throbbing pain in her toe had abated significantly. The redness and swelling also seemed to have lessened slightly.

Mia S. is a 37-year-old woman who complains of increasing muscle fatigue, which she notices mostly with eating: halfway through a meal she has trouble chewing her food. If she rests for five to ten minutes, her strength returns to normal. She also notes that if she talks on the phone, her ability to form words gradually decreases because of fatigue of the muscles of speech. She also reports that by evening, her upper eyelids droop to the point that she has to pull her upper lids back to see normally. These symptoms are becoming increasingly severe. When she is asked to sustain an upward gaze, her upper eyelids eventually drift downward involuntarily. When she is asked to hold both arms straight out in front of her for as long as she is able, both arms begin to drift downward within minutes. Her physician suspects that **Mia S.** has myasthenia gravis and orders a test to determine whether she has antibodies in her blood directed against the acetylcholine receptor.

Acetylcholine is released by neurons and acts on acetylcholine receptors at neuromuscular junctions to stimulate muscular contraction. Myasthenia gravis is an acquired autoimmune disease in which most patients have developed pathogenic antibodies against these receptors. **Mia S.**'s decreasing ability to form words and her other symptoms of muscle weakness are being caused by the inability of acetylcholine to stimulate repeated muscle contraction when the numbers of effective acetylcholine receptors at neuromuscular junctions are greatly reduced.

Ann R., who suffers from anorexia nervosa, has increased her weight from 85 to 102 lb (see Chapter 9). On the advice of her physician, she has been eating more to prevent fatigue during her daily jogging regimen. She runs about 10 miles before breakfast every other day and forces herself to drink a high-energy supplement immediately afterward.

I. Compartmentation in Cells

The structure of a typical eukaryotic cell is shown in Figure 10.1. The cells of humans and other animals are classified as **eukaryotes** because the genetic material is organized into a membrane-enclosed nucleus. In contrast, bacteria are classified as **prokaryotes**, as they do not contain a compartmentalized nucleus or other organelles typically found in eukaryotic cells.

Endocrine hormones enable **Ann R.** to mobilize fuels from her adipose tissue during her periods of fasting and during jogging. While she fasts overnight, α -cells of her pancreas increase secretion of the polypeptide hormone glucagon. The stress of prolonged fasting and chronic exercise stimulates release of cortisol, a steroid hormone, from her adrenal cortex. The exercise of jogging also increases secretion of the hormones epinephrine and norepinephrine from the adrenal medulla. Each of these hormones is being released in response to a specific signal and causes a characteristic response in a target tissue, enabling her to exercise. However, each of these hormones binds to a different type of receptor and works in a different way.

Membranes are lipid-containing structures that separate the contents of the compartment they surround from its environment. An outer plasma membrane separates the cell from the external environment. Organelles (such as the nucleus, mitochondria, lysosomes, and peroxisomes) are also surrounded by membrane systems that separate the internal compartment of the organelle from the intracellular milieu, known as the cytosol. The function of these membranes is to allow the organelle to collect or concentrate enzymes and other molecules serving a common function into a compartment within a localized environment. The transporters and receptors in each membrane system control this localized environment and facilitate communication of the cell or organelle with the surrounding milieu.

The following sections describe the various organelles and membrane systems found in most human cells and outline the relationship between their properties and function. Not all cells in the human are alike. Different cell types differ qualitatively or quantitatively in their organelle content, and their organelles may contain vastly different amounts of a particular enzyme, **consistent with the function of the cell**. For example, liver mitochondria contain a key enzyme for synthesizing ketone bodies, but they lack a key enzyme required for their use. The reverse is true in muscle mitochondria. Thus, the enzyme content of the organelles varies somewhat from cell type to cell type.

Bacteria are single cells surrounded by a cell membrane and a cell wall exterior to the membrane. They are prokaryotes, which do not contain nuclei or other organelles (i.e., membrane-surrounded subcellular structures) found in eukaryotic cells. Nonetheless, bacteria carry out many similar metabolic pathways, with the enzymes located in either the intracellular compartment or the cell membrane.

The *Vibrio cholerae* responsible for **Dennis V.**'s cholera are gram-negative bacteria. Their plasma membrane is surrounded by a thin cell wall composed of a protein–polysaccharide structure called peptidoglycan and an outer membrane. In contrast, gram-positive bacteria have a plasma membrane and a thick peptidoglycan cell wall that retains the Gram stain. *Vibrio* grow best under aerobic conditions but also can grow under low-oxygen conditions. They possess enzymes similar to those in human cells for glycolysis, the TCA cycle, and oxidative phosphorylation. They have a low tolerance for acid, which partially accounts for their presence in slightly basic seawater and shellfish.

II. Plasma Membrane

A. Structure of the Plasma Membrane

All mammalian cells are enclosed by a plasma membrane composed of a **lipid bilayer** (two layers) containing embedded proteins (Fig. 10.3). The membrane layer facing the “inside” of the organelle or cell is termed the **inner leaflet**; the other layer is the **outer**, or **external, leaflet**. The membranes are continuous and sealed so that the hydrophobic lipid bilayer selectively restricts the exchange of polar compounds between the external fluid and the intracellular compartment. The membrane is referred to as a fluid mosaic because it consists of a mosaic of proteins and lipid molecules that can for the most part move laterally in the plane of the membrane. The proteins are classified as **integral proteins**, which span the cell membrane, or **peripheral proteins**, which are attached to the membrane surface through electrostatic bonds to lipids or integral proteins. Many of the proteins and lipids on the external leaflet of the plasma membrane contain covalently bound carbohydrate chains and therefore are called **glycoproteins** and **glycolipids**. This layer of carbohydrate on the outer surface of the cell is called the **glycocalyx**. The variable carbohydrate components of the glycolipids on the cell surface function, in part, as cell recognition markers for small molecules or other cells.

FIGURE 10.3 Basic structure of a mammalian cell membrane.

1. Lipids in the Plasma Membrane

Each layer of the plasma membrane lipid bilayer is formed primarily by **phospholipids**, which are arranged with their hydrophilic head groups facing the aqueous medium and their fatty acyl tails forming a hydrophobic membrane core (see Fig. 10.3). The principal phospholipids in the membrane are the glycerol lipids **phosphatidylcholine** (also named lecithin), **phosphatidylethanolamine**, and **phosphatidylserine**, and the sphingolipid **sphingomyelin** (the structure of the phospholipids can be seen in Chapters 5 and 31). Sphingosine also forms the base for the glycosphingolipids, which are membrane-anchored lipids with carbohydrates attached. The lipid composition varies among different cell types, with phosphatidylcholine being the major plasma membrane phospholipid in most cell types and glycosphingolipids the most variable.

The lipid composition of the bilayer is asymmetrical, with a higher content of phosphatidylcholine and sphingomyelin in the outer leaflet and a higher content of phosphatidylserine and phosphatidylethanolamine in the inner leaflet. Phosphatidylinositol, which can also function in the transfer of information from hormones and neurotransmitters across the cell membrane (see Section XII.C.3 of this chapter), is also primarily found in the inner leaflet. Phosphatidylserine contains a net negative charge that contributes to the membrane potential and may be important for binding positively charged molecules within the cell.

One of the bacterial toxins secreted by *Clostridium perfringens*, the bacteria that cause gas gangrene (clostridial myonecrosis), is a lipase that hydrolyzes phosphocholine from phosphatidylcholine and sphingomyelin. The resulting lysis (breakage) of the cell membrane releases intracellular contents that provide the bacteria with nutrients for rapid growth. These bacteria are strict anaerobes and grow only in the absence of oxygen. As their toxins lyse membranes in the endothelial cells of blood vessels, the capillaries are destroyed, and the bacteria are protected from oxygen transported by the red blood cells. They are also protected from antibiotics and components of the immune system carried in the blood.

Cholesterol, which is interspersed between the phospholipids, maintains membrane fluidity. The presence of cholesterol and the *cis* unsaturated fatty acids in the membrane prevent the hydrophobic chains from packing too closely together. As a consequence, lipid and protein molecules that are not bound to external or internal structural proteins can rotate and move laterally in the plane of the leaflet. This movement enables the plasma membrane to partition between daughter cells during cell division, to reorganize as cells pass through

capillaries, and to form and fuse with vesicle membranes. Cholesterol can also stabilize very fluid membranes by increasing interactions between the fatty acids of phospholipids through hydrophobic interactions with the cholesterol ring structure. The fluidity of the membrane is also partially determined by the unsaturated fatty acid content in the membrane lipids.

AI M. is suffering from both short-term and long-term effects of ethanol on his central nervous system. Data support the theory that the short-term effects of ethanol on the brain arise partly from an increase in membrane fluidity caused when ethanol intercalates between the membrane lipids. The changes in membrane fluidity may affect proteins that span the membrane (integral proteins), such as ion channels and receptors for neurotransmitters involved in conducting the nerve impulse.

2. Proteins in the Plasma Membrane

Integral proteins contain transmembrane domains with hydrophobic amino acid side chains that interact with the hydrophobic portions of the lipids to seal the membrane (see Fig. 10.3). Hydrophilic regions of the proteins protrude into the aqueous medium on both sides of the membrane. Many of these proteins function as either channels or transporters for the movement of compounds across the membrane, as receptors for the binding of hormones and neurotransmitters, or as structural proteins (Fig. 10.4).

FIGURE 10.4 Proteins in the red blood cell membrane. The proteins named Band 3 (the bicarbonate–chloride exchange transporter) and glycophorin (provides an external negative charge that repels other cells) both contain nonpolar α -helical segments spanning the lipid bilayer. These proteins contain a large number of polar and charged hydrophilic amino acids in the intracellular and extracellular domains. On the inside of the cell, they are attached to peripheral proteins comprising the inner membrane skeleton. Band 3 is connected to spectrin filaments via the protein ankyrin. Glycophorin is connected to short actin filaments and spectrin via protein 4.1. Band 3 allows the transport of bicarbonate into the red blood cell in exchange for chloride. This allows bicarbonate transport to the lung, where it is expired as carbon dioxide.

Peripheral membrane proteins, which were originally defined as those proteins that can be released from the membrane by ionic solvents, are bound through weak electrostatic interactions with the polar head groups of lipids or with integral proteins. One of the best-characterized classes of peripheral proteins is the **spectrin** family of proteins, which are bound to the intracellular membrane surface and provide mechanical support for the membrane. Spectrin is bound to actin, which together forms a structure that is called the inner membrane skeleton or the cortical skeleton (see Fig. 10.4).

A third classification of membrane proteins consists of **lipid-anchored proteins** bound to the inner or outer surface of the membrane. The **glycophosphatidylinositol glycan (GPI) anchor** is a covalently attached lipid that anchors proteins to the external surface of the membrane (Fig. 10.5). Several proteins involved in hormonal regulation are anchored to the internal surface of the membrane through palmityl (C16) or myristyl (C14) fatty acyl groups or through geranylgeranyl (C20) or farnesyl (C15) isoprenyl groups (see Fig. 6.12). However, many integral proteins also contain attached lipid groups to increase their stability in the membrane.

FIGURE 10.5 An example of a glycosylphosphatidylinositol glycan anchor (GPI). The carboxy terminus of the protein is attached to phosphoethanolamine, which is bound to a branched oligosaccharide that is attached to the inositol portion of phosphatidylinositol. The hydrophobic fatty acyl chains of the phosphatidylinositol portion are bound in the hydrophobic core of the membrane.

B. Transport of Molecules across the Plasma Membrane

Membranes form hydrophobic barriers around cells to control the internal environment by restricting the entry and exit of molecules. As a consequence, cells require **transport systems** to permit the entry of small polar compounds or ions that they need (e.g., glucose) to concentrate inside the cell (e.g., K^+) and to expel other compounds (e.g., Ca^{2+} and Na^+). The transport systems for small organic molecules and inorganic ions generally fall into four categories: first is **simple diffusion** through the lipid bilayer (examples include gases such as oxygen and carbon dioxide, and lipid-soluble substances, such as steroid hormones); second is **facilitative diffusion** (many sugars are transported by facilitative diffusion); third is **gated channels** (transmembrane proteins form a pore for ions that is either opened or closed in response to a stimulus, whether it be voltage changes across the membrane, the binding of a compound, or a regulatory change in the intracellular domain); and fourth is **active transport pumps** (energy, usually in the form of ATP hydrolysis, is used to allow compounds to move against their concentration gradient) (Fig. 10.6). These transport mechanisms are classified as passive if energy is not required, or active if energy is required. Primary active transport occurs when a gradient is established across the membrane, using energy. The Na^+ , K^+ -ATPase creates both sodium and potassium gradients across the membrane, by transporting three sodium ions out of the cell in exchange for two potassium ions entering the cell, powered by the hydrolysis of ATP. The creation of the sodium gradient (the sodium concentration outside the cell is much greater than the sodium concentration inside the cell) leads to secondary active transport of glucose and amino acids. The transporters for these compounds bind sodium and the co substrate (either glucose or an amino acid), and then using the sodium gradient as a driving force, transports both the sodium and the co substrate into the cell. Thus, glucose and amino acids are concentrated within cells via the creation of the sodium gradient by the Na^+ , K^+ -ATPase.

FIGURE 10.6 Common types of transport mechanisms for human cells. The electrochemical gradient consists of the concentration gradient of the compound and the distribution of charge on the membrane, which affects the transport of charged ions such as Cl^- . Both protein amino acid residues and lipid polar head groups contribute to the net negative charge on the inside of the membrane. Generally, the diffusion of uncharged molecules (passive transport) is net movement from a region of high concentration to a region of low concentration, and active transport (energy-requiring) is net movement from a region of low concentration to one of high concentration. ATP, adenosine triphosphate.

All cells contain an inner membrane skeleton of spectrin-like proteins. Red blood cell spectrin was the first member of the spectrin family to be described. The protein dystrophin, present in skeletal muscle cells, is a member of the spectrin family. Genetic defects in the dystrophin gene are responsible for Duchenne and Becker muscular dystrophies.

The prion protein, present in neuronal membranes, provides an example of a protein attached to the membrane through an anchor. This is the protein that develops an altered pathogenic conformation in both mad cow disease (Bovine spongiform encephalopathy) and Creutzfeldt–Jakob disease (see Chapter 7, Section IX.C.3).

The A, B, and O blood groups are determined by the carbohydrate composition of the glycolipids on the surface of red blood cells. Glycolipids on other cell surfaces may also serve as binding sites for viruses and bacterial toxins before penetrating the cell. For example, the cholera AB toxin (which is affecting **Dennis V.**) binds to GM₁-gangliosides on the surface of the intestinal epithelial cells. The toxin is then endocytosed in caveolae (invaginations or “caves” that can form in specific regions of the membrane). Once inside the cell, the toxin can alter normal cellular metabolism.

In addition to these mechanisms for the transport of small individual molecules, cells use a process named **endocytosis**. The plasma membrane extends or invaginates to surround a particle, a foreign cell, a membrane receptor, or extracellular fluid, which then closes into a vesicle that is released into the cytoplasm (see Fig. 10.6). Receptor-mediated endocytosis can occur in either of two ways. The first is the formation of clathrin-coated vesicles that mediate the internalization of membrane-bound receptors in vesicles coated on the intracellular side with subunits of the protein clathrin. Cholesterol uptake, as mediated by the low-density lipoprotein (LDL) receptor, occurs via this mechanism. The second is caveolar endocytosis, in which caveolae (small invaginations of the plasma membrane) oligomerize and form endocytotic vesicles containing a receptor. Insulin uptake in fat cells occurs via this mechanism. Potocytosis is the name given to endocytosis that occurs via caveolae (small invaginations or “caves”), which are regions of the cell membrane with a unique lipid and protein composition (including the protein caveolin-1). The transport of the vitamin folate occurs via potocytosis.

Dennis V. has become dehydrated because he has lost so much water through vomiting and diarrhea (see Chapter 4). Cholera toxin increases the efflux of sodium and chloride ions from his intestinal mucosal cells into the intestinal lumen. The increase of water in his stools results from the passive transfer of water from inside the cell and body fluids, where it is in high concentration (i.e., intracellular Na⁺ and Cl⁻ concentrations are low), to the intestinal lumen and bowel, where water is in lower concentration (relative to high Na⁺ and Cl⁻). The watery diarrhea is also high in K⁺ ions and bicarbonate. The signs and symptoms of cholera generally are derived from this fluid loss.

III. Lysosomes

Lysosomes are the intracellular organelles of digestion and are enclosed by a single membrane that prevents the release of its digestive enzymes into the cytosol. They are central to a wide variety of bodily functions that involve the elimination of unwanted material and recycling of their components, including the destruction of infectious bacteria and yeast, recovery from injury, tissue remodeling, involution of tissues during development, and normal turnover of cells and organelles. The lysosomal digestive enzymes include **nucleases, phosphatases, glycosidases, esterases, and proteases** (Fig. 10.7). These enzymes are all hydrolases, enzymes that cleave amide, ester, and other bonds through the addition of water. Many of the products of lysosomal digestion, such as amino acids, return to the cytosol. Lysosomes are therefore involved in recycling compounds. The proteases are classified as serine, cysteine, or aspartyl proteases, depending on the amino acid residue at the active site of the enzyme involved in the hydrolytic reaction. The cysteine proteases are also known as cathepsins. Most of these lysosomal hydrolases have their highest activity near a pH of approximately 5.5 (the optimal pH for hydrolysis). The intralysosomal pH is maintained near 5.5 principally by v-ATPases (vesicular ATPases), which actively pump protons into the lysosome at the expense of ATP hydrolysis. The cytosol and other cellular compartments have a pH nearer to 7.2 and are therefore protected from escaped lysosomal hydrolases.

FIGURE 10.7 Lysosomal reactions. Most lysosomal enzymes are hydrolases, which cleave peptide, ester, and glycosidic bonds by adding the components of water across the bond. These enzymes are active at the acidic pH found within the lysosome and therefore are inactive if accidentally released into the cytosol.

All of the cells in the body have facilitative glucose transporters that transport glucose across the plasma membrane down an electrochemical (concentration) gradient as it is rapidly metabolized in the cell. In muscle and adipose tissue, insulin increases the content of facilitative glucose transporters in the cell membrane, thus increasing the ability of these tissues to take up glucose. Patients with type 1 diabetes mellitus, who do not produce insulin (e.g., **Dianne A.**, see Chapter 7), have a decreased ability to transport glucose into these tissues, thereby contributing to hyperglycemia (high blood glucose).

The cystic fibrosis transmembrane conductance regulator (CFTR) was named for its role in cystic fibrosis. Individuals homozygous for mutations in CFTR display cystic fibrosis; heterozygotes for the mutated gene are thought to have protection against cholera. A nonfunctional CFTR leads to an inability to release chloride ions from cells into the extracellular space, with a concomitantly reduced diffusion of water into the same space. Thus, a consequence of the CFTR mutation is the dehydration of respiratory and interstitial mucosal linings, leading to a plugging of airways and ducts with a thick mucus. The CFTR is also involved in the dehydration experienced by cholera patients such as **Dennis V.** In intestinal mucosal cells, the cholera A subunit indirectly promotes phosphorylation of the regulatory domain of CFTR by protein kinase A. Thus, the channel stays open and Cl⁻ and H₂O flow from the cell into the intestinal lumen, resulting in dehydration.

The dehydration of cholera is often treated first with an intravenous rehydration solution followed by an oral rehydration solution containing Na⁺, K⁺, and glucose or a diet of rice (which contains glucose and amino acids). Glucose is absorbed from the intestinal lumen via the Na⁺-dependent glucose cotransporters, which cotransport Na⁺ into the cells together with glucose. Many amino acids are also absorbed by Na⁺-dependent cotransport. With the return of Na⁺ to the cytoplasm, the release of water from the cell into the intestinal lumen decreases.

IV. Mitochondria

Mitochondria contain most of the enzymes for the pathways of fuel oxidation and oxidative phosphorylation and thus generate most of the ATP required by mammalian cells. Each mitochondrion is surrounded by two membranes, a mostly impermeable **outer membrane** and a highly impermeable **inner membrane**, separating the mitochondrial **matrix** from the intermembrane space (Fig. 10.8). The inner membrane forms invaginations known as **cristae** containing the electron transport chain and ATP synthase. Most of the enzymes for the Krebs tricarboxylic acid (TCA) cycle and other pathways for oxidation are located in the mitochondrial matrix, the compartment enclosed by the inner mitochondrial membrane. (The TCA cycle and the electron transport chain are described in more detail in Chapters 23 and 24.)

FIGURE 10.8 Mitochondrion. Electron micrograph (*top*); three-dimensional drawing (*bottom*).

Genetic defects in lysosomal enzymes, or in proteins such as the mannose 6-phosphate receptors required for targeting the enzymes to the lysosome, lead to an abnormal accumulation of undigested material in lysosomes that may be converted to residual bodies. The accumulation may be so extensive that normal cellular function is compromised, particularly in neuronal cells. Genetic diseases such as the **Tay–Sachs** disease (an accumulation of partially digested gangliosides in lysosomes), and **Pompe** disease (an accumulation of glycogen particles in lysosomes) are caused by the absence or deficiency of specific lysosomal enzymes. Such diseases, in which a lysosomal function is compromised, are known as **lysosomal storage diseases**.

The inner mitochondrial membrane is highly impermeable, and the proton gradient that is built up across this membrane during oxidative phosphorylation is essential for ATP generation from adenosine diphosphate (ADP) and phosphate. The transport of ions and other small molecules across the inner mitochondrial membrane occurs principally through facilitative transporters in a type of secondary active transport powered by a proton gradient established by the electron transport chain. The outer membrane contains pores made from proteins called **porins** and is permeable to molecules with a molecular weight of up to about 1,000 Da.

The elevated level of uric acid in **Lotta T.**'s blood led to the deposition of monosodium urate crystals in the joint space (synovial fluid) of her right great toe, resulting in podagra (painful great toe). Neutrophils, the mediators of the acute inflammation that followed, attempted to phagocytose the urate crystals. The engulfed urate crystals were deposited in the late endosomes and lysosomes of the neutrophil. Because urate crystals are particles that cannot be degraded by any of the lysosomal acid hydrolases, their accumulation caused lysis of the lysosomal membranes, followed by cell lysis and release of lysosomal enzymes into the joint space. The urate crystals also resulted in the release of chemical mediators of inflammation that recruited other cells into the area. This further amplified the acute inflammatory reaction in the tissues of the joint capsule (synovitis), leading to the extremely painful swelling of acute gouty arthritis.

Mitochondria can replicate by division; however, most of their proteins must be imported from the cytosol. Mitochondria contain a small amount of DNA, which encodes for 13 different subunits of proteins involved in oxidative phosphorylation, as well as for genes encoding tRNA molecules, which are needed for protein synthesis. Most of the enzymes and proteins in mitochondria are encoded by nuclear DNA and synthesized on cytoplasmic ribosomes. They are imported through membrane pores by a receptor-mediated process involving members of the heat-shock family of proteins (proteins whose synthesis is induced by an elevation of temperature or other indicators of stress). Mutations in mitochondrial DNA result in a number of genetic diseases that affect skeletal muscle, neuronal tissue, and renal tissue (known as **mitochondrial disorders**). Mitochondrial inheritance is maternal, as the sperm do not contribute mitochondria to the fertilized egg. Spontaneous mutations within mitochondrial DNA have been implicated with the mechanism of aging.

Pyruvate transfer across the inner mitochondrial membrane is dependent on the proton gradient, and the carrier for pyruvate transports both pyruvate and a proton into the matrix of the mitochondria. Such transport allows for the accumulation of pyruvate within the organelle at concentrations greater than in the cytosol. This is an example of which type of transport?

V. Peroxisomes

Peroxisomes are cytoplasmic organelles, similar in size to lysosomes, that are involved in **oxidative reactions** using **molecular oxygen**. These reactions produce the toxic chemical **hydrogen peroxide** (H_2O_2), which is subsequently used or degraded within the peroxisome by catalase and other enzymes. Peroxisomes function in the oxidation of very long-chain fatty acids (containing 20 or more carbons) to shorter-chain fatty acids, the conversion of cholesterol to bile acids, and the synthesis of **ether lipids** called **plasmalogens**. They are bounded by a single membrane.

Like mitochondria, peroxisomes can replicate by division. However, they are dependent on the import of proteins to function. They do not contain DNA.

VI. Nucleus

The largest of the subcellular organelles of animal cells is the **nucleus** (Fig. 10.9). Most of the genetic material of the cell is located within the chromosomes in the nucleus, which are composed of DNA, an equal weight of small, positively charged proteins called **histones**, and a variable amount of other proteins. These nucleoprotein

complexes comprise what is called **chromatin**. The **nucleolus**, a substructure of the nucleus, is the site of **ribosomal RNA** (rRNA) transcription and processing, and of **ribosome assembly**. Ribosomes are required for the synthesis of proteins. Replication, transcription, translation, and the regulation of these processes are the major focus of the molecular biology section of this text (see Section III).

FIGURE 10.9 Nucleus. Electron micrograph (*top*); three-dimensional drawing (*bottom*). RER, rough endoplasmic reticulum.

The nucleus is separated from the rest of the cell (the cytoplasm) by the nuclear envelope, which consists of two membranes joined at **nuclear pores**. The outer nuclear membrane is continuous with the rough endoplasmic reticulum. Transport through the pores is bidirectional. An example of such transport is the initial phase of protein synthesis. To convert the genetic code of the DNA into the primary sequence of a protein, DNA is transcribed into RNA, which is spliced and modified into mRNA. The mRNA travels through the nuclear pores into the cytoplasm, where it is translated into the primary sequence of a protein on ribosomes. Ribosomes, which are generated in the nucleolus, also must travel through nuclear pores to the cytoplasm. Conversely, proteins required for replication, transcription, and other processes enter into the nucleus through these pores. Proteins contain specific sequences of amino acids known as a nuclear localization signal (NLS) or nuclear export signal (NES) that dictate whether a protein may move out of or into the nucleus. Thus, the direction of transport through the pore is specific for the molecule or complex being transported across the membrane.

VII. Endoplasmic Reticulum

The **endoplasmic reticulum** (ER) is a network of membranous tubules within the cell consisting of **smooth endoplasmic reticulum** (SER), which lacks ribosomes, and **rough endoplasmic reticulum** (RER), which is studded with ribosomes (Fig. 10.10). The SER has a number of functions. It contains enzymes for the synthesis of many lipids, such as triacylglycerols and phospholipids. It also contains the **cytochrome P450 oxidative enzymes** involved in the metabolism of drugs and toxic chemicals like ethanol and the synthesis of hydrophobic molecules like steroid hormones. Glycogen is stored in regions of liver cells that are rich in SER.

Ribosomes

Rough endoplasmic reticulum (RER)

B

FIGURE 10.10 **A.** Smooth endoplasmic reticulum. **B.** Rough endoplasmic reticulum. **A** and **B** are electron micrographs. A three-dimensional drawing is in the middle.

The RER is involved in the synthesis of proteins, which are targeted to the plasma membrane, for secretion, or to another intracellular organelle. Ribosomes attached to the membranes of the RER give them their “rough” appearance. Proteins produced on these ribosomes enter the lumen of the RER, travel to another membrane system (the **Golgi complex**) in vesicles, and are subsequently either secreted from the cell, sequestered within membrane-enclosed organelles such as lysosomes, or embedded in the plasma membrane. **Posttranslational modifications** of these proteins, such as the initiation of ***N*-linked glycosylation** and the addition of lipid-based anchors, and disulfide formation, occur in the RER. In contrast, proteins encoded by the nucleus and found in the cytoplasm, peroxisomes, or mitochondria are synthesized on free ribosomes in the cytosol and are seldom modified by the attachment of oligosaccharides.

Several diseases are associated with peroxisomes. Peroxisomal diseases are caused by mutations that affect either the synthesis of functional peroxisomal enzymes or their incorporation into peroxisomes. For example, **adrenoleukodystrophy** involves a mutation that decreases the content of a fatty acid transporter in the peroxisomal membrane. **Zellweger syndrome** is caused by the failure to produce proteins required for peroxisome synthesis.

VIII. Golgi Complex

The **Golgi complex** is involved in modifying proteins produced in the RER and in **sorting and distributing** these proteins to the lysosomes, secretory vesicles, or the plasma membrane. It consists of a curved stack of flattened vesicles in the cytoplasm that is generally divided into three compartments: the *cis* Golgi network, which is often convex and faces the nucleus; the *medial* Golgi stacks; and the *trans*-Golgi network, which often faces the plasma membrane. Vesicles transport material to and from the Golgi. The Golgi complex also participates in posttranslational modification of proteins, such as complex branched-chain oligosaccharide addition, sulfation, and phosphorylation.

Cotransport of pyruvate and a proton, down the proton's electrochemical gradient, is an example of secondary active transport. Energy has been expended, during the transfer of electrons through the electron transfer chain, to generate a proton gradient across the inner mitochondrial membrane. The energy of the proton gradient is then used by the carrier to carry protons down their electrochemical gradient (favorable), bringing pyruvate along with the protons. This will allow active transport of pyruvate secondary to favorable proton entry into the mitochondrial matrix.

IX. Cytoskeleton

The structure of the cell, the shape of the cell surface, and the arrangement of subcellular organelles are organized by three major protein components: **microtubules** composed of **tubulin**, which move and position organelles and vesicles; **thin filaments** composed of **actin**, which form a cytoskeleton; and **intermediate filaments** composed of different fibrous proteins. Actin and tubulin, which are also involved in cell movement, are dynamic structures composed of continuously associating and dissociating globular subunits. Intermediate filaments, which play a structural role, are composed of stable fibrous proteins that turn over more slowly than do the components of microtubules and thin filaments. Cytoskeletal components can also be regulated by receptor-mediated signaling activity.

Chronic ingestion of ethanol has increased the content of MEOS, the microsomal ethanol oxidizing system, in **Al M.**'s liver. MEOS is a cytochrome P450 enzyme that catalyzes the conversion of ethanol, NADPH, and O₂ to acetaldehyde, NADP⁺, and 2H₂O (see Chapter 9). The adjective “microsomal” is a term derived from experimental cell biology that is sometimes used for processes that occur in the ER. When cells are lysed in the laboratory, the ER is fragmented into vesicles called microsomes, which can be isolated by centrifugation. Microsomes, as such, are not naturally present in cells.

X. General Features of Chemical Messengers

Certain universal characteristics of chemical messenger systems are illustrated in Figure 10.2. Signaling generally follows the sequence: (1) the chemical messenger is secreted from a specific cell in response to a stimulus; (2) the messenger diffuses or is transported through blood or other extracellular fluid to the target cell; (3) a molecule in the target cell, termed a receptor (a plasma membrane receptor or intracellular receptor)

specifically binds the messenger; (4) binding of the messenger to the receptor elicits a response; (5) the signal ceases and is terminated. Chemical messengers elicit their response in the target cell without being metabolized by the cell, although the messengers can be internalized and degraded in the lysosomes.

The monomeric G-protein Arf (a member of the ras superfamily of regulatory proteins, see Section III.C.2 in Chapter 9) was named for its contribution to the pathogenesis of cholera and not for its normal function in the assembly of intracellular vesicles. In the case of cholera, it is required for the transport of *V. cholerae* A toxin subunit into the cell. The cholera toxin is endocytosed in caveolae vesicles that subsequently merge with lysosomes (or are transformed into lysosomes), where the acidic pH contributes to activation of the toxin. As the toxin is transported through the Golgi and ER, it is further processed and activated. Arf forms a complex with the A subunit that promotes its travel between compartments. The A subunit is actually an ADP-ribosylase (an enzyme that cleaves NAD and attaches the ADP portion to a protein; see Chapter 6, Fig. 6.12), and hence, Arf became known as the ADP-ribosylating factor. The ADP-ribosylation of proteins regulating the CFTR chloride channel led to **Dennis V.**'s dehydration and diarrhea.

An additional feature of chemical messenger systems is that the specificity of the response is dictated by the type of receptor and its location. Generally, each receptor binds only one specific chemical messenger, and each receptor initiates a characteristic signal transduction pathway that will ultimately activate or inhibit certain processes in the cell. Only cells that express receptors for that messenger are capable of responding to its message.

The means of signal termination is an exceedingly important aspect of cell signaling, and failure to properly terminate a signal contributes to a number of diseases, such as cancer and heart disease.

A. General Features of Chemical Messenger Systems Applied to the Nicotinic Acetylcholine Receptor

The individual steps involved in cell signaling by chemical messengers are illustrated with **acetylcholine** (ACh), a neurotransmitter that acts on **nicotinic acetylcholine receptors** on the plasma membrane of certain muscle cells. This system exhibits the classic features of chemical messenger release and specificity of response.

Neurotransmitters are secreted from neurons in response to an electrical stimulus called the **action potential** (a voltage difference across the plasma membrane caused by changes in Na^+ and K^+ gradients that is propagated along a nerve). The neurotransmitters diffuse across a synapse to another excitable cell, where they elicit a response (Fig. 10.11). Acetylcholine is the neurotransmitter at neuromuscular junctions, where it transmits a signal from a motor nerve to a muscle fiber that elicits contraction of the fiber. Before release, acetylcholine is sequestered in vesicles clustered near an active zone in the **presynaptic membrane**. This membrane also has voltage-gated Ca^{2+} channels that open when the action potential reaches them, resulting in an influx of Ca^{2+} . The Ca^{2+} triggers fusion of the vesicles with the plasma membrane, and acetylcholine is released into the synaptic cleft. Thus, the chemical messenger is released from the nerve cell in response to a specific stimulus. The mechanism of vesicle fusion with the plasma membrane is common to the release of many second messengers.

FIGURE 10.11 Acetylcholine (ACh) receptors at the neuromuscular junction. A motor nerve terminates in several branches; each branch terminates in a bulb-shaped structure called the *presynaptic bouton*. Each bouton synapses with a region of the muscle fiber that contains junctional folds. At the crest of each fold, there is a high concentration of ACh receptors, which are gated ion channels.

Lotta T. was given colchicine, a drug that is frequently used to treat gout in its initial stages. One of colchicine's actions is to prevent phagocytic activity by binding to dimers of the α - and β -subunits of tubulin. When the tubulin dimer–colchicine complexes bind to microtubules, further polymerization of the microtubules is inhibited, depolymerization predominates, and the microtubules disassemble. Microtubules are necessary for vesicular movement of urate crystals during phagocytosis and release of mediators that activate the inflammatory response. Thus, colchicine diminishes the inflammatory response, swelling, and pain caused by the formation of urate crystals.

Ann R.'s fasting is accompanied by high levels of the endocrine hormone glucagon, which is secreted in response to low blood glucose levels. It enters the blood and acts on the liver to stimulate a number of pathways, including the release of glucose from glycogen stores (glycogenolysis) (see Chapter 3). The specificity of its action is determined by the location of receptors. Although liver parenchymal cells have glucagon receptors, skeletal muscle and many other tissues do not. Therefore, glucagon cannot stimulate glycogenolysis in those tissues.

Myasthenia gravis is a disease of autoimmunity, which in most cases is caused by the production of an antibody directed

against the acetylcholine receptor in skeletal muscle. In this disease, B- and T-lymphocytes cooperate in producing a variety of antibodies against the nicotinic acetylcholine receptor. The antibodies then bind to various locations in the receptor and cross-link the receptors, forming a multireceptor antibody complex. The complex is endocytosed and incorporated into lysosomes, where it is degraded. **Mia S.**, therefore, has fewer functional receptors on the muscle cell membrane for acetylcholine to activate.

Acetylcholine diffuses across the synaptic cleft to bind to the nicotinic acetylcholine receptor on the plasma membrane of the muscle cells (Fig. 10.12). The subunits of the receptor are assembled around a channel, which has a funnel-shaped opening in the center. As acetylcholine binds to one of the subunits of the receptor, a conformational change opens the narrow portion of the channel (the gate), allowing Na^+ to diffuse in and K^+ to diffuse out (a uniform property of all receptors is that signal transduction begins with conformational changes in the receptor). The change in ion concentration activates a sequence of events that eventually triggers the cellular response—contraction of the fiber.

FIGURE 10.12 The nicotinic acetylcholine (ACh) receptor. Each receptor is composed of five subunits, and each subunit has four membrane-spanning helical regions. For clarity, only three subunits are shown in this figure. The two α -subunits are identical and contain binding sites for ACh. When two ACh molecules are bound, the subunits change their conformation so that the channel in the center of the receptor is open, allowing K^+ ions to diffuse out and Na^+ ions to diffuse in.

 Acetylcholine acts on two different types of receptors: nicotinic and muscarinic. Nicotinic receptors (for which nicotine is an activator) are found at the neuromuscular junction of skeletal muscle cells, as well as in the parasympathetic nervous system. Muscarinic receptors (for which muscarine, a mushroom toxin, is an activator) are found at the neuromuscular junction of cardiac and smooth muscle cells, as well as in the sympathetic nervous system. Curare (a paralyzing agent) is an inhibitor of nicotinic acetylcholine receptors, whereas atropine is an inhibitor of muscarinic acetylcholine receptors. Atropine can be

used under conditions in which acetylcholinesterase has been inactivated by various nerve gases or chemicals such that atropine will block the effects of the excess acetylcholine present at the synapse.

Once acetylcholine secretion stops, the message is rapidly terminated by **acetylcholinesterase**, an enzyme located on the postsynaptic membrane that cleaves acetylcholine. It is also terminated by diffusion of acetylcholine away from the synapse. Rapid termination of messages is a characteristic of systems that require a rapid response from the target cell.

B. Endocrine, Paracrine, Autocrine, and Juxtacrine Actions

The actions of chemical messengers are often classified as endocrine, paracrine, autocrine, or juxtacrine (Fig. 10.13). Each endocrine hormone (e.g., insulin) is secreted by a specific cell type (generally in an endocrine gland), enters the blood, and exerts its actions on specific target cells, which may be some distance away. In contrast to endocrine hormones, paracrine actions are those carried out on nearby cells, in which ligand is released by a cell that is close or nearby to the cell which will bind the ligand, and the location of the cells plays a role in the specificity of the response. Synaptic transmission by acetylcholine and other neurotransmitters (sometimes called neurocrine signaling) is an example of paracrine signaling. Acetylcholine activates only those acetylcholine receptors that are located across the synaptic cleft from the signaling nerve, not every muscle cell with acetylcholine receptors. Paracrine actions are also very important in limiting the immune response to a specific location in the body, a feature that helps prevent the development of autoimmune disease. Autocrine actions involve a messenger that acts on the cell from which it is secreted or on nearby cells that are the same type as the secreting cells. An example of autocrine stimulation is T-cell secretion and response to the cytokine interleukin-2 (IL-2). Juxtacrine actions require cell–cell contact, in which receptors on one cell bind with ligands on another cell. An example of the juxtacrine mode of signal transduction is the Notch system of cell activation.

D. Juxtacrine

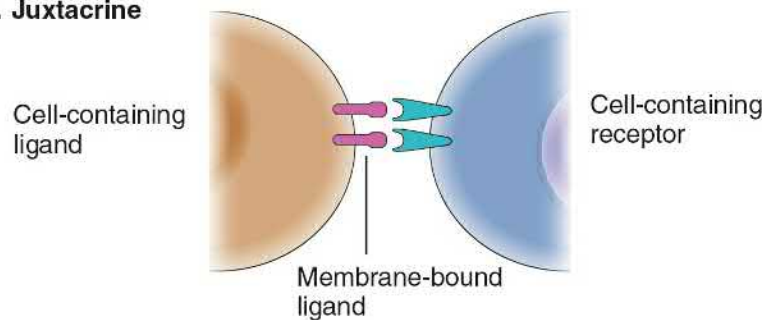

FIGURE 10.13 Endocrine (A), paracrine (B), autocrine (C), and juxtacrine (D) action of hormones. In all cases, other chemical messengers may also fall into one of these categories.

Historically, patients like **Mia S.** could be tested for the diagnosis of myasthenia gravis with an inhibitor of acetylcholinesterase, edrophonium chloride, which is administered intravenously. After this drug inactivates acetylcholinesterase, acetylcholine that is released from the nerve terminal accumulates in the synaptic cleft. Even though **Mia S.** expresses fewer acetylcholine receptors on her muscle cells (due to the autoantibody– induced degradation of receptors), by increasing the local concentration of acetylcholine, these receptors have a higher probability of being occupied and activated. Therefore, acute intravenous administration of this short-acting drug briefly improves muscular weakness in patients with myasthenia gravis.

C. Types of Chemical Messengers

There are three types of major signaling systems in the body employing chemical messengers: the nervous system, the endocrine system, and the immune system. The major properties of these messengers are summarized in Table 10.1. It is important to realize that many of the hundreds of chemical messengers have their own specific receptor, which will usually bind no other messenger (although there are certain exceptions). There are also some compounds normally considered hormones that are more difficult to categorize. For example, retinoids, which are derivatives of vitamin A (also called retinol) and vitamin D (which is also derived from cholesterol) are usually classified as hormones, although they are not synthesized in endocrine cells.

TABLE 10.1 Types of Chemical Messengers

SYSTEM	TYPES OF MESSENGERS	EXAMPLES OF MESSENGERS
Nervous (neurotransmitters act as messengers)	Biogenic amines Neuropeptides	Acetylcholine γ-aminobutyrate (GABA) Endorphins Neuropeptide-Y
Endocrine (molecule secreted by one organ, but acts on another organ)	Polypeptide Catecholamines Steroid hormones (lipophilic) Chemokines	Insulin Glucagon Epinephrine Dopamine Estrogen Cortisol Interleukin-1
Immune (alters gene transcription in target cells)	Cytokines	Interleukins Colony stimulating factors Interferons
Eicosanoids (control cellular function in response to injury)	Primarily 20 carbon lipids	Prostaglandins Leukotrienes
Growth factors (goes across all systems)	Proteins	Platelet-derived growth factor (PDGF) Epidermal growth factor (EGF)

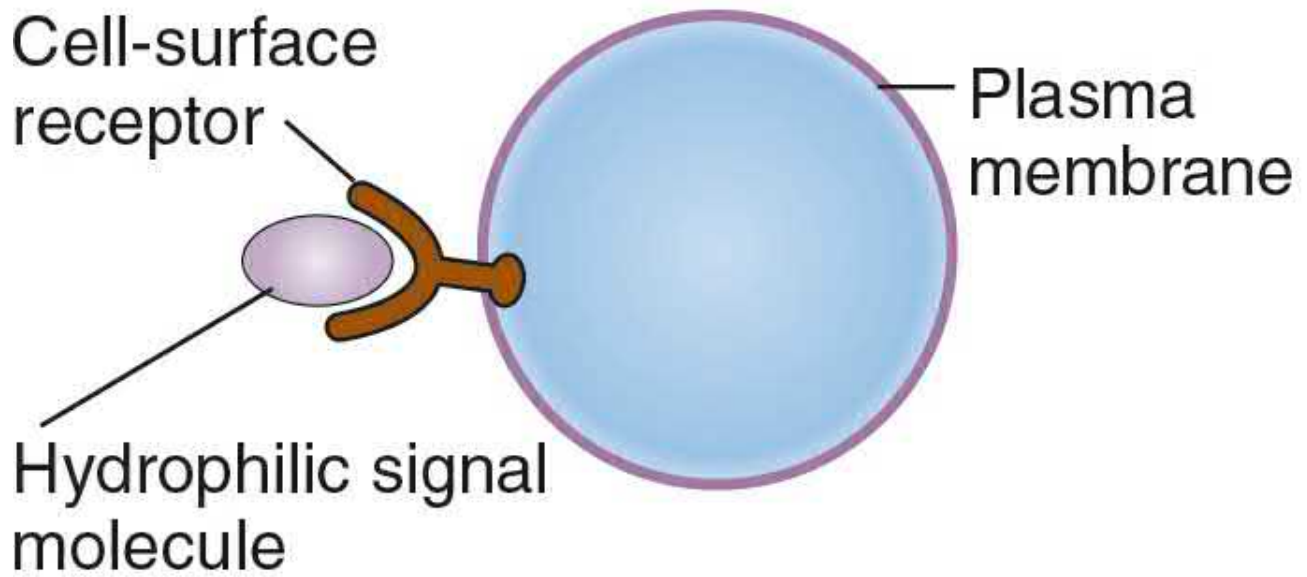

XI. Intracellular Transcription Factor Receptors

A. Intracellular versus Plasma Membrane Receptors

The structural properties of a messenger determine, to some extent, the type of receptor it binds. Most receptors fall into two broad categories: **intracellular receptors** or **plasma membrane receptors** (Fig. 10.14). Messengers using intracellular receptors must be hydrophobic molecules able to diffuse through the plasma membrane into cells. In contrast, polar molecules such as peptide hormones, cytokines, and catecholamines

cannot rapidly cross the plasma membrane and must bind to a plasma membrane receptor.

Cell-surface receptors

Intracellular receptors

FIGURE 10.14 Intracellular versus plasma membrane receptors. Plasma membrane receptors have extracellular or cell surface binding domains. Intracellular receptors bind steroid hormones or other messengers that are able to diffuse through the plasma membrane. Their receptors may reside in the cytoplasm and translocate to the nucleus, reside in the nucleus bound to DNA, or reside in the nucleus bound to other proteins.

The catecholamine hormone epinephrine (also called adrenaline) is the fight and flight hormone. Epinephrine and the structurally similar hormone norepinephrine are released from the adrenal medulla in response to a variety of immediate stresses, including pain, hemorrhage, exercise, hypoglycemia, and hypoxia. Thus, as **Ann R.** begins to jog, there is a rapid release of epinephrine and norepinephrine into her blood.

Most of the intracellular receptors for lipophilic messengers are **gene-specific transcription factors**. A transcription factor is a protein that binds to a specific sequence on DNA and regulates the rate of transcription of a gene (i.e., synthesis of mRNA, see Chapter 15). External signaling molecules bind to transcription factors that bind to a specific sequence on DNA and regulate the expression of only certain genes; they are called gene-specific or site-specific transcription factors. All genes which contain the appropriate DNA sequence can be regulated by the same transcription factor.

B. The Steroid Hormone/Thyroid Hormone Superfamily of Receptors

Lipophilic hormones that use intracellular gene-specific transcription factors include the steroid hormones (such as estrogen and cortisol), thyroid hormone, retinoic acid (the active form of vitamin A), and vitamin D (Fig. 10.15). Because these compounds are water-insoluble, they are transported in the blood bound to serum albumin, which has a hydrophobic binding pocket, or to more specific transport proteins, such as steroid hormone-binding globulin (SHBG) or thyroid hormone-binding globulin (TBG). The intracellular receptors for these hormones are structurally similar and are referred to as the steroid hormone/thyroid hormone superfamily of receptors.

A. Cortisol**B. Aldosterone****C. Thyroid hormone (T₃)****3,5,3'-Triiodothyronine (T₃)****D. Vitamin D₃****1,25-Dihydroxycholecalciferol

Lotta T. suffered enormously painful gout attacks affecting her great toe (see Clinical Comments, Chapter 8). The extreme pain was caused by the release of a leukotriene that stimulated pain receptors. The precipitated urate crystals in her big toe stimulated recruited inflammatory cells to release the leukotriene.

The steroid hormone/thyroid hormone superfamily of receptors resides primarily in the nucleus, although some members are also found in the cytoplasm. The glucocorticoid receptor, for example, exists as cytoplasmic multimeric complexes associated with heat-shock proteins. When the hormone cortisol (a glucocorticoid) binds, the receptor undergoes a conformational change and dissociates from the heat-shock proteins, exposing a nuclear translocation signal (a signal specifying its transport to the nucleus). The receptors dimerize, and the

complex (including bound hormone) translocates to the nucleus, where it binds to a portion of the DNA called the hormone response element (e.g., the glucocorticoid receptor binds to the glucocorticoid response element, GRE). The majority of the intracellular receptors, however, reside principally in the nucleus, and some of these are constitutively bound to their response element in DNA (e.g., the thyroid hormone receptor). Binding of the hormone changes their activity and their ability to associate with, or disassociate from, DNA. Regulation of gene transcription by these receptors is described in more detail in Chapter 15.

The steroid hormone cortisol is synthesized and released from the adrenal cortex in response to the polypeptide hormone adrenocorticotropic hormone (ACTH). Chronic stress (pain, hypoglycemia, hemorrhage, and exercise) signals are passed from the brain cortex to the hypothalamus to the anterior pituitary, which releases ACTH. Cortisol acts on tissues to change enzyme levels and redistribute nutrients in preparation for acute stress. For example, it increases transcription of the genes for regulatory enzymes in the pathway of gluconeogenesis (called gene-specific activation of transcription, or induction of protein synthesis). The net result of this activity is an increased cellular content of the enzymes. Induction of gluconeogenic enzymes prepares the liver to respond rapidly to hypoglycemia with increased synthesis of glucose. **Ann R.**, who has frequently been fasting and exercising, has an increased capacity for gluconeogenesis in her liver.

XII. Plasma Membrane Receptors and Signal Transduction

All plasma membrane receptors are proteins with certain features in common: an **extracellular domain** that may bind the chemical messenger, one or more **membrane-spanning domains** that are α -helices, and may also bind the chemical messenger, and an **intracellular domain** that initiates signal transduction. As the ligand binds to the binding domain of its receptor, it causes a **conformational change** that is communicated to the intracellular domain through the rigid α -helix of the transmembrane domain. The activated intracellular domain initiates a characteristic **signal transduction pathway** that usually involves the binding of specific intracellular signal transduction proteins. Signal transduction pathways run in one direction. From a given point in a signal transduction pathway, events closer to the receptor are referred to as “**upstream**” or “**proximal**” and events closer to the response are referred to as “**downstream**” or “**distal**.”

The pathways of signal transduction for plasma membrane receptors have two major types of effects on the cell: (1) rapid and immediate effects on cellular ion levels or activation/inhibition of enzymes and (2) slower changes in the rate of gene expression for a specific set of proteins. Often, a signal transduction pathway will ultimately produce both kinds of effects.

A. Ion-Channel Receptors

The ion-channel receptors are similar in structure to the previously discussed nicotinic acetylcholine receptor (see Fig. 10.12). Signal transduction consists of the conformational change when ligand binds, and changes in ion concentrations both intracellularly and extracellularly. The changes in ion concentration alter the membrane potential, which affects voltage-gated receptors and can propagate or inhibit an action potential. Most small-molecule neurotransmitters and some neuropeptides use ion-channel receptors.

B. Receptors That Are Kinases or That Bind Kinases

There are several types of receptors that are kinases or bind kinases, as illustrated in Figure 10.16. Protein kinases transfer a phosphate group from ATP to the hydroxyl group of a specific amino acid side chain in the target protein. Their common feature is that the intracellular kinase domain of the receptor (or the kinase domain of the associated protein) is activated when the messenger binds to the extracellular domain. The receptor kinase phosphorylates an amino acid residue (serine, threonine, tyrosine, or, rarely, histidine) on the receptor (autophosphorylation) itself or on an associated protein. The message is propagated downstream through signal transducer proteins that bind to the activated messenger–receptor complex. Several types of these receptors are outlined in Table 10.2. We will examine one of these pathways in more detail, the tyrosine kinase pathway of receptor signaling.

TABLE 10.2 Types of Plasma Membrane–Associated Kinase Receptors

TYPE	EXAMPLE	SUMMARY
Tyrosine kinase receptors	EGF receptor	Binding of the messenger to the receptor activates receptor dimerization and kinase activation, which phosphorylates both the receptor (in <i>trans</i>) and target proteins on

tyrosine residues. Second messengers include ras and mitogen-activated protein kinases (MAP kinase), and, for some receptors, derivatives of phosphatidylinositol. Ras is a critical molecule for signal transduction and is activated through binding GTP.

JAK-STAT receptors	Cytokines	JAK is a kinase that binds to the receptor and is activated when the receptor binds the cytokine. Activated JAK phosphorylates STAT (signal transducer and activator of transcription), which acts as a gene-specific transcription factor after being translocated to the nucleus.
Serine/Threonine receptor kinases	TGF- β	TGF- β binding brings together the type 1 and type 2 receptors, leading to the activation of the receptor kinase, which results in the phosphorylation and activation of SMAD proteins, which, like STAT, are gene-specific transcription factors and are translocated to the nucleus to alter gene expression.

FIGURE 10.16 Receptors that are kinases or that bind kinases. The kinase domains are shown in red, and the phosphorylation sites are indicated with red arrows. **A.** Tyrosine kinase receptors. **B.** Janus kinase (JAK)-signal transducer and activator of transcription (STAT) receptors. STAT proteins are phosphorylated by the activated JAK kinase, which is associated with the cytokine receptor. **C.** Serine-threonine kinase receptors. SMAD proteins are phosphorylated by the activated receptors.

1. Signal Transduction through Tyrosine Kinase Receptors

The tyrosine kinase receptors are depicted in Figure 10.16A. They generally exist in the membrane as monomers with a single membrane-spanning helix. Either one molecule of the stimulating factor (or a dimer of the stimulating factor) generally binds two molecules of the receptor and promotes their dimerization (Fig. 10.17). Once the receptor dimer has formed, the intracellular tyrosine kinase domains of the receptor phosphorylate each other on specific tyrosine residues (autophosphorylation). The phosphotyrosine residues form docking sites for signal transducer proteins.

FIGURE 10.17 Signal transduction by tyrosine kinase receptors. (1) Binding and dimerization. (2) Autophosphorylation. (3) Binding of Grb2 and SOS. (4) SOS is a guanine nucleotide exchange factor (GEF) that binds Ras, a monomeric G-protein anchored to the plasma membrane. (5) GEF activates the exchange of guanosine triphosphate (GTP) for bound guanosine diphosphate (GDP) on Ras. (6) Activated Ras containing GTP binds the target enzyme Raf, thereby activating it and a series of downstream kinases known as the mitogen-activated protein (MAP) kinase pathway.

2. Ras and the MAP Kinase Pathway

The ras-MAP kinase pathway serves as a good example of how receptor tyrosine kinases can activate signaling through the assembly of protein complexes, that occur as a result of protein–protein interactions. In this pathway, one of the domains of the receptor containing a phosphotyrosine residue forms a binding site for intracellular proteins with a specific three-dimensional structure known as the SH2 domain (the Src homology 2 domain, named for the first protein in which it was found, the src protein of the Rous sarcoma virus). The adaptor protein Grb2 is an example of an SH2 domain-containing protein that uses this domain to bind to phosphotyrosine residues on activated growth factor receptors. Binding of the SH2 domain to the receptor leads to the binding of the protein SOS (SOS is an acronym for “son of sevenless,” a name that is not related to the function or structure of the protein) to an SH3 domain on Grb2. SOS is a guanine nucleotide exchange factor (GEF) for Ras, a monomeric G-protein located in the plasma membrane (see Chapter 9, Section III.C.2). SOS catalyzes exchange or replacement of guanosine diphosphate (GDP) for guanosine triphosphate (GTP) on Ras, causing a conformational change in Ras that promotes binding of the protein Raf. Raf is a serine protein kinase that is also called MAPKKK (**mitogen-activated protein kinase kinase kinase**). Raf begins a sequence of successive phosphorylation steps called a phosphorylation cascade. When one of the kinases in a cascade is phosphorylated, it binds and phosphorylates the next enzyme downstream in the cascade. The MAP kinase cascade ultimately leads to an alteration of gene transcription factor activity, thereby either up regulating or down regulating transcription of many genes involved in cell survival and proliferation.

Although many different signal transducer proteins have SH2 domains, and many receptors have phosphotyrosine residues, a signal transducer protein may only be utilized for one type of receptor. This specificity of binding results from the fact that each phosphotyrosine residue has a different amino acid sequence around it that forms the binding domain. Similarly, the SH2 domain of the transducer protein is only part of its binding domain. Conversely, however, a number of transducer proteins will bind to more than one receptor (such as Grb2).

Many tyrosine kinase receptors (as well as heptahelical/G-protein-coupled receptors) also have additional signaling pathways involving intermediates such as phosphatidylinositol phosphates.

3. Phosphatidylinositol Phosphates in Signal Transduction

Phosphatidylinositol-linked signaling molecules can be generated through either tyrosine kinase receptors or heptahelical receptors. Phosphatidylinositol phosphates serve two different functions in signal transduction: (1) Phosphatidylinositol 4',5'-bisphosphate (PI-4,5-bisP, PIP_2) can be cleaved to generate the two intracellular second messengers, diacylglycerol (DAG) and inositol trisphosphate (IP_3); and (2) phosphatidylinositol 3',4',5'-trisphosphate (PI-3,4,5-trisP, PIP_3) can serve as a plasma membrane docking site for signal transduction

proteins.

Phosphatidylinositol, which is present in the inner leaflet of the plasma membrane, is converted to PI-4,5-bisP (PIP₂) by kinases that phosphorylate the inositol ring at the 4' and 5' positions (Fig. 10.18). PIP₂, which has three phosphate groups, is cleaved by a phospholipase C-isozyme to generate IP₃ and DAG. The phospholipase isozyyme C γ (PLC γ) is activated by tyrosine kinase growth factor receptors, and phospholipase C β (PLC β) is activated by a heptahelical receptor–G-protein signal transduction pathway.

FIGURE 10.18 Major route for generation of the phosphatidylinositide signal molecules, inositol 1,4,5-trisphosphate (IP₃), and phosphatidylinositol 3,4,5-trisphosphate (PI-3,4,5-trisP). Phosphatidylinositol 3'-kinase (PI-3-kinase) phosphorylates phosphatidylinositol 4',5'-bisphosphate (PI-4,5-bisP) and phosphatidylinositol 4'-phosphate (not shown) at the three position. Prime symbols are sometimes used in these names to denote the inositol ring. Diacylglycerol (DAG) is also a second messenger. PLC, phospholipase C.

PI-4,5-bisP can also be phosphorylated at the 3' position of the inositol ring by the enzyme phosphatidylinositol 3'-kinase (PI-3-kinase) to form PIP₃ (see Fig. 10.18). PIP₃ (and PIP₂) form membrane docking sites for proteins that contain a certain sequence of amino acids called the pleckstrin homology (PH) domain. PI-3-kinase contains an SH2 domain and is activated by binding to a specific phosphotyrosine site on a tyrosine kinase receptor or receptor-associated protein. The protein PTEN (phosphatase and tensin homolog) catalyzes the dephosphorylation of PIP₃ to PIP₂, thereby removing the primary signal from the pathway. Mutations within PTEN, or decreased expression of PTEN, can lead to cancer (see Chapter 17).

The insulin receptor, a member of the tyrosine kinase family of receptors, provides a good example of how signal transduction through a single receptor can lead to activation of multiple downstream pathways depending on which proteins the activated receptor binds to intracellularly. Unlike other growth factor receptors, the insulin receptor exists in the membrane as a preformed dimer, with each half containing an α - and a β -subunit (Fig. 10.19). The β -subunits autophosphorylate each other when insulin binds, thereby activating the receptor. The activated phosphorylated receptor binds a protein called IRS (insulin receptor substrate). The activated receptor kinase phosphorylates IRS at multiple sites, creating multiple binding sites for different proteins with SH2 domains. One of the sites binds the adapter protein Grb2 (an adapter protein has no enzymatic activity but has binding sites for different proteins, and brings those proteins together), which leads to the activation of Ras and the MAP kinase pathway. At another phosphotyrosine site, PI-3-kinase binds and is activated. This pathway will lead to the activation of the protein kinase AKt (also called protein kinase B, PKB). At a third site, phospholipase C γ (PLC γ) binds and is activated. The insulin receptor can also transmit signals through direct docking with other signal transduction intermediates.

FIGURE 10.19 Insulin receptor signaling. The insulin receptor is a dimer of two membrane-spanning α - β pairs. The tyrosine kinase domains are shown in red, and arrows indicate auto cross phosphorylation. The activated receptor binds IRS molecules

(insulin receptor substrates) and phosphorylates IRS at multiple sites, thereby forming binding sites for proteins with SH2 domains, examples being Grb2, phospholipase Cy (PLCy), and PI 3-kinase. Both PLCy and PI 3-kinase are associated with various phosphatidylinositol phosphates (all designated with PIP) in the plasma membrane and are an important part of second messenger production. Grb2 associates with a protein known as GAP1 (Grb2-associated protein), which has a pleckstrin homology domain that associates with phosphatidylinositol phosphates in the membrane.

 Insulin is a growth factor that is essential for cell viability and growth. It increases general protein synthesis, which strongly affects muscle mass through hypertrophy. However, it also regulates immediate nutrient availability and storage, including glucose transport into skeletal muscle and glycogen synthesis. Thus, **Dianne A.** and other patients with type I diabetes mellitus who lack insulin rapidly develop hyperglycemia once insulin levels drop too low. They also exhibit muscle "wasting." To mediate the diverse regulatory roles of insulin, the signal transduction pathway diverges after activation of the receptor and phosphorylation of IRS, which has multiple binding sites for different signal-mediator proteins.

The signal pathway initiated by the insulin receptor complex involving PI 3-kinase leads to activation of AKT, a serine–threonine kinase that mediates many of the downstream effects of insulin (Fig. 10.20). PI 3-kinase binds to IRS and phosphorylates PIP₂ in the membrane to form PIP₃. **AKT** and **PDK1** (**phosphoinositide-dependent kinase-1**) are recruited to the membrane by their PH domains, where PDK1 phosphorylates and activates AKT. One of the signal transduction pathways for AKT leads to the effects of insulin on glucose metabolism. Other pathways result in the phosphorylation of a host of other proteins that affect cell growth and survival. The action of insulin is covered in more detail in Chapters 26, 36, and 43. It is important to note that other receptor tyrosine kinase receptors will also lead to the activation of the AKT pathway, through the direct binding of PI 3-kinase to activated receptors.

FIGURE 10.20 The insulin receptor–AKT (protein kinase B) signaling pathway. AKT, protein kinase B; Ins, insulin; IRS, insulin receptor substrate; PH domains, pleckstrin homology domains; PDK1, phosphoinositide-dependent protein kinase 1; PI-3,4,5-trisP, phosphatidylinositol 3',4',5'-trisphosphate; PI 3-kinase, phosphatidylinositol 3'-kinase.

Thus, insulin binding to its receptor can lead to the generation of many diverse signals, depending on which secondary signal transduction proteins are activated at the time.

C. Heptahelical Receptors

Heptahelical receptors (also called **G-protein coupled receptors**, GPCR) contain seven membrane-spanning α-helices and are the most common type of plasma membrane receptor (Fig. 10.21). They work through second messengers, which are small nonprotein compounds, such as cAMP or IP₃, generated inside the cell in response to messenger binding to the receptor. They continue intracellular transmission of the message from the hormone/cytokine/neurotransmitter, which is the "first" messenger. Second messengers are present in low

concentrations so that modulation of their level, and hence the message, can be rapidly initiated and terminated.

Heptahelical receptors

FIGURE 10.21 G-protein coupled receptors and second messengers. The secreted chemical messenger (hormone, cytokine, or neurotransmitter) is the first messenger, which binds to a plasma membrane receptor such as the heptahelical receptors. The activated hormone–receptor complex activates a heterotrimeric G-protein (via an exchange of GTP for the bound GDP; see Fig. 10.22) and, via stimulation of membrane-bound enzymes, different G-proteins lead to generation of one or more intracellular second messengers, such as 3',5'-cyclic adenosine monophosphate (cAMP), diacylglycerol (DAG), or inositol trisphosphate (IP₃).

The heptahelical receptors are named for their seven membrane-spanning domains, which are α -helices (see Fig. 10.21; see also Fig. 7.9). Although hundreds of hormones and neurotransmitters work through heptahelical receptors, the extracellular binding domain of each receptor is specific for primarily one polypeptide hormone, chemokine, catecholamine, or neurotransmitter (or a close structural analog, although exceptions do exist in that a receptor may respond to multiple signals). Heptahelical receptors have no intrinsic kinase activity but initiate signal transduction through heterotrimeric G-proteins composed of α -, β -, and γ -subunits. However, different types of heptahelical receptors bind different G-proteins, and different G-proteins exert different effects on their target proteins. The activation of the G-protein often leads to second messenger production within the cells (although the activation of the Rho family of GTP-binding proteins does not require a second

messenger). Second messengers are present in low concentrations, so that modulation of their level, and hence the message, can be rapidly initiated and terminated.

1. Heterotrimeric G-Proteins

The function of heterotrimeric G-proteins is illustrated in Figure 10.22 using a hormone that activates adenylyl cyclase (e.g., glucagon or epinephrine). While the α -subunit contains bound GDP, it remains associated with the β - and γ -subunits, either free in the membrane or bound to an unoccupied receptor (see Fig. 10.22, part 1). When the hormone binds, it causes a conformational change in the receptor that promotes GDP dissociation and GTP binding. The exchange of GTP for bound GDP causes dissociation of the α -subunit from the receptor and also from the β - and γ -subunits (see Fig. 10.22, part 2). The α - and γ -subunits are tethered to the intracellular side of the plasma membrane through lipid anchors but can still move laterally on the membrane surface. The GTP- α subunit binds its target enzyme in the membrane, thereby changing its activity. In this example, the α -subunit binds and activates adenylyl cyclase, thereby increasing the synthesis of cAMP (see Fig. 10.22, part 3).

FIGURE 10.22 Serpentine receptors and heterotrimeric G-proteins. (1) The intracellular domains of the receptor form a binding site for a G-protein that contains guanosine diphosphate (GDP) bound to the α -subunit. (2) Hormone binding to the receptor promotes the exchange of guanosine triphosphate (GTP) for GDP. As a result, the complex disassembles, releasing the G-protein α -subunit from the β - γ complex. (3) The G_s α -subunit binds to a target enzyme (in the example shown, the target is adenylyl cyclase), thereby changing its activity (for the “s” G-proteins, the activity is stimulated). The β - γ complex may simultaneously target another protein and change its activity. (4) Over time, bound GTP is hydrolyzed to GDP, causing dissociation of the α -subunit from the target protein, thereby reducing the activity of the target protein. (5) The GDP α -subunit reassociates with the β - γ -subunits and the hormone receptor. ATP, adenosine triphosphate; cAMP, 3',5'-cyclic adenosine monophosphate.

 Acetylcholine has two types of receptors: nicotinic ion-channel receptors, the receptors inhibited by antibodies in myasthenia gravis, and muscarinic receptors, which exist as a variety of subtypes. The M2 muscarinic receptors activate a $G_{\alpha_{i/o}}$ heterotrimeric G-protein in which release of the $\beta\gamma$ -subunit controls K^+ channels and pacemaker activity in the heart. Epinephrine has several types and subtypes of heptahelical receptors: β -adrenergic receptors work through a G_{α_s} to stimulate adenylyl cyclase; α_2 -adrenergic receptors in other cells work through a G_{α_i} protein and inhibit adenylyl cyclase; α_1 -adrenergic receptors work through G_{α_q} subunits and activate phospholipase C β . This variety in receptor types allows a single messenger (epinephrine) to have different actions in different cells.

With time, the $G\alpha$ -subunit inactivates itself by hydrolyzing its own bound GTP to GDP and P_i (an **intrinsic GTPase activity**). This action is unrelated to the number of cAMP molecules formed. Like the monomeric G-proteins, the α subunit now containing GDP dissociates from its target protein, adenylyl cyclase (see Fig. 10.22, part 4). It reforms the trimeric G-protein complex, which may return to bind the empty hormone receptor. As a result of this GTPase “internal inactivation signal,” sustained elevation of hormone levels is necessary for continued signal transduction and elevation of cAMP. G-proteins in which the internal clock has become defective (either through mutation or modification by toxins) can become permanently activated, thereby continuously stimulating their signal transduction pathway.

There are a large number of different heterotrimeric G-protein complexes, which are generally categorized according to the activity of the α -subunit (Table 10.3). The 20 or so different isoforms of $G\alpha$ fall into five broad categories: $G\alpha_s$, $G\alpha_{i/o}$, $G\alpha_T$, $G\alpha_{q/11}$, and $G\alpha_{12/13}$. $G\alpha_s$ refers to α -subunits, which, like the one in Figure 10.22, stimulate adenylyl cyclase (hence the “s”). $G\alpha$ -subunits that inhibit adenylyl cyclase are called $G\alpha_i$. The β - and γ -subunits likewise exist as different isoforms, which also transmit messages. $G\alpha_q$ subunits activate phospholipase $C\beta$ which generates messengers based on phosphatidylinositol. $G\alpha_T$ subunits activate cGMP phosphodiesterase. $G\alpha_{12/13}$ subunits activate a GEF, which activates the small GTP-binding protein rho, which is involved in cytoskeletal alterations.

TABLE 10.3 Subunits of Heterotrimeric G-Proteins

$G\alpha$ SUBUNIT	ACTION	SOME PHYSIOLOGICAL USES
α_s ; $G\alpha(s)^a$	Stimulates adenylyl cyclase	Glucagon and epinephrine to regulate metabolic enzymes, regulatory polypeptide hormones to control steroid hormone and thyroid hormone synthesis, and by some neurotransmitters (e.g., dopamine) to control ion channels
$\alpha_{i/o}$; $G\alpha(i/o)$ (signal also flows through $\beta\gamma$ -subunits)	Inhibits adenylyl cyclase	Epinephrine; many neurotransmitters, including acetylcholine, dopamine, serotonin
α_t ; $G\alpha(t)$	Stimulates cGMP phosphodiesterase	Has a role in the transducin pathway, which mediates detection of light in the eye
$\alpha_{q/11}$; $G\alpha(q/11)$	Activates phospholipase $C\beta$	Epinephrine, acetylcholine, histamine, thyroid-stimulating hormone (TSH), interleukin-8, somatostatin, angiotensin
$\alpha_{12/13}$; $G\alpha(12/13)$	Activate Rho-GEF (guanine nucleotide exchange factor)	Thromboxane A2, lysophosphatidic acid act as signals to alter cytoskeletal elements

^aThere is a growing tendency to designate the heterotrimeric G-protein subunits without using subscripts so that they are actually visible to the naked eye.

2. Adenylyl Cyclase and cAMP Phosphodiesterase

cAMP is referred to as a second messenger because changes in its concentration reflect changes in the concentration of the hormone (the first messenger). When a hormone binds and adenylyl cyclase is activated, it synthesizes cAMP from adenosine triphosphate (ATP). cAMP is hydrolyzed to AMP by cAMP phosphodiesterases, which also reside in the plasma membrane (Fig. 10.23). The concentration of cAMP and other second messengers is kept at very low levels in cells by balancing the activity of these two enzymes (the cyclase and the phosphodiesterase) so that cAMP levels can change rapidly when hormone levels change. Some hormones change the concentration of cAMP by targeting the phosphodiesterase enzyme rather than adenylyl cyclase. For example, insulin lowers cAMP levels by causing phosphodiesterase activation.

FIGURE 10.23 Formation and cleavage of the cyclic phosphodiester bond in 3',5'-cyclic adenosine monophosphate (cAMP). When activated by G_{α_s} , adenylyl cyclase converts adenosine triphosphate (ATP) to cyclic AMP + pyrophosphate (PP_i). cAMP phosphodiesterase hydrolyzes cAMP to 5'-AMP.

cAMP exerts diverse effects in cells. It is an allosteric activator of protein kinase A (see Chapter 9, Section III.B.3), which is a serine–threonine protein kinase that phosphorylates a large number of metabolic enzymes, thereby providing a rapid response to hormones like glucagon and epinephrine. It is also the enzyme that phosphorylates the CFTR, activating the channel. PKA substrates also include, among many, phosphorylase kinase (regulation of glycogen degradation) and phospholamban (regulation of cardiac contractility). The catalytic subunits of protein kinase A also enter the nucleus and phosphorylate a gene-specific transcription factor called CREB (cyclic AMP response element-binding protein). Thus, cAMP also activates a slower response pathway, gene transcription. In other cell types, cAMP activates ligand-gated channels directly.

Dennis V. was hospitalized for dehydration resulting from cholera toxin. The cholera toxin A subunit was absorbed into the intestinal mucosal cells, where it was processed and complexed with Arf (ADP-ribosylation factor), a small G-protein that is normally involved in vesicular transport. Cholera A toxin is an NAD-glycohydrolase, which cleaves NAD and transfers the ADP-ribose portion to other proteins. It ADP-ribosylates the G_{α_s} subunit of heterotrimeric G-proteins, thereby inhibiting their GTPase activity. As a consequence, they remain actively bound to adenylyl cyclase, resulting in increased production of cAMP. The CFTR channel is activated, resulting in secretion of chloride ion and Na^+ ion into the intestinal lumen. The ion secretion is followed by loss of water, resulting in vomiting and watery diarrhea.

Some signaling pathways cross from the receptor tyrosine kinase pathway of MAP kinase activation to CREB activation, and the heterotrimeric G-protein pathways diverge to include a route to the MAP kinase pathway. These types of complex interconnections in signaling pathways are sometimes called hormone cross-talk.

3. Phosphatidylinositol Signaling by Heptahelical Receptors

Certain heptahelical receptors bind the q isoform of the G_{α} -subunit (G_{α_q}), which activates the target enzyme phospholipase C β (see Fig. 10.18). When it is activated, phospholipase C β hydrolyzes the membrane lipid phosphatidyl inositol bisphosphate (PI-4,5-bisP) into two second messengers, diacylglycerol (DAG), and 1,4,5-inositol trisphosphate (IP_3). IP_3 has a binding site in the sarcoplasmic reticulum and the ER that stimulates the release of Ca^{2+} . Ca^{2+} activates enzymes containing the calcium–calmodulin subunit, including a protein kinase. Diacylglycerol, which remains in the membrane, activates, along with calcium-binding, protein kinase C, which

then propagates the response by phosphorylating target proteins.

D. Juxtacrine Signaling

The classic example of juxtacrine signaling is the Notch signaling pathway (Fig. 10.24). As indicated in Figure 10.13D juxtacrine signaling requires cell–cell interactions, in which one cell expresses the ligand, and the neighboring cell a receptor for the ligand. Upon ligand binding to receptor, a series of events is initiated leading to alterations in gene transcription in the cell expressing the receptor. For vertebrate systems, the ligands are named Delta (three different forms) and Jagged (two different forms), and the receptor is named Notch (four different forms) (see Fig. 10.24). When Delta or Jagged binds to the Notch receptor, the binding event initiates a cleavage event with Notch (using an extracellular protease of the ADAM family), which removes most of the extracellular Notch protein, while the remaining section of Notch in the target cell is cleaved by a second protease (via γ , secretase). This allows the cytoplasmic domain of Notch (Nidc, or notch intracellular domain) to move to the nucleus, where it leads to the activation of a repressed transcription factor (CSL) and new transcription is initiated, allowing the cell to respond to the Delta signal, which originated the signal transduction pathway. Notch signaling has been implicated in neurogenesis and embryonic development.

FIGURE 10.24 Notch signaling. This is an example of juxtacrine signaling, leading to the activation of the CSL transcription factor. More details can be found in the text.

XIII. Signal Termination

Some signals, such as those that modify the metabolic responses of cells or that transmit neural impulses, need to turn off rapidly when the hormone is no longer being produced. Other signals, such as those that stimulate proliferation, turn off more slowly. In contrast, signals regulating differentiation may persist throughout our

lifetime. Many chronic diseases are caused by failure to terminate a response at the appropriate time, such as Cushing syndrome, cardiac hypertrophy, and osteoporosis.

Tissues vary in their ability to respond to a message through changes in receptor activity or number. Many receptors contain intracellular phosphorylation sites that alter their ability to transmit signals. Receptor number is also varied through downregulation. After a hormone binds to the receptor, the hormone–receptor complex may be taken into the cell by the process of endocytosis in clathrin-coated pits, such as occurs when LDL binds to the LDL receptor. The receptors may then be degraded or recycled back to the cell surface. This internalization of receptors decreases the number available on the surface under conditions of constant high hormone levels when hormones occupy more of the receptors and results in decreased synthesis of new receptors. Hence, it is called downregulation.

Signal transduction pathways can be terminated by a variety of means (Fig. 10.25). The first level of termination is the chemical messenger itself. When the stimulus is no longer applied to the secreting cell, the messenger is no longer secreted. Existing messenger is then subsequently catabolized. For example, many polypeptide hormones such as insulin are taken up into the liver and degraded. Termination of the acetylcholine signal by acetylcholinesterase has already been mentioned.

FIGURE 10.25 Sites of signal termination. Processes that terminate signals are shown in red.

Within each pathway of signal transduction, the signal may be turned off at specific steps. For example, serpentine receptors can be desensitized to the messenger by phosphorylation, internalization, and degradation.

G-proteins, both monomeric and heterotrimeric, automatically terminate messages as they hydrolyze GTP via their intrinsic GTPase activity. Although G-proteins do have intrinsic GTPase activity, this activity is relatively weak and can be accelerated through interaction with a class of proteins known as GAPs, for GTPase-activating proteins. Termination also can be achieved through degradation of the second messenger (e.g., phosphodiesterase cleavage of cAMP). Each of these terminating processes is also highly regulated.

Another important pathway for reversing the message typically utilized by receptor kinase pathways is through protein phosphatases, enzymes that reverse the action of kinases by removing phosphate groups from proteins. These are specific tyrosine or serine–threonine phosphatases (enzymes that remove the phosphate group from specific proteins) for all of the sites that are phosphorylated by signal transduction kinases. There are even receptors themselves that can act as protein phosphatases. However, there are also receptor phosphatases, which can activate intracellular signaling pathways.

CLINICAL COMMENTS

Al M. has been drinking heavily for a period of 5 years and has begun to exhibit mental and systemic effects of chronic alcohol consumption. In his brain, ethanol has altered the fluidity of neuronal lipids, causing changes in their response to neurotransmitters released from exocytotic vesicles. In his liver, increased levels of the microsomal ethanol oxidizing system (MEOS, CYP2E1) located in the smooth ER have increased his rate of ethanol oxidation to acetaldehyde, a compound that is toxic to the cell. His liver also continues to oxidize ethanol to acetaldehyde through a cytosolic enzyme, liver alcohol dehydrogenase.

One of the toxic effects of acetaldehyde is inhibition of tubulin polymerization. Tubulin is used in the liver for the secretion of very-low-density lipoprotein (VLDL) particles containing newly synthesized triacylglycerols. As a result, these triacylglycerols accumulate in the liver, and he has begun to develop a fatty liver. Acetaldehyde may also damage protein components of the inner mitochondrial membrane and affect its ability to pump protons to the cytosol.

Colchicine, an initial drug used to treat **Lotta T.**, has a narrow therapeutic index (i.e., the amount of drug that produces the desirable therapeutic effect is not much lower than the amount that produces an adverse effect). Its therapeutic effect depends on inhibiting tubulin synthesis in neutrophils, but it can also prevent tubulin synthesis (and, thus, cell division and other cellular processes) in other cells. Fortunately, neutrophils concentrate colchicine, so they are affected at lower concentrations of colchicine than other cell types. Neutrophils lack the transport protein P-glycoprotein, a member of the ABC cassette family (which includes the CFTR channel). In most other cell types, P-glycoprotein exports chemicals such as colchicine, thus preventing their accumulation.

Lotta T. had a rapid and gratifying clinical response to the hourly administration of colchicine. This drug diminishes phagocytosis and the subsequent release of the lysosomal enzymes that initiate the inflammatory response in synovial tissue.

The inflammatory response that causes the symptoms of an acute gout attack begins when neutrophils and macrophages ingest urate crystals. In neutrophils, urate activates the conversion of the polyunsaturated fatty acid arachidonic acid (present in membrane phospholipids) to leukotriene B₄. The release of this messenger contributes to the pain. Colchicine, through its effect on tubulin, inhibits phagocytosis, leukotriene B₄ release, and recruitment and cell division of additional cells involved in inflammation. Colchicine also inhibits the tubulin-dependent release of histamine from mast cells. As a result, there was a rapid improvement in the pain and swelling in **Lotta T.**'s great toe.

After the gout attack subsided, **Lotta T.** was placed on daily allopurinol, a drug that inhibits urate production (see Chapter 8). During the next 6 months of allopurinol therapy, **Lotta T.**'s blood urate levels decreased. She did not have another gout attack during this time.

Dennis V. was diagnosed with cholera. He was placed on intravenous rehydration therapy, followed by oral rehydration therapy with high glucose- and Na⁺-containing fluids.

Vibrio cholerae secretes a toxin consisting of one A and multiple B subunits. The B subunits allow binding to the intestinal epithelia, and the A subunit is processed and transported into the cell, where it associates with the monomeric G-protein Arf (ADP-ribosylation factor). The cholera toxin A subunit ADP-ribosylates the G α -subunit of the heterotrimeric G-protein Gas. The net result is activation of protein kinase A, which then phosphorylates the CFTR chloride channel so that it remains open for an extended period

of time. The subsequent efflux of chloride, sodium, and water into the bowel lumen is responsible for **Dennis V.**'s diarrhea and subsequent dehydration.

CFTR (cystic fibrosis transmembrane conductance regulator) is a chloride channel that provides an example of a ligand-gated channel regulated through phosphorylation (phosphorylation-gated). CFTR is a member of the ABC (adenine nucleotide-binding cassette, or ATP binding cassette) superfamily of transport proteins, and is the protein mutated in cystic fibrosis. CFTR consists of two transmembrane domains that form a closed channel, each connected to an ATP binding site, and a regulatory domain that sits in front of the channel. When the regulatory domain is phosphorylated by a kinase, its conformation changes and it moves away from the ATP binding domains. As ATP binds and is hydrolyzed, the transmembrane domains change conformation and open the channel, and chloride ions diffuse through. As the conformation reverts back to its original form, the channel closes. Individuals homozygous for mutations in CFTR display cystic fibrosis; heterozygotes for the mutated gene are thought to have protection against cholera. An inactive CFTR leads to an inability to release chloride ions from cells into the extracellular space, with a concomitantly reduced diffusion of water into the same space. Thus, a consequence of the CFTR mutation is the dehydration of respiratory and interstitial mucosal linings, leading to a plugging of airways and ducts with a thick mucus.

In the emergency room, **Dennis V.** initially received intravenous rehydration therapy (normal saline [0.9% NaCl]) and later, oral hydration therapy containing Na^+ , K^+ , and glucose. He was also given rice, which contains glucose and amino acids. Glucose is absorbed from the intestinal lumen via the sodium-dependent glucose cotransporters, which cotransport Na^+ into the cells together with glucose. Many amino acids are also absorbed by Na^+ -dependent cotransport. With the return of Na^+ to the cytoplasm, water efflux from the cell into the intestinal lumen decreases. **Dennis V.** quickly recovered from his bout of cholera. Cholera is a self-limiting disease process, possibly because the bacteria remain in the intestinal lumen where they are washed out of the system by diffuse watery diarrhea. Antibiotics (tetracyclines, macrolides, or fluoroquinolones) can also be used, particularly in severe cases, to decrease the duration of diarrhea and vibrio excretion. Over the past 3 years, **Percy V.** has persevered through the death of his wife and the subsequent calamities of his grandson, **Dennis V.**, including salicylate poisoning, suspected malathion poisoning, and now cholera. **Percy V.** has decided to send his grandson home for the remainder of the summer.

Mia S. has myasthenia gravis, an autoimmune disease caused by the production of antibodies affecting the neuromuscular junction. These antibodies are directed against the nicotinic acetylcholine receptor in skeletal muscles in about 85% of these patients. In about 10% to 15% of patients, the antibodies are directed against other proteins in the neuromuscular junction. The diagnosis is made by history (presence of typical muscular symptoms), physical examination (presence of inability to do specific repetitive muscular activity over time), and the presence of antibodies against acetylcholine receptors. The diagnosis can be further confirmed by neurophysiology testing, including a diagnostic procedure involving repetitive electrical nerve stimulation and an electromyogram (EMG) showing a partial blockade of ion flux across muscular membranes. The prognosis for this otherwise debilitating disease has improved dramatically with the advent of new therapies. Virtually all myasthenia patients can live full productive lives with proper treatment. These therapies include anticholinesterase agents; immunosuppressive drugs, such as glucocorticoids, azathioprine, or mycophenolate; thymectomy (removal of the thymus gland, which offers long-term benefit which may eliminate the need for a continuing medical therapy by reducing immunoreactivity); intravenous immunoglobulin (IVIG, which decreases the effect of autoantibodies); and plasmapheresis (which reduces antiacetylcholine receptor antibody levels). IVIG and plasmapheresis are reserved as a means of rapidly helping the patient through an exacerbation of myasthenia gravis with serious signs and symptoms.

A laboratory test to confirm the diagnosis of myasthenia gravis utilizes the patient's sera as a source of antibodies directed against the acetylcholine receptor. Human cell lines, grown in the laboratory and producing the acetylcholine receptor, are used as a source of soluble receptor (the cells are lysed and a solubilized membrane fraction, which contains the receptor, is obtained). The soluble receptor is incubated with radioactively labeled α -bungarotoxin, which binds very specifically and tightly to the acetylcholine receptor. A sample of the patient's sera is incubated with the bungarotoxin-receptor complex, and the extent to which antibodies bind to the receptor complex is determined as a measurement of reduced bungarotoxin binding to the receptor. A positive result indicates the presence of anti-acetylcholine receptor antibodies in the sera.

Ann R. Anorexia nervosa presents with abnormally low body weight and a distorted perception of body image often associated with compulsive exercise. Although **Ann R.** has been gaining weight, she is still relatively low on stored fuels needed to sustain the metabolic requirements of exercise. Her prolonged starvation has resulted

in the release of the steroid hormone cortisol and the polypeptide hormone glucagon, whereas levels of the polypeptide hormone insulin have decreased. Cortisol activates the transcription of genes for some of the enzymes of gluconeogenesis (the synthesis of glucose from amino acids and other precursors; see Chapter 3). Glucagon binds to heptahelical receptors in liver and adipose tissue and, working through cAMP and protein kinase A, activates many enzymes involved in fasting fuel metabolism. Insulin, which is released when **Ann R.** drinks her high-energy supplement, works through a specialized tyrosine kinase receptor to promote fuel storage. Epinephrine, a catecholamine released when she exercises that works through a heptahelical receptor, promotes fuel mobilization.

BIOCHEMICAL COMMENTS

Guanylyl Cyclase Receptors. Membrane-bound guanylyl cyclase receptors convert GTP to the second messenger 3',5'-cyclic GMP (cGMP), which is analogous to cAMP. These receptors will directly synthesize cGMP in response to binding the appropriate ligand, unlike G_s -coupled heptahelical receptors, which require G-protein signaling to adenylyl cyclase to produce cAMP. Like cAMP, cGMP is degraded by a membrane-bound phosphodiesterase. Elevated cGMP activates protein kinase G, which then phosphorylates target proteins to propagate the response. To date, seven such receptors have been identified.

A soluble form of guanylyl cyclase exists, located in the cytoplasm, and is a receptor for nitric oxide (NO), a neurotransmitter/neurohormone. NO is a lipophilic gas that is able to diffuse into the cell. This receptor thus is an exception to the general finding that intracellular receptors are gene transcription factors. The membrane-bound receptors will bind atrial natriuretic peptides, brain natriuretic peptide, and C-type natriuretic peptide, as well as guanylin.

cGMP-elevating drugs have been used in humans to treat a variety of disorders, such as angina pectoris (glycerol trinitrate decomposes to NO, which activates a guanylyl cyclase), heart failure (using nesiritide, which is synthetic β -natriuretic peptide, a ligand for activation of a guanylyl cyclase receptor), and erectile dysfunction (through drugs that inhibit a cGMP phosphodiesterase [designated PDE5], such as sildenafil).

KEY CONCEPTS

- ◆ The cell is the basic unit of living organisms.
- ◆ Unique features of each cell type define tissue specificity and function.
- ◆ Despite the variety of cell types, there are many common features that all cells share, such as the presence of a plasma membrane.
 - ◆ The plasma membrane is composed primarily of lipids and proteins (both integral and peripheral).
 - ◆ Specific transport proteins are required to allow compounds to cross membranes, either by facilitative diffusion, gated channels, or active transport.
 - ◆ Eukaryotes contain intracellular organelles, while prokaryotic cells do not.
- ◆ In eukaryotes, the intracellular organelles consist of lysosomes, the nucleus, the ER, the Golgi apparatus, mitochondria, peroxisomes, and the cytoplasm. Each organelle contributes a different function to the cell. Some cells may lack one or more of these internal organelles.
 - ◆ Lysosomes are the intracellular organelles of digestion.
 - ◆ The nucleus contains the genetic material of the cell and is the site of RNA synthesis.
 - ◆ Ribosomes are intracellular organelles on which protein synthesis occurs.
 - ◆ The ER contains enzymes for the synthesis of many lipids, for drug and toxic chemical metabolism, and for posttranslational modification of proteins.
 - ◆ The Golgi complex modifies proteins produced in the ER and sorts and distributes them to other organelles.
 - ◆ The mitochondria are the cells' power plants, synthesizing ATP.
 - ◆ The peroxisomes sequester various oxidative reactions that have the potential to generate dangerous radical species.
 - ◆ The cytoskeleton aids in defining the structure of the cell, the shape of the cell surface, and the arrangement of subcellular organelles within the cytoplasm.
- ◆ To integrate cellular function with the needs of the organism, cells communicate with each other via

chemical messengers. Chemical messengers include neurotransmitters (for the nervous system), hormones (for the endocrine system), cytokines (for the immune system), retinoids, eicosanoids, and growth factors.

- ◆ Chemical messengers transmit their signals by binding to receptors on target cells. When a messenger binds to a receptor, a signal transduction pathway is activated, which generates second messengers within the cell. Examples of second messengers include cAMP and various derivatives of phosphatidylinositol.
- ◆ Receptors can be either plasma membrane proteins or intracellular binding proteins.
- ◆ Intracellular receptors act primarily as transcription factors, which regulate gene expression in response to a signal being released.
- ◆ Plasma membrane receptors fall into different classes, such as ion-channel receptors, tyrosine kinase receptors, tyrosine kinase–associated receptors, serine–threonine kinase receptors, or G-protein coupled receptors (GPCRs), also known as serpentine or heptahelical receptors.
 - ◆ Ion-channel receptors respond to a stimulus by allowing ion flux across the membrane.
 - ◆ Tyrosine kinase and tyrosine kinase–associated receptors respond to a stimulus through activation of a tyrosine kinase activity, which phosphorylates specific target proteins to elicit a cellular response.
 - ◆ Serine–threonine kinase receptors respond to a stimulus that activates a serine–threonine kinase, which then transmits signals through activation of SMAD proteins (see Fig. 10.16), which are transcription factors.
 - ◆ GPCR respond to a stimulus by activating a guanine nucleotide-binding protein (G-protein), which, in its activated GTP-binding state, activates or inhibits a target protein. G-proteins contain intrinsic GTPase activity, thereby limiting the time for which they are active.
- ◆ Signal termination can occur via a variety of mechanisms, such as destruction of the chemical messenger, internalization of the receptor, inactivation of second messengers, such as loss of cAMP, or removal of covalent bonds added as a result of the primary message (e.g., dephosphorylation).
- ◆ Diseases discussed in this chapter are summarized in Table 10.4.

TABLE 10.4 Diseases Discussed in Chapter 10

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
Myasthenia gravis	Environmental	Autoantibodies to the acetylcholine receptor (and others at the neuromuscular junction), leading to neuromuscular dysfunction.
Cholera	Environmental	Watery diarrhea leading to dehydration and hypovolemic shock due to cholera toxin ADP-ribosylating a class of G-proteins, altering their function and affecting water and salt transport across the intestinal mucosa. Main treatment is with a glucose-electrolyte solution to increase coupled glucose-sodium uptake into the intestinal epithelial cells, reversing the loss of water from these cells.
Anorexia nervosa	Both	Effects of inadequate nutrition on hormone release and response. Cortisol, glucagon, and epinephrine levels are all increased under these conditions.
Gout	Both	Treat by inhibiting xanthine oxidase, thereby reducing the production of uric acid, using the analog allopurinol. Before allopurinol, the patient is treated with colchicine, which blocks microtubule formation and the migration of neutrophils to the affected area.
Gas gangrene	Environmental	Bacterial infection that secretes a toxin which is a phospholipase, leading to cell membrane destruction. This leads to capillary destruction, and impaired blood flow to the affected area.
Alcohol use disorder	Both	Ethanol poisoning due to increased production of acetaldehyde, due to the combined actions of alcohol dehydrogenase and the induction of the microsomal ethanol oxidizing system (MEOS). MEOS is induced because of the high levels of ethanol in the patient's diet.

REVIEW QUESTIONS—CHAPTER 10

1. Bacteria contain a cell wall and a plasma membrane. Antibiotics targeting the cell wall do not affect human cells since the human cells do not express a cell wall. However, antibiotics cannot target plasma membranes

since both bacteria and humans express such membranes. Which one of the following is a characteristic of the eukaryotic plasma membrane?

- A. It is composed principally of triacylglycerols and cholesterol.
 - B. It contains principally nonpolar lipids.
 - C. It contains phospholipids with their acyl groups extending into the cytosol.
 - D. It contains more phosphatidylserine in the inner than the outer leaflet.
 - E. It contains oligosaccharides sandwiched between the inner and outer leaflets.
2. A marathon runner releases epinephrine before a race, which binds to a receptor with seven transmembrane domains. Such transmembrane proteins can be best described by which one of the following?
- A. They can usually be dissociated from membranes without disrupting the lipid bilayer.
 - B. They are classified as peripheral membrane proteins.
 - C. They contain hydrophobic amino acid residues at their carboxy terminus.
 - D. They contain hydrophilic amino acid residues extending into the lipid bilayer.
 - E. They contain membrane-spanning regions that are α -helices.
3. A patient had a sudden heart attack caused by inadequate blood flow through the vessels of the heart. As a consequence, there was an inadequate supply of oxygen to generate ATP in his cardiomyocytes. The compartment of the cardiomyocyte most directly involved in ATP generation is which one of the following?
- A. Mitochondrion
 - B. Peroxisome
 - C. Lysosome
 - D. Nucleus
 - E. Golgi
4. One manner in which type 2 diabetes occurs is via a reduction in the release of insulin from the pancreas. The release of insulin from the β -cells of the pancreas requires Ca^{2+} influx through a channel that is activated by a change in the membrane potential across the plasma membrane. The movement of calcium across the membrane is an example of which one of the following?
- A. Voltage-gated channel
 - B. Passive diffusion
 - C. Active transport
 - D. Ligand-gated channel
 - E. Phosphorylation-gated channel
5. Lysosomes function to help fight infection and to degrade unwanted metabolites in the cell. ATP is required for the appropriate functioning of the lysosome because of which one of the following?
- A. Maintaining an acidic environment in the lysosome
 - B. Maintaining a basic environment in the lysosome
 - C. Regulation of enzyme activity
 - D. Activation of lysosomal zymogens
 - E. It acts as a cofactor for lysosomal hydrolases
6. Mature red blood cells are different from most other cells in the human body in that they do not contain a nucleus and must use anaerobic metabolism instead of aerobic metabolism. Anaerobic metabolism is required for these cells due to which one of the following?
- A. Oxygen cannot enter red blood cells.
 - B. The red blood cells lack a plasma membrane.
 - C. The red blood cells lack mitochondria.
 - D. The red blood cells lack enzymes for glucose metabolism.
 - E. Oxygen cannot bind to any proteins in the red blood cell.
7. Normal or physiological serum sodium (Na^+) levels are around 140 mEq/L whereas potassium (K^+) levels are 3.5 to 5.0 mEq/L. Intracellular concentrations are reversed with a high K^+ level and much lower Na^+ level. This ion imbalance is accomplished by the Na^+ , K^+ -ATPase, which is a protein that can be best described by which one of the following?
- A. It catalyzes simple diffusion.
 - B. It catalyzes primary active transport.
 - C. It exchanges two Na^+ ions for three K^+ ions.
 - D. It catalyzes the transport of glucose down its concentration gradient.
 - E. It catalyzes the efflux of urea from the cell.

Questions 8 and 9 are based on the following patient.

8. A patient has severe weakness of a muscle group after repeatedly contracting that muscle group. After rest, the muscle appears to function normally, unless repeatedly contracted again. The antibody causing this disease process would directly affect which one of the following?
- The number of acetylcholine vesicles
 - Voltage-gated Ca^{2+} channels
 - Na^+ and K^+ gradients
 - Acetylcholine receptors in smooth muscle
 - Acetylcholine receptors in skeletal muscle
9. In the patient described in the previous question, acetylcholine (ACh) and other similar neurotransmitters utilize which one of the following modes of action to transmit their signal?
- Endocrine
 - Paracrine
 - Autocrine
 - Neuropeptide
 - Cytokine

Use the following information to answer Questions 10 and 11. You do not need to know more about parathyroid hormone or pseudohypoparathyroidism than the information given.

Pseudohypoparathyroidism is a heritable disorder caused by target-organ unresponsiveness to parathyroid hormone (a polypeptide hormone secreted by the parathyroid gland). One of the mutations that causes this disease occurs in the gene encoding $G_s \alpha$ in certain cells.

0. The receptor for parathyroid hormone is most likely which one of the following?
- An intracellular transcription factor
 - A cytoplasmic guanylyl cyclase
 - A receptor that must be endocytosed in clathrin-coated pits to transmit its signal
 - A heptahelical receptor
 - A tyrosine kinase receptor
1. This mutation most likely has which one of the following characteristics?
- It is a gain-of-function mutation.
 - It decreases the GTPase activity of the $G\alpha_s$ subunit.
 - It decreases synthesis of cAMP in response to parathyroid hormone.
 - It decreases the generation of IP_3 in response to parathyroid hormone.
 - It decreases synthesis of phosphatidylinositol 3,4,5-trisphosphate in response to parathyroid hormone.
2. Techniques are available to allow one to introduce mutations in proteins at a selected amino acid residue (site-directed mutagenesis). Which step of the signal transduction pathway would be blocked if you created a tyrosine kinase receptor in which all of the tyrosine residues normally phosphorylated on the receptor were converted to phenylalanine residues?
- GRB2 binding to the receptor to propagate the response
 - Binding of the growth factor to the receptor
 - Induction of a conformational change in the receptor upon growth factor binding
 - Activation of the receptor's intrinsic tyrosine kinase activity
 - Dimerization of the receptors
3. A patient has been diagnosed with a glucagonoma, a pancreatic tumor that independently and episodically secretes glucagon. Which one of the following would be expected in this patient?
- Low serum glucose
 - Increased glycogenolysis in the liver
 - Increased glycogenolysis in muscle tissue
 - Increased glycogenesis in the liver
 - Increased glycogenesis in muscle tissue
4. Curare has been given as a paralyzing agent in patients undergoing surgical procedures, and its mode of action is best described by inhibiting the action of which one of the following?
- Atropine
 - Muscarinic receptors
 - Nicotinic receptors
 - The formation of acetylcholine
 - The breakdown of acetylcholine
5. A patient with allergies is taking a drug that blocks the actions of leukotrienes. The leukotrienes are derived

from which one of the following molecules?

- A. Oleic acid
- B. Linolenic acid
- C. Stearic acid
- D. Arachidonic acid
- E. Palmitic acid

ANSWERS TO REVIEW QUESTIONS

1. **The answer is D.** Phosphatidylserine, the only lipid with a net negative charge at neutral pH, is located in the inner leaflet, where it contributes to the more negatively charged intracellular side of the membrane. The expression of phosphatidylserine in the outer leaflet of the plasma membrane is often associated with aging. The membrane is composed principally of phospholipids and cholesterol (thus, answer A is incorrect). Phospholipids are amphipathic (contain polar and nonpolar ends, see Chapter 5), with their polar head groups extending into the aqueous medium inside and outside of the cell. The fatty acyl groups of the two layers face each other on the inside of the bilayer, and the polar oligosaccharides groups of glycoproteins and glycolipids extend into the aqueous medium (thus, answers B, C, and E are incorrect).
2. **The answer is E.** The transmembrane regions are α -helices with hydrophobic amino acid side chains binding to membrane lipids. The hydrophobic interactions hinder their extraction (thus, A and D are incorrect). Because they are not easily extracted, they are classified as integral proteins (thus, B is incorrect). The carboxy and amino terminals of transmembrane proteins extend into the aqueous intra- and extracellular medium and thus need to contain many hydrophilic residues (thus, C is incorrect).
3. **The answer is A.** Most of fuel oxidation and ATP generation occurs in the mitochondrion. Although some may also occur in the cytosol, the amount produced in the cytoplasm is much smaller than in the mitochondria in most cells.
4. **The answer is A.** Channels that open in response to a change in ion concentration across the membrane (which results in a change in membrane potential, or voltage, across the membrane), are known as voltage-gated channels. The calcium influx is not passive diffusion, as a carrier is required (the channel). This is not an active transport process, as calcium is flowing down its concentration gradient, and the cell is not concentrating calcium within it. A ligand-gated channel opens when a particular ligand binds to it, not when the membrane potential changes. There is no phosphorylation event required in the opening of this calcium channel, so it is not an example of a phosphorylation-gated channel.
5. **The answer is A.** ATP is required by the vesicular ATPase, which uses the energy of ATP hydrolysis to concentrate protons within the lysosome, which generates the acidic environment required for enzyme activity. Answer B is, therefore, incorrect because lysosomes are acidic compared to the cytoplasm, not basic. ATP is not required to either activate, regulate, or as a cofactor, for any lysosomal hydrolase.
6. **The answer is C.** Oxygen enters red blood cells via diffusion across its plasma membrane and binds to hemoglobin within the cell. Aerobic metabolism requires the presence of mitochondria, which are lacking in red blood cells. The red blood cell metabolizes glucose for energy, so the enzymes for glucose metabolism are present in the cell.
7. **The answer is B.** Energy is needed to create the ion imbalance across the membrane, so the protein does not catalyze simple diffusion. The Na^+ , K^+ ATPase catalyzes the hydrolysis of ATP to create the ion gradient by exchanging three sodium ions (from the cytoplasm) for two potassium ions (from outside the cell). This results in the export of sodium, and uptake of potassium, in an electrogenic manner (charge imbalance across the membrane). This is an example of primary active transport. The Na^+ gradient then powers the transport of glucose into the cell against its concentration gradient (an example of secondary active transport). Urea leaving liver cells is not powered by a sodium gradient.
8. **The answer is E.** This patient has myasthenia gravis caused by the production of an antibody directed against acetylcholine receptors in skeletal muscles (not smooth muscle) resulting in fewer functional receptors but not affecting the number of acetylcholine vesicles, Na^+ and K^+ gradients, or voltage-gated Ca^{2+} channels.
9. **The answer is B.** Endocrine action is defined as a hormone secreted by a specific cell type with action on specific target cells usually some distance away. Paracrine actions are hormones secreted by a cell and binding to nearby cells. Autocrine action involves a messenger that acts on the cell from which it was secreted. ACh activates only those ACh receptors located across the synaptic cleft from the signaling

- nerve, and not every cell, which contains ACh receptors. ACh is a nitrogen-containing small-molecule neurotransmitter or biogenic amine, not a neuropeptide. Cytokines are messengers of the immune system.
10. **The answer is D.** Parathyroid hormone is a polypeptide hormone and thus must bind to a plasma membrane receptor instead of an intracellular receptor (thus, A and B are incorrect). Hormones that bind to plasma membrane receptors do not need to enter the cell to transmit their signals (thus, C is incorrect). Heptahelical receptors work through heterotrimeric G-proteins that have an α -subunit, and tyrosine kinase receptors work through phosphorylating target proteins on tyrosine sidechains (thus, D is correct and E is incorrect).
 11. **The answer is C.** $G\alpha_s$ normally activates adenylyl cyclase to generate cAMP in response to parathyroid hormone. Because the patient has end-organ unresponsiveness, they must have a deficiency in the signaling pathway (thus, A is incorrect) and cAMP will be decreased. Decreased GTPase activity will increase binding to adenylyl cyclase and increase responsiveness (thus, B is incorrect). Neither IP_3 nor phosphatidylinositol 3,4,5-trisphosphate are involved in signal transduction by the $G\alpha_s$ subunit.
 12. **The answer is A.** GRB2 binding to the receptor requires phosphotyrosine residues on the receptor. GRB2 normally binds to the receptor through its SH2 domains, which recognize phosphotyrosine residues on the receptor. In the absence of these phosphotyrosine residues, GRB2 would not be able to bind to the receptor. Growth factor binding to the receptor does not require phosphotyrosine residues. It is the binding of the growth factor to the receptor, through a conformational change in the receptor that activates the intrinsic tyrosine kinase of the receptor, which then leads to autophosphorylation of the receptor. The lack of intracellular tyrosine residues on the receptor will not alter the events initiated by the conformational change of the receptor. Dimerization of receptors occurs upon binding growth factor and is not dependent on the activation of the tyrosine kinase activity, nor of autophosphorylation of the receptor.
 13. **The answer is B.** Glucagon increases blood/serum glucose by stimulating the release of glucose from liver glycogen stores. Liver parenchymal cells express glucagon receptors but muscle cells do not, so muscle cells do not respond to glucagon. Glucagon, therefore, stimulates liver glycogenolysis but has no effect on muscle cells. Glycogenesis, the synthesis of glycogen, is an effect of insulin, but not glucagon.
 14. **The answer is C.** Curare is an inhibitor of nicotinic (skeletal and parasympathetic) ACh receptors causing muscle paralysis but curare does not affect the heart or the sympathetic nervous system (which express muscarinic ACh receptors). Curare inhibits only ACh receptors, not acetylcholine production or elimination. Atropine blocks the effects of excess ACh and is a completely different medication than curare.
 15. **The answer is D.** Prostaglandins, thromboxanes, and leukotrienes are eicosanoids and are all derived from arachidonic acid, a 20-carbon fatty acid derived from linoleic acid, an essential fatty acid. Arachidonic acid cannot be derived from any of the other fatty acids listed as possible answers.

11

Structure of the Nucleic Acids

Nucleotides in DNA (deoxyribonucleic acid) and RNA (ribonucleic acid). Nucleotides are the monomeric units of the nucleic acids, DNA (deoxyribonucleic acid) and RNA (ribonucleic acid). Each nucleotide consists of a heterocyclic **nitrogenous base**, a **sugar**, and **phosphate**. DNA contains the purine bases **adenine** (A) and **guanine** (G) and the pyrimidine bases **cytosine** (C) and **thymine** (T). RNA contains A, G, and C, but it has **uracil** (U) instead of thymine. In DNA, the sugar is **deoxyribose**, whereas in RNA it is **ribose**.

Polynucleotides such as DNA and RNA are linear sequences of nucleotides linked by **3'- to 5'-phosphodiester bonds** between the sugars (Fig. 11.1). The bases of the nucleotides can interact with other bases or with proteins.

FIGURE 11.1 Structure of a polynucleotide. The 5'-carbon of the top sugar and the 3'-carbon of the bottom sugar are indicated. Because the sugar is ribose, this is an example of RNA.

DNA Structure. Genetic information is encoded by the sequence of different nucleotide bases in DNA. DNA is **double stranded**; it contains **two antiparallel polynucleotide strands**. The two strands are joined by hydrogen bonding between their bases to form **base pairs (bp)**. **Adenine** pairs with **thymine**, and **guanine** pairs with **cytosine**. The two DNA strands run in **opposite directions**. One strand runs 5' to 3', and the other strand runs 3' to 5'. The two DNA strands wind around each other, forming a **double helix**.

Transcription of a gene generates a **single-stranded RNA** that is identical in nucleotide sequence to one of the strands of the duplex DNA (except for U in RNA where T is in DNA). The three major types of RNA are **messenger RNA (mRNA)**, **ribosomal RNA (rRNA)**, and **transfer RNA (tRNA)**.

RNA Structures. **mRNAs** contain the nucleotide sequence that is converted into the amino acid sequence of a protein in the process of translation. Eukaryotic mRNA has a structure known as a **cap** at the 5'-end, a sequence of adenine nucleotides (a **poly[A] tail**) at the 3'-end, and a **coding region** in between containing **codons** that dictate the sequence of amino acids in a protein or relay a signal. Each codon in the genetic code is a different sequence of three nucleotides.

rRNAs and tRNAs are part of the apparatus for protein synthesis, but they do not encode proteins. **rRNA** has **extensive internal base pairing** and complexes with proteins to form **ribonucleoprotein particles** called **ribosomes**. The ribosomes bind mRNA and tRNAs during translation. Each **tRNA** binds and **activates a specific amino acid** for insertion into the polypeptide chain and therefore has a somewhat different nucleotide sequence than other tRNAs. A unique trinucleotide sequence on each tRNA called an **anticodon** binds to a complementary codon on the mRNA, thereby ensuring insertion of the correct amino acid. In spite of their differences, all tRNAs contain a number of unusual nucleotides and assume a similar **cloverleaf** structure.

THE WAITING ROOM

Isabel S. is a 26-year-old who suffers from opioid use disorder and uses intravenous (IV) opioids. She presented to the emergency department with a painful, swollen left arm and was found to have an abscess on her arm where she injects. She reported that a few months ago, she had a 3-week course of a flulike syndrome with fever, malaise, and muscle aches. She was offered an HIV (human immunodeficiency virus) test, which was positive and a multidrug regimen was initiated.

An adenoma is a mass of rapidly proliferating cells, called a neoplasm (neo = new; plasm = growth), which is formed from epithelial cells growing into a gland-like structure. The cells lining all the external and internal organs are epithelial cells, and most human tumors are adenocarcinomas. Adenomatous polyps are adenomas that grow into the lumen of the colon or rectum. The term malignant applied to a neoplasm refers to invasive unregulated growth. **Clark T.** has an adenocarcinoma, which is a malignant adenoma that has started to grow through the wall of the colon into surrounding tissues. Cells from adenocarcinomas can break away and spread through the blood or lymph to other parts of the body, where they form "colony" tumors. This process is called metastasis.

Clark T. had a screening colonoscopy at age 50 where they removed several intestinal polyps, whose pathology was consistent with adenomas. He did not return for a 3-year colonoscopic examination as instructed for surveillance. At age 59, he reappeared, complaining of maroon-colored stools, an indication of intestinal bleeding. The source of the blood loss was an adenocarcinoma growing from a colonic polyp of the large intestine. A computed tomography (CT) scan of the abdomen and pelvis showed the tumor likely invading the gut wall with enlarged pericolic lymph nodes and several small masses in the liver, which confirmed metastatic cancer. Following resection of the tumor in both the colon and liver, the oncologist began treatment with 5-fluorouracil (5-FU) combined with other chemotherapeutic agents.

The Gram stain is a standard laboratory test that can be used to determine what type of bacteria is present in an infection. The test is based on the cell wall of the bacteria trapping a specific dye (crystal violet). Gram-positive bacteria, which trap the dye, have a thicker cell wall than gram-negative bacteria, which exclude the dye. Gram-positive and gram-negative bacteria have differences in the sugar and protein composition of their outer cell walls, as well as the lipid components associated with the cell walls. Because of these differences in cell-wall structure, antibiotics will affect each class of bacteria differently. Typing the bacteria using the Gram stain should allow the appropriate treatment options for the patient to be better determined.

Paul T. complains to his physician of a 3-day history of worsening fever and cough. His cough produces thick yellow-brown sputum. He has crackles on pulmonary examination at the right base of his lungs. A chest X-ray is ordered and demonstrates an infiltrate in the right base consistent with pneumonia, and he is empirically started on azithromycin for community-acquired pneumonia. His physician

was able to obtain a sputum sample from **Paul T.**, which was sent for stain and culture. The stain of his sputum shows many gram-positive diplococci. A sputum culture is initiated to determine whether he has been infected with *Streptococcus pneumoniae*.

I. DNA Structure

A. Location of DNA

DNA and **RNA** serve as the genetic material for prokaryotic and eukaryotic cells, viruses, and plasmids, each of which stores it in a different arrangement or location. In prokaryotes, DNA is not separated from the rest of the cellular contents. In eukaryotes, however, DNA is located in the nucleus, where it is separated from the rest of the cell by the nuclear envelope (see Fig. 10.9) and in the mitochondria. Eukaryotic nuclear DNA is bound to proteins, forming a complex called **chromatin**. During interphase (when cells are not dividing), some of the chromatin are diffuse (euchromatin) and some are dense (heterochromatin), but no distinct structures can be observed. However, before mitosis (when cells divide), the DNA is replicated, resulting in two identical chromosomes called sister chromatids. During metaphase (a period in mitosis), these condense into discrete, visible chromosomes.

DNA is a double-stranded molecule that forms bp, via hydrogen bonding, between strands (see section I.C). The bp designation is often used to indicate the size of a DNA molecule. For example, in a stretch of DNA 200 bp long, both strands are included, with 200 bases in each strand, for a total of 400 bases.

Less than 0.1% of the total DNA in a cell is present in mitochondria. The genetic information in a mitochondrion is encoded in <20,000 bp of DNA; the information in a human haploid nucleus (i.e., an egg or a sperm cell) is encoded in about 3×10^9 (3 billion) bp. The DNA and protein-synthesizing systems in mitochondria more closely resemble the systems in bacteria, which do not have membrane-enclosed organelles, than those in the eukaryotic nucleus and cytoplasm. It has been suggested that mitochondria were derived from ancient bacterial invaders of primordial eukaryotic cells.

Viruses are small infectious particles consisting of a DNA or RNA genome (but not both), proteins required for pathogenesis or replication, and a protein coat. They lack, however, complete systems for DNA replication, production of RNA (transcription), and synthesis of proteins (translation). Consequently, viruses must invade other cells and commandeer their DNA, RNA, and protein-synthesizing machinery to reproduce. Both eukaryotes and prokaryotes can be infected by viruses. Viruses that infect bacteria are known as bacteriophages (or more simply as phage).

Plasmids are small, circular DNA molecules that can enter bacteria and replicate autonomously, that is, outside the host genome. In contrast to viruses, plasmids are not infectious; they do not convert their host cells into factories devoted to plasmid production. Plasmids do, however, often carry genes, some of which confer resistance to antibiotics. Genetic engineers utilize plasmids as tools for transfer of foreign genes into bacteria because segments of DNA can readily be incorporated into plasmids.

B. Determination of the Structure of DNA

In 1869, Friedrich Miescher first isolated DNA, obtaining it from pus scraped from surgical bandages. Initially, scientists speculated that DNA was a cellular storage form for inorganic phosphate, an important but unexciting function that did not spark widespread interest in determining its structure. In fact, the details of DNA structure were not fully determined until 1953, almost 90 years after it had first been isolated, but only 9 years after it had been identified as the genetic material.

Early in the 20th century, the **bases** of DNA were identified as the purines adenine (A) and guanine (G), and the pyrimidines cytosine (C) and thymine (T) (Fig. 11.2). The sugar was found to be deoxyribose, a derivative of ribose, lacking a hydroxyl group on carbon 2 (see Fig. 11.2).

A**Purines****Adenine (A)****Guanine (G)****Pyrimidines****Cytosine (C)****Thymine (T)****B****Deoxyribose**

FIGURE 11.2 A. Purine and pyrimidine bases in DNA. **B.** Deoxyribose and ribose, the sugars of DNA and RNA. The carbon atoms are numbered from 1 to 5. When the sugar is attached to a base, the carbon atoms are numbered from 1' to 5' to distinguish it from the base. In deoxyribose the X = H; in ribose the X = OH.

Nucleotides, composed of a base, a sugar, and phosphate, were found to be the monomeric units of the nucleic acids (Table 11.1). In nucleosides, the nitrogenous base is linked by an *N*-glycosidic bond to the anomeric carbon of the sugar, either ribose or deoxyribose. The atoms in the sugar are numbered using the prime symbol (') to distinguish them from the numbering of the atoms in the nitrogenous base. A nucleotide is a nucleoside with an inorganic phosphate attached to a 5'-hydroxyl group of the sugar in ester linkage (Fig. 11.3). The names and abbreviations of nucleotides specify the base, the sugar, and the number of phosphates attached (MP, **mon**ophosphate; DP, **di**phosphate; TP, **tri**phosphate). In deoxynucleotides, the prefix “d” precedes the abbreviation. For example, GDP is guanosine diphosphate (the base guanine attached to a ribose that has two phosphate groups) and dATP is deoxyadenosine triphosphate (the base adenine attached to deoxyribose with three phosphate groups).

BASE	NUCLEOSIDE
Adenine (A)	Adenosine
Guanine (G)	Guanosine
Cytosine (C)	Cytidine
Thymine (T)	Thymidine
Uracil (U)	Uridine
Hypoxanthine (I)	Inosine ^b

^aIf the sugar is deoxyribose rather than ribose, the nucleoside has “deoxy” as a prefix (e.g., deoxyadenosine). Nucleotides are given the name of the nucleoside plus mono-, di-, or triphosphate (e.g., adenosine triphosphate or deoxyadenosine triphosphate).

^bThe base hypoxanthine is not found in DNA but is produced during the degradation of the purine bases. It is found in certain tRNA molecules. Its nucleoside, inosine, is produced during the synthesis of the purine nucleotides (see Chapter 41).

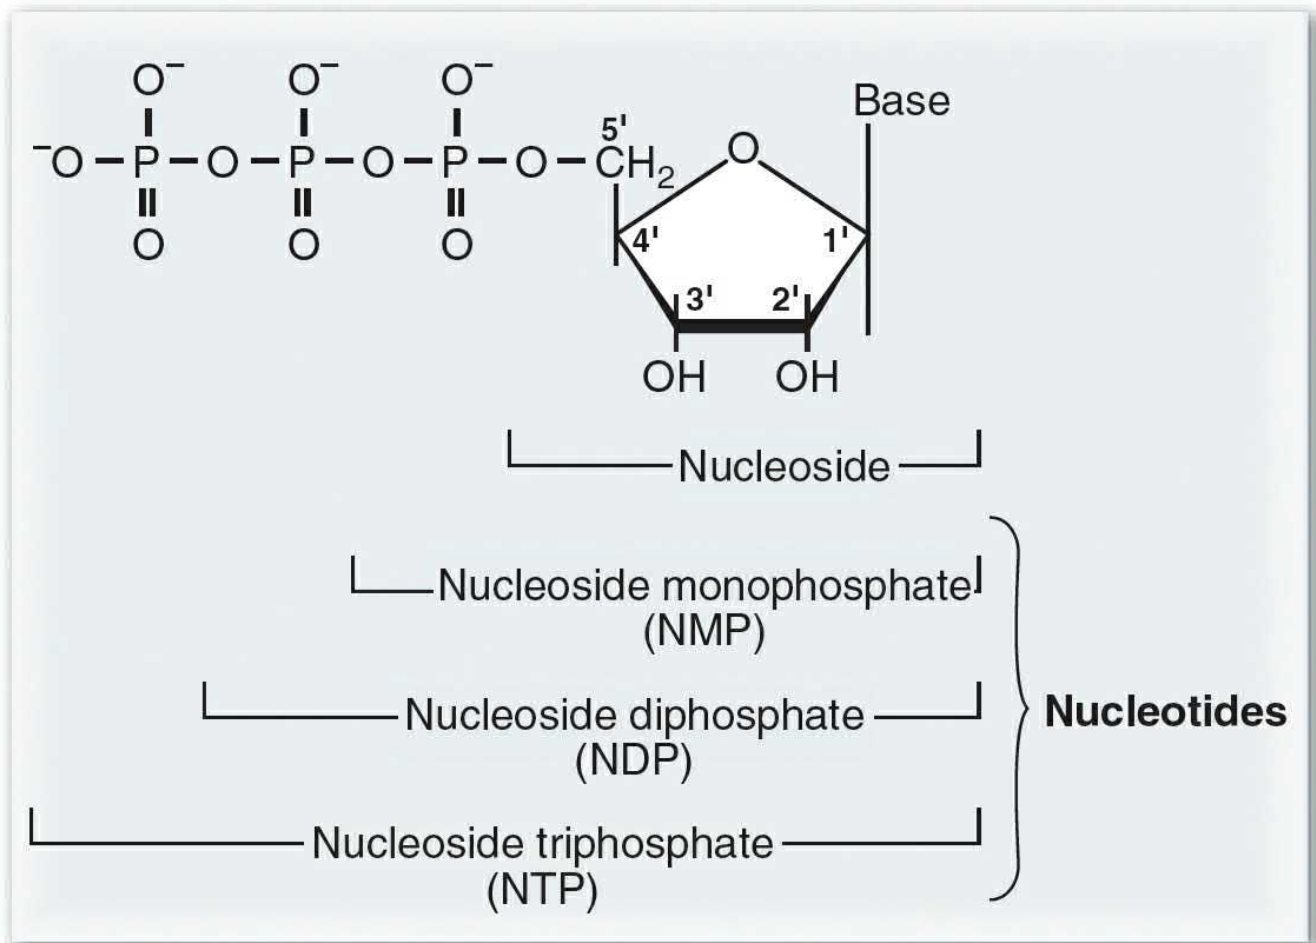

FIGURE 11.3 Nucleoside and nucleotide structures displayed with ribose as the sugar. The corresponding deoxyribonucleotides are abbreviated dNMP, dNDP, and dNTP. N = any base (A, G, C, U, or T). The hydrogen atoms (H) have been removed from the figure to improve clarity.

In 1944, after Oswald Avery's experiments establishing DNA as the genetic material were published, interest in determining the structure of DNA intensified. Digestion with enzymes of known specificity proved that inorganic phosphate joined the nucleotide monomers, forming a phosphodiester bond between the 3'-carbon of one sugar and the 5'-carbon of the next sugar along the polynucleotide chain (Fig. 11.4). Another key to DNA structure was provided by Erwin Chargaff. He analyzed the base composition of DNA from various sources and concluded that on a molar basis the amount of adenine was always equal to the amount of thymine, and the amount of guanine was equal to the amount of cytosine.

FIGURE 11.4 A segment of a polynucleotide chain of DNA. The dashes at the 5'- and 3'-ends indicate that the molecule contains more nucleotides than are shown. The hydrogen atoms (H) have been omitted from the sugar structures to increase the clarity of the figure.

After **Isabel S.** was diagnosed with HIV, she was treated with a multidrug regimen. One of the first drugs used to treat HIV was zidovudine (ZDV), formerly called AZT. This is a nucleoside analog reverse transcriptase inhibitor drug and is an analog of the thymine nucleotide found in DNA (the modified group is shown in the yellow box). ZDV is phosphorylated in the body by the kinases that normally phosphorylate nucleosides and nucleotides. As the viral DNA chain is being synthesized in a human cell, ZDV is then added to the growing 3'-end by viral reverse transcriptase. However, ZDV lacks a 3'-OH group, and therefore no additional nucleotides can be attached through a 5' → 3'-bond. Thus, chain elongation of the DNA is terminated. Reverse transcriptase has a higher affinity for ZDV than does normal human cellular DNA polymerases, enabling the drug to target viral replication more specifically than cellular replication. Lamivudine (3TC, 2',3'-dideoxy-3'-thiacytidine) is also a nucleoside analog reverse transcriptase inhibitor, with an analog of cytidine.

ZDV, an analog of deoxythymidine

During this era, James Watson and Francis Crick joined forces and, using the X-ray diffraction data of Maurice Wilkins and Rosalind Franklin, incorporated the available information into a model for DNA structure. In 1953, they published a brief paper (approximately 900 words), describing DNA as a double helix consisting of two polynucleotide strands joined by pairing between the bases (adenine with thymine and guanine with cytosine). The model of **base pairing** they proposed and the implications of the model for understanding DNA replication formed the basis of modern molecular biology.

C. Concept of Base Pairing

As proposed by Watson and Crick, each DNA molecule consists of two polynucleotide chains joined by hydrogen bonds between the bases. In each bp, a purine on one strand forms hydrogen bonds with a pyrimidine on the other strand. In one type of bp, adenine on one strand pairs with thymine on the other strand (Fig. 11.5). This bp is stabilized by two hydrogen bonds. The other bp, formed between guanine and cytosine, is stabilized by three hydrogen bonds. As a consequence of base pairing, the two strands of DNA are complementary; that is, adenine on one strand corresponds to thymine on the other strand, and guanine corresponds to cytosine.

FIGURE 11.5 Base pairs of DNA. Note that the purine bases are “flipped over” from the positions in which they are usually shown (see Fig. 11.4). The bases must be in this orientation to form base pairs. The *dotted lines* indicate hydrogen bonds between the bases. Although the hydrogen bonds participate in holding the bases and thus the two DNA strands together, they are weaker than covalent bonds and allow the DNA strands to separate during replication and transcription.

The concept of base pairing proved to be essential for determining the mechanism of DNA replication (in which the copies of DNA produced are distributed to daughter cells) and the mechanisms of transcription and translation (in which mRNA is produced from genes and used to direct the process of protein synthesis). As Watson and Crick implied in their article, base pairing allows one strand of DNA to serve as a template for the synthesis of the other strand (Fig. 11.6). Base pairing also allows a strand of DNA to serve as a template for the synthesis of a complementary strand of RNA.

FIGURE 11.6 DNA strands serve as templates. During replication, the strands of the helix separate in a localized region. Each parental strand serves as a template for the synthesis of a new DNA strand.

D. DNA Strands Are Antiparallel

As concluded by Watson and Crick, the two complementary strands of DNA run in opposite directions (antiparallel). On one strand, the 5'-carbon of the sugar is above the 3'-carbon (Fig. 11.7). This strand is said to run in a 5'-to-3' direction. On the other strand, the 3'-carbon is above the 5'-carbon. This strand is said to run in a 3'-to-5' direction. Thus, the strands are antiparallel (i.e., they run in opposite directions). This concept of directionality of nucleic acid strands is essential for understanding the mechanisms of replication and transcription.

FIGURE 11.7 Antiparallel strands of DNA. For the strand on the left, the 5'-carbon of each sugar is above the 3'-carbon, so the 5'-to-3' direction is from top to bottom. For the strand on the right, the 5'-carbon of each sugar is below the 3'-carbon, so the 5'-to-3' direction is from bottom to top.

E. The Double Helix

Because each bp contains a purine bonded to a pyrimidine, the strands are equidistant from each other throughout. If two strands that are equidistant from each other are twisted at the top and the bottom, they form a double helix (Fig. 11.8). In the **double helix** of DNA, the bp that join the two strands are stacked like a spiral staircase along the central axis of the molecule. The electrons of the adjacent bp interact, generating **hydrophobic stacking** forces that, in addition to the hydrogen bonding of the bp, stabilize the helix.

A

B

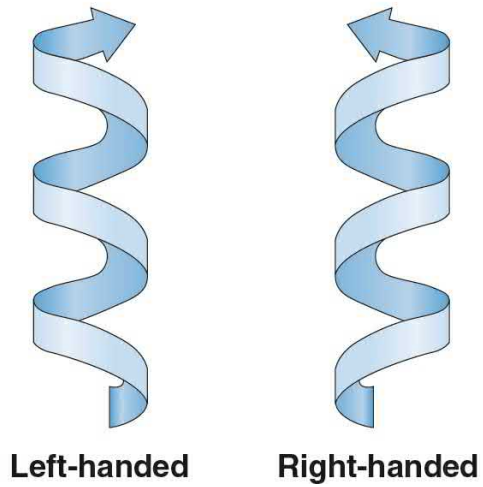

FIGURE 11.8 A. Two DNA strands twist to form a double helix. The distance between the two phosphodiester backbones is about 11 Å. The hydrogen-bonded base pairs, shown bonded by dotted lines, create stacking forces with adjacent base pairs. Each phosphate group contains one negatively charged oxygen atom that provides the phosphodiester backbone with a negative charge. Because of the twisting of the helix, grooves are formed along the surface, the larger one being the major groove and the smaller one the minor groove. **B.** If you look up through the bottom of a helix along the central axis and the helix spirals away from you in a clockwise direction (toward the *arrowhead* in the drawing), it is a right-handed helix. If it spirals away from you in a counterclockwise direction, it is a left-handed helix.

The phosphate groups of the sugar–phosphate backbones are outside the helix (see Fig. 11.8). Each phosphate has two oxygen atoms forming the phosphodiester bonds that link adjacent sugars. However, the third –OH group on the phosphate is free and dissociates a hydrogen ion at physiologic pH. Therefore, each DNA helix has negative charges coating its surface, which facilitate the binding of specific proteins.

The helix contains grooves of alternating size, known as the major and minor grooves (see Fig. 11.8). The bases in these grooves are exposed and therefore can interact with proteins or other molecules.

Multidrug regimens used to treat cancers (e.g., lymphomas) sometimes include the drug doxorubicin (adriamycin). It is a natural product with a complex multiring structure that intercalates or slips in between the stacked base pairs of DNA and inhibits replication and transcription. It will inhibit DNA synthesis in all cells but will preferentially affect rapidly growing cells (such as tumor cells as compared to normal cells).

Watson and Crick described the B form of DNA, a right-handed helix, with 3.4 Å ($1 \text{ Å} = 10^{-8} \text{ cm}$) between bp and 10.4 bp per turn. Although this form predominates in vivo, other forms also occur (Fig. 11.9). The A form, which predominates in DNA–RNA hybrids, is similar to the B form but is more compact (2.3 Å between bp and 11 bp per turn). In the Z form, the bases of the two DNA strands are positioned toward the periphery of a left-handed helix. There are 3.8 Å between bp and 11 bp per turn in Z-DNA. This form of the helix was designated “Z” because, in each strand, a line connecting the phosphates “zigs” and “zags” (see Fig. 11.9). Z-DNA is formed transiently in cells and can be stabilized by specific Z-DNA–binding proteins. Z-DNA formation has been linked to transcriptional initiation (the initiation of RNA synthesis from the DNA template); however, its physiologic significance is still elusive. For the rest of this text, we will focus only on B-DNA.

FIGURE 11.9 Z, B, and A forms of DNA. The solid red lines connect one phosphate group to the next. (Modified by permission from Saenger W. DNA structure. In: Saenger W, ed. *Principles of Nucleic Acid Structure*. Springer-Verlag; 1984:253–282. ©

F. Characteristics of DNA

Both alkali and heat cause the two strands of the DNA helix to separate (denature). Many techniques used to study and analyze DNA or to produce recombinant DNA molecules make use of this property. Although alkali causes the two strands of DNA to separate, it does not break the phosphodiester bonds (Fig. 11.10). In contrast, the phosphodiester bonds of RNA are cleaved by alkali because of the hydroxyl group on the 2'-carbon losing its proton, allowing the negatively charged oxygen to attack and break the phosphodiester linkage. Therefore, alkali is used to remove RNA from DNA and to separate DNA strands before or after electrophoresis (separation by size in an electric field) on polyacrylamide or agarose gels.

FIGURE 11.10 Effect of alkali on DNA and RNA. DNA strands stay intact, but they separate. RNA strands are degraded to nucleotides.

Heat alone converts double-stranded DNA to single-stranded DNA. The separation of strands is called melting, and the temperature at which 50% of the DNA is separated is called the T_m (the melting temperature). If the temperature is slowly decreased, complementary single strands can realign and base-pair, re-forming a double helix that is essentially identical to the original DNA. This process is known as renaturation, reannealing, or hybridization. The process by which a single-stranded DNA anneals with complementary strands of RNA is also called **hybridization** (Fig. 11.11). Hybridization is used extensively in research and clinical testing (see Chapter 16).

FIGURE 11.11 Hybridization of DNA and complementary RNA.

II. Structure of Chromosomes

A. Size of DNA Molecules

A prokaryotic cell generally contains a single **chromosome** composed of double-stranded DNA that forms a circle. These circular DNA molecules are extremely large. The entire chromosome of the bacterium *Escherichia coli*, composed of a single, circular double-stranded DNA molecule, contains over 4×10^6 bp. Its molecular weight is over $2,500 \times 10^6$ g/mol (compared to the molecular weight for a glucose molecule of 180 g/mol). If this molecule were linear, its length would measure almost 2 mm. DNA from eukaryotic cells is approximately 1,000 times larger than that from bacterial cells. In eukaryotes, each chromosome contains one continuous, linear DNA helix. The DNA of the longest human chromosome is over 7 cm in length. In fact, if the DNA from all 46 chromosomes in a diploid human cell were placed end to end, our total DNA would span a distance of about 2 m (over 6 ft). Our total DNA contains about 6×10^9 bp.

B. Packaging of DNA

DNA molecules require special packaging to enable them to reside within cells because the molecules are so

large. In *E. coli*, the circular DNA is supercoiled and attached to an RNA-protein core. Recall that DNA consists of a double helix, with the two strands of DNA wrapping around each other to form a helical structure. In order to compact, the DNA molecule coils about itself to form a structure called a supercoil. A telephone cord, which connects the handpiece to the ancient landline phone, displays supercoiling when the coiled cord wraps about itself. When the strands of a DNA molecule separate and unwind over a small local region (which occurs during DNA replication), supercoils are introduced into the remaining portion of the molecule, thereby increasing stress on this portion of the molecule. Enzymes known as topoisomerases relieve this stress so that unwinding of the DNA strands can occur. This will be discussed in greater detail in Chapter 12.

Packaging of eukaryotic DNA is much more complex than that of prokaryotic DNA because eukaryotic DNA is larger and must be contained within the nucleus of the cell. Eukaryotic DNA binds to an equal weight of **histones**, which are small basic proteins containing large amounts of arginine and lysine. The complex of DNA and proteins is called **chromatin**. The organization of eukaryotic DNA into chromatin is essential for controlling transcription as well as for packaging. When chromatin is extracted from cells, it has the appearance of beads on a string (Fig. 11.12). The beads with DNA protruding from each end are known as **nucleosomes**, and the beads themselves are known as nucleosome cores (Fig. 11.13). Two molecules of each of four histone classes (histones H2A, H2B, H3, and H4) form the center of the core around which approximately 140 bp of double-stranded DNA are wound. The DNA wrapped around the nucleosome core is continuous and joins one nucleosome core to the next. The DNA joining the cores is complexed with the fifth type of histone, H1. Further compaction of chromatin occurs as the strings of nucleosomes wind into helical tubular coils called **solenoid** structures.

FIGURE 11.12 Chromatin showing “beads on a string” structure.

FIGURE 11.13 A polynucleosome, indicating the histone cores and linker DNA. The DNA is depicted in *blue*, whereas the histones are depicted as *light brown spheres*.

Although complexes of DNA and histones form the nucleosomal substructures of chromatin, other types of proteins are also associated with DNA in the nucleus. These proteins were given the unimaginative name of “nonhistone chromosomal proteins.” The cells of different tissues contain different amounts and types of these proteins, which include enzymes that act on DNA and factors that regulate transcription.

If histones contain large amounts of arginine and lysine, will their net charge be positive or negative?

C. The Human Genome

The **genome**, or total genetic content, of a human **haploid** cell (a sperm or an egg) is distributed in 23 chromosomes. Haploid cells contain one copy of each chromosome. The haploid **egg** and haploid sperm cells combine to form the **diploid** zygote, which continues to divide to form our other cells (mitosis), also diploid. Thus, in diploid cells, there are 22 pairs of **autosomal chromosomes**, with each pair composed of two **homologous chromosomes** containing a similar series of genes (Fig. 11.14). In addition to the autosomal chromosomes, each diploid cell has two **sex chromosomes**, designated X and Y. A female has two X chromosomes, and a male has one X and one Y chromosome. The total number of chromosomes per diploid cell is 46.

FIGURE 11.14 Human chromosomes from a male diploid cell. Each diploid cell contains 22 pairs of autosomes (the numbered chromosomes 1 through 22) plus one X and one Y. Each female diploid cell contains two X chromosomes. Each haploid cell contains chromosomes 1 through 22 plus either an X or a Y. (Reprinted with permission from Gelehrter TD, Collins FS, Ginsburg D. *Principles of Medical Genetics*. 2nd ed. Williams & Wilkins; 1998:18.)

At physiologic pH, arginine and lysine carry positive charges on their side chains; therefore, histones have a net positive charge. The arginine and lysine residues are clustered in regions of the histone molecules. These positively charged regions of the histones interact with the negatively charged DNA phosphate groups.

Genes are arranged linearly along each chromosome. A **gene**, in genetic terms, is the fundamental unit of heredity. In structural terms, a gene encompasses the DNA sequence that encodes the structural components of the gene product (whether it be a polypeptide chain or RNA molecule) along with the DNA sequences adjacent to the 5'-end of the gene that regulates its expression. A **genetic locus** is a specific position or location on a chromosome. Each gene on a chromosome in a diploid cell is matched by an alternate version of the gene at the same genetic locus on the homologous chromosome (Fig. 11.15). These alternate versions of a gene are called **alleles**. We thus have two alleles of each gene, one from our mother and one from our father. If the alleles are

identical in base sequence, we are homozygous for this gene. If the alleles differ, we are heterozygous for this gene and may produce two versions of the encoded protein that differ somewhat in primary structure.

FIGURE 11.15 Homologous chromosomes and their protein products. A set of homologous chromosomes is shown diagrammatically. (Of course, during interphase, when they are producing their protein products, they cannot be visualized as discrete entities.) Four genes are shown as examples on each homolog. The genes of the homologs are alleles (e.g., *AA*, *Bb*, *CC*, *dD*). They may be identical (e.g., *AA*, *CC*), or they may differ (e.g., *Bb*, *dD*) in DNA sequence. Thus, the corresponding protein products may be identical, or they may differ in amino acid sequence.

 **Will S.** has sickle cell anemia (see Chapters 6 and 7). He has two alleles for the β -globin gene that both generate the mutated form of hemoglobin, HbS. His younger sister Amanda, a carrier for sickle cell trait, has one normal allele (which produces HbA) and one that produces HbS. A carrier would theoretically be expected to produce HbA:HbS in a 50:50 ratio. However, what is generally seen in electrophoresis is 60:40 ratio of HbA:HbS. Dramatic deviations from this ratio imply the occurrence of an additional hemoglobin mutation (e.g., thalassemia).

The genomes of prokaryotic and eukaryotic cells differ in size. The genome of the bacterium *E. coli* contains approximately 3,000 genes. All of this bacterial DNA has a function; it either codes for proteins, rRNA, and tRNA, or serves to regulate the synthesis of these gene products. In contrast, the genome of the human haploid cell contains between 20,000 and 25,000 genes, about seven to eight times the number in *E. coli*. The function of most of this extra DNA has not been determined (an issue considered in more detail in Chapter 13).

 **Clark T.**'s original benign adenomatous polyp was located in the ascending colon. Because his father died of cancer of the colon, his physician had warned him that his risk for developing colon cancer was two to three times higher than for the general population. Unfortunately, **Clark T.** neglected to have a repeat colonoscopic examination after 3 years as recommended, and he developed an adenocarcinoma that metastasized.

Clark T. is being treated with several chemotherapy agents, including 5-fluorouracil (5-FU), a pyrimidine base similar to uracil and thymine. 5-FU inhibits the synthesis of the thymine nucleotides required for DNA replication. Thymine is normally produced by a reaction catalyzed by thymidylate synthase, an enzyme that converts deoxyuridine monophosphate (dUMP) to deoxythymidine monophosphate (dTMP). 5-FU is converted in the body to 5-FdUMP, which binds tightly to thymidylate synthase in a transition-state complex and inhibits the reaction (recall that thymine is 5-methyluracil). Thus, thymine nucleotides cannot be generated for DNA synthesis, and the rate of cell proliferation decreases.

5-Fluorouracil (5-FU), an analog of uracil or thymine

III. Structure of RNA

A. General Features of RNA

RNA is similar to DNA. Like DNA, it is composed of nucleotides joined by 3'- to 5'-phosphodiester bonds, the purine bases adenine and guanine, and the pyrimidine base cytosine. However, its other pyrimidine base is uracil rather than thymine. Uracil and thymine are identical bases except that thymine has a methyl group at position 5 of the ring (Fig. 11.16). In RNA, the sugar is ribose, which contains a hydroxyl group on the 2'-carbon (see Fig. 11.2; the prime refers to the position on the ribose ring). As indicated previously, the presence of the 2'-hydroxyl is what renders RNA susceptible to alkaline hydrolysis.

A**Uracil (U)**
(in RNA)**Thymine (T)**
(in DNA)**B****FIGURE 11.16** **A.** Comparison of the structures of uracil and thymine. They differ in structure only by a methyl group, shown in the yellow box. **B.** A uracil–adenine base pair in RNA.

RNA chains are usually single stranded and lack the continuous helical structure of double-stranded DNA. However, RNA still has considerable secondary and tertiary structure because bp can form in regions where the strand loops back on itself. As in DNA, pairing between the bases is complementary and antiparallel. But in RNA, adenine pairs with uracil rather than thymine (see Fig. 11.16B). Base pairing in RNA can be extensive, and the irregular looped structures that are generated are important for the binding of molecules, such as enzymes, that interact with specific regions of the RNA.

The three major types of RNA (mRNA, rRNA, and tRNA) participate directly in the process of protein synthesis. Other, less abundant RNAs are involved in replication or the processing of RNA, that is, in the

conversion of RNA precursors to their mature forms, or destruction of existing RNA molecules (see Chapter 16). Other forms of RNA are involved in gene regulation (such as micro RNAs; see Chapter 15).

Some RNA molecules are capable of catalyzing reactions. Thus, RNA, as well as protein, can have enzymatic activity. Certain rRNA precursors can remove internal segments of themselves, splicing the remaining fragments together. Because this RNA is changed by the reaction that it catalyzes, it is not truly an enzyme and therefore has been termed a **ribozyme**. Other RNAs act as true catalysts, serving as ribonucleases that cleave other RNA molecules or as a peptidyl transferase, the enzyme in protein synthesis that catalyzes the formation of peptide bonds.

B. Structure of mRNA

Each mRNA molecule contains a nucleotide sequence that is converted into the amino acid sequence of a polypeptide chain in the process of translation. In eukaryotes, mRNA is transcribed from protein-coding genes as a long primary transcript that is processed in the nucleus to form mRNA. The various processing intermediates, which are mRNA precursors, are called pre-mRNA or hnRNA (**heterogenous nuclear RNA**). mRNA travels through nuclear pores to the cytoplasm, where it binds to ribosomes and tRNAs and directs the sequential insertion of the appropriate amino acids into a polypeptide chain.

Eukaryotic mRNA consists of a leader sequence at the 5'-end, a coding region, and a trailer sequence at the 3'-end (Fig. 11.17). The leader sequence begins with a guanosine cap structure at its 5'-end. The coding region begins with a trinucleotide start codon that signals the beginning of translation, followed by the trinucleotide codons for amino acids, and ends at a termination signal. The trailer sequence terminates at its 3'-end with a poly(A) tail that may be up to 200 nucleotides long. Most of the leader sequence, all of the coding region, and most of the trailer are formed by transcription of the complementary nucleotide sequence in DNA. However, the terminal guanosine in the cap structure and the poly(A) tail do not have complementary sequences; they are added after transcription has been completed (posttranscriptionally).

FIGURE 11.17 The regions of eukaryotic mRNA. The wavy line indicates the polynucleotide chain of the mRNA and the As comprise the poly(A) tail. The 5'-cap consists of a guanosine residue linked at its 5'-hydroxyl group to three phosphates, which are linked to the 5'-hydroxyl group of the next nucleotide in the RNA chain (a 5'-5' triphosphate linkage). The start and stop codons represent where protein synthesis is initiated and terminated from this mRNA.

C. Structure of rRNA

Ribosomes are subcellular ribonucleoprotein complexes on which protein synthesis occurs. Different types of ribosomes are found in prokaryotes and in the cytoplasm and mitochondria of eukaryotic cells (Fig. 11.18). Prokaryotic ribosomes contain three types of rRNA molecules with sedimentation coefficients of 16S, 23S, and 5S. A sedimentation coefficient is a measure of the rate of sedimentation of a macromolecule in a high-speed centrifuge (ultracentrifuge). The units of sedimentation are expressed in Svedberg units (S). The 30S ribosomal subunit contains the 16S rRNA complexed with proteins, and the 50S ribosomal subunit contains the 23S and 5S rRNAs complexed with proteins. The 30S and 50S ribosomal subunits join to form the 70S ribosome, which participates in protein synthesis. Although larger macromolecules generally have higher sedimentation coefficients than do smaller macromolecules, sedimentation coefficients are not additive. Because frictional forces acting on the surface of a macromolecule slow its migration through the solvent, the rate of sedimentation depends not only on the density of the macromolecule but also on its shape.

Prokaryotes

Eukaryotes

FIGURE 11.18 Comparison of prokaryotic and eukaryotic ribosomes. The cytoplasmic ribosomes of eukaryotes are shown. Mitochondrial ribosomes are similar to prokaryotic ribosomes, but they are smaller (55S rather than 70S). rRNA, ribosomal RNA.

Cytoplasmic ribosomes in eukaryotes contain four types of rRNA molecules of 18S, 28S, 5S, and 5.8S. The 40S ribosomal subunit contains the 18S rRNA complexed with proteins, and the 60S ribosomal subunit contains the 28S, 5S, and 5.8S rRNAs complexed with proteins. In the cytoplasm, the 40S and 60S ribosomal subunits combine to form the 80S ribosomes that participate in protein synthesis.

Mitochondrial ribosomes, with a sedimentation coefficient of 55S, are smaller than cytoplasmic ribosomes. Their properties are similar to those of the 70S ribosomes of bacteria.

rRNAs contain many loops and exhibit extensive base pairing in the regions between the loops. The sequences of the rRNAs of the smaller ribosomal subunits exhibit secondary structures that are common to many different species.

D. Structure of tRNA

During protein synthesis, **tRNA** molecules carry amino acids to ribosomes and ensure that they are incorporated into the appropriate positions in the growing polypeptide chain. This is done through base pairing in an antiparallel manner of three bases of the tRNA (the anticodon) with the three base codons within the coding region of the mRNA. Therefore, cells contain at least 20 different tRNA molecules that differ somewhat in nucleotide sequence, one for each of the amino acids found in proteins. Many amino acids have more than one tRNA.

tRNA molecules contain not only the usual nucleotides but also derivatives of these nucleotides that are produced by posttranscriptional modifications. In eukaryotic cells, 10% to 20% of the nucleotides of tRNA are modified. Most tRNA molecules contain ribothymidine (rT), in which a methyl group is added to uridine to form ribothymidine. They also contain dihydrouridine (D), in which one of the double bonds of the base is reduced; and pseudouridine (ψ), in which uracil is attached to ribose by a carbon–carbon bond rather than a nitrogen–carbon bond (see Chapter 13). The base at the 5'-end of the anticodon of tRNA is also frequently modified.

Azithromycin, the antibiotic used to treat **Paul T.**, inhibits protein synthesis on prokaryotic ribosomes but not on eukaryotic ribosomes. It binds to the 50S ribosomal subunit, which is absent in eukaryotes. Therefore, it will selectively inhibit bacterial growth. However, because mitochondrial ribosomes are similar to those of bacteria, mitochondrial protein synthesis can also be inhibited. This fact is important in understanding some of the side effects of antibiotics that work by inhibiting bacterial protein synthesis.

tRNA molecules are rather small compared with both mRNA and the large rRNA molecules. On average, tRNA molecules contain about 80 nucleotides and have a sedimentation coefficient of 4S. Because of their small size and high content of modified nucleotides, tRNAs were the first nucleic acids to be sequenced. Since 1965 when Robert Holley deduced the structure of the first tRNA, the nucleotide sequences of many different tRNAs have been determined. Although their primary sequences differ, all tRNA molecules can form a structure resembling a cloverleaf (discussed in more detail in Chapter 13).

E. Other Types of RNA

In addition to the three major types of RNA described above, other RNAs are present in cells. These RNAs include the **oligonucleotides** that serve as primers for DNA replication and the RNAs in the **small nuclear ribonucleoproteins** (snRNPs or snurps) that are involved in the splicing and modification reactions that occur during the maturation of RNA precursors (see Chapter 13). Also included are **microRNAs**, which participate in the regulation of gene expression (see Chapters 15 and 17).

CLINICAL COMMENTS

Isabel S.'s infection with HIV was from needles contaminated with HIV. Without treatment, her HIV will progress and will result in the development of AIDS (acquired immunodeficiency syndrome). The progressive immunologic deterioration that accompanies this disease ultimately results in life-threatening opportunistic

infections with fungi (e.g., *Candida*, *Cryptococcus*, *Pneumocystis jirovecii* [formerly known as *Pneumocystis carinii*]), other viruses (e.g., cytomegalovirus, herpes simplex), and bacteria (e.g., *Mycobacterium* and *Salmonella*). The immunologic incompetence also frequently results in the development of certain neoplasms (e.g., Kaposi sarcoma, non-Hodgkin lymphoma) as well as meningitis, neuropathies, and neuropsychiatric disorders causing cognitive dysfunction. Although recent advances in drug therapy can slow or stop the course of the disease, no cure is yet available.

Clark T. tolerated his first course of chemotherapy with only mild anorexia and diarrhea and with only a mild leukopenia (a decreased white blood cell count; leuko = white). Two weeks later he received his second course.

Because 5-fluorouracil (5-FU) inhibits the synthesis of thymine, DNA synthesis is affected in all cells that are rapidly dividing in the human body, such as the cells in the bone marrow that produce leukocytes and the mucosal cells lining the intestines. Inhibition of DNA synthesis in rapidly dividing cells contributes to the side effects of 5-FU and many other chemotherapeutic drugs.

Clark T.'s original benign adenomatous polyp was located on the right side of the colon, which is less common than the left side, but is increasing in incidence. Because his father died from cancer of the colon, his physician had warned him that his risk for developing colon cancer was two to three times higher than for the general population. Unfortunately, **Clark T.** neglected to have his annual colonoscopic examinations as prescribed, and he developed an adenocarcinoma that metastasized.

The most malignant characteristic of neoplasms is their ability to metastasize, that is, form a new neoplasm at a noncontiguous site. The initial site of metastasis for a tumor is usually at the first capillary bed encountered by the malignant cells once they are released. Thus, cells from tumors of the gastrointestinal tract often pass through the portal vein to the liver, which is **Clark T.**'s site of metastasis. Because his adenocarcinoma has metastasized, there is less chance of eradicating it, and his therapy with 5-FU and other chemotherapy agents is mostly palliative (directed toward reducing the severity of the disease and alleviating the symptoms without actually curing the disease).

5-FU containing creams are often prescribed by dermatologists for the treatment of sun-damaged skin, which can lead to actinic keratosis and basal cell carcinomas. Daily application of the cream for 3 to 4 weeks results in peeling and death of the precancerous cells, which are replaced by healthy skin cells.

Paul T.'s infection was treated with azithromycin, a macrolide antibiotic. Because this agent can inhibit mitochondrial protein synthesis in eukaryotic cells, it has the potential to alter host-cell function, leading to side effects such as epigastric distress, diarrhea, and, infrequently, cholestatic jaundice.

BIOCHEMICAL COMMENTS

Retroviruses. RNA also serves as the genome for certain types of viruses, including retroviruses. HIV, the human immunodeficiency virus, is an example of a retrovirus (Fig. 11.19). Viruses must invade host cells to reproduce. They are not capable of reproducing independently. Some viruses that are pathogenic to humans contain DNA as their genetic material. Others contain RNA as their genetic material. HIV invades cells of the immune system and prevents the affected individual from mounting an adequate immune response to combat infections.

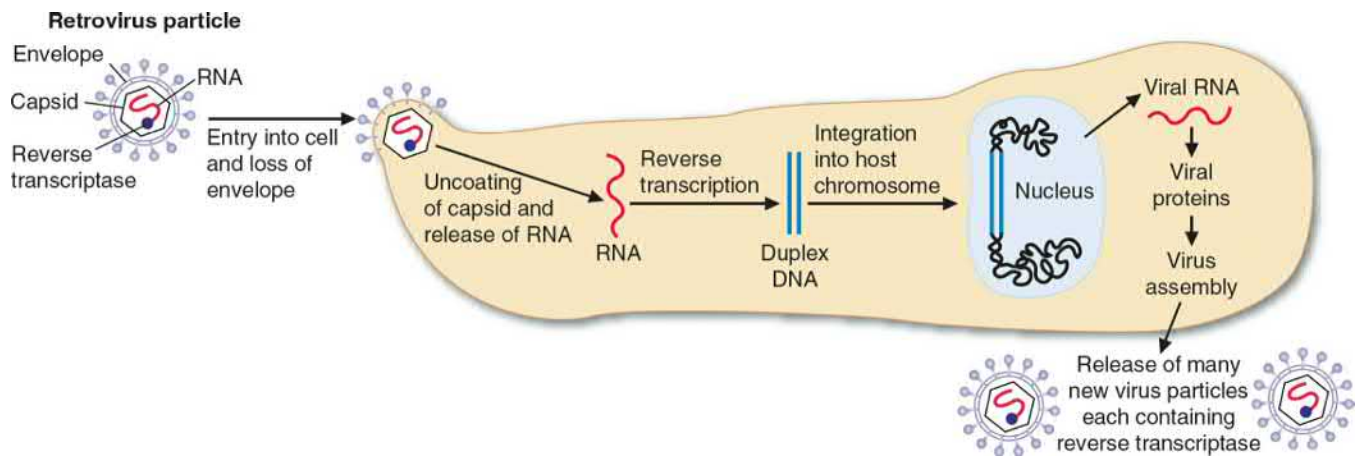

FIGURE 11.19 The life cycle of a retrovirus. The virus contains two identical RNA strands, only one of which is shown for clarity. After penetrating the plasma membrane, the single-stranded viral RNA genome is reverse-transcribed to a double-stranded DNA form. The viral DNA migrates to the nucleus and integrates into the chromosomal DNA, where it is transcribed to form a viral RNA transcript. The viral transcript can form the viral RNA genome for progeny viruses, or it can be translated to generate viral structural proteins.

According to the “central dogma” proposed by Francis Crick, information flows from DNA to RNA to proteins. For the most part, this concept holds true. However, retroviruses provide one violation of this rule. When retroviruses invade cells, their RNA genome is transcribed to produce a DNA copy. The enzyme that catalyzes this process is encoded in the viral RNA and is known as reverse transcriptase. This DNA copy integrates into the genome of the infected cell, and enzymes of the host cell are used to produce many copies of the viral RNA, as well as viral proteins, which can be packaged into new viral particles.

KEY CONCEPTS

- ◆ The central dogma of molecular biology is that DNA is transcribed to RNA, which is translated to protein.
- ◆ Nucleotides, consisting of a nitrogenous base, a five-carbon sugar, and phosphate, are the monomeric units of the nucleic acids, DNA and RNA (see Chapter 5).
- ◆ DNA contains the sugar 2'-deoxyribose; RNA contains ribose.
- ◆ DNA and RNA contain the purine bases adenine (A) and guanine (G).
- ◆ DNA contains the pyrimidine bases cytosine (C) and thymine (T), whereas RNA contains C and uracil (U).
- ◆ DNA and RNA are linear sequences of nucleotides linked by phosphodiester bonds between the 3'-sugar of one nucleotide and the 5'-sugar of the next nucleotide.
- ◆ Genetic information is encoded by the sequence of the nucleotide bases in DNA.
- ◆ DNA is double stranded; one strand runs in the 5'-to-3' direction, whereas the other is antiparallel and runs in the 3'-to-5' direction.
- ◆ The two strands of DNA wrap about each other to form a double helix and are held together by hydrogen bonding between bases in each strand and hydrophobic interactions between the stacked bases in the core of the molecule.
- ◆ The base adenine hydrogen bonds to thymine, whereas cytosine hydrogen bonds to guanine.
- ◆ Transcription of a gene generates a single-stranded RNA; the three major types of RNA are mRNA, rRNA, and tRNA.
- ◆ Eukaryotic mRNA is modified at both the 5'- and 3'-ends. In between, it contains a coding region for the synthesis of a protein.
- ◆ Codons within the coding region dictate the sequence of amino acids in a protein. Each codon is three nucleotides long.
- ◆ rRNA and tRNA are required for protein synthesis.
 - ◆ rRNA is complexed with proteins to form ribonucleoprotein particles called ribosomes, which bind mRNA and tRNAs during translation.
 - ◆ The tRNA contains an anticodon that binds to a complementary codon on mRNA, ensuring insertion of the correct amino acid into the protein being synthesized.

◆ The diseases discussed in this chapter are summarized in Table 11.2.

TABLE 11.2 Diseases Discussed in Chapter 11

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
Acquired immunodeficiency syndrome (AIDS)	Environmental	AIDS is owing to infection by the human immunodeficiency virus (HIV), a retrovirus containing an RNA genome. Through its growth in immune cells, active infection by the virus leads to an immunocompromised state. Nucleoside analogs are one class of drugs used to treat those with HIV infections.
Adenocarcinoma	Both	Use of nucleotide analogs as chemotherapeutic agents. Specifically, 5-fluorouracil is used to inhibit deoxythymidine monophosphate (dTMP) synthesis by the enzyme thymidylate synthase, which will lead to the death of rapidly proliferating cells.
Pneumonia	Environmental	A bacteria-induced illness in the lungs, leading to fever and cough. Treated with antibiotics. Certain antibiotics target bacterial protein synthesis but may also inhibit mitochondrial protein synthesis.

REVIEW QUESTIONS—CHAPTER 11

Directions: For each question below, select the single best answer.

1. Viruses cause many human infections such as hepatitis, encephalitis, COVID-19, and the “common cold.” Which one of the following is a common trait of all these viruses?
 - A. They are small, circular DNA molecules that enter bacteria and replicate outside the host genome.
 - B. Upon infecting eukaryotic cells, they are called phages.
 - C. All the common cold viruses contain both DNA and RNA genomes.
 - D. In order to reproduce, they must use the infected cell’s DNA, RNA, and protein-synthesizing machinery.
 - E. Upon becoming infectious, they are called plasmids.
2. Many drugs used to treat cancers inhibit DNA replication, whereas some will inhibit the pathways required to synthesize proteins from certain genes. Which one of the following accurately describes a step leading from DNA replication to the synthesis of a protein?
 - A. Translation of a gene generates a single-stranded RNA that is complementary to both strands of the DNA.
 - B. Transcription of a gene generates a single-stranded RNA that is complementary to one of the DNA strands.
 - C. tRNA encodes the proteins during translation.
 - D. mRNA encodes the proteins during transcription.
 - E. rRNA encodes the proteins during transcription.
3. Gout is caused by the deposition of urate crystals in the joints and kidneys. Purines are metabolized to uric acid whereas pyrimidines, when metabolized, do not generate uric acid. Which one of the following should be restricted in the diet of a patient with gout?
 - A. Cytosine
 - B. Guanine
 - C. Thymine
 - D. Uracil
 - E. Deoxyribose
4. A patient has microcytic, hypochromic anemia. To ascertain the cause of the anemia the patient’s hemoglobin was isolated, and it was determined that there was much more β -chain present than α -chain, indicating an α -thalassemia. To determine the genetic basis of the thalassemia, nucleic acids were isolated from the blood of the patient. During the procedure of isolating the nucleic acids, both heat and alkali

- treatment were required. The alkali and heat were included owing to which one of the following?
- Alkali causes the two strands of DNA and RNA to separate.
 - Heat causes the two strands of DNA and RNA to separate.
 - Alkali cleaves the phosphodiester bonds of DNA and RNA degrading them to nucleotides.
 - Alkali separates the strands of DNA and degrades RNA to nucleotides.
 - Alkali separates the strands of RNA and degrades DNA to nucleotides.
- Targeting certain structural features of eukaryotic mRNA can result in an inhibition of protein synthesis. Which one of the following describes a unique aspect of eukaryotic mRNA?
 - A polyguanosine tail is found at the 3'-end.
 - The 5'-end begins with a leader sequence that contains an adenine cap.
 - The cap and tail of the mRNA are added posttranscriptionally.
 - The leader sequence contains a guanosine cap at the 3'-end of the mRNA.
 - The poly(A) tail is found at the 3'-end of the mRNA.
 - Some chemotherapeutic drugs alter the ability of DNA polymerase to faithfully replicate. For the DNA sequence, 5'-ATCGATCGATCGATCG-3', which one of the following represents the sequence and polarity of the complementary strand?
 - 5'-ATCTATCGATCGATCG-3'
 - 3'-ATCGATCGATCGATCG-5'
 - 5'-CGAUCGAUCAUCGAU-3'
 - 5'-CGATCGATCGATCGAT-3'
 - 3'-CGATCGATCGATCGAT-5'
 - Certain drugs inhibit bacterial RNA synthesis. If the DNA strand, 5'-GCTATGCATCGTGATCGAATTGCGT-3', serves as a template for the synthesis of RNA, which one of the following choices gives the sequence and polarity of the newly synthesized RNA?
 - 5'-ACGCAATTCGATCACGATGCATAGC-3'
 - 5'-UGCGUUAAGCUAGUGCUACGUAUCG-3'
 - 5'-ACGCAAUUCGAUCACGAUGCAUAGC-3'
 - 5'-CGAUACGUAGCACUAGCUUAACGCA-3'
 - 5'-GCTATGCATCGTGATCGAATTGCGT-3'
 - Understanding the structure of DNA, and the process of replication, enabled various drugs to be developed, which interfered with DNA replication. In DNA, the bond between the deoxyribose sugar and the phosphate is best described by which one of the following?
 - A polar bond
 - An ionic bond
 - A hydrogen bond
 - A covalent bond
 - A van der Waals bond
 - Certain drugs can intercalate between DNA bases and alter the backbone of the DNA. The backbone of a DNA strand is composed of which of the following? Choose the one best answer.
 - Phosphates and sugars
 - Bases and phosphates
 - Nucleotides and sugars
 - Phosphates and nucleosides
 - Sugars and bases
 - Analysis of one strand of a double-stranded piece of DNA displayed 20 mol % A, 25 mol % T, 30 mol % G, and 25 mol % C. Which one of the following accurately represents the composition of the complementary strand?
 - [A] is 25 mol %, [T] is 20 mol %, [G] is 25 mol %, and [C] is 30 mol %.
 - [A] is 25 mol %, [U] is 20 mol %, [G] is 25 mol %, and [C] is 30 mol %.
 - [U] is 25 mol %, [T] is 20 mol %, [G] is 25 mol %, and [C] is 30 mol %.
 - [A] is 25 mol %, [T] is 25 mol %, [G] is 25 mol %, and [C] is 25 mol %.
 - The composition of the complementary strand cannot be determined from the data given.
 - Eukaryotic DNA is a tightly condensed structure within the nucleus, complexed with histones and non-histone chromosome-associated proteins. The overall structure can be modified by acetylation of lysine side chains on histones. Such modifications would be expected to accomplish which one of the following?
 - Stabilize the existing chromosomal structure through ionic interactions.

- B. Destabilize the existing chromosomal structure through a reduction in ionic interactions.
 - C. Stabilize the existing chromosomal structure through increased hydrogen bond formation.
 - D. Destabilize the existing chromosomal structure owing to a reduction in hydrogen bond formation.
 - E. Stabilize the existing chromosomal structure owing to an increase in hydrophobic interactions.
 - F. Destabilize the existing chromosomal structure as a result of a decrease in hydrophobic interactions.
2. Ribonucleotides have the capacity to form three phosphodiester bonds, whereas deoxyribonucleotides can only form 2 phosphodiester bonds. The carbons that can form phosphodiester bonds in a ribonucleotide include which of the following?
 - A. 1', 2', and 3'
 - B. 2', 3', and 4'
 - C. 3', 4', and 5'
 - D. 2', 3', and 5'
 - E. 1', 3', and 5'
 3. The formation of a DNA double helix generates grooves in the DNA structure through which proteins can bind to the DNA in a DNA base sequence-specific manner. The interaction between the proteins and the DNA occurs through which one of the following?
 - A. Base pairing between the amino acid side chains and the bases in DNA
 - B. Hydrophobic interactions between amino acid side chains and deoxyribose
 - C. Ionic interactions between amino acid side chains and the phosphates in the phosphodiester bonds
 - D. Hydrogen bonds between the amino acid side chains and the bases in DNA
 - E. Hydrogen bonds between the amide hydrogen and carbonyl group of the peptide bonds in the protein and the bases in DNA
 4. Posttranscriptional modifications of RNA have important biologic roles. Which one of the following is an example of such a posttranscriptional event?
 - A. The formation of A:U hydrogen bonds in the RNA structure
 - B. The formation of A:T hydrogen bonds in the RNA structure
 - C. The inclusion of thymine bases in the RNA structure
 - D. The generation of phosphodiester bonds in the RNA
 - E. The generation of a stop codon in messenger RNA
 5. The use of dideoxynucleotides as a treatment of HIV infection has proven to be efficacious. One reason that such agents do not interfere with the synthesis of RNA in normal cells is which one of the following?
 - A. Dideoxynucleotides would not block phosphodiester bond formation in RNA synthesis.
 - B. The lack of a 2'-hydroxyl group
 - C. The lack of a 3'-hydroxyl group
 - D. Only reverse transcriptase will recognize dideoxynucleotides as a substrate.
 - E. All dideoxyribonucleotides are based on zidovudine, which is a thymine analog, and thymine is not found in RNA.

ANSWERS TO REVIEW QUESTIONS

1. **The answer is D.** Viruses consist of either a DNA or RNA genome but not both. All the viruses that cause the common cold are RNA viruses. When viruses infect bacteria (prokaryotes), they are called bacteriophages or phages. Plasmids are not viruses and are not infectious. Plasmids are small, circular DNA molecules that can replicate autonomously whereas viruses cannot and must utilize the host cell's DNA, RNA, and protein-synthesizing machinery.
2. **The answer is B.** rRNA and tRNA are part of the apparatus for protein synthesis, but the sequences of rRNA and tRNA do not encode proteins. mRNA carries the genetic information that is converted into the amino acid sequence of a protein, but that is used in the process of translation. Transcription of a gene from DNA generates RNA that is complementary to only one strand of DNA.
3. **The answer is B.** Adenine and guanine are purines, which form urate during their metabolism. Cytosine, thymine, and uracil are pyrimidines that follow different metabolic pathways and do not form uric acid. Deoxyribose is a component of DNA, but it is a sugar, and not a purine base, and is not converted to uric acid.
4. **The answer is D.** Both alkali and heat cause the two strands of DNA to separate. Alkali does not break the phosphodiester bonds of DNA but does cleave the phosphodiester bonds of RNA, degrading RNA to

nucleotides. RNA is single stranded, not double stranded. In the analysis of DNA, many techniques call for its separation from RNA (the alkali treatment) and its denaturation (separation of the double strands).

5. **The answer is E.** The leader sequence begins with a N^7 -methyl guanosine cap at the 5'-end of the mRNA. The coding region of the mRNA then follows. The 3'-end of the mRNA contains a polyadenine tail that aids in the stability of the mRNA. The tail of the mRNA is added after transcription of the mRNA, whereas the cap can be added before transcription has been completed.
6. **The answer is D.** The complementary strand must run in the opposite direction, so the 5'-end must base-pair with the G at the 3'-end of the given strand. Therefore, the 5'-end of the complementary strand must be C. G would then base-pair to C, A to T, and T to A. B is incorrect because the bases do not base-pair with each other with the sequences indicated, C is incorrect because U is not found in DNA, and E is incorrect because it has the wrong polarity (the 5'-T in answer E would not base-pair with the 3'-G in the given sequence).
7. **The answer is C.** The RNA strand must be complementary to the DNA strand, and A in DNA base-pairs with U in RNA, whereas T in DNA base-pairs with A in RNA, G in DNA base-pairs with C in RNA, and C in DNA base-pairs with G in RNA. A and E are incorrect because they contain T, which is found in DNA, not RNA. B is incorrect because the base-pairing rules are broken when the strands are aligned in an antiparallel fashion. D is incorrect because the polarity of the strand is incorrect (if one were to switch the 5'- and 3'-ends, the answer would be correct).
8. **The answer is D.** The phosphate is in an ester bond between two deoxyribose groups, generating the phosphodiester bond in the DNA backbone (these are covalent bonds). None of the other types of bonds is correct.
9. **The answer is A.** The DNA backbone is composed of phosphates and deoxyribose in phosphodiester linkages. The bases are internal to the backbone, base-paired to bases in the complementary strand, and forming stacking interactions within the double helix.
10. **The answer is A.** The base pairs in double-stranded DNA require that $[A] = [T]$, and $[G] = [C]$. Therefore, if the concentration of A in one strand is 20 mol %, the concentration of T in the complementary strand must also be 20 mol %. For the example given, $[A]$ would be 25 mol %, $[T]$ would be 20 mol %, $[G]$ would be 25 mol %, and $[C]$ would be 30 mol %.
11. **The answer is B.** Histones are positively charged proteins that bind to DNA through ionic interactions with the negatively charged phosphate groups in the phosphodiester bonds in the DNA backbone. Acetylation of the lysine side chain removes the positive charge from the side chain and weakens the interactions of the histone with the DNA. This allows for localized relaxation of the condensed DNA structure in the regions of histone acetylation. The acetylation does not lead to a significant increase (or decrease) in hydrogen bond formation, nor is there any appreciable change in hydrophobic interactions between histones and DNA after acetylation.
12. **The answer is D.** When ribose forms its cyclic structure, there are hydroxyl groups on carbons 1, 2, 3, and 5. The hydroxyl group that was on carbon 4 now has its oxygen atom as part of the furanose ring of ribose. When a base is added to a ribose to form a nucleoside it occurs at carbon 1, so there is no free hydroxyl group on carbon 1 when a nucleoside is formed. A ribonucleotide has a phosphate added to carbon 5, along with free hydroxyl groups at carbons 2 and 3. Any of those three hydroxyl groups can participate in phosphodiester bond formation. DNA lacks a hydroxyl group at position 2 of the ribose (forming deoxyribose), which is why deoxyribonucleotides can only form two phosphodiester bonds, at both the 3' and 5' positions.
13. **The answer is D.** A protein binds to DNA through the formation of hydrogen bonds between amino acid side chains (not components of the peptide bond) of the protein and the bases in the DNA. The side chains have access to the bases through one of the grooves in the DNA (usually the major groove). Proteins do not contain nitrogenous bases, so proteins do not base-pair with the DNA. There would be no specificity of binding if the amino acid side chains of the protein formed ionic interactions with the phosphates of DNA because the backbone of DNA has many phosphates that are not present in a sequence-specific manner. Deoxyribose is hydrophilic and would not form hydrophobic interactions with amino acid side chains.
14. **The answer is C.** During the synthesis of RNA uracil is placed into the RNA, and after transcription, certain uracil bases are converted to thymine bases via a methylation reaction. The formation of RNA secondary structure (looping requiring base pairing between A and U bases, along with C and G bases) does not require posttranscriptional modifications to the RNA structure. Phosphodiester bonds are formed when RNA is synthesized, so it is not a posttranscriptional event. The stop codon is generated by

transcription and is not added after transcription has been completed.

15. **The answer is B.** RNA polymerase recognizes substrates that contain a hydroxyl group at the 2' carbon of ribose, whereas DNA polymerase recognizes substrates lacking a hydroxyl group at the 2' carbon of ribose. Because dideoxynucleotides lack hydroxyl groups at the 2' carbon, only DNA polymerase will recognize them as a substrate and RNA polymerase will not utilize them. Dideoxynucleotides exist for all four bases (not just thymine). Normal cellular DNA polymerases will recognize dideoxynucleotides as substrates, although at a lower affinity than does reverse transcriptase.

SECTION

III

Gene Expression and the Synthesis of Proteins

In the middle of the 20th century, DNA was identified as the genetic material and its structure was determined. Using this knowledge, researchers then discovered the mechanisms by which genetic information is inherited and expressed. During the last quarter of the 20th century, our understanding of this critical area of science, known as molecular biology, grew at an increasingly rapid pace. We now have techniques to probe the human genome that will completely revolutionize the way medicine is practiced in the 21st century.

Many drugs used in medicine to treat bacterial infections are targeted to interfere with the bacteria's ability to synthesize RNA and proteins. Thus, medical students need to know the basics of bacterial DNA replication, RNA synthesis, and protein synthesis to understand the mechanism of action of these drugs.

The genome of a cell consists of all its genetic information, encoded in DNA (**d**eoxyribo**n**ucleic **a**cid). In eukaryotes, DNA is located mainly in nuclei, but small amounts are also found in mitochondria. Nuclear genes are packaged in chromosomes that contain DNA and protein in tightly coiled structures (Chapter 11).

The molecular mechanism of inheritance involves a process known as replication, in which the strands of parental DNA serve as templates for the synthesis of DNA copies (Fig. III.1) (Chapter 12). After DNA replication, cells divide, and these DNA copies are passed to daughter cells. Alterations in genetic material occur by recombination (the exchange of genetic material between chromosomes) and by mutation (the result of chemical changes that alter DNA). DNA repair mechanisms correct much of this damage, but, nevertheless, many gene alterations are passed to daughter cells.

FIGURE III.1 Replication, transcription, and translation. Replication: DNA serves as a template for producing DNA copies. Transcription: DNA serves as a template for the synthesis of RNA. Translation: RNA provides the information for the synthesis of proteins.

The expression of genes within cells requires two processes: transcription and translation (see Fig. III.1) (Chapters 13 and 14). DNA is transcribed to produce ribonucleic acid (RNA). Three major types of RNA are transcribed from DNA and subsequently participate in the process of translation (the synthesis of proteins). Messenger RNA (mRNA) carries the genetic information from the nucleus to the cytoplasm, where translation occurs on ribosomes, structures that contain proteins complexed with ribosomal RNA (rRNA). Transfer RNA (tRNA) carries individual amino acids to the ribosomes, where they are joined in peptide linkage to form proteins. During translation, the sequence of nucleic acid bases in mRNA is read in sets of three (each set of three bases constitutes a codon). The sequence of codons in the mRNA dictates the sequence of amino acids in the protein. Proteins function in cell structure, signaling, and catalysis and, therefore, determine the appearance and behavior of cells and the organism as a whole. The regulation of gene expression (Chapter 15) determines which proteins are synthesized and the amount synthesized at any time, thus allowing cells to undergo development and differentiation and to respond to changing environmental conditions.

 Ethical dilemmas have come together with technological advances in molecular biology. Consider the case of a patient with a mild case of ornithine transcarbamoylase deficiency, a urea-cycle defect that, if untreated, leads to elevated ammonia levels and nervous system dysfunction. The patient was being treated effectively by dietary restriction of protein. However, in 1999, he volunteered to be treated with a common virus carrying the normal gene for ornithine transcarbamoylase. The patient developed a severe immune response to the virus and died as a result of the treatment. This case history raises the issues of appropriate patient consent, appropriate criteria to be included in this type of study, and the types of diseases for which gene therapy is appropriate. These are issues that are still applicable over 20 years after this unfortunate incident, and that you, the student, will be facing as you enter your practice of medicine.

Research in molecular biology has produced a host of techniques, known collectively as recombinant DNA technology, biotechnology, or genetic engineering, that can be used for the diagnosis and treatment of disease (Chapter 16). These techniques can detect a number of genetic diseases that previously could only be diagnosed

after symptoms appeared. Diagnosis of these diseases can now be made with considerable accuracy even before birth, and carriers of these diseases also can be identified.

With recent developments in the field of gene therapy, diseases that for centuries have been considered hopeless are now potentially curable. Much of the therapy for these diseases is currently experimental. However, during the 21st century, physicians may be using genetic engineering techniques routinely for both the diagnosis and treatment of their patients.

Tumors may be benign or malignant. A tumor is malignant if it invades locally or if cells break away from the tumor, enter the blood stream, travel to other parts of the body where they establish new growths (a process called metastasis), resulting in destruction of the tissues they invade. Many of the drugs used to treat malignant tumors are directed toward inhibition of DNA replication. These chemotherapeutic drugs are more toxic to cancer cells than normal cells, because the cancer cells divide more rapidly. However, such drugs also may inhibit normal rapidly dividing cells, such as the cells of the bone marrow (causing a decrease in white blood cell count) or cells in the hair follicles (resulting in hair loss during chemotherapy).

Replication and cell division are highly regulated processes in the human. Cancer is a group of diseases in which a cell in the body has been transformed and begins to grow and divide out of control (Chapter 17). It results from multiple mutations or changes in DNA structure in the genes that activate cell growth, called proto-oncogenes, and those that ensure that DNA replication and repair are normal, called growth-suppressor or tumor-suppressor genes. Mutations that activate proto-oncogenes to oncogenes disturb the regulation of the cell cycle and the rate of cell proliferation. Mutations that disrupt tumor-suppressor genes lead to an increased incidence of these proto-oncogene-activating mutations. Such mutations may be inherited, causing a predisposition to a type of cancer. They also may arise from DNA replication or copying errors that remain uncorrected, from chemicals or radiation that damages DNA, from translocation of pieces of chromosomes from one chromosome to another during replication, or from incorporation of viral-encoded DNA into the genome.

The transmission of DNA from parents to children is studied in the field of Human Genetics (Chapter 18). The transmission of genetically inherited traits may occur through various Mendelian mechanisms (autosomal recessive, autosomal dominant, X-linked recessive, X-linked dominant) or alternative mechanisms (mitochondrial inheritance, genomic imprinting, triplet repeat expansions). Alterations in chromosome number (monosomy or trisomy) or structure (deletions, translocations, insertions) can lead to disease states. The combination of modern molecular techniques (described in Chapter 17) and the study of gene transmission (Chapter 18) opens the possibility of new fields of therapy for diseases that had, until now, been recalcitrant to effective treatments.

Synthesis of DNA

DNA synthesis occurs by the process of **replication**. During replication, each of the two parental strands of DNA serves as a **template** for the synthesis of a complementary strand. Thus, each DNA molecule generated by the replication process contains one intact parental strand and one newly synthesized strand (Fig. 12.1). In eukaryotes, **DNA replication** occurs during the **S phase** of the **cell cycle**, which is followed by the G₂ phase. The cell **divides** during the next phase (**M**), and each daughter cell receives an exact copy of the DNA of the parent cell.

FIGURE 12.1 A replicating DNA helix. The parental strands separate at the replication fork. Each parental strand serves as a template for the synthesis of a new strand.

The Replication Fork. In both prokaryotes and eukaryotes, the site at which replication is occurring at any given moment is called the **replication fork**. As replication proceeds, the two parental strands

separate in front of the fork. Behind the fork, each newly synthesized strand of DNA base-pairs with its complementary parental template strand. A complex of proteins is involved in replication. **Helicases** and **topoisomerases** unwind the parental strands, and **single-strand binding proteins** prevent them from reannealing.

The major enzyme involved in replication is a **DNA polymerase** that copies each parental template strand in the 3'-to-5' direction, producing new strands in a 5'-to-3' direction. **Deoxyribonucleoside triphosphates** serve as the precursors. One strand of newly synthesized DNA grows continuously, whereas the other strand is synthesized discontinuously in short segments known as **Okazaki fragments**. These fragments are subsequently joined by **DNA ligase**.

Initiation. **DNA polymerase cannot initiate** the synthesis of new strands. Therefore, a short **primer** is produced, which contains ribonucleotides (RNA). DNA polymerase can add deoxyribonucleotides to the 3'-end of this primer. This RNA primer is subsequently removed and replaced by deoxyribonucleotides.

Telomeres. The ends of linear chromosomes are called **telomeres**. The enzyme **telomerase**, an RNA-dependent DNA polymerase that carries its own RNA template, is required for their replication.

Errors and Repair. **Errors** that occur **during replication** can lead to deleterious **mutations**. However, many errors are corrected by enzyme activities associated with the complex at the replication fork. The **error rate** is thus kept at a very low level.

Damage to DNA molecules also causes mutations. **Repair mechanisms** correct DNA damage, usually by removing and replacing the damaged region. The intact, undamaged strand serves as a template for the DNA polymerase involved in the repair process.

Recombination. Although cells have mechanisms to correct replication errors and to repair DNA damage, some genetic change is desirable. It produces new proteins or variations of proteins that may increase the survival rate of the species. Genetic change is produced by unrepaired mutations and by a mechanism known as **recombination**, in which portions of chromosomes are exchanged. Recombination can also be used to repair double-strand breaks (DSBs) in DNA.

THE WAITING ROOM

Like many patients, **Isabel S.** is finding it difficult to comply with her treatment regimen, which includes daily medications. She often forgets to take her pills. When she returns for a checkup, she asks if it is that important to take her pills every day for treatment of HIV.

Collection of a patient's urine allows many variables to be examined, including sugar (glucose) levels, creatinine (kidney function) levels, ketone bodies (significant fatty acid oxidation), and crystal or bacterial infiltration. In the case of bacteria, the finding of any bacteria in the urine is unusual, because normal urine is sterile. If large numbers of organisms are seen microscopically and they are accompanied by white blood cells, a urinary tract infection is the diagnosis. In **Dianne A.**'s case, the bacteria were demonstrated to be gram-negative (see Chapter 11), specifically *E. coli*. Typing the bacteria will allow the appropriate antibiotic to be given to cure the infection.

Dianne A. responded to treatment for her diabetes mellitus but subsequently developed a low-grade fever, an increase in urinary urgency and frequency, and burning at the urethral opening with urination (dysuria). A urinalysis showed a large number of white blood cells and many gram-negative bacilli. A urine culture indicated many colonies of *Escherichia coli*, which is sensitive to several antibiotics, including the quinolone ciprofloxacin.

Calvin A. is a 46-year-old man who noted a superficial, brownish-black, 5-mm nodule with irregular borders in the skin on his chest. He was scheduled for outpatient surgery, at which time a wide excision biopsy was

performed such that the complete mole is removed and biopsied. Examination of the nodule revealed histological changes characteristic of a malignant melanoma reaching a thickness of only 0.7 mm (Stage I).

Michael T. is a 62-year-old electrician who has smoked two packs of cigarettes a day for 40 years. He recently noted that his chronic cough had gotten worse. His physician ordered a chest radiograph, which showed a 2-cm nodule in the upper lobe of the right lung. A computed tomography (CT) scan was performed and confirmed a 2-cm nodule very concerning for malignancy. The patient was taken for surgery and the nodule excised. The pathology showed a poorly differentiated adenocarcinoma of the lung. Malignant neoplasms (new growth, a tumor) of epithelial cell origin (including the intestinal lining, cells of the skin, and cells lining the airways of the lungs) are called **carcinomas**. If the cancer grows in a gland-like pattern, it is an **adenocarcinoma**.

I. DNA Synthesis in Prokaryotes

The basic features of the mechanism of DNA replication are illustrated by the processes occurring in the bacterium *E. coli*. This bacillus grows symbiotically in the human colon. It has been extensively studied and serves as a model for the more complex, and consequently less well understood, processes that occur in eukaryotic cells.

A. Bidirectional Replication

Replication of the circular double-stranded DNA of the chromosome of *E. coli* begins with the binding of approximately 30 molecules of the protein DnaA at a single point of origin (known as the origin of replication), designated *oriC*, where the DNA coils around the DnaA core (Fig. 12.2). With the assistance of other proteins (e.g., a helicase, gyrase, and single-stranded binding protein), the two parental strands separate within this region, and both strands are copied simultaneously. Synthesis begins at the origin and occurs at two **replication forks** that move away from the origin bidirectionally (in both directions at the same time). The complex of proteins required for DNA replication is known as the **replisome**. Each replication fork contains its own replisome. Replication ends on the other side of the chromosome at a termination point. One round of synthesis, involving the incorporation of over 4 million nucleotides in each new strand of DNA, is completed in approximately 40 minutes. However, a second round of synthesis can begin at the origin before the first round is finished. These multiple initiations of replication allow bacterial multiplication to occur much more quickly than the time it takes to complete a single round of replication.

Origin of replication

Replication forks

New strands

Parental strands

FIGURE 12.2 Bidirectional replication of a circular chromosome. Replication begins at the point of origin (*oriC*) and proceeds in both directions at the same time. Parental strands are shown in *blue*; newly synthesized strands are shown in *red*.

B. Semiconservative Replication

Each daughter chromosome contains one of the parental DNA strands and one newly synthesized, complementary strand. Therefore, replication is said to be **semiconservative**; that is, the parental strands are conserved but are no longer together. Each one is paired with a newly synthesized strand (see Figs. 12.1 and 12.2).

C. DNA Unwinding

Replication requires separation of the parental DNA strands and unwinding of the helix ahead of the replication fork. **Helicases** (an example of which is the protein DnaB) separate the DNA strands and unwind the parental duplex. Single-strand binding proteins prevent the strands from reassociating and protect them from enzymes that cleave single-stranded DNA (Fig. 12.3). **Topoisomerases**, enzymes that can break phosphodiester bonds and rejoin them, relieve the supercoiling of the parental duplex caused by unwinding. The protein DNA gyrase is a major topoisomerase in bacterial cells.

FIGURE 12.3 Proteins involved in separating and unwinding parental DNA strands at the replication fork in prokaryotes.

D. DNA Polymerase Action

Enzymes that catalyze the synthesis of DNA are known as **DNA polymerases**. *E. coli* has three DNA polymerases: Pol I, Pol II, and Pol III. Pol III is the major replicative enzyme (Table 12.1). All DNA polymerases that have been studied copy a DNA template strand in its 3'-to-5' direction, producing a new strand in the 5'-to-3' direction (Fig. 12.4). Deoxyribonucleoside triphosphates (dATP, dGTP, dCTP, and dTTP)

serve as substrates for the addition of nucleotides to the growing chain.

TABLE 12.1 Functions of Bacterial DNA Polymerases

POLYMERASES	FUNCTIONS ^a	EXONUCLEASE ACTIVITY ^b
Pol I	Filling of gap after removal of RNA primer DNA repair Removal of RNA primer in conjunction with RNase H	5'-to-3' and 3'-to-5'
Pol II	DNA repair	3'-to-5'
Pol III	Replication; synthesis of DNA	3'-to-5'

^aSynthesis of new DNA strands always occurs 5'-to-3'.

^bExonucleases remove nucleotides from the ends of DNA strands, acting either at the 5'-end (cleaving 5'-to-3') or at the 3'-end (cleaving 3'-to-5'). Endonucleases cleave bonds within polynucleotide chains.

FIGURE 12.4 Action of DNA polymerase. Deoxyribonucleoside triphosphates serve as precursors (substrates) used by DNA polymerase to lengthen the DNA chain. DNA polymerase copies the DNA template strand in the 3'-to-5' direction. The new strand grows 5'-to-3'. dGTP, deoxyguanosine triphosphate.

The incoming nucleotide forms a base pair with its complementary nucleotide on the template strand. Then, an ester bond is formed between the first (or α) 5'-phosphate of the incoming nucleotide and the free 3'-hydroxyl group at the end of the growing chain. Pyrophosphate is released. The release of pyrophosphate (formed from the β - and γ -phosphates of the nucleotide) and its subsequent cleavage by a pyrophosphatase provide the energy that drives the polymerization reaction.

Dianne A.'s urinary tract infection was treated with ciprofloxacin, a fluorinated member of the quinolone family. This group of drugs inhibits bacterial DNA gyrase, a topoisomerase that unwinds the closed circular bacterial DNA helix ahead of the replication fork and thus inhibits bacterial DNA synthesis. Because eukaryotic cells utilize a different protein as a topoisomerase and do not contain DNA gyrase, they are not affected by quinolones.

DNA polymerases that catalyze the synthesis of new strands during replication exhibit a feature called **processivity**. They remain bound to the parental template strand while continuing to “process” down the chain rather than dissociating and reassociating as each nucleotide is added. Consequently, synthesis is much more rapid than it would be with an enzyme that was not processive.

E. Base-Pairing Errors

In *E. coli*, the replicative enzyme Pol III also performs a proofreading or editing function. This enzyme has 3'-to-5'-exonuclease activity in addition to its polymerase activity (see Table 12.1). If the nucleotide at the end of the growing chain is incorrectly base-paired with the template strand, Pol III removes this nucleotide before continuing to lengthen the growing chain. This proofreading activity eliminates most base-pairing errors as they occur. Only about one base pair in a million is mismatched in the final DNA product; the error rate is about 10^{-6} . If this proofreading activity is experimentally removed from the enzyme, the error rate increases to about 10^{-3} .

One of the drugs that can be used to treat **Isabel S.** is lamivudine, a nucleotide reverse transcriptase inhibitor (NRTI). It is a dideoxynucleoside, an example of which is shown in the following. For an early generation NRTI, didanosine, the base in the drug is hypoxanthine. For lamivudine, the base is cytosine.

A dideoxynucleoside

The dideoxynucleosides do not have a hydroxyl group on either the 2'- or 3'-carbon. They can be converted to dideoxynucleoside triphosphates in cells and, like zidovudine (ZDV), terminate chain growth when incorporated into DNA. In the case of the dideoxynucleosides, chain termination results from the absence of a hydroxyl group on the 3'-carbon. The HIV mutates very rapidly (mostly because reverse transcriptase lacks 3'-to-5' exonuclease activity, the proofreading activity) and frequently develops resistance to one or more of these drugs. Therefore, it is recommended that patients with HIV take several drugs, including two NRTIs.

After replication, other mechanisms replace mismatched bases that escaped proofreading so that the fidelity of DNA replication is very high. The two processes of proofreading and postreplication mismatch repair result in an overall error rate of about 10^{-10} , that is, <1 mismatched base pair in 10 billion.

F. RNA Primer Requirement

DNA polymerase cannot initiate the synthesis of new strands; it requires the presence of a free 3'-OH group to function. Therefore, a **primer** is required to supply the free 3'-OH group. This primer is an RNA oligonucleotide. It is synthesized in a 5'-to-3' direction by an RNA polymerase (**primase**) that copies the DNA template strand. DNA polymerase initially adds a deoxyribonucleotide to the 3'-hydroxyl group of the primer and then continues adding deoxyribonucleotides to the 3'-end of the growing strand (Fig. 12.5).

FIGURE 12.5 Synthesis of DNA at the replication fork. (See Fig. 12.6 for the ligation reaction.)

G. The Replication Fork

Both parental strands are copied at the same time in the direction of the replication fork, an observation that is difficult to reconcile with the known activity of DNA polymerase, which can produce chains only in a 5'-to-3' direction. Because the parental strands run in opposite directions relative to each other, synthesis should occur in a 5'-to-3' direction **toward** the fork on one template strand and in a 5'-to-3' direction **away** from the fork on the other template strand.

Okazaki resolved this dilemma by showing that synthesis on one strand, called the **leading strand**, is continuous in the 5'-to-3' direction toward the fork. The other strand, called the **lagging strand**, is synthesized discontinuously in short fragments (see Fig. 12.5). These fragments, named for Okazaki, are produced in a 5'-to-3' direction (away from the fork), but then are joined together so that, overall, synthesis proceeds toward the replication fork.

RNase H is a ribonuclease that specifically degrades RNA from an RNA–DNA hybrid. The HIV (see Chapter 11) converts an RNA genome to a double-stranded DNA copy using the enzyme reverse transcriptase. An intermediate in the conversion of the single-stranded RNA genome to double-stranded DNA is an RNA–DNA hybrid. To remove the RNA so a double-stranded DNA molecule can be made, reverse transcriptase also contains RNase H activity. Because reverse transcriptase lacks error-checking capabilities, the HIV genome can mutate at a rapid rate. **Isabel S.** takes many drugs because of the need to block HIV replication at multiple steps, to “keep ahead” of the high mutation rate of the virus. The RNase H activity of reverse transcriptase has proven to be a difficult target for drug development to block HIV genome replication, although research in this area is still quite active.

H. DNA Ligase

As replication progresses, the RNA primers are removed from Okazaki fragments, probably by the combined action of DNA polymerase I (Pol I, using its 5'-to-3' exonuclease activity) and RNase H, an enzyme that removes RNA from DNA:RNA hybrids. Pol I fills in the gaps produced by removal of the primers. Because DNA polymerases cannot join two polynucleotide chains together, an additional enzyme, **DNA ligase**, is required to perform this function. The 3'-hydroxyl group at the end of one fragment is ligated to the phosphate group at the 5'-end of the next fragment (Fig. 12.6).

FIGURE 12.6 Action of DNA ligase. Two polynucleotide chains, one with a free 3'-OH group and one with a free 5'-phosphate group, are joined by DNA ligase, which forms a phosphodiester bond.

II. DNA Synthesis in Eukaryotes

The process of replication in eukaryotes is similar to that in prokaryotes. Differences in the processes are related mainly to the vastly larger amount of DNA in eukaryotic cells (over 1,000 times the amount in *E. coli*) and the association of eukaryotic DNA with histones in nucleosomes. Enzymes with DNA polymerase, primase, ligase, helicase, and topoisomerase activity are all present in eukaryotes, although these enzymes differ in some respects from those of prokaryotes.

A. Eukaryotic Cell Cycle

The **cell cycle** of eukaryotes consists of four phases (Fig. 12.7). The first three phases (G_1 , S, and G_2) constitute **interphase**. Cells spend most of their time in these three phases, carrying out their normal metabolic activities. The fourth phase is **mitosis**, the process of cell division. This phase is very brief.

FIGURE 12.7 Eukaryotic cell cycle. The times given for the length of each phase are for cells growing in culture. DNA content is expressed as $2N$ (diploid), and after DNA replication, as $4N$ (tetraploid).

The first phase of the cell cycle, G_1 (the first “gap” phase), is the most variable in length. Late in G_1 , the cells prepare to duplicate their chromosomes (e.g., by producing nucleotide precursors). In the second or S phase, DNA replicates. Nucleosomes disassemble as the replication forks advance. Throughout S phase, the synthesis of histones and other proteins associated with DNA is markedly increased. The amount of DNA and histones both double and chromosomes are duplicated. Histones complex with DNA, and nucleosomes are formed very rapidly behind the advancing replication forks.

Although Prometheus was chained to a rock as punishment for his theft of fire from the gods, and a vulture pecked at his liver each day, he survived. Can you guess why?

During the third phase of the cell cycle, G_2 (the second “gap” phase), the cells prepare to divide and synthesize tubulin for the construction of the microtubules of the spindle apparatus. Finally, division occurs in the brief mitotic or M phase.

Following mitosis, some cells reenter G_1 , repeatedly going through the phases of the cell cycle and dividing. Other cells arrest in the cycle after mitosis, never to divide again, or they enter an extended G_1 phase (sometimes called G_0), in which they remain quiescent but metabolically active for long periods of time. Upon the appropriate signal, cells in G_0 are stimulated to reenter the cycle and divide.

B. Points of Origin for Replication

In contrast to bacterial chromosomes (see Section I.A of this chapter), eukaryotic chromosomes have multiple points of origin at which replication begins. “Bubbles” appear at these points on the chromosomes. At each end

of a bubble, a replication fork forms; thus, each bubble has two forks. DNA synthesis occurs at each of these forks, as illustrated in Figure 12.8. As the bubbles enlarge, they eventually merge, and replication is completed. Because eukaryotic chromosomes contain multiple points of origin of replication (and, thus, multiple replicons, or units of replication), duplication of such large chromosomes can occur within a few hours.

FIGURE 12.8 Replication of a eukaryotic chromosome. Synthesis is bidirectional from each point of origin (O) and semiconservative. Each daughter DNA helix contains one intact parental strand (*blue line*) and one newly synthesized strand (*red line*).

Liver cells are in G_0 . Up to 90% of the human liver can be removed. The remaining liver cells are stimulated to re-enter the cell cycle and divide, regenerating a mass equivalent to the original mass of the liver within a few weeks. The myth of Prometheus indicates that the capacity of the liver to regenerate was recognized even in ancient times.

In the human body, many cells cycle frequently, for example, hair follicles, skin cells, and cells of the duodenal crypts. Other cells, such as the precursors of red blood cells, divide a number of times, then lose their nuclei and leave the cell cycle to form mature red blood cells. These cells transport oxygen and carbon dioxide between the lungs and other tissues for about 120 days, then die. Other cells are normally quiescent (in G_0). However, they can be stimulated to divide. In many instances, the stimuli are growth factors or hormones (e.g., mammary alveolar cells and uterine cells). In the case of liver cells, the stimulus is produced by the death of some of the cells.

C. Eukaryotic DNA Polymerases

Sixteen different DNA polymerases have been identified in eukaryotic cells. Examples of some of these polymerases, and their properties, are shown in Table 12.2. Polymerases δ (Pol δ) and ϵ (Pol ϵ) are the major replicative enzymes. Pol α is also involved in replication. Polymerases δ and ϵ , as well as Pol α , appear to be involved in DNA repair. Pol γ is located in mitochondria and replicates the DNA of this organelle. Polymerases ζ , κ , η , and ι , which lack 5'-exonuclease activity, are used when DNA is damaged and are known as bypass polymerases because they can “bypass” the damaged area of DNA and continue replication.

TABLE 12.2 Functions of Some Eukaryotic DNA Polymerases

POLYMERASE	FUNCTIONS ^a	EXONUCLEASE ACTIVITY
Pol α	Replication (in a complex with primase and aids in starting the primer) DNA repair	None
Pol β	DNA repair exclusively	None
Pol γ	DNA replication in mitochondria	3'-to-5'
Pol δ	Replication (processive DNA synthesis on lagging strand) ^b DNA repair	3'-to-5'
Pol ϵ	Replication (processive DNA synthesis on leading strand) ^b DNA repair	3'-to-5'
Pol κ	DNA repair (bypass polymerase) ^c	None
Pol η	DNA repair (bypass polymerase)	None
Pol ξ	DNA repair (bypass polymerase)	None
Pol ι	DNA repair (bypass polymerase)	None

^aSynthesis of new DNA strands always occurs 5'-to-3'.

^bRecent evidence suggests that leading strand synthesis utilizes both Pol δ and ϵ .

^cBypass (translesion) polymerases are able to “bypass” areas of DNA damage and continue DNA replication. Some enzymes are error free and insert the correct bases; other enzymes are error-prone and sometimes insert incorrect bases.

D. The Eukaryotic Replication Complex

Many proteins bind at or near the replication fork and participate in the process of duplicating DNA (Fig. 12.9 and Table 12.3). Polymerases δ and ϵ are the major replicative enzymes. However, before the DNA polymerases can act, a primase associated with polymerase α (Pol α) produces an RNA primer (~10 nucleotides in length). Then, Pol α adds about 20 deoxyribonucleotides to this RNA and dissociates from the template because of the low processivity of Pol α . Pol α also lacks proofreading activity (3'-to-5' exonuclease activity). On the leading strand, Pol ϵ adds deoxyribonucleotides to this RNA–DNA primer, continuously producing this strand. Pol ϵ is a highly processive enzyme.

TABLE 12.3 Major Proteins Involved in Replication

DNA polymerases	Add nucleotides to a strand growing 5'-to-3', copying a DNA template 3'-to-5'
Primase	Synthesizes RNA primers
Helicases	Separate parental DNA strands, i.e., unwind the double helix
Single-strand binding proteins	Prevent single strands of DNA from reassociating
Topoisomerases	Relieve torsional strain on parental duplex caused by unwinding
Enzymes that remove primers	RNase H hydrolyzes RNA of DNA-RNA hybrids
	Flap endonuclease 1 (FEN1) recognizes "flap"
	(Unannealed portion of RNA) near 5'-end of primer and cleaves downstream in DNA region of primer; the flap is created by polymerase δ displacing the primer as the Okazaki fragment is synthesized
DNA ligase	Joins, by forming a phosphodiester bond, two adjacent DNA strands that are bound to the same template
PCNA	Enhances processivity of the DNA polymerases; binds to many proteins present at the replication fork

PCNA, proliferating cell nuclear antigen.

FIGURE 12.9 Replication complex in eukaryotes. The lagging strand is shown looped around the replication complex to demonstrate that all DNA synthesis is in the 5'-to-3' direction. Single-strand binding proteins (not shown) are bound to the unpaired, single-stranded DNA. Other proteins also participate in this complex (see text).

The lagging strand is produced from a series of Okazaki fragments (see Fig. 12.5). Synthesis of each Okazaki fragment is initiated by pol α and its associated primase, as described previously. After Pol α dissociates, Pol δ adds deoxyribonucleotides to the primer, producing an Okazaki fragment. Pol δ stops synthesizing one fragment when it reaches the start of the previously synthesized Okazaki fragment (see Fig. 12.5). The primer of the previously synthesized Okazaki fragment is removed by flap endonuclease 1 (FEN1) and RNase H. The gap left by the primer is filled by Pol δ using the parental DNA strand as its template and the newly synthesized Okazaki fragment as its primer. DNA ligase subsequently joins the Okazaki fragments together (see Fig. 12.6). Okazaki fragments are much smaller in eukaryotes than in prokaryotes (about 200 nucleotides vs. 1,000 to 2,000). Because the size of eukaryotic Okazaki fragments is equivalent to the size of the DNA found in nucleosomes, it seems likely that one nucleosome at a time may release its DNA for replication.

Obviously, eukaryotic replication requires many proteins. The complexity of the fork and the fact that it is not completely understood limits the detail shown in Figure 12.9. One protein that is not shown in Figure 12.9 is proliferating cell nuclear antigen (PCNA), which is involved in organizing and orchestrating the replication process on both the leading and lagging strands. PCNA is often used clinically as a diagnostic marker for proliferating cells.

Additional activities that occur during replication include proofreading and DNA repair. Pols δ and ϵ , which are part of the replication complex, exhibit the 3'-to-5' exonuclease activity required for proofreading. Enzymes that catalyze repair of mismatched bases are also present (see Section III.B.3). Consequently, eukaryotic replication occurs with high fidelity; approximately one mispairing occurs for every 10^9 to 10^{12} nucleotides incorporated into growing DNA chains.

E. Replication at the Ends of Chromosomes

Eukaryotic chromosomes are linear, and the ends of the chromosomes are called telomeres. As DNA replication approaches the end of the chromosome, a problem develops in the lagging strand (Fig. 12.10). Either primase cannot lay down a primer at the very end of the chromosome, or, after DNA replication is complete, the RNA at the end of the chromosome is degraded. Consequently, the newly synthesized strand is shorter at the 5'-end, and there is a 3'-overhang in the DNA strand being replicated. If the chromosome became shorter with each successive replication, genes would be lost. How is this problem solved?

FIGURE 12.10 The end replication problem in linear chromosomes. After replication and removal of the RNA primers, the telomeres have 3'-overhangs. When these molecules are replicated, chromosome shortening will result. The figure depicts a linear chromosome with one origin of replication. At the origin, two replication forks are generated, moving in opposite directions, labeled as Fork 1 and Fork 2. As Fork 1 moves to the right, the bottom strand is read in the 3'-to-5' direction, which means it is the template for the leading strand. The newly synthesized DNA complementary to the upper strand at Fork 1 will be the lagging strand. Now consider Fork 2. As this replication fork moves to the left, the upper strand is read in the 3'-to-5' direction, so the newly synthesized DNA complementary to this strand will be the leading strand. For this fork, the newly synthesized DNA complementary to the bottom strand will be the lagging strand. The overhangs result from degradation of the RNA primers at the 5'-ends of the lagging strand, resulting in a 3'-overhang.

The 3'-overhang is lengthened by the addition of nucleotides so that primase can bind and synthesize a primer for the complementary strand. Telomeres consist of a repeating sequence of bases (TTAGGG for humans), which may be repeated thousands of times. The enzyme telomerase contains both proteins and RNA and acts as an RNA-dependent DNA polymerase (just like reverse transcriptase). The RNA within telomerase contains the complementary copy of the repeating sequence in the telomeres and can base-pair with the existing 3'-overhang (Fig. 12.11). The polymerase activity of telomerase then uses the existing 3'-hydroxyl group of the overhang as a primer and its own RNA as a template and synthesizes new DNA that lengthens the 3'-end of the DNA strand. The telomerase moves down the DNA toward the new 3'-end and repeats the process many times. When the 3'-overhang is sufficiently long, primase binds, and synthesis of the complementary strand is initiated. Even after this lengthening process, there is still a 3'-overhang that forms a complicated structure with

telomere-binding proteins to protect the ends of the chromosomes from damage and nuclease attack once they have been lengthened.

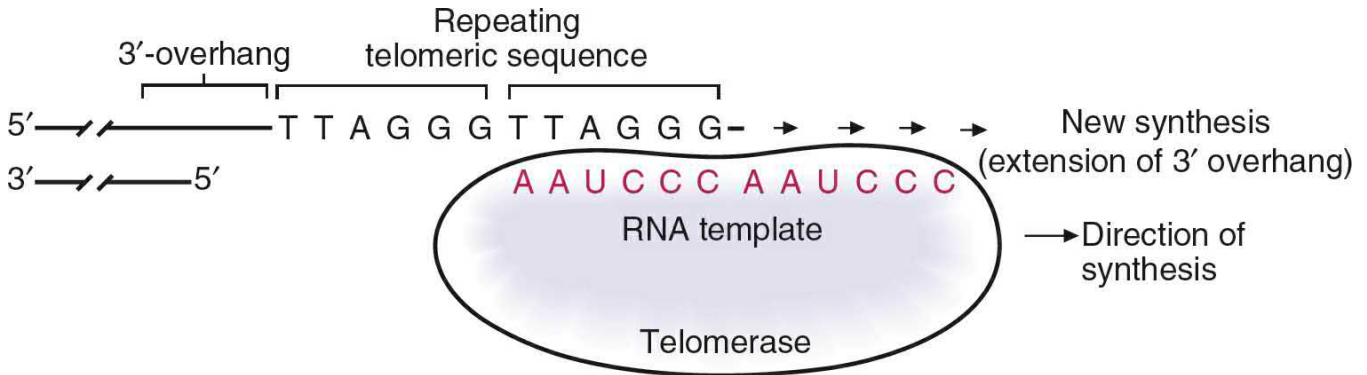

FIGURE 12.11 Telomerase action. The RNA present in telomerase base-pairs with the overhanging 3'-end of telomeres and extends it by acting as both a template and a reverse transcriptase. After copying a small number of repeats, the complex moves down to the 3'-end of the overhang and repeats the process.

 An inability to replicate telomeres has been linked to cell aging and death. Many somatic cells do not express telomerase; when they are placed in culture, they survive a fixed number of population doublings, enter senescence, and then die. Analysis has shown significant telomere shortening in those cells. In contrast, stem cells do express telomerase and appear to have an infinite lifetime in culture. Research is underway to understand the role of telomeres in cell aging, growth, and cancer.

III. DNA Repair

A. Actions of Mutagens

Despite proofreading and mismatch repair (see below) during replication, some mismatched bases do persist. Additional problems may arise from DNA damaged by **mutagens**, chemicals produced in cells, inhaled, or absorbed from the environment that cause mutations. Mutagens that cause normal cells to become cancer cells are known as carcinogens. Unfortunately, mismatching of bases and DNA damage produce thousands of potentially mutagenic lesions in each cell every day. Without repair mechanisms, we could not survive these assaults on our genes.

 **Michael T.** has been smoking for 40 years because of the highly addictive nature of nicotine in tobacco in spite of the warnings on cigarette packs that this habit can be dangerous and even deadly. The burning of tobacco, and, for that matter, the burning of any organic material, produces many different carcinogens, such as benzo[a]pyrene. These carcinogens coat the airways and lungs. They can cross cell membranes and interact with DNA, causing damage to bases that interfere with normal base pairing. If these DNA lesions cannot be repaired or if they are not repaired rapidly enough, a permanent mutation can be produced when the cells replicate. Some mutations are silent, whereas other mutations can lead to abnormal cell growth, and cancer results.

DNA damage can be caused by radiation and by chemicals (Fig. 12.12). These agents can directly affect the DNA or they can act indirectly. For example, X-rays, a type of ionizing radiation, act indirectly to damage DNA by exciting water in the cell and generating the hydroxyl radical, which reacts with DNA, thereby altering the structure of the bases or cleaving the DNA strands.

FIGURE 12.12 Oxidation of benzo[a]pyrene and covalent binding to DNA. Benzo[a]pyrene is not carcinogenic until it is oxidized within cells. Then it can bind covalently to guanine residues in DNA, interrupting hydrogen bonding in G–C base pairs and producing distortions of the helix, interfering with the replication of the DNA at this site.

Although exposure to X-rays is infrequent, it is more difficult to avoid exposure to cigarette smoke and virtually impossible to avoid exposure to sunlight. Cigarette smoke contains carcinogens such as the aromatic polycyclic hydrocarbon benzo[a]pyrene (see Fig. 12.12). When this compound is oxidized by cellular enzymes, which normally act to make foreign compounds more water-soluble and easy to excrete, it becomes capable of forming bulky adducts with guanine residues in DNA. Ultraviolet rays from the sun, which also produce distortions in the DNA helix, excite adjacent pyrimidine bases on DNA strands, causing them to form covalent dimers, usually in the form of thymine dimers (Fig. 12.13).

Thymine dimer

FIGURE 12.13 A thymine dimer in a DNA strand. Ultraviolet light can cause two adjacent pyrimidines to form a covalent dimer.

B. Repair Mechanisms

The mechanisms used for the repair of DNA have many similarities (Fig. 12.14). First, a distortion in the DNA helix is recognized, and the region containing the distortion is removed. The gap in the damaged strand is replaced by the action of a DNA polymerase that uses the intact, undamaged strand as a template, and synthesizes DNA in the 5'-to-3' direction. Finally, a ligase seals the nick in the strand that has undergone repair. The one exception to this scheme occurs in bacteria. Bacteria can remove thymine dimers by photoactivating enzymes that cleave the bonds between the bases using energy from visible light. In this process, nucleotides are not released from the damaged DNA.

FIGURE 12.14 Common steps in DNA repair mechanisms.

1. Nucleotide Excision Repair

Nucleotide excision repair (NER) involves local distortions of the DNA helix, such as mismatched bases or bulky adducts (e.g., oxidized benzo[*a*]pyrene) (Fig. 12.15; see also Fig. 12.14). Specific repair endonucleases cleave the abnormal chain and remove the distorted region. The gap is then filled by a DNA polymerase that adds deoxyribonucleotides, one at a time, to the 3'-end of the cleaved DNA, using the intact, complementary DNA strand as a template. The newly synthesized segment is joined to the 5'-end of the remainder of the original DNA strand by a DNA ligase.

FIGURE 12.15 Types of damage and various repair mechanisms. In base excision repair, the glycosylase cleaves the glycosidic bond between the altered base (shown with an X) and ribose. In nucleotide excision repair, the entire nucleotide is removed at once. The gap formed by the incision (cut) and excision (removal) endonucleases is usually several nucleotides wider than that shown.

Melanomas develop from exposure of the skin to the ultraviolet rays of the sun. The ultraviolet radiation causes pyrimidine dimers to form in DNA. Mutations may result from nonrepair of the dimers that produce melanomas, appearing as dark brown growths on the skin.

Fortunately, **Calvin A.**'s malignant skin lesion was discovered at an early stage. Because there was no evidence of cancer in the margins of the resected mass, full recovery was expected. However, lifelong surveillance for return of the melanoma was recommended.

Pyrimidine dimers occur frequently in the skin. Usually, repair mechanisms correct this damage, and cancer rarely occurs. However, in individuals with XP, cancers are extremely common. These individuals have defects in their DNA repair systems. The first defect to be identified was a deficiency of the endonuclease involved in the removal of pyrimidine dimers from DNA. Because of the inability to repair DNA, the frequency of mutation increases. A cancer develops once proto-oncogenes or tumor-suppressor genes mutate (see Chapter 17). By scrupulously avoiding sunlight, these individuals can reduce the number of skin cancers that develop.

2. Base Excision Repair

DNA glycosylases recognize small distortions in DNA involving lesions caused by damage to a single base. A glycosylase cleaves the *N*-glycosidic bond that joins the damaged base to deoxyribose (see Fig. 12.15). The sugar–phosphate backbone of the DNA now lacks a base at this site (known as an apurinic or apyrimidinic site, or an AP site). Then, an AP endonuclease cleaves the sugar–phosphate strand at this site. Subsequently, the same types of enzymes involved in other types of repair mechanisms restore this region to normal.

3. Mismatch Repair

Mismatched bases (bases that do not form normal Watson–Crick base pairs) are recognized by enzymes of the mismatch-repair system. Because neither of the bases in a mismatch is damaged, these repair enzymes must be able to determine which base of the mismatched pair to correct.

The mismatch-repair enzyme complex (a function of the replisome) acts during replication when an incorrect but normal base (i.e., A, G, C, or T) is incorporated into the growing chain (Fig. 12.16). In bacteria, parental DNA strands contain methyl groups on adenine bases in specific sequences. During replication, the newly synthesized strands are not immediately methylated. Before methylation occurs, the proteins involved in mismatch repair can distinguish parental from newly synthesized strands. A region of the new, unmethylated strand, containing the mismatched base, is removed and replaced.

FIGURE 12.16 Mismatch repair. Normal, undamaged, but mismatched bases bind proteins of the mismatch-repair system. In bacteria, these proteins recognize the older, parental strand because it is methylated and replace a segment of newly synthesized (and unmethylated) DNA containing the mismatched base. The mechanism for distinguishing between parental and newly synthesized strands in humans is not as well understood.

Human enzymes also can distinguish parental from newly synthesized strands and repair mismatches. However, the mechanism for strand recognition has not yet been as clearly defined as those in bacteria. Otherwise, the process in bacteria, and eukaryotes, is very similar.

4. Transcription-Coupled Repair

Genes that are actively transcribed to produce mRNA are preferentially repaired. The RNA polymerase that is transcribing a gene (see Chapter 13 for a description of the process) stalls when it encounters a damaged region of the DNA template. Excision repair proteins are attracted to this site and repair the damaged region, similar to the process of NER. Subsequently, RNA polymerase can resume transcription.

 Spontaneous deamination occurs frequently in human DNA, and cytosine is a base that is often deaminated. How will cytosine deamination, if not repaired, lead to a mutation in the DNA?

 Hereditary nonpolyposis colorectal cancer (a human cancer that does not arise from intestinal polyps) is caused by mutations in genes for proteins involved in mismatch repair (MLH1, MSH2, MSH6, and PMS2, with MLH1 and MSH2

being the genes most often mutated). The inability to repair mismatches increases the mutation frequency, resulting in cancers from mutations in growth-regulatory genes.

When cytosine is deaminated uracil is produced. Uracil is not normally found in DNA and is potentially harmful because U pairs with A, forming U–A base pairs instead of the normal C–G pairs. Therefore, if not repaired, after one round of DNA replication, one of the daughter cells will have a U-A base pair in this position instead of the normal C–G base pair. To prevent this change from occurring, a uracil *N*-glycosylase removes uracil, and it is replaced by a cytosine via base excision repair.

5. Single- and Double-Strand Break Repairs

The process of repairing single- and double-strand breaks in DNA, which can occur through a variety of mechanisms, is discussed in the next section of the text.

IV. Genetic Rearrangements

The exchange of segments between DNA molecules occurs quite frequently and is responsible for genetic alterations that can have beneficial or devastating consequences for affected individuals and, in some instances, for their offspring. The DNA segments that are exchanged may be homologous (i.e., of very similar sequence), or they may be totally unrelated. The size of these segments can range from a few nucleotides to tens of thousands of nucleotides and can include many different genes or portions of genes. Many of the enzymes involved in these exchanges are the same as or similar to those used for replication and repair and include endonucleases, exonucleases, unwinding enzymes, topoisomerases, DNA polymerases, and ligases.

One type of genetic rearrangement that has been observed for many years is “crossing-over” between homologous chromosomes during meiosis. Another type occurs in stem cells as they differentiate into lymphocytes. Segments of the genes of stem cells are rearranged so that the mature cell is capable of producing only a single type of antibody (see Figs. 15.10 and 7.19). Other types of genetic exchanges involve transposable elements (transposons) that can move from one site in the genome to another or produce copies that can be inserted into new sites. Translocations occur when chromosomes break and portions randomly become joined to other chromosomes, producing gross changes that can be observed under the light microscope. Genetic exchanges can even occur between species, for example, when foreign DNA is inserted into the human genome as a result of viral infection.

A. General or Homologous Recombination

Various models, supported by experimental evidence, have been proposed for the mechanism of recombination between homologous DNA sequences. Although these mechanisms are complex, a simplified scheme for one type of recombination is presented in Figure 12.17.

FIGURE 12.17 Key steps in HR. D loop, displacement loop.

Initially, two homologous chromosomes or segments of double-helical (duplex) DNA that have very similar, but not necessarily identical, sequences become aligned (see Fig. 12.17). One strand of one duplex is nicked by an enzyme and invades the other DNA duplex, base-pairing with a region of complementary sequence. The match between the sequences does not have to be perfect, but a significant number of bases must pair so that the strand displaced from its partner can form a displacement (D) loop. This D loop is nicked, and the displaced strand now base-pairs with the former partner of the invading strand. Ligation occurs, and a Holliday structure is generated (see Fig. 12.17). The branch point of the Holliday structure can migrate and may move many thousands of nucleotides from its original position. The Holliday structure, named for the scientist who discovered it, is finally cleaved and then religated, forming two chromosomes that have exchanged segments. In addition to enzymes similar to those used in DNA replication, enzymes for strand invasion, branch migration, and cleavage of the Holliday structure are required. Homologous recombination is also an important component of repairing DSBs in DNA.

B. Translocations

Breaks in chromosomes, caused by agents such as X-rays or chemical carcinogens, can result in gross chromosomal rearrangements (Fig. 12.18). If the free ends of the DNA at the break point reseat with the free ends of a different broken chromosome, a translocation is produced. These exchanges of large portions of chromosomes can have deleterious effects and are frequently observed in cancer cells.

Normal
chromosome 8

Normal
chromosome 14

Translocation

FIGURE 12.18 A chromosomal translocation. A portion of the long arm of chromosome 8 is exchanged for a portion of the long arm of chromosome 14. This chromosomal translocation occurs in Burkitt lymphoma.

C. Repair of Single- and Double-Strand Breaks in DNA

1. Single-Strand Break Repair

Single-strand breaks (SSBs) are created in DNA during normal replication (the action of topoisomerase), base excision repair, and environmental agents, such as X-ray exposure. If something were to go wrong with either of those processes, the DNA could be left with a break in one of its strands. SSBs need to be faithfully repaired to prevent mutations from arising.

The repair of SSBs in DNA follows the paradigm of base excision repair. The first step is detection of the SSB, the second step is preparing the ends of the break for DNA synthesis, the third step is using a repair DNA polymerase to fill in the gap created by the second step, using the intact strand as a template, and the final step is catalyzed by DNA ligase, creating the final phosphodiester bond between the newly synthesized DNA and the existing DNA.

There are two key proteins involved in repairing SSBs. Poly ADP-ribose polymerase 1 (PARP1) and X-ray cross-complementary protein 1 (XRCC1). PARP1 is the major PARP (there are 16 different proteins with PARP activity), and PARP1 recognizes SSBs in the DNA and binds to that region of DNA. Upon binding the enzymatic activity of PARP is activated, and using NAD^+ as a substrate, transfers ADP-ribose to amino acid sidechains of proteins surrounding the damage (primarily histones, other DNA repair proteins, and transcription factors). PARP1 will create polymers of ADP-ribose, both linear and branched, on these proteins to act as a signal for other proteins to find the damage to bind to this region such that repair can begin. PARP1 also auto-modifies itself, and having done so, weakens its interaction with DNA and dissociates from the complex. PARP1 does not participate in the actual mechanism of DNA repair.

Mice have been genetically engineered to lose expression of the XRCC1 gene. Such mice exhibit a three- to six-fold increase in chromosomal damage and mutation rate as compared to mice in which the gene has not been knocked out, indicating the critical role that XRCC1 plays in repairing single-strand breaks in DNA.

Once poly ADP-ribose chains are synthesized, XRCC1 is recruited to the site of damage, and once XRCC1 is bound, other DNA repair enzymes are recruited by XRCC1 to carry out the repair of the SSB (Fig. 12.19). XRCC1 itself does not have enzymatic activity but is rather a scaffold upon which the other repair enzymes can bind to repair the DNA.

FIGURE 12.19 Repair of single-strand breaks in DNA. The damage is detected by PARP1, which binds to the damaged region and generates polymers of ADP-ribose on histones and on itself. The Poly (ADP-ribose) polymers signal for XRCC1 to bind to the DNA, bringing with it the proteins required for repairing the single-strand break. The ADP-ribosylated PARP1 leaves the

complex as XRCC1 binds.

2. Repair of Double-Strand Breaks in DNA

DSBs in DNA can occur through ionizing radiation, DNA interactions with reactive oxygen species, DNA replication errors, or other mistakes made by nuclear enzymes. Failure to repair DSBs is detrimental to the cell and could lead to apoptosis or transformation (into a cancer cell).

There are two major pathways for repairing DSBs; homologous recombination (HR) or nonhomologous end joining (NHEJ). HR is basically error free but requires a homologous chromosome (usually a sister chromatid) to template from to repair the damage (see Fig. 12.17). NHEJ does not require a homologous chromosome for repair but has the capability of introducing mutations into the repaired region of the DNA and increasing genomic instability.

The ATM protein is mutated in the disorder ataxia telangiectasia (A-T), which is a rare autosomal disorder affecting the nervous and immune systems. Such individuals are also susceptible to cancer, particularly leukemias and lymphomas. The mutation in ATM reduces the ability of such individuals to repair double-strand breaks in the DNA, such that individuals with A-T are very sensitive to radiation exposure, such as medical X-rays.

A simplified version of the repair of DSBs is given below. In the case of HR, the damage is recognized by the MRN complex (consisting of proteins named MRE11, RAD50, and NBS1), which activates the ataxia telangiectasia mutated (ATM) kinase.

The activation of ATM leads to a full DNA repair response requiring the participation of numerous proteins, including both *BRCA1* and *BRCA2* (breast cancer type 1 [or 2] susceptibility gene). The complex of proteins now bound to the DSB initiate HR, providing a sister chromatid is available.

If a homologous DNA strand is not available, then NHEJ will occur. This process is initiated by the Ku family of proteins binding to the ends of the DSB (Fig. 12.20), following by a DNA-dependent protein kinase (DNA-PKcs), and then exo- and endonucleases to trim the broken ends and ligate the two ends together. NHEJ can lead to mutations in the repaired area due to the lack of a template to direct repair synthesis.

FIGURE 12.20 Repair of double-strand breaks in DNA. Double-strand breaks can be repaired by the error-free HR system if a homologous chromosome is available, or by the error-prone non homologous end joining procedure if a homologous chromosome is not available for recombination. *BRCA1* and *BRCA2* are required for HR to occur.

D. Transposable Elements

Movable (or transposable) genetic elements, “jumping genes,” were first observed by Barbara McClintock in the 1940s. Her work, initially greeted with skepticism, was ultimately accepted, and she was awarded the Nobel Prize in 1983.

Transposons are segments of DNA that can move from their original position in the genome to a new location (Fig. 12.21). They are found in all organisms. Transposons contain the gene for an enzyme called a transposase, which is involved in cleaving the transposon from the genome and moving it from one location to another.

FIGURE 12.21 Transposons. The steps involved in transposition are shown. Direct repeats (the areas in *blue*) are regions of DNA that have the same base sequence in the 5'-to-3' direction. They are created after the transposon integrates into the chromosome.

Retroposons are similar to transposons except that they involve an RNA molecule. Reverse transcriptase (see below) makes a single-stranded DNA copy of the RNA, which is converted to a double-stranded DNA. The double-stranded DNA is then inserted into the genome at multiple locations, forming a repetitive element in the DNA.

V. Reverse Transcriptase

Reverse transcriptase is an enzyme that uses a single-stranded RNA template and makes a DNA copy (Fig. 12.22). The RNA template can be transcribed from DNA by RNA polymerase or obtained from another source, such as an RNA virus. The DNA copy of the RNA produced by reverse transcriptase is known as complementary DNA (because it is complementary to the RNA template), or cDNA. Retroviruses (RNA viruses) contain a reverse transcriptase, which copies the viral RNA genome. A double-stranded cDNA is produced, which can become integrated into the human genome (see Fig. 11.19). After integration, the viral genes may be inactive, or they may be transcribed, sometimes causing diseases such as AIDS or cancer (see Chapter 17). The integration event may also disrupt an adjacent cellular gene, which may also lead to disease (see Chapter 17).

FIGURE 12.22 Action of reverse transcriptase. This enzyme catalyzes the production of a DNA copy (cDNA) from an RNA template. The RNA of a DNA–RNA hybrid is degraded by an associated activity of Reverse Transcriptase (designated as *RNase H*), and the single DNA strand is used as a template to make double-stranded DNA. This figure is a simplified version of a more complex process.

CLINICAL COMMENTS

Isabel S. contracted HIV when she used needles contaminated with HIV to inject drugs intravenously. In 2018, 7% of newly diagnosed HIV cases were among people who inject drugs (69% were among men who have sex with men and 24% among heterosexuals). HIV mutates rapidly, and therefore current treatment involves a combination of drugs that affect different aspects of its life cycle (designated ART, for antiretroviral therapy). This multidrug therapy lowers the viral titer (the number of viral particles found in a given volume of blood), sometimes to undetectable levels. However, if treatment is not followed carefully, the titer increases rapidly. Therefore, **Isabel S.**'s physician emphasized that she must carefully follow her drug regimen and worked with her to ensure she was able to take all her medications. This is easier than in the past, as there are several combination pills available.

Dianne A.'s poorly controlled diabetes mellitus predisposed her to a urinary tract infection because glucose in the urine serves as a “culture medium” for bacterial growth. The kidney glomerulotubular unit reabsorbs filtered glucose so that, normally, the urine is glucose-free. However, when serum blood glucose levels exceed 175 to 185 mg/dL (the tubular threshold for glucose), the capacity for reabsorption is exceeded. In **Dianne A.**'s case, blood glucose levels frequently exceed this threshold.

Calvin A. The average person has about 30 moles on the body surface, yet only about 20 people out of every 100,000 develop malignant melanoma. The incidence of malignant melanoma has been rising, although with improved treatment, the rate of mortality has decreased. However, about 10% of patients with malignant melanoma still die as a result of this cancer, so the physician's decision to biopsy a pigmented mole with an irregular border and variation of color probably saved **Calvin A.**'s life.

Michael T. Lung cancer currently accounts for about 13% of all cancers in men and women. The overall 5-year survival rate is approximately 20%. Thankfully, cigarette smoking has declined in the United States. Whereas 50% of men and 32% of women smoked in 1965, these figures have, in 2019, fallen to 15.3% and 12.7%, respectively.

BIOCHEMICAL COMMENTS

DNA repair and disease. DNA serves a unique role within a cell in that it produces the blueprint for gene expression throughout the lifetime of the cell. However, DNA is present in limited copies within cells (unlike RNA and proteins), and various agents often compromise its structural integrity. The DNA, then, must be continually monitored for damage, and when damage is found, repair mechanisms are required to restore the DNA to its original structure. If the integrity of the DNA cannot be maintained deleterious mutations may accumulate in the genome, ultimately negatively impacting the person as a whole. Failures in DNA repair mechanisms will lead to disease, as indicated by the examples below.

DNA can undergo various types of damage within the cells aqueous environment. DNA undergoes spontaneous hydrolysis of the *N*-glycosidic bonds, generating apurinic or apyrimidinic sites within the DNA. Failure to repair these sites (via base excision repair) will lead to changes in nucleotide sequence of the DNA. DNA, when exposed to ultraviolet light rapidly forms thymine dimers, which will interfere with DNA replication unless repaired. DNA exposure to X-rays or ionizing radiation will lead to SSB or DSB within the DNA. Failure to repair these breaks will lead to replicative errors. The DNA is also exposed to environmental toxins, leading to chemically modified bases, which need to be repaired before DNA replication occurs, otherwise, the risk of inappropriate base pairing during replication is greatly increased.

DNA repair disorders, due to mutations in single genes, often give rise to a cell that actively accumulates mutations and can eventually turn into a cancer cell (see Chapter 17). A common theme in DNA repair enzyme mutations is the clinical display of cancer. It is important to note that the mutations themselves do not directly lead to cancer, rather successive cell generations, each with accumulated mutations due to DNA repair defects, will eventually acquire a mutation which leads to growth advantages, and cancer. Distinct examples of such diseases are described below.

The first example is the mutations that give rise to xeroderma pigmentosum (XP). XP is primarily a defect in NER (see Fig. 12.15). There are at least 12 genes responsible for XP and its variants, all of which are

involved in NER or transcription-coupled repair. The disorder is seen clinically as sun hypersensitivity resulting in skin abnormalities. It leads to a significantly greater risk of developing skin cancer, in particular at a younger age than in the general population. This results from an inability to remove UV-induced thymine dimers in the DNA, leading to mismatches being created during DNA replication through the thymine dimer.

Mutations in proteins specifically responsible for transcription-coupled repair lead to Cockayne syndrome, which presents clinically as failure to thrive and delayed development. Cells with these mutations cannot transcribe damaged genes. If the DNA cannot be repaired due to the defect in transcription-coupled repair, premature cell death can result from the reduction of gene expression. There are also specific mutations within the XP constellation of genes that give rise to a phenotype that reflects traits of both XP and Cockayne syndrome, indicating that there are commonalities in symptoms when either NER or transcription-coupled repair is defective.

Hereditary nonpolyposis colon cancer (HNPCC) and hereditary breast cancer both result from inherited mutations in genes involved in DNA repair (see Chapter 11).

HNPCC is estimated to account for about 3% of all colon cancer cases. These syndromes are heterogenous, due, most likely, to the finding that mutations in any of five genes could lead to colon cancer. The disease genes include *hMSH2*, *hMLH1*, *hPMS1*, *hPMS2*, and *hMSH6*. These genes all play a role in DNA mismatch repair, and all act as tumor suppressors (a loss of function is required for the tumor to develop).

It is important to understand that the lack of a DNA mismatch-repair enzyme actually does not directly lead to cancer (such as an activating mutation in *myc* would do, for example). However, the lack of a functional mismatch-repair system increases the frequency at which new mutations are introduced into somatic cells (particularly rapidly proliferating cells, such as the colonic epithelium), such that eventually, a mutation will result in a gene necessary for proper growth control. Once that mutation occurs, tumors can begin to develop.

Five percent to 10% of all breast cancer cases have been traced to inherited mutations in either one of two genes, *BRCA1* and *BRCA2*. *BRCA1* maps to chromosome 17 and acts as a tumor suppressor. The biochemical function of *BRCA1* is to participate in the response to DNA damage. *BRCA1* is phosphorylated by a variety of kinases, each of which is activated by a different form of DNA damage. *BRCA1* is primarily involved in repairing DSBs in DNA and in transcription-coupled repair. Once *BRCA1* is phosphorylated it will signal for cell cycle arrest, to allow the DNA damage to be repaired.

Women who carry a *BRCA1* mutation have a 55% to 65% risk of developing breast cancer, and about a 40% to 45% risk of ovarian cancer, by the age of 70. Men who carry *BRCA1* mutations have been shown to have a slight increase in breast cancer and prostate cancer.

The other gene involved in hereditary breast cancer is *BRCA2*, located on chromosome 13. *BRCA2* is required for DNA DSB repair, which is usually caused by ionizing radiation. As such, loss of *BRCA2* activity is required for cancer to develop, classifying *BRCA2* as a tumor suppressor. *BRCA2* is also required for HR between sister chromatids during meiosis and mitosis. *BRCA2* mutations have also been linked to an increased incidence of breast and ovarian cancer in women, and breast cancer and prostate cancer in men. *BRCA1* and *BRCA2* mutations account for about 20% to 25% of all hereditary breast cancer cases.

An understanding of the roles of *BRCA1* and *BRCA2* in repairing DSBs in DNA has led to the development of poly-ADP-ribose polymerase (PARP-1) inhibitors for the treatment of *BRCA1*- or *BRCA2*-induced breast cancers. DSB repair occurs either by HR (requiring the activities of *BRCA1* and *BRCA2* proteins) or through NHEJ, which is an error-prone process, due to trimming of the DNA ends before ligation (see Fig. 12.20).

SSBs in DNA are more common than DSBs. The cellular mechanism for repairing SSBs is dependent on PARP-1. PARP-1 produces large-branched chains of poly (ADP-ribose) (derived from NAD^+) at the site of damage, which acts as a docking station for proteins involved in repairing the SSB. Inhibiting PARP-1 would lead to an accumulation of SSBs in the DNA.

PARP-1 inhibitors are effective in killing *BRCA1* or *BRCA2* mutated cells in that when SSBs are not repaired, they often are converted to DSBs when the replisome tries to replicate through the break. In a cell lacking *BRCA1* or *BRCA2* activity, the only way the DNA can be repaired is by NHEJ, which is an error-prone process. This leads to the cells accumulating a large number of mutations, eventually leading to cell death. Cells with functional *BRCA1* or *BRCA2* activity will not undergo that fate. Drugs that inhibit PARP-1 activity have recently (2018) been granted FDA approval for the treatment of ovarian and certain types of breast cancer.

KEY CONCEPTS

- ◆ Replication of the genome requires DNA synthesis.

- ◆ During replication, each of the two parental strands of DNA serves as a template for the synthesis of a complementary strand.
- ◆ The site at which replication is occurring is called the replication fork.
- ◆ Helicases and topoisomerases are required to unwind the DNA helix of the parental strands.
- ◆ DNA polymerase is the major enzyme involved in the replication.
- ◆ DNA polymerase copies each parental template strand in the 3'-to-5' direction, producing new strands in a 5'-to-3' direction.
- ◆ The precursors for replication are deoxyribonucleotide triphosphates.
- ◆ As DNA synthesis proceeds in the 5'-to-3' direction, one parental strand is synthesized continuously, whereas the other exhibits discontinuous synthesis, creating small fragments named Okazaki fragments, that are subsequently joined. This is necessary because DNA polymerase can only synthesize DNA in the 5'-to-3' direction.
- ◆ DNA polymerase requires a free 3'-hydroxyl group of a nucleotide primer to replicate DNA. The primer is synthesized by the enzyme primase, which provides an RNA primer.
- ◆ The enzyme telomerase synthesizes the replication of the ends of linear chromosomes (telomeres).
- ◆ Errors during replication can lead to mutations, so error checking and repair systems function to maintain the integrity of the genome.
- ◆ Table 12.4 summarizes the diseases discussed in this chapter.

TABLE 12.4 Disease Discussed in Chapter 12

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
HIV/acquired immunodeficiency disease syndrome (AIDS)	Environmental	The rationale for multidrug regime for patients with HIV is explained.
Urinary tract infection	Environmental	Antibiotics to treat such infections can target prokaryotic specific enzymes involved in DNA synthesis.
Melanoma	Both	Drugs used to treat cancer can inhibit DNA replication, by a variety of mechanisms.
Lung cancer	Both	Drugs used to treat cancer can inhibit DNA replication.
Hereditary non polyposis colon cancer	Genetic	Mutations in enzymes which are required for DNA mismatch repair, which can lead to mutations in genes regulating cell proliferation.
Cockayne syndrome	Genetic	Mutations in enzymes which are required for transcription-coupled DNA repair. Leads to premature cell death, and a failure to thrive and developmental delay.
Xeroderma pigmentosum	Genetic	Mutations which are involved in nucleotide excision repair, leading to a greatly elevated risk for the development of skin cancer.
Hereditary breast cancer	Genetic	Mutations in the genes <i>BRCA1</i> and <i>BRCA2</i> , which lead to defects in the repair of single-strand and double-strand breaks in DNA.
Ataxia telangiectasia	Genetic	Mutations in the <i>ATM</i> gene lead to increased susceptibility to leukemia/lymphoma due to reduced efficiency of repairing strand breaks in DNA.

REVIEW QUESTIONS—CHAPTER 12

1. A variety of drugs can alter DNA replication in eukaryotic cells. Which one of the following steps could be a target for such a drug? Choose the one best answer.
 - A. The enzyme family of DNA polymerases, which unwinds parental strands
 - B. The enzyme family of topoisomerases, which copy each parental strand in 3'-to-5' direction
 - C. The enzyme family of helicases, which copy each parental strand in 5'-to-3' direction
 - D. The finding that both strands of newly synthesized DNA always grow continuously
 - E. The enzyme DNA ligase, which joins Okazaki fragments
2. There are a variety of DNA polymerases in both bacterial and eukaryotic cells. Targeting which one of the following properties of DNA polymerases would result in inhibiting DNA synthesis?
 - A. The initiation de novo of the synthesis of new DNA strands
 - B. The formation of phosphodiester bonds through hydrogen bonding
 - C. The cleavage of released pyrophosphate that provides the energy for the polymerization reaction
 - D. The dissociation and reassociation of the enzyme with DNA as each nucleotide is added to an existing DNA chain
 - E. The process of copying a template strand in its 3'-to-5' direction, producing a new strand in the 5'-to-3' direction
3. An antibiotic that inhibits bacterial DNA polymerases can damage human mitochondria due to which one of the following eukaryotic DNA polymerases being most similar to a prokaryotic DNA polymerase?
 - A. α
 - B. β
 - C. γ
 - D. δ
 - E. ϵ
4. A drug that inhibits DNA replication, but is inactivated by chromosomes containing telomeres, would prove to be a very useful antibiotic. Telomeres can be best described by which one of the following?
 - A. Telomeres are only present in circular chromosomes.
 - B. Before telomerase action, and after DNA replication, there is a 3' overhang at the telomere.
 - C. Before telomerase action, and after DNA replication, there is a 5' overhang at the telomere.
 - D. In human DNA telomeres consist of repeating sequences of TTAGGT.
 - E. Somatic eukaryotic cells do not contain telomeres
5. Diseases caused by defects in DNA repair systems put the patient at risk for developing cancers. DNA repair mechanisms can be best described by which one of the following?
 - A. Proofreading works as the bases are paired and eliminates all base-pairing errors
 - B. After replication no further repairs are possible
 - C. Genes that produce mRNA have a unique repair system
 - D. Genes that produce tRNA have a unique repair system
 - E. DNA glycosylases recognize distortion of the DNA helix due to bulky adducts being present on a base within the DNA
6. Translocations cause some of the most recognized genetic syndromes in human offspring. A translocation can be best described by which one of the following?
 - A. They always produce cancer
 - B. They always produce intellectual disability
 - C. They have to involve the exchange of an entire chromosome
 - D. They can only occur in the presence of reverse transcriptase
 - E. They can occur in somatic or stem cells
7. The retroviruses, including HIV, utilize an RNA genome. To generate DNA from the genomic RNA the enzyme reverse transcriptase is required. Reverse transcriptase differs specifically from DNA polymerase δ by which one of the following?
 - A. Synthesizing DNA in the 5'-to-3' direction
 - B. Expressing 3'-to-5' exonuclease activity
 - C. Utilizes Watson-Crick base-pair rules during DNA synthesis
 - D. Synthesizing DNA in the 3'-to-5' direction
 - E. Inserting inosine into a growing DNA chain
8. The large DNA molecules in human chromosomes take more time to replicate than do the smaller, circular bacterial chromosomes. If a 1,000-kilobase (kb) fragment of DNA has 10 evenly spaced and symmetric replication origins and DNA polymerase moves at 1 kb per second, how many seconds will it take to

produce two daughter molecules (ignore potential problems at the ends of this linear piece of DNA)?

Assume that the 10 origins are evenly spaced from each other, but not from the ends of the chromosome.

- A. 20
 - B. 30
 - C. 40
 - D. 50
 - E. 100
9. DNA replication is a different process than DNA repair. Mutations in DNA repair enzymes can lead to disease, especially certain forms of cancer. Primase is not required during DNA repair processes because of which one of the following?
- A. All of the primase is associated with replication origins.
 - B. RNA would be highly mutagenic at a repair site.
 - C. Repair DNA polymerases do not require a primer.
 - D. Replicative DNA polymerases do not require a primer.
 - E. DNA polymerases (both repair and replicative) can use any 3'-OH for elongation.
10. The key mechanistic failure in patients with XP involves which one of the following?
- A. Mutation in the primase gene
 - B. Inability to excise a section of the UV-damaged DNA
 - C. Mutation of one of the mismatch-repair components
 - D. Inability to synthesize DNA across the damaged region
 - E. Loss of proofreading capacity
11. The action of PARP1 is required for the repair of which one of the following types of DNA damage?
- A. Base excision repair
 - B. Nucleotide excision repair
 - C. Mismatch repair
 - D. Single-strand break repair
 - E. Double-strand break repair
12. A 32-year-old female was recently diagnosed with breast cancer. Genetic analysis indicated that she had a germline mutation in the *BRCA2* gene. Further diagnostic work indicated treatment with a PARP inhibitor. The effectiveness of PARP inhibitors in treating such cancers is which one of the following?
- A. The cancer cells are unable to undergo base excision repair.
 - B. The cancer cells are unable to undergo nucleotide excision repair.
 - C. The cancer cells have lost the ability to catalyze mismatch repair.
 - D. The cancer cells are unable to repair SSBs in their DNA.
 - E. The cancer cells are unable to repair DSBs in their DNA.
13. A eukaryotic cell line, in the G1 phase of the cell cycle, has undergone a DSB due to X-ray exposure. The most likely mode of repair of this defect is which one of the following?
- A. Nucleotide excision repair
 - B. Base excision repair
 - C. Mismatch repair
 - D. Homologous recombination
 - E. Non homologous end joining
14. A temperature-sensitive bacterial cell line was discovered which would grow normally at 25°C, but not at 42°C. Analysis of the DNA at the higher temperature indicated many small fragments, on the order of 1,000 nucleotides. Treating the cells with ultraviolet light at 25°C indicated that normal DNA repair processes of the cell were operational, but at 42°C multiple SSBs were discovered in the DNA after UV light exposure. The enzyme which has most likely lost its activity at 42°C is which one of the following?
- A. Polymerase I
 - B. Polymerase II
 - C. Polymerase III
 - D. DNA primase
 - E. DNA ligase
15. Which of the following processes is carried out by the bacterial replisome complex? Choose the one best answer.

	Leading Strand Synthesis	Lagging Strand Synthesis	Proofreading	Base Excision Repair	Mismatch Repair
A	Yes	Yes	Yes	No	No
B	Yes	No	No	Yes	Yes
C	Yes	Yes	Yes	No	Yes
D	No	No	No	Yes	No
E	No	Yes	Yes	No	No
F	No	No	No	Yes	Yes

ANSWERS TO REVIEW QUESTIONS

- The answer is E.** Helicases and topoisomerases unwind the parental strands. DNA polymerases copy each parental template in the 3'-to-5' direction producing new strands in a 5'-to-3' direction. One strand of newly synthesized DNA grows continuously but the other strand is synthesized discontinuously in short segments known as Okazaki fragments. These fragments are subsequently joined by DNA ligase. Targeting a single enzyme with a drug is more likely to succeed than inhibiting an entire family of enzymes.
- The answer is E.** DNA polymerases catalyze the synthesis of DNA but cannot initiate the synthesis of new strands de novo, as a short primer must be first synthesized by DNA primase (a DNA-dependent RNA polymerase). Phosphodiester bonds, which link the backbone, are covalent bonds and are not formed from hydrogen bonds. During the course of adding a nucleotide to an existing DNA chain pyrophosphate is released, and its subsequent hydrolysis (pyrophosphate contains a high energy bond) by the enzyme pyrophosphatase (not DNA polymerase) provides the energy that drives the polymerization reactions. DNA polymerases exhibit processivity, in which the enzyme remains bound to the parental template strand as the enzyme creates new phosphodiester bonds while reading the template. The enzyme does not dissociate and reassociate after each nucleotide is added to the existing DNA strand. DNA polymerases copy a template in the 3'-to-5' direction producing new strands in a 5'-to-3' direction.
- The answer is C.** Mitochondria in human cells are very similar to bacteria and are theorized to have arisen from bacteria that developed a symbiotic relationship with the host cell. Polymerase γ is located in mitochondria and replicates the DNA of this organelle. Polymerases δ and ϵ are the major replicative enzymes in the eukaryotic nucleus. Polymerase α is involved in DNA repair. Polymerase β participates in base excision repair.
- The answer is B.** Eukaryotic chromosomes are linear and the ends of the chromosomes are called telomeres. Bacteria have circular DNA and therefore no telomeres. Telomeres in humans consist of a repeating sequence of TTAGGG. The newly synthesized DNA strand, before telomerase action, is shorter at the 5'-end so there is an overhang at the 3'-end. Somatic cells have telomeres, but as they age their expression of telomerase decreases, so the cells only survive for a fixed number of population doublings.
- The answer is C.** Proofreading, an inherent property of most DNA polymerase due to its 3'-to-5' exonuclease activity, eliminates base-pairing errors as they occur during replication but proofreading does not eliminate all errors made by DNA polymerase. Postreplication error repair systems replace mismatched bases that are missed by proofreading. Genes that produce mRNA contain a unique transcription-coupled repair system (repair occurs as the genes are transcribed). NER involves local distortion of the DNA helix such as in bulky adducts, whereas DNA glycosylases recognize damage to a single base.

6. **The answer is E.** Translocations can occur in both somatic and stem cells. Translocations occur frequently and can either be beneficial or devastating. Some translocations can lead to developmental delay, and some can lead to a higher risk of developing cancer, but they can also be beneficial or have no discernable effect. Translocation consists of a portion of one chromosome being exchanged for a portion of another chromosome. Reverse transcriptase is found in RNA viruses and has no role in human translocation.
7. **The answer is B.** A DNA polymerase's 3'-to-5' exonuclease activity is required for proofreading (check the base just inserted, and if it is incorrect, remove it), and reverse transcriptase does not have this activity, whereas pol δ does. Both reverse transcriptase and pol δ synthesize DNA in the 5'-to-3' directions (all DNA polymerases do this), and both follow standard Watson–Crick base-pairing rules (A with T or U, G with C). Neither polymerase can synthesize DNA in the wrong direction (3'-to-5') or insert inosine into a growing DNA chain. Thus, the only difference between the two polymerases is described in answer choice B. Polymerase δ is used primarily for lagging strand synthesis during DNA replication, although it also has repair functions.
8. **The answer is D.** In 50 seconds, each replication origin will have synthesized 100 kb of DNA (50 in each direction). Because there are 10 origins, 10×100 will yield the 1,000 kb needed to replicate the DNA. The first origin will be 50 kb from one end, and the remaining nine origins will each be 100 kb apart.
9. **The answer is E.** The role of the primer is to provide a free 3'-OH group for DNA polymerase to add the next nucleotide and form a phosphodiester bond. When DNA repair occurs, one of the remaining bases in the DNA will have a free 3'-OH, which repair DNA polymerases (such as DNA polymerase I in bacteria) will use to begin the extension of the DNA.
10. **The answer is B.** XP is a set of diseases all related to an inability to repair thymine dimers, leading to an inability to excise UV-damaged DNA. It does not affect bypass polymerases, which can synthesize across the damaged region, sometimes making mutations in its path. The primase gene, or mismatch repair, is not involved in excising thymine dimers. Proofreading ability of DNA polymerases is likewise not involved in this process.
11. **The answer is D.** PARP1 binds to single-strand damage in DNA and creates polymers of ADP-ribose at the site of the injury. The polymers act as a signal for more repair proteins to join the complex and repair the single-strand break. PARP1 is not involved in any other repair process—base excision repair, NER, mismatch repair, or DSB repair.
12. **The answer is D.** PARP inhibitors block the action of PARP1 such that SSBs in DNA cannot be repaired (due to an inability of targeting repair proteins to the site of damage). SSBs, if not repaired, can convert to DSBs during DNA replication, and if repaired by non homologous end joining can introduce mutations in the genome. Once a cancer cell accumulates a sufficient number of such mutations tumor cell growth can become compromised, and the cells will die. Inhibition of PARP1 will not interfere with the ability to repair other types of DNA damage.
13. **The answer is E.** DSBs in DNA can be repaired by either HR or non homologous end joining. For HR to proceed a copy of the normal chromosome is required (a sister chromatid), which occurs after DNA replication (thus, in either the S or G2 phases of the cell cycle). In the G1 phase of the cell cycle, DNA replication has not occurred, and sister chromatids are not available, so DSBs are repaired by nonhomologous end joining.
14. **The answer is E.** DNA ligase seals gaps in DNA strands which contain a 3'-hydroxyl group and 5'-phosphate group. This is required for lagging strand DNA replication (to connect the Okazaki fragments), and for both base excision repair and NER. At 25°C the enzyme works normally, but at 42°C the enzyme is defective. Thus, at the higher temperature, Okazaki fragments would not be able to be ligated together, giving rise to the large nucleotide fragments found in the cell. Since the removal of thymine dimers (as created by UV irradiation) requires ligase to seal a gap after the dimer has been removed, the lack of ligase activity would result in DNA containing SSBs. Mutations in DNA primase would not allow for any DNA synthesis at the elevated temperature. A mutation in polymerase I or II would not create SSBs in DNA after UV irradiation, and a mutation in polymerase III would lead to very little DNA synthesis at the non permissive temperature.
15. **The answer is C.** The replisome contains the major DNA biosynthetic enzyme, which is responsible for both leading and lagging strand synthesis. As the polymerase contains proofreading activity, such error correction also occurs within the replisome. Mismatch repair is also a function of the replisome, whereas base excision repair is done by a separate system. The replisome does not contain the proteins necessary to carry out base excision repair.

Transcription: Synthesis of RNA

Synthesis of RNA from a **DNA template** is called **transcription**. Genes are transcribed by enzymes called **RNA polymerases** that generate a **single-stranded RNA** identical in sequence (with the exception of U in place of T) to one of the strands of the double-stranded DNA. The DNA strand that directs the sequence of nucleotides in the RNA by **complementary base pairing** is the template strand. The RNA strand that is initially generated is the **primary transcript**. The **DNA template is copied** in the **3'-to-5' direction**, and the **RNA transcript is synthesized** in the **5'-to-3' direction**. RNA polymerases differ from DNA polymerases in that they can **initiate** the **synthesis** of new strands in the absence of a primer.

In addition to catalyzing the polymerization of **ribonucleotides**, RNA polymerases must be able to recognize the appropriate gene to transcribe, the appropriate strand of the double-stranded DNA to copy, and the **start point** of transcription (Fig. 13.1). Specific sequences on DNA, called **promoters**, determine where the RNA polymerase binds and how frequently it initiates transcription. Other regulatory sequences, such as **promoter-proximal elements** and **enhancers**, also affect the frequency of transcription.

FIGURE 13.1 Regions of a gene. A gene is a segment of DNA that functions as a unit to generate an RNA product or, through the processes of transcription and translation, a polypeptide chain. The transcribed region of a gene contains the template for synthesis of an RNA, which begins at the start point. A gene also includes regions of DNA that regulate production of the encoded product, such as a promoter region. In a structural gene, the transcribed region contains the coding sequences that dictate the amino acid sequence of a polypeptide chain.

In **bacteria**, a **single RNA polymerase** produces the primary transcript precursors for all three major classes of RNA: messenger RNA (mRNA), ribosomal RNA (rRNA), and transfer RNA (tRNA). Because bacteria do not contain nuclei, ribosomes bind to mRNA as it is being transcribed, and protein synthesis occurs simultaneously with transcription.

Eukaryotic genes are transcribed in the nucleus by **three different RNA polymerases**, each principally responsible for one of the major classes of RNA. The primary transcripts are **modified** and **trimmed** to produce the mature RNAs. The precursors of **mRNA** (called **pre-mRNA**) have a **guanosine “cap”** added at the 5'-end and a **poly(A) “tail”** at the 3'-end. **Exons**, which contain the coding sequences for the proteins, are separated in **pre-mRNA** by **introns**, regions that have no

coding function. During **splicing reactions**, introns are removed and the exons connected to form the mature mRNA. In eukaryotes, tRNA and rRNA precursors are also modified and trimmed, although not as extensively as pre-mRNA.

THE WAITING ROOM

Lisa N. is a 4-year-old girl of Mediterranean ancestry whose height and body weight are below the 20th percentile for girls of her age. She tires easily and complains of loss of appetite and shortness of breath on exertion. A dull pain has been present in her right upper quadrant for the last 3 months and she appears pale. Initial laboratory studies indicate a severe anemia (decreased red blood cell count) with a hemoglobin of 7.0 g/dL (reference range, 12 to 16 g/dL). A battery of additional hematologic tests reveals that **Lisa N.** has β^+ -thalassemia, intermediate type.

The thalassemias are a heterogeneous group of hereditary anemias that constitute the most common gene disorder in the world, with a carrier rate of almost 5%. The disease was first discovered in countries around the Mediterranean Sea and was named for the Greek word “thalassa,” meaning “sea.” However, it is also present in areas extending into India and China that are near the Equator.

The thalassemia syndromes are caused by mutations that decrease or abolish the synthesis of the α - or β -chains in the adult hemoglobin A tetramer. Individual syndromes are named according to the chain whose synthesis is affected and the severity of the deficiency. Thus, in β^0 -thalassemia, the superscript 0 denotes none of the β -chain is present; in β^+ -thalassemia, the + denotes a partial reduction in the synthesis of the β -chain. More than 170 different mutations have been identified that cause β -thalassemia; most of these interfere with the transcription of β -globin mRNA or its processing or translation.

Isabel S., a patient with HIV (see Chapters 11 and 12), has developed a cough with gray, slightly blood-tinged sputum. A chest X-ray indicates a cavitory infiltrate in the right upper lung field. A stain of sputum shows the presence of acid-fast bacilli, suggesting a diagnosis of pulmonary tuberculosis caused by *Mycobacterium tuberculosis*.

Catherine T. picked mushrooms in a wooded area near her home. A few hours after eating one small mushroom, she experienced mild nausea and diarrhea. She brought a mushroom with her to the hospital emergency room. A poison expert identified it as *Amanita phalloides* (the “death cap”). These mushrooms contain the toxin α -amanitin.

Sarah L., a 28-year-old computer programmer, notes increasing fatigue, pleuritic chest pain, and a nonproductive cough. In addition, she complains of joint pains, especially in her hands. A rash on both cheeks and the bridge of her nose (“butterfly rash”) has been present for the last 6 months. Initial laboratory studies reveal a subnormal white blood cell count and a mild reduction in hemoglobin. Tests result in a diagnosis of systemic lupus erythematosus (SLE) (frequently called lupus).

The measurement of hemoglobin levels in blood is important for the appropriate diagnosis of many diseases, such as anemia. Laboratories measure hemoglobin content by first exposing the sample (usually lysed blood cells, to release the hemoglobin from the red blood cells) to an oxidizing agent, which converts the ferrous iron in hemoglobin to its ferric state. The level of ferric iron is then determined with a second reagent (either a cyanide or an azide derivative), which reacts with the ferric iron and generates a colored product, whose concentration can be determined spectrophotometrically.

I. Action of RNA Polymerase

Transcription, the synthesis of RNA from a DNA template, is carried out by **RNA polymerases** (Fig. 13.2). Like DNA polymerases, RNA polymerases catalyze the formation of ester bonds between nucleotides that base-pair with the complementary nucleotides on the DNA template. Unlike DNA polymerases, RNA polymerases can initiate the synthesis of new chains in the absence of primers. They also lack the 3'-to-5' exonuclease activity found in DNA polymerases, although they do perform rudimentary error-checking through a different mechanism. A strand of DNA serves as the template for RNA synthesis and is copied in the 3'-to-5' direction. Synthesis of the new RNA molecule occurs in the 5'-to-3' direction. The ribonucleoside triphosphates

adenosine triphosphate (ATP), guanosine triphosphate (GTP), cytidine triphosphate (CTP), and uridine triphosphate (UTP) serve as the precursors. Each nucleotide base sequentially pairs with the complementary deoxyribonucleotide base on the DNA template (A, G, C, and U pair with T, C, G, and A, respectively). The polymerase forms an ester bond between the α -phosphate on the ribose 5'-hydroxyl of the nucleotide precursor and the ribose 3'-hydroxyl at the end of the growing RNA chain. The cleavage of a high-energy phosphate bond in the nucleotide triphosphate and release of pyrophosphate (from the β - and γ -phosphates) provides the energy for this polymerization reaction. Subsequent cleavage of the pyrophosphate by a pyrophosphatase also helps to drive the polymerization reaction forward by removing a product. The overall error rate of RNA polymerase is 1 in 100,000 bases.

FIGURE 13.2 RNA synthesis. The α -phosphate from the added nucleotide connects the ribosyl groups.

 Patients with AIDS frequently develop tuberculosis. After **Isabel S.**'s sputum stain suggested that she had tuberculosis, a multidrug antituberculous regimen, which includes an antibiotic of the rifamycin family (rifampin), was begun. A culture of her sputum was taken to confirm the diagnosis.

Rifampin inhibits bacterial RNA polymerase, selectively killing the bacteria that cause the infection. The nuclear RNA polymerase from eukaryotic cells is not affected. Although rifampin can inhibit the synthesis of mitochondrial RNA, the concentration required is considerably higher than that used for treatment of tuberculosis.

RNA polymerases must be able to recognize the start point for transcription of each gene and the appropriate strand of DNA to use as a template. They also must be sensitive to signals that reflect the need for the gene product and control the frequency of transcription. A region of regulatory sequences called the **promoter** (often composed of smaller sequences called **boxes** or **elements**), usually contiguous with the transcribed region, controls the binding of RNA polymerase to DNA and identifies the start point (see Fig. 13.1). The frequency of transcription is controlled by regulatory sequences within the promoter and nearby the promoter (promoter-proximal elements) and by other regulatory sequences, such as enhancers (also called distal-promoter elements), that may be located at considerable distances—sometimes thousands of nucleotides—from the start point. Both the promoter-proximal elements and the enhancers interact with proteins that stabilize RNA polymerase binding to the promoter.

The mushrooms picked by **Catherine T.** contained α -amanitin, an inhibitor of eukaryotic RNA polymerases:

It is particularly effective at blocking the action of RNA polymerase II. This toxin initially causes gastrointestinal disturbances, then electrolyte imbalance and fever, followed by liver and kidney dysfunction. Around 10% to 15% of individuals who ingest α -amanitin die within ten days.

II. Types of RNA Polymerases

Bacterial cells have a single RNA polymerase that transcribes DNA to generate all of the different types of RNA (mRNA, rRNA, and tRNA). The RNA polymerase of *Escherichia coli* contains five subunits (2α , β , β' , and ω), which form the core enzyme. Another protein called a σ (sigma) factor binds the core enzyme and directs binding of RNA polymerase to specific promoter regions of the DNA template. The σ factor dissociates shortly after transcription begins. *E. coli* has a number of different σ factors that recognize the promoter regions of different groups of genes. The major σ factor is σ^{70} , a designation related to its molecular weight of 70,000 Da.

In contrast to prokaryotes, eukaryotic cells have three nuclear RNA polymerases (Table 13.1). Polymerase I

produces most of the rRNAs, polymerase II produces mRNA and microRNAs (microRNAs regulate gene expression and are discussed in more detail in Chapter 15), and polymerase III produces small RNAs, such as tRNA and 5S rRNA. All of these RNA polymerases have the same mechanism of action. However, they recognize different types of promoters. The mitochondria has its own RNA polymerase to transcribe genes located on the mitochondrial genome.

TABLE 13.1 Products of Nuclear Eukaryotic RNA Polymerases

POLYMERASE	PRODUCT
RNA polymerase I	rRNA
RNA polymerase II	mRNA + micro RNA (miRNA)
RNA polymerase III	tRNA + other small RNAs

A. Sequences of Genes

Double-stranded DNA consists of a **coding strand** and a **template strand** (Fig. 13.3). The DNA template strand is the strand that is actually used by RNA polymerase during the process of transcription. It is complementary and antiparallel both to the coding (nontemplate) strand of the DNA and to the RNA transcript produced from the template. Thus, the coding strand of the DNA is identical in base sequence and direction to the RNA transcript, except, of course, that wherever this DNA strand contains a T, the RNA transcript contains a U. By convention, the nucleotide sequence of a gene is represented by the letters of the nitrogenous bases of the coding strand of the DNA duplex. It is written from left to right in the 5'-to-3' direction.

FIGURE 13.3 Relationship between the coding strand of DNA (also known as the sense strand, or the nontemplate strand), the DNA template strand (also known as the antisense strand), the mRNA transcript, and the protein produced from the gene. The bases in mRNA are used in sets of three (called codons) to specify the order of the amino acids inserted into the growing polypeptide chain during the process of translation (see Chapter 14).

During translation, mRNA is read 5' to 3' in sets of three bases, called **codons**, that determine the amino acid sequence of the protein (see Fig. 13.3). Thus, the base sequence of the coding strand of the DNA can be used to determine the amino acid sequence of the protein. For this reason, when gene sequences are given, they refer to the coding strand.

A gene consists of the transcribed region and the regions that regulate transcription of the gene (e.g., promoter and enhancer regions) (Fig. 13.4). The base in the coding strand of the gene serving as the start point for transcription is numbered +1. This nucleotide corresponds to the first nucleotide incorporated into the RNA at the 5'-end of the transcript. Subsequent nucleotides within the transcribed region of the gene are numbered +2, +3, and so on, toward the 3'-end of the gene. Untranscribed sequences to the left of the start point, known as the **5'-flanking** region of the gene, are numbered -1, -2, -3, and so on, starting with the nucleotide (-1) immediately to the left of the start point (+1) and moving from right to left. By analogy to a river, the sequences to the left of the start point are said to be **upstream** from the start point and those to the right are said to be **downstream**.

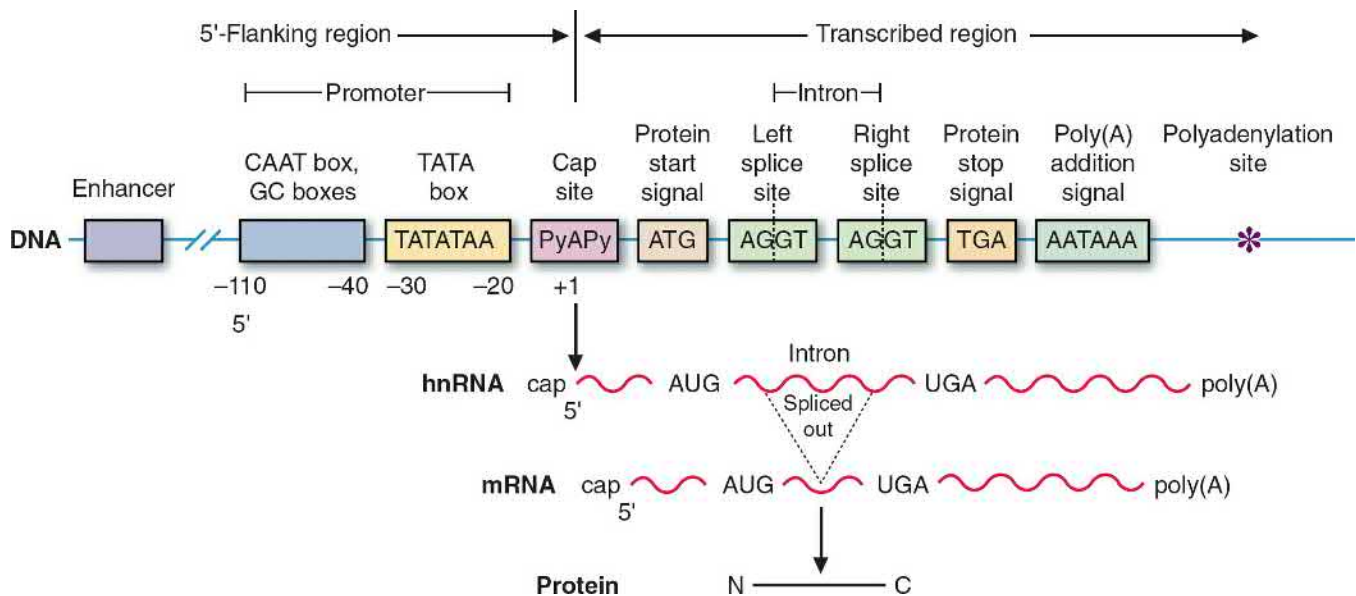

FIGURE 13.4 A schematic view of a eukaryotic gene, and steps required to produce a protein product. The gene consists of promoter and transcribed regions. The transcribed region contains introns, which do not contain coding sequences for proteins, and exons, which do carry coding sequences for proteins. The first RNA form produced is heterogeneous nuclear RNA (hnRNA), which contains both intronic and exonic sequences. The hnRNA is modified such that a cap is added at the 5'-end (cap site) and a poly(A) tail is added to the 3'-end. The introns are removed (a process called splicing) to produce the mature mRNA, which leaves the nucleus to direct protein synthesis in the cytoplasm. Py is pyrimidine (C or T). Although the TATA box is still included in this figure for historical reasons, only 12.5% of eukaryotic promoters contain this sequence.

B. Recognition of Genes by RNA Polymerase

For genes to be expressed, RNA polymerase must recognize the appropriate point at which to start transcription and the strand of the DNA to transcribe (the template strand). RNA polymerase also must recognize which genes to transcribe because transcribed genes are only a small fraction of the total DNA. The genes that are transcribed differ from one type of cell to another and change with alterations in physiologic conditions. These signals in DNA that RNA polymerase recognizes are called promoters. Promoters are sequences in DNA (often composed of smaller sequences called boxes or elements) that determine the start point and the frequency of transcription. Because they are located on the same molecule of DNA and near the gene they regulate, they are said to be *cis*-acting (i.e., “*cis*” refers to acting on the same side). Proteins that bind to these DNA sequences and facilitate or prevent the binding of RNA polymerase are said to be *trans*-acting.

Why is it important for RNA polymerase to distinguish between the two DNA strands at the promoter?

C. Promoter Regions of Genes for mRNA

The binding of RNA polymerase and the subsequent initiation of gene transcription involves a number of **consensus sequences** in the promoter regions of the gene (Fig. 13.5). A consensus sequence is the sequence that is most commonly found in a given region when many genes are examined. In prokaryotes, an adenine- and thymine-rich consensus sequence in the promoter determines the start point of transcription by binding proteins that facilitate the binding of RNA polymerase. In the prokaryote *E. coli*, this consensus sequence is TATAAT, which is known as the TATA or Pribnow box. It is centered about -10 and is recognized by the sigma factor σ^{70} . A similar sequence in the -25 region of about 12.5% of eukaryotic genes has a consensus sequence of TATA(A/T)A. (The [A/T] in the fifth position indicates that either A or T occurs with equal frequency.) This eukaryotic sequence is also known as a TATA box, but it is sometimes named the Hogness or Hogness–Goldberg box after its discoverers. Other consensus sequences involved in binding of RNA polymerase are found farther upstream in the promoter region (see Fig. 13.5) or downstream after the transcriptional start signal. Bacterial promoters contain a sequence TTGACA in the -35 region. Eukaryotes frequently have disparate sequences, such as the TFIIB-recognition element (a GC-rich sequence, abbreviated as BRE), the initiator element, the downstream promoter element (DPE), and the motif ten element (MTE). The DPE and MTE are found downstream from the transcription start site. Eukaryotic genes also contain promoter-

proximal elements (in the region of -100 to -200), which are sites that bind other gene regulatory proteins. Genes vary in the number of such sequences present. An analysis of close to 10,000 promoter sequences indicated that the initiator element was the most common element in these promoters (about 50%), whereas BRE and DPE were present in about 15% of the promoters, and TATA the least abundant, at 12.5% of the promoters.

Prokaryotic promoters

Eukaryotic promoters

Upstream elements

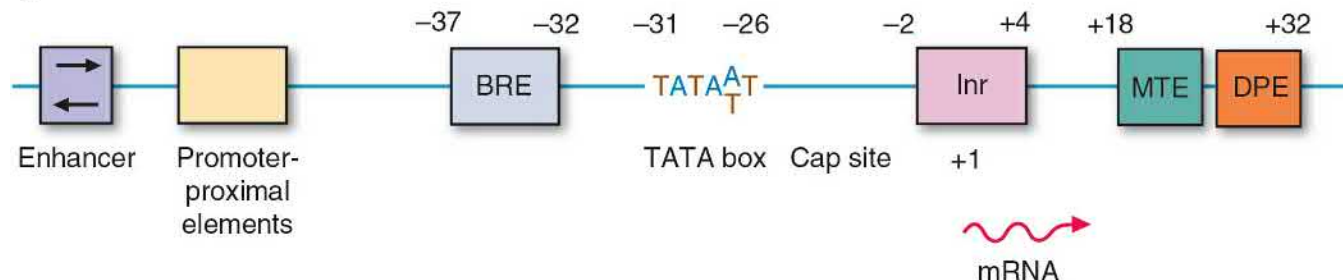

FIGURE 13.5 Prokaryotic and eukaryotic promoters. The promoter-proximal region contains binding sites for transcription factors that can accelerate the rate at which RNA polymerase binds to the promoter. BRE, TFIIIB-recognition element; DPE, downstream promoter element; Inr, initiator element; MTE, motif ten element; Pu, purine; Py, pyrimidine.

Lisa N. has a β^+ -thalassemia classified clinically as β -thalassemia intermedia. She produces an intermediate amount of functional β -globin chains (her hemoglobin is 7.0 g/dL; normal is 12 to 16 g/dL). β -Thalassemia intermedia is usually the result of two different mutations (one that mildly affects the rate of synthesis of β -globin and one severely affecting its rate of synthesis) or, less frequently, homozygosity for a mild mutation in the rate of synthesis, or a complex combination of mutations. For example, mutations within the promoter region of the β -globin gene could result in a significantly decreased rate of β -globin synthesis in an individual who is homozygous for the allele, without completely abolishing synthesis of the protein.

Two of the point mutations that result in a β^+ -phenotype are within the TATA box (A \rightarrow G or A \rightarrow C in the -28 to -31 region) for the β -globin gene. These mutations reduce the accuracy of the start point of transcription so that only 20% to 25% of the normal amount of β -globin is synthesized. Other mutations that also reduce the frequency of β -globin transcription have been observed farther upstream in the promoter region (-87 C \rightarrow G and -88 C \rightarrow T).

In bacteria, a number of protein-producing genes may be linked together and controlled by a single promoter. This genetic unit is called an **operon** (Fig. 13.6). One mRNA is produced that contains the coding information for all of the proteins encoded by the operon. Proteins bind to the promoter and either inhibit or facilitate transcription of the operon. **Repressors** are proteins that bind to a region in the promoter known as the operator and inhibit transcription by preventing the binding of RNA polymerase to DNA. **Activators** are proteins that stimulate transcription by binding within the -35 region or upstream from it, facilitating the binding of RNA polymerase. (Operons are described in more detail in Chapter 15.)

FIGURE 13.6. Bacterial operon. A cistron encodes a single polypeptide chain. In bacteria, a single promoter may control transcription of an operon containing many cistrons. A single polycistronic mRNA is transcribed. Its translation produces a number of polypeptide chains.

In eukaryotes, proteins known as **general transcription factors** (or basal factors) bind to the TATA box (or other promoter elements, in the case of TATA-less promoters) and facilitate the binding of RNA polymerase II, the polymerase that transcribes mRNA (Fig. 13.7). This binding process involves at least six basal transcription factors (labeled as TFII, transcription factors for RNA polymerase II). The TATA-binding protein (TBP), which is a component of TFIID, initially binds to the TATA box. TFIID consists of both the TBP and a number of transcriptional coactivators. Components of TFIID will also recognize initiator and DPE boxes in the absence of a TATA box. TFIIA and TFIIB interact with TBP. RNA polymerase II binds to the complex of transcription factors and to DNA and is aligned at the start point for transcription. TFIIIE, TFIIF, and TFIIH subsequently bind, cleaving adenosine triphosphate (ATP), and transcription of the gene is initiated.

FIGURE 13.7 Transcription apparatus. The TATA-binding protein (TBP), a component of TFIID, binds to the TATA box. Transcription factors TFII A and B bind to TBP. RNA polymerase binds, then TFII E, F, and H bind. This complex can transcribe at a basal level. Some coactivator proteins are present as a component of TFIID, and these can bind to other regulatory DNA-binding proteins (called specific transcription factors or transcriptional activators). TFIID also recognizes the initiator element (Inr) and the DPE in the case of TATA-less promoters (see Fig. 13.5).

A The two strands of DNA are antiparallel, with complementary nucleotides at each position. Because RNA synthesis always occurs in the 5'-to-3' direction, each strand would produce a different mRNA, resulting in different codons for amino acids and a different protein product. Therefore, it is critical that RNA polymerase transcribe the correct strand.

With only these transcription (or basal) factors and RNA polymerase II attached (the basal transcription complex), the gene is transcribed at a low or basal rate. TFIID plays a number of roles in both transcription and DNA repair. In both processes, it acts as an ATP-dependent DNA helicase, unwinding DNA for either transcription or repair to occur. Two of the forms of xeroderma pigmentosum (XPB and XPD; see Chapter 12) arise from mutations within two different helicase subunits of TFIID. TFIID also contains a kinase activity, and RNA polymerase II is phosphorylated by this factor during certain phases of transcription.

Q What property of an AT-rich region of a DNA double helix makes it suitable to serve as a recognition site for the start point of transcription?

The rate of transcription can be further increased by binding of other regulatory DNA-binding proteins to additional gene regulatory sequences (such as the promoter-proximal or enhancer regions). These regulatory DNA-binding proteins are called **gene-specific transcription factors** (or transactivators) because they are specific to the gene involved (see Chapter 15). They interact with coactivators in the basal transcription complex. These are depicted in Figure 13.7 under the general term “coactivators.” Coactivators consist of transcription associated factors (TAFs) that interact with transcription factors through an activation domain on the transcription factor (which is bound to DNA). The TAFs interact with other factors (described as the mediator proteins), which in turn interact with the RNA polymerase complex. These interactions are further discussed in Chapter 15.

III. Transcription of Bacterial Genes

In bacteria, binding of RNA polymerase with a σ factor to the promoter region of DNA causes the two DNA strands to unwind and separate within a region approximately 10 to 20 nucleotides in length. As the polymerase transcribes the DNA, the untranscribed region of the helix continues to separate, whereas the transcribed region of the DNA template rejoins its DNA partner (Fig. 13.8). The σ factor is released when the growing RNA chain is approximately 10 nucleotides long. The elongation reactions continue until the RNA polymerase encounters a transcription termination signal. One type of termination signal involves the formation of a hairpin loop in the

transcript, preceding a number of U residues. The second type of mechanism for termination involves the binding of a protein, the rho factor, which causes release of the RNA transcript from the template in an energy-requiring mechanism. The signal for both termination processes is the sequence of bases in the newly synthesized RNA.

FIGURE 13.8 An overview of transcription at the site of RNA synthesis.

A In regions where DNA is being transcribed, the two strands of the DNA must be separated. AT base pairs in DNA are joined by only two hydrogen bonds while GC pairs have three hydrogen bonds. Therefore, in AT-rich regions of DNA, the two strands can be separated more readily than in regions that contain GC base pairs.

A **cistron** is a region of DNA that encodes a single polypeptide chain. In bacteria, mRNA is usually generated from an operon as a **polycistronic transcript** (one that contains the information to produce a number of different proteins). Because bacteria do not contain a nucleus, the polycistronic transcript is translated as it is being transcribed. This process is known as **coupled transcription translation**. This transcript is not modified and trimmed, and it does not contain introns (regions within the coding sequence of a transcript that are removed before translation occurs). Several different proteins are produced during translation of the polycistronic transcript, one from each cistron (see Fig. 13.6).

In prokaryotes, rRNA is produced as a single, long transcript that is cleaved to produce the 16S, 23S, and 5S ribosomal RNAs. tRNA is also cleaved from larger transcripts (Fig. 13.9). One of the cleavage enzymes, RNase P, is a protein containing an RNA molecule. This RNA actually catalyzes the cleavage reaction.

FIGURE 13.9 Bacterial ribosomal RNA (rRNA) and transfer RNA (tRNA) transcripts. One large precursor is cleaved (at arrows) to produce 16S, 23S, and 5S rRNA and some tRNAs.

IV. Transcription of Eukaryotic Genes

The process of transcription in eukaryotes is similar to that in prokaryotes. RNA polymerase binds to the transcription factor complex in the promoter region and to the DNA, the helix unwinds within a region near the start point of transcription, DNA strand separation occurs, synthesis of the RNA transcript is initiated, and the RNA transcript is elongated, copying the DNA template. The DNA strands separate as the polymerase approaches and rejoin as the polymerase passes.

One of the major differences between eukaryotes and prokaryotes is that eukaryotes have more elaborate mechanisms for processing the transcripts, particularly the precursors of mRNA (pre-mRNA). Eukaryotes also have three polymerases, rather than just the one present in prokaryotes. Other differences include the facts that eukaryotic mRNA usually contains the coding information for only one polypeptide chain and that eukaryotic RNA is transcribed in the nucleus and migrates to the cytoplasm where translation occurs. Thus, coupled transcription translation does not occur in eukaryotes.

A. Synthesis of Eukaryotic mRNA

In eukaryotes, extensive processing of the primary transcript occurs before the mature mRNA is formed and can migrate to the cytosol where it is translated into a protein product. RNA polymerase II synthesizes a large primary transcript from the template strand that is capped at the 5'-end as it is transcribed (Fig. 13.10). The transcript also rapidly acquires a poly(A) tail at the 3'-end. Pre-mRNAs thus contain untranslated regions at both the 5'- and 3'-ends (the leader and trailing sequences, respectively). These untranslated regions are retained in the mature mRNA. The coding region of the pre-mRNA, which begins with the start codon for protein synthesis and ends with the stop codon, contains both exons and introns. **Exons** consist of the nucleotide codons that dictate the amino acid sequence of the eventual protein product. Between the exons, interspersing regions called **introns** contain nucleotide sequences that are removed by splicing reactions to form the mature RNA. The mature RNA thus contains a leader sequence (that includes the cap), a coding region comprising exons, and a trailing sequence that includes the poly(A) tail.

FIGURE 13.10 Overview of eukaryotic messenger RNA (mRNA) synthesis. Transcription produces heterogeneous nuclear RNA (hnRNA; also known as pre-mRNA) from the DNA template. hnRNA processing involves addition of a 5'-cap and a poly(A) tail and splicing to join exons and remove introns. The product, mRNA, migrates to the cytoplasm, where it will direct protein synthesis.

There are three different types of methyl caps, shown in red:

CAP 0 refers to the methylated guanosine (on the nitrogen at the seven position, N^7) added in the 5'-to-5' linkage to the mRNA; CAP 1 refers to CAP 0 with the addition of a methyl group to the 2'-carbon of ribose on the nucleotide (N_1) at the 5'-end of the chain; and CAP 2 refers to CAP 1 with the addition of another 2'-methyl group to the next nucleotide (N_2). The methyl groups are donated by SAM.

Once SAM donates its methyl group, it must be regenerated by reactions that require the vitamins folate and B_{12} . Thus, formation of mRNA is also one of the processes affected by a deficiency of these vitamins.

This mature mRNA complexes with the poly(A)-binding protein and other proteins. It travels through pores in the nuclear envelope into the cytoplasm. There it combines with ribosomes and directs the incorporation of amino acids into proteins.

1. Transcription and Capping of mRNA

Capping of the primary transcript synthesized by RNA polymerase II occurs at its 5'-end as it is being transcribed (Fig. 13.11). The 5'-terminal, the initial nucleotide of the transcript, is a pyrimidine with three phosphate groups attached to the 5'-hydroxyl of the ribose. To form the cap, the terminal triphosphate loses one

phosphate, forming a 5'-diphosphate. The β -phosphate of the diphosphate then attacks the α -phosphate of GTP, liberating pyrophosphate, and forming an unusual 5'-to-5' triphosphate linkage. A methyl group is transferred from *S*-adenosylmethionine (SAM), a universal methyl donor, to position 7 of the added guanine ring. Methylation also occurs on the ribose 2'-hydroxyl group in the terminal nucleotide to which the cap is attached, and sometimes the 2'-hydroxyl group of the adjacent nucleotide ribose. This cap seals the 5'-end of the primary transcript and decreases the rate of degradation. It also serves as a recognition site for the binding of the mature mRNA to a ribosome at the initiation of protein synthesis.

FIGURE 13.11 The cap structure in eukaryotic mRNA. The phosphates in red originated from the original RNA transcript; the phosphate in black comes from guanosine triphosphate (GTP). *S*-adenosylmethionine (SAM) donates the methyl groups (shown in red) required for cap synthesis. A CAP 1 structure is shown.

2. Addition of a Poly(A) Tail

After the RNA polymerase transcribes the stop codon for protein translation, it passes a sequence called the **polyadenylation signal** (AAUAAA) (Fig. 13.12). It continues past the polyadenylation signal until it reaches an unknown, and possibly nonspecific, termination signal many nucleotides later. However, as the primary transcript is released from the RNA polymerase elongation complex, an enzyme complex binds to the polyadenylation signal and cleaves the primary transcript approximately 10 to 20 nucleotides downstream, thereby forming the 3'-end. Following this cleavage, a poly(A) tail that can be >200 nucleotides in length is added to the 3'-end. Thus, there is no poly(dT) sequence in the DNA template that corresponds to this tail; it is added after transcription is completed. ATP serves as the precursor for the sequential addition of the adenine nucleotides. They are added one at a time, with poly(A) polymerase catalyzing each addition. The poly(A) tail is a protein-binding site that protects the mRNA from degradation.

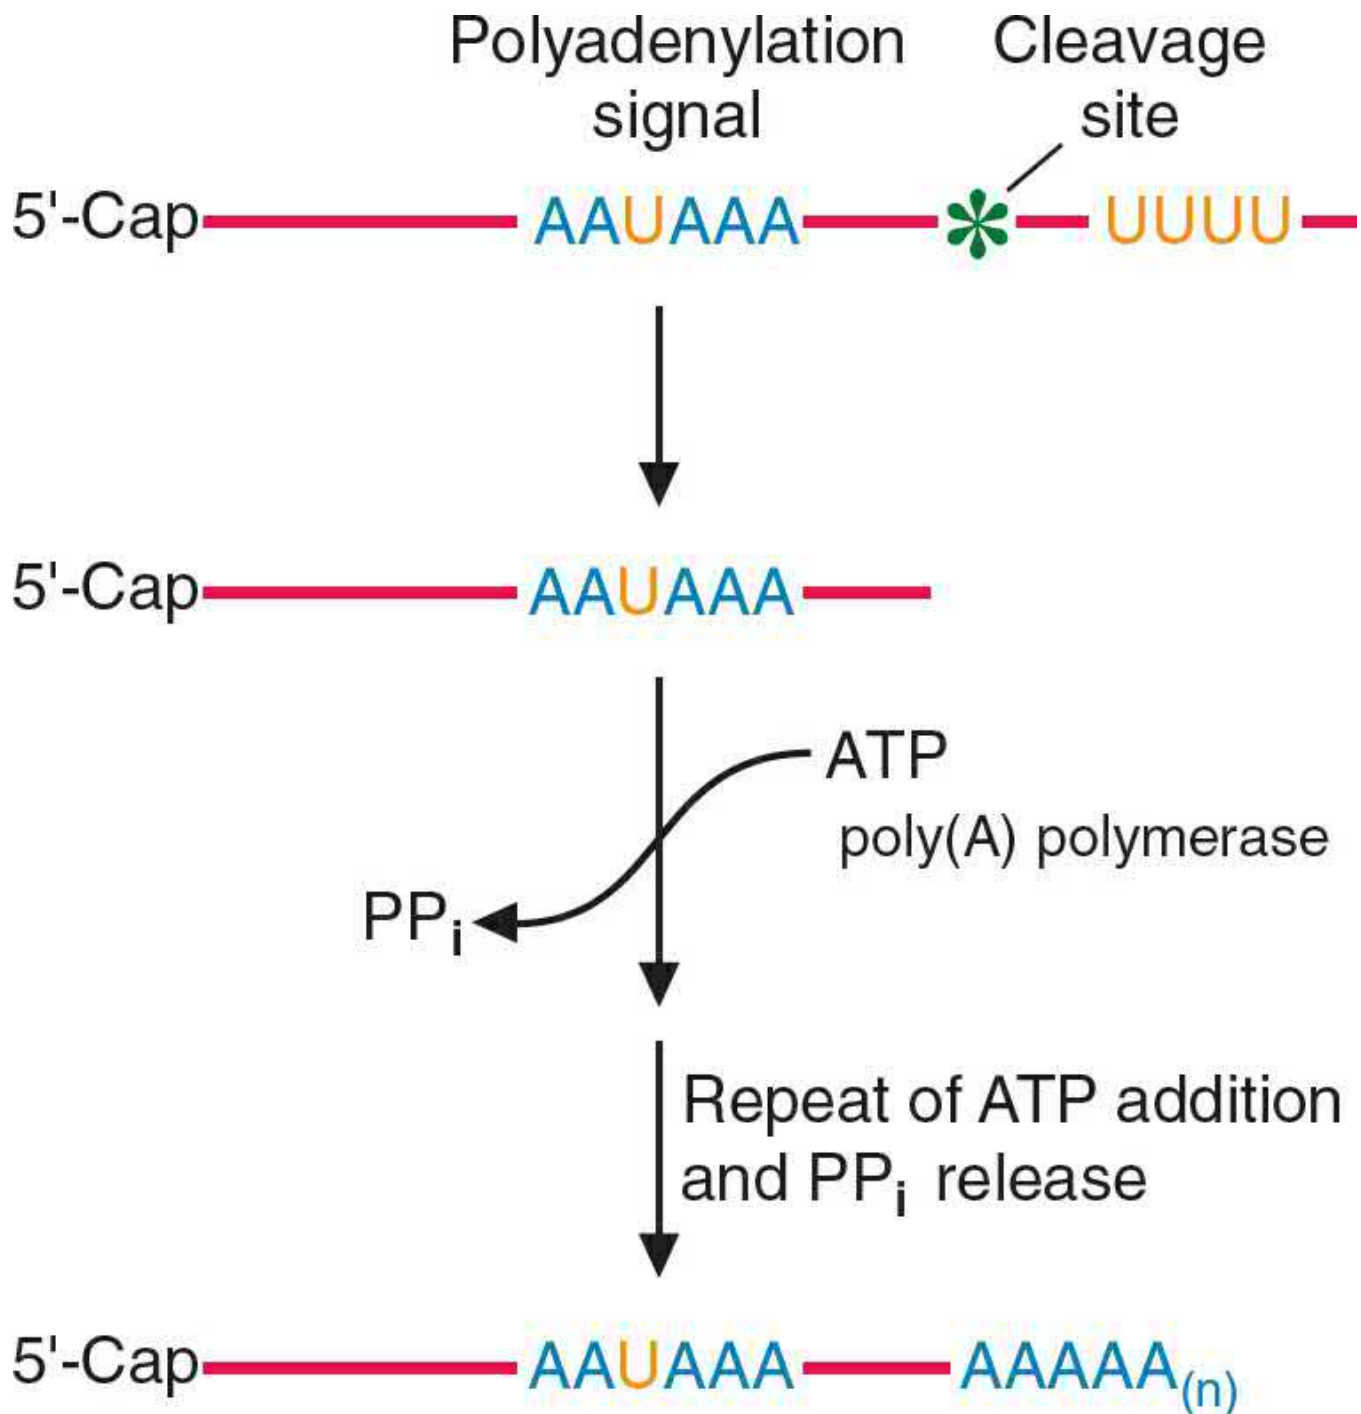

FIGURE 13.12 Synthesis of the poly(A) tail. As RNA polymerase continues to transcribe the DNA, enzymes cleave the transcript (heterogeneous nuclear RNA [hnRNA]) at a point 10 to 20 nucleotides beyond an AAUAAA sequence, just before a run of Us (or Gs). Approximately 250 adenine nucleotides are then added to the 3'-end of the hnRNA, one at a time, by poly(A) polymerase.

Within about four weeks of initiation of treatment for tuberculosis, culture results of **Isabel S.**'s sputum confirmed the diagnosis of pulmonary tuberculosis caused by *M. tuberculosis*. Therefore, the multidrug therapy, which included the antibiotic rifampin, was continued. Rifampin binds to the RNA polymerases of several bacteria. *M. tuberculosis* rapidly develops resistance to rifampin through mutations that result in an RNA polymerase that cannot bind the complex structure. Simultaneous treatment with drugs that work through different mechanisms decreases the selective advantage of the mutation and the rate at which resistance develops.

3. Removal of Introns

Eukaryotic pre-mRNA transcripts contain regions known as exons and introns. Exons appear in the mature mRNA; introns are removed from the transcript and are not found in the mature mRNA (see Fig. 13.10).

Therefore, introns do not contribute to the amino acid sequence of the protein. Some genes contain 50 or more introns. These introns are carefully removed from the pre-mRNA transcript and the exons are spliced together, so that the appropriate protein is produced from the gene.

Lisa N. has β^+ -thalassemia (enough of the β -chain is produced to maintain blood hemoglobin levels above 6.0 g/dL).

One mutation resulting in β^+ -thalassemia is a point mutation (AATAAA \rightarrow AACAAA) that changes the sequence in hnRNA at the polyadenylation signal site from AAUAAA to AACAAA. Homozygous individuals with this mutation produce only one tenth the amount of normal β -globin mRNA.

The consensus sequences at the intron/exon boundaries of the pre-mRNA are AG:GU (AGGT in the DNA) at the 5'-end and AG:G at the 3'-end of the intron. The sequences vary to some extent on the exon side of the boundaries, but almost all introns begin with a 5'-GU and end with a 3'-AG (Fig. 13.13). These intron sequences at the left splice site (5'-end) and the right splice site (3'-end) are therefore invariant. Because every 5'-GU and 3'-AG combination does not result in a functional splice site, clearly other features (still to be determined) within the exon or intron help to define the appropriate splice sites.

FIGURE 13.13 Splice junctions in heterogeneous nuclear RNA (hnRNA). The intron sequences shown in the boxes are invariant. They always appear at this position in introns. The sequences on the exon side of the splice sites are more variable.

A complex structure known as a **spliceosome** ensures that exons are spliced together with great accuracy (Fig. 13.14). **Small nuclear ribonucleoproteins** (snRNPs), called “snurps,” are involved in formation of the spliceosome. Because snurps are rich in uracil, they are identified by numbers preceded by a U.

FIGURE 13.14 Simplified splicing process. Nuclear ribonucleoproteins (snurps U1 to U6) bind to the intron, causing it to form a loop. The complex is called a spliceosome. The U1 snurp binds near the first exon/intron junction, and U2 binds within the intron in a region containing an adenine nucleotide residue. Another group of snurps, U4, U5, and U6, binds to the complex, and the loop is formed. The phosphate attached to the G residue at the 5'-end of the intron forms a 2'-5' linkage with the 2'-hydroxyl group of the adenine nucleotide residue. Cleavage occurs at the end of the first exon, between the AG residues at the 3'-end of the exon and the GU residues at the 5'-end of the intron. The complex continues to be held in place by the spliceosome. A second cleavage occurs at the 3'-end of the intron after the AG sequence. The exons are joined together. The intron, shaped like a lariat, is released and degraded to nucleotides.

 Some types of β^0 -thalassemia (little or none of the hemoglobin β -chain produced) are caused by homozygous mutations in the splice-junction sequences at intron/exon boundaries. In some individuals, an AT replaces a GT in the gene at the 5'-end of the first or second intron. Mutations also occur within the splice-junction sequences at the 3'-ends of introns (which are normally GT at the donor-site 5'-end and AG at the acceptor-site 3'-end). Mutations at either site totally abolish normal splicing and result in β^0 -thalassemia.

Exons frequently code for separate functional or structural domains of proteins. Proteins with similar functional regions (e.g., ATP- or NAD-binding regions) frequently have similar domains, although their overall structure and amino acid sequence is quite different. A process known as **exon shuffling** has probably occurred throughout evolution, allowing new proteins to develop with functions similar to those of other proteins.

B. Synthesis of Eukaryotic rRNA

Ribosomal RNAs (rRNAs) form the ribonucleoprotein complexes on which protein synthesis occurs. In eukaryotes, the rRNA gene exists as many copies in the nucleolar organizer region of the nucleus (Fig. 13.15, circle 1). Each gene produces a large, 45S transcript (synthesized by RNA polymerase I) that is cleaved to produce the 18S, 28S, and 5.8S rRNAs. Approximately 1,000 copies of this gene are present in the human genome. The genes are linked in tandem, separated by spacer regions that contain the termination signal for one gene and the promoter for the next. Promoters for rRNA genes are located in the 5'-flanking region of the genes and extend into the region surrounding the start point. rRNA genes caught in the act of transcription by electron micrographs show that many RNA polymerase I molecules can be attached to a gene at any given time, all moving toward the 3'-end as the 45S rRNA precursors are synthesized.

FIGURE 13.15 Ribosomal RNA (rRNA) and ribosome synthesis. The 5S rRNA is transcribed in the nucleoplasm and moves into the nucleolus. The other rRNAs are transcribed from DNA and mature in the nucleolus, forming the 40S and 60S ribosomal subunits, which migrate to the cytoplasm. See the text for a detailed explanation.

As the 45S rRNA precursors are released from the DNA, they complex with proteins, forming ribonucleoprotein particles that generate the granular regions of the nucleolus (see Fig. 13.15, circle 2). Processing of the transcript occurs in the granular regions. 5S rRNA, produced by RNA polymerase III from genes located outside the nucleolus in the nucleoplasm, migrates into the nucleolus and joins the ribonucleoprotein particles.

One to two percent of the nucleotides of the 45S precursor become methylated, primarily on the 2'-hydroxyl groups of ribose moieties (see Fig. 13.15, circle 3). These methyl groups may serve as markers for cleavage of the 45S precursors and are conserved in the mature rRNA. A series of cleavages in the 45S transcripts occur to produce the mature rRNAs.

In the production of cytoplasmic ribosomes in human cells, one portion of the 45S rRNA precursor becomes the 18S rRNA that, complexed with proteins, forms the small 40S ribosomal subunit (Fig. 13.15, circle 4). Another segment of the precursor folds back on itself and is cleaved, forming 28S rRNA, hydrogen-bonded to the 5.8S rRNA. The 5S rRNA, transcribed from non-nucleolar genes, and a number of proteins

complex with the 28S and 5.8S rRNAs to form the 60S ribosomal subunit (Fig. 13.15, circle 5). The ribosomal subunits migrate through the nuclear pores. In the cytoplasm, the 40S and 60S ribosomal subunits interact with mRNA, forming the 80S ribosomes on which protein synthesis occurs.

SLE is an autoimmune disease characterized by a particular spectrum of autoantibodies against many cellular components, including chromatin, ribonucleoprotein, and cell membrane phospholipids. In this disorder, the body makes these antibodies against its own components. snRNPs are one of the targets of these antibodies. In fact, snRNPs were discovered as a result of studies using antibodies obtained from patients with SLE.

Tests were performed on **Sarah L.**'s blood to detect levels of antibodies, including antibodies to nuclear antigens (ANAs), antibodies to double-stranded DNA (anti-ds DNA), and antibodies to ribonucleoproteins (these were historically known as Smith proteins, for the first patient in which they were discovered. It has since been shown that the snRNPs correspond to the Smith antigens). The tests were strongly positive and, in conjunction with her symptoms, led to a diagnosis of SLE.

C. Synthesis of Eukaryotic tRNA

A transfer RNA has one binding site for a specific sequence of three nucleotides in mRNA (the anticodon site) and another binding site for the encoded amino acid. Thus, tRNAs ensure that the genetic code is translated into the correct sequence of amino acids. At least 20 types of tRNAs occur in cells, one for every amino acid that is incorporated into growing polypeptide chains during the synthesis of proteins. tRNAs have a cloverleaf structure that folds into a three-dimensional L-shape and contain a number of bases that are modified posttranscriptionally (Fig. 13.16). The loop closest to the 5'-end is known as the **D-loop** because it contains dihydrouridine (D). The second, or **anticodon loop**, contains the trinucleotide anticodon that base-pairs with the codon on mRNA. The third loop (the **T Ψ C loop**) contains both ribothymidine (T) and pseudouridine (Ψ). A fourth loop, known as the **variable loop** because it varies in size, is frequently found between the anticodon and T Ψ C loops. Base pairing occurs in the stem regions of tRNA, and a three-nucleotide sequence (e.g., CCA) at the 3'-end is the attachment site for the specific amino acid carried by each tRNA. Different tRNAs bind different amino acids. The three-dimensional structure of tRNA has been determined and is shown in Figure 13.17. tRNA is produced by RNA polymerase III, which recognizes, along with promoter-proximal elements, a split promoter within the transcribed region of the gene (Fig. 13.18). One segment of the promoter is located between +8 and +19. A second segment is 30 to 60 base pairs downstream from the first.

FIGURE 13.16 The transfer RNA (tRNA) cloverleaf. Bases that commonly occur in a particular position are indicated by letters. Base pairing in stem regions is indicated by *lines* between the strands. The locations of the modified bases dihydrouridine (D), ribothymidine (T), and pseudouridine (Ψ) are indicated.

FIGURE 13.17 The three-dimensional folding of transfer RNA (tRNA). (Republished with permission from Kim SH, Suddath FL, Quigley GJ, et al. Three-dimensional tertiary structure of yeast phenylalanine transfer RNA. *Science*. 1974;185(4149):435–440. © 1974. American Association for the Advancement of Science; permission conveyed through Copyright Clearance Center, Inc.)

FIGURE 13.18 Promoter for transfer RNA (tRNA) transcription. The segments of the genes from which the mature tRNA is produced are indicated by the *purple* color. The two regions of the promoter lie within these segments and are indicated by the *green* color.

tRNA precursors of approximately 100 nucleotides in length are generated (Fig. 13.19, circle 1). The pre-tRNA assumes a cloverleaf shape and is subsequently cleaved at the 5'- and 3'-ends (see Fig. 13.19, circle 2). The enzyme that acts at the 5'-end is RNase P, similar to the RNase P of bacteria. Both enzymes contain a small RNA (M1) that has catalytic activity and serves as an endonuclease. Some tRNA precursors contain introns that are removed by endonucleases. To close the opening, a 2'- or 3'-phosphate group from one end is ligated to a 5'-hydroxyl on the other end by an RNA ligase.

FIGURE 13.19 Overview of transfer RNA (tRNA) synthesis. D, T, Ψ , and ■ indicate modified bases. D, dihydrouracil; T, ribothymine; Ψ , pseudouridine; ■, other modified bases.

The bases are modified at the same time the endonucleolytic cleavage reactions are occurring (see Fig. 13.19, circle 3). Three modifications occur in most tRNAs: (1) Uracil is methylated by *S*-adenosylmethionine (SAM) to form thymine; (2) one of the double bonds of uracil is reduced to form dihydrouracil; and (3) a uracil residue (attached to ribose by an *N*-glycosidic bond) is rotated to form pseudouridine, which contains uracil

linked to ribose by a carbon–carbon bond (see Fig. 13.16). Other, less common but more complex, modifications also occur and involve bases other than uracil. Of particular note is the deamination of adenine in the nucleoside adenosine to form the base hypoxanthine and the nucleoside inosine.

The final step in forming the mature tRNA is the addition of a CCA sequence at its 3'-end (see Fig 13.19, circle 4). These nucleotides are added one at a time by nucleotidyltransferase. The tRNA then migrates to the cytoplasm. The terminal adenosine at the 3'-end is the site at which the specific amino acid for each tRNA is bound and activated for incorporation into a protein. The base modifications in tRNA appear to have two major roles; stabilizing the three-dimensional structure of the tRNA and facilitating codon–anticodon interactions.

V. Differences in Size between Eukaryotic and Prokaryotic DNA

A. Diploid versus Haploid

Except for the germ cells, most normal human cells are diploid. Therefore, they contain two copies of each chromosome, and each chromosome contains genes that are alleles of the genes on the homologous chromosome. Because one chromosome in each set of homologous chromosomes is obtained from each parent, the alleles can be identical, containing the same DNA sequence, or they can differ. A diploid human cell contains 2,000 times more DNA than the genome of the bacterium in the haploid *E. coli* cell (approximately 4×10^6 base pairs).

Calculate the number of different proteins, 300 amino acids in length, that could be produced from the *E. coli* genome (4×10^6 base pairs of DNA).

B. Introns

Eukaryotic introns contribute to the DNA size difference between bacteria and human cells. In eukaryotic genes, introns (noncoding regions) occur within sequences that code for proteins. Consequently, the primary transcript (heterogeneous nuclear RNA or hnRNA) averages roughly 10 times longer than the mature mRNA produced by removal of the introns. In contrast, bacterial genes do not contain introns.

C. Repetitive Sequences in Eukaryotic DNA

Although being diploid and containing introns account for some of the difference between the DNA content of humans and bacteria, a large difference remains that is related to the greater complexity of the human organism. Bacterial cells have a single copy of each gene, called **unique DNA**, and they contain very little DNA that does not produce functional products. Eukaryotic cells contain substantial amounts of DNA that does not code for functional products (i.e., proteins or rRNA and tRNA). In addition, some genes that encode functional products are present in multiple copies, called **highly repetitive** or **moderately repetitive** DNA. About 64% of the DNA in the human genome is unique, consisting of DNA sequences present in one or a very few copies in the genome. Some of the unique DNA sequences are transcribed to generate mRNA, which is translated to produce proteins.

Four million base pairs contain $(4 \times 10^6)/3$ or 1.33 million codons. If each protein contained approximately 300 amino acids, *E. coli* could produce about 4,000 different proteins $[(1.33 \times 10^6)/300]$.

Highly repetitive DNA consists of sequences approximately 6 to 100 base pairs in length that are present in hundreds of thousands to millions of copies, clustered within a few locations in the genome. It occurs in centromeres (which join sister chromatids during mitosis) and in telomeres (the ends of chromosomes). This DNA represents approximately 10% of the human genome. It is not transcribed.

Alu sequences in DNA were named for the enzyme Alu (obtained from *Arthrobacter luteus*), which is able to cleave them. Alu sequences make up 6% to 8% of the human genome. In some cases of familial hypercholesterolemia, homologous recombination is believed to have occurred between two Alu repeats, resulting in a large deletion in the low-density lipoprotein (LDL)–receptor gene. The LDL receptor mediates uptake of the cholesterol-containing LDL particle into many cell types, and in the absence of functional LDL receptors, blood cholesterol levels are elevated. Patients who are homozygous for this mutation may die from cardiac disease as early as in their second or third decade of life.

Moderately repetitive DNA is present in a few to tens of thousands of copies in the genome. This fraction constitutes approximately 25% of the human genome. It contains DNA that is functional and transcribed to produce rRNA, tRNA, and also some mRNA. The histone genes, present in a few hundred copies in the genome, belong to this class. Moderately repetitive DNA also includes some gene sequences that are functional but not transcribed. Promoters and enhancers (which are involved in regulating gene expression) are examples of gene sequences in this category. Other groups of moderately repetitive gene sequences that have been found in the human are called the **Alu sequences** (approximately 300 base pairs in length). Alu sequences are also examples of **Short INterspersed Elements (SINEs)**. The **Long INterspersed Elements (LINEs)** are 6,000 to 7,000 base pairs in length. The functions of the Alu and LINE sequences have not been determined.

The mutations that cause the thalassemias affect the synthesis of either the α - or the β -chains of adult hemoglobin, causing an anemia. They are classified by the chain affected (α - or β -) and by the amount of chain synthesized (0 for no synthesis and + for synthesis of some functional chains). They are also classified as major, intermediate, or minor, according to the severity of the clinical disorder and more recently as whether they are transfusion-dependent or transfusion-independent. β -Thalassemia major (also called homozygous β -thalassemia) is a clinically severe disorder requiring frequent blood transfusions. It is caused by the inheritance of two alleles for a severe mutation. In β -thalassemia intermedia, the patient exhibits a less severe clinical phenotype and is able to maintain hemoglobin levels >6 to 7 g/dL. It is usually the result of two different mild mutations or homozygosity for a mild mutation. β -Thalassemia minor (also known as β -thalassemia trait) is a heterozygous disorder involving a single mutation that is often clinically asymptomatic.

During embryonic and fetal life, the β -chain is replaced by the ϵ - and γ -chains, respectively. As a result, patients with severe mutations in the α -chain tend to die in utero, whereas those with mutations in the β -chains exhibit symptoms postnatally, as hemoglobin F ($\alpha_2\gamma_2$) is normally replaced with adult hemoglobin A ($\alpha_2\beta_2$) after birth.

D. Summary of the Differences between Eukaryotic and Prokaryotic DNA and RNA

A number of differences between eukaryotes and prokaryotes affect the processes of replication, transcription, and translation, in addition to the content of their DNA. Eukaryotic DNA is complexed with histones and prokaryotic DNA is not. In eukaryotic cells, the process of transcription, which occurs in the nucleus, is separated by the nuclear envelope from the process of translation (protein synthesis from the mRNA template), which occurs in the cytoplasm. Because prokaryotes lack nuclei, the processes of transcription and translation occur simultaneously. Transcription of bacterial DNA requires only one promoter per operon. In contrast, human DNA requires one promoter for each gene.

Complexity may explain some of the differences between the DNA content of bacteria and humans. But an extension of this line of reasoning would lead to the conclusion that frogs are more complex than humans, because frogs have 8 ft of DNA per diploid nucleus compared to the 6 ft in a human cell. Logic, or perhaps vanity, suggests that the amount of DNA per cell does not necessarily reflect the complexity of the organism. One of the features of frog DNA that may explain its length is that frogs have more repetitive DNA than humans. More than 75% of the frog genome is in the moderately and highly repetitive category, whereas only about 35% of the human genome is repetitive.

Major differences between prokaryotic and eukaryotic DNA and RNA are summarized in Table 13.2. LINEs make up about 5% of the human genome. In some patients with hemophilia (a disease in which blood does not clot normally), a LINE sequence has been inserted into exon 13 of the gene for Factor VIII, a protein of the blood-clotting system. The insertion of the LINE sequence leads to the production of a nonfunctional protein.

TABLE 13.2 Differences between Eukaryotes and Prokaryotes

	EUKARYOTES (HUMAN)	PROKARYOTES (<i>E. coli</i>)
Nucleus	Yes	No
Chromosomes		
Number	23 per haploid cell	1 per haploid cell
DNA	Linear	Circular
Histones	Yes	No
Genome		
Diploid	Somatic cells	No
Haploid	Germ cells	All cells
Size	3×10^9 base pairs per haploid cell	4×10^6 base pairs

Genes		
Unique	64%	100%
Repetitive		
Moderately	25%	None
Highly	10%	None
Operons	No	Yes
mRNA		
Polycistronic	No	Yes
Introns (hnRNA)	Yes	No
Translation	Separate from transcription	Coupled with transcription

CLINICAL COMMENTS

Lisa N. Patients with β^+ -thalassemia who maintain their hemoglobin levels above 6.0 to 7.0 g/dL are usually classified as having thalassemia intermedia. In the β -thalassemias, the α -chains of adult hemoglobin A ($\alpha_2\beta_2$) continue to be synthesized at a normal rate. These chains accumulate in the bone marrow in which the red blood cells are synthesized during the process of erythropoiesis (generation of red blood cells). The accumulation of α -chains diminishes erythropoiesis, resulting in an anemia. Individuals who are homozygous for a severe mutation require constant transfusions.

Individuals with thalassemia intermedia, such as **Lisa N.**, could have inherited two different defective alleles, one from each parent. One parent may be a “silent” carrier, with one normal allele and one mildly affected allele. This parent produces enough functional β -globin so few or no clinical symptoms of thalassemia appear. (However, they generally have a somewhat decreased amount of hemoglobin, resulting in microcytic hypochromic red blood cells.) When this parent contributes the mildly defective allele and the other heterozygous parent contributes a more severely defective allele, thalassemia intermedia occurs in the child. The child is thus heterozygous for two different defective alleles.

Isabel S. was treated with a multidrug regimen for tuberculosis because the microbes that cause the disease frequently become resistant to the individual drugs. The current approach in patients with *Mycobacterium tuberculosis* is to initiate antimycobacterial therapy with four agents because the mycobacteria frequently become resistant to one or more of the individual antitubercular drugs. The same approach is taken for patients with HIV, with careful attention to drug interactions. **Isabel S.** was started on isoniazid (INH), rifampin, pyrazinamide, and ethambutol. Isoniazid inhibits the biosynthesis of mycolic acids, which are important constituents of the mycobacterial cell wall. Isoniazid is prescribed with vitamin B₆ (pyridoxine), as isoniazid can interfere with the activation of this vitamin (to pyridoxal phosphate), which can lead to an alteration in normal cellular metabolism and result in a clinical neuropathy. Rifampin binds to and inhibits bacterial RNA polymerase, which selectively kills the bacteria that cause the infection. Pyrazinamide, a synthetic analog of nicotinamide, targets the mycobacterial fatty acid synthase I gene involved in mycolic acid biosynthesis in *M. tuberculosis*. Ethambutol blocks arabinosyl transferases that are involved in cell wall biosynthesis.

Just as bacteria can become resistant to drugs, so can HIV. Because of this concern, patients with HIV are treated with multidrug regimens. Multidrug regimens usually include two nucleoside reverse transcriptase inhibitors (NRTIs), as well as a third agent. The third agent is usually either a nonnucleoside reverse transcriptase inhibitor (NNRTIs), an example of which is efavirenz; a protease inhibitor (PI), an example of which is indinavir; or an integrase inhibitor. PIs prevent the HIV polyprotein from being cleaved into its mature products (see Biochemical Comments). The drugs are often combined into one pill to make it easier to take.

Studies have indicated that a failure to dispose properly of cellular debris, a normal by-product of cell death, may lead to the induction of autoantibodies directed against chromatin in patients with SLE. Normal cells have a finite lifetime and are programmed to die (apoptosis) through a distinct biochemical mechanism. One of the steps in this mechanism is the stepwise degradation of cellular DNA (and other cellular components). If the normal intracellular components are exposed to the immune system, autoantibodies against them may be generated. The enzyme in cells that degrades DNA is deoxyribonuclease I (DNase I), and individuals with SLE have reduced serum activity levels of DNase I compared with individuals who do not have the disease. Through an understanding of the molecular mechanism whereby autoantibodies are generated, it may be possible to develop therapies to combat this disorder.

Catherine T. The toxin α -amanitin is capable of causing irreversible hepatocellular and renal dysfunction through inhibition of mammalian RNA polymerases. α -Amanitin is particularly effective at blocking the action of RNA polymerase II. Fortunately, **Catherine T.**'s toxicity proved mild. She developed only gastrointestinal symptoms and slight changes in her hepatic and renal function, which returned to normal within a few weeks. Treatment was primarily supportive, with fluid and electrolyte replacement for that lost through the gastrointestinal tract. No effective antidote is available for the *Amanita phalloides* toxin.

Sarah L. SLE is a multisystem disease characterized by inflammation related to the presence of autoantibodies in the blood. These autoantibodies react with antigens normally found in the nucleus, cytoplasm, and plasma membrane of the cell. Such “self” antigen–antibody (autoimmune) interactions initiate an inflammatory cascade that produces the broad symptom profile of multiorgan dysfunction found in **Sarah L.**

Pharmacologic therapy for SLE involves anti-inflammatory drugs and immunosuppressive agents. It can include nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, antimalarials, or immunosuppressive drugs. Plaquenil is an antimalarial drug used to treat skin and joint symptoms in SLE, although its exact mechanism of action in these patients is not fully understood. **Sarah L.** was placed on such a drug regimen.

BIOCHEMICAL COMMENTS

Production of the Virus that Causes AIDS. AIDS is caused by the HIV. Two major forms of the virus have been discovered, HIV-1, which is prevalent in industrialized countries, and HIV-2, which is prevalent in certain regions of Africa and small sections of India. Eight to 10 years or more can elapse between the initial infection and development of the full-blown syndrome.

Proteins in the viral coat bind to membrane protein receptors (named CD4) of helper T-lymphocytes, a class of cells involved in the immune response. Subsequently, conformational changes occur that allow the viral-coat proteins to bind to a chemokine coreceptor in the cell membrane. The lipid in the viral coat then fuses with the cell membrane, and the viral core enters the cell, releasing its RNA and enzymes (including the reverse transcriptase) by a process called “uncoating.” Reverse transcriptase uses the viral RNA as a template to produce a single-stranded DNA copy, which then serves as a template for synthesis of a double-stranded DNA. An integrase enzyme, also carried by the virus, enables this DNA to integrate into the host cell genome as a provirus (Fig. 13.20).

FIGURE 13.20 Infection of a host cell by HIV. The HIV virus particle binds to the CD4 receptor and a chemokine coreceptor in the host cell membrane. The virus enters the cell and uncoats, releasing its RNA and proteins. The viral enzyme reverse transcriptase produces a double-stranded DNA copy that is integrated into the host cell genome. HIV is now a provirus. Transcripts of the viral DNA are spliced and translated to produce the proteins Tat, Rev, and Nef. Tat stimulates transcription of the viral DNA, and Rev causes the viral RNA transcripts to leave the nucleus unspliced. The unspliced RNA serves as the viral genome and also codes for the proteins of the viral core and envelope. The envelope proteins (gp41 and gp120, which are derived from the env protein), enter the cell membrane. The viral core proteins are synthesized as a polyprotein, which is cleaved by a protease as the viral particles form and bud from the cell membrane. The particles carry membrane lipid as a coat that contains gp41 and gp120. Nef indirectly aids in the assembly of viral particles. Pol is the reverse transcriptase produced from the viral RNA.  stimulates.

In the initial stage of transcription of the provirus, the transcript is spliced, and three proteins, Nef, Tat, and Rev, are produced. Tat stimulates transcription of the viral genes. As Rev accumulates, it allows unspliced viral RNA to leave the nucleus and to produce proteins of the viral envelope and viral core, including reverse transcriptase. Two of the envelope glycoproteins (gp41 and gp120, which are derived from the env gene product) form a complex that embeds in the cell membrane. The other proteins, which are translated as a polyprotein and cleaved by the viral protease (one of the targets of anti-HIV drugs), combine with the full-length viral RNA to form core viral particles, which bud from the cell membrane. Thus, the virus obtains its lipid coat from the host cell membrane, and the coat contains the viral proteins gp41 and gp120. These surface proteins of the virus bind to CD4 receptors on other human helper T-lymphocytes and the infection spreads.

In an uninfected person, helper T-lymphocytes usually number approximately 1,000/mL. Infection with HIV causes the number of these cells to decrease, which results in a deficiency of the immune system. When the number of T-lymphocytes drops to <200/mL, the disease is in an advanced stage, and opportunistic infections, such as tuberculosis, occur. Although macrophages and dendritic cells lack CD4 receptors, they can also become infected with HIV and can carry the virus to the central nervous system.

Drugs currently used to treat HIV act on the viral reverse transcriptase or the protease (see Fig. 13.20). The nonnucleoside drugs (e.g., efavirenz) bind to reverse transcriptase and inhibit its action. The nucleoside analogs (e.g., lamivudine) add to the 3'-end of the growing DNA transcript produced by reverse transcriptase and prevent further elongation. The PIs (e.g., indinavir) bind to the protease and prevent it from cleaving the polyprotein.

The most effective means of combating HIV infection involves the use of drugs that inhibit the viral reverse transcriptase or the viral protease. However, these drugs only hold the infection at bay; they do not effect a cure.

KEY CONCEPTS

- ◆ Transcription is the synthesis of RNA from a DNA template.
- ◆ The enzyme RNA polymerase transcribes genes into a single-stranded RNA.
- ◆ The RNA produced is complementary to one of the strands of DNA, which is known as the template strand. The other DNA strand is the coding, or sense strand.
- ◆ Bacteria contain a single RNA polymerase; eukaryotic cells utilize three different RNA polymerases.
- ◆ The DNA template is copied in the 3'-to-5' direction and the RNA transcript is synthesized in the 5'-to-3' direction.
- ◆ In contrast to DNA polymerases, RNA polymerases do not require a primer to initiate transcription, nor do they contain extensive error-checking capabilities.
- ◆ Promoter regions, specific sequences in DNA, determine where on the DNA template RNA polymerase binds to initiate transcription.
- ◆ Transcription initiation requires a number of protein factors to allow for efficient RNA polymerase binding to the promoter.
- ◆ Other DNA sequences, such as promoter-proximal elements and enhancers, affect the rate of transcription initiation through the interactions of DNA-binding proteins with RNA polymerase and other initiation factors.
- ◆ Eukaryotic genes contain exons and introns. Exons specify the coding region of proteins, whereas introns have no coding function.
- ◆ The primary transcript of eukaryotic genes is modified to remove the introns (splicing) before a final,

mature mRNA is produced.

- ◆ Table 13.3 summarizes the diseases discussed in this chapter.

TABLE 13.3 Diseases Discussed in Chapter 13

DISORDER OF CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
β -Thalassemia	Genetic	An anemia because of an imbalance in β - and α -globin chain synthesis. For a β -thalassemia, more α -chain is synthesized than functional β -chain.
Tuberculosis	Environmental	The drug rifampin, among others, is used to treat tuberculosis, via inhibition of bacterial RNA polymerase.
Mushroom poisoning (α -amanitin poisoning)	Environmental	Inhibition of RNA polymerase II by α -amanitin. There is no effective antidote for this poison.
Systemic lupus erythematosus (SLE)	Both	The development of autoantibodies directed against various cellular proteins, including those involved in RNA processing (such as complexes involved in RNA splicing, the snurps)

REVIEW QUESTIONS—CHAPTER 13

- A gene would need to contain which one of the following templates to generate the short transcript AUCCGUACG (note that all sequences are written from 5' to 3')?
 - ATCCGTACG
 - CGTACGGAT
 - AUCCGUACG
 - TAGGCATGC
 - GCATGCCTA
- Given that the LD_{50} (the dose at which 50% of the recipients die) of amanitin is 0.1 mg/kg body weight and that the average mushroom contains 7 mg amanitin, how many mushrooms must be consumed by **Catherine T.** (50-kg body weight) to be above the LD_{50} ?
 - 1
 - 2
 - 3
 - 4
 - 5
- Mutations in DNA large distances from a structural gene can lead to over- or underexpression of that gene. Which one of the following eukaryotic DNA control sequences does not need to be in a fixed location, and is most responsible for high rates of transcription of particular genes?
 - Promoter
 - Promoter-proximal element
 - Enhancer
 - Operator
 - Splice donor site
- Which one of the following is true of both eukaryotic and prokaryotic gene expression, and would therefore not be an effective target for drug development?
 - After transcription, a 3'-poly(A) tail and a 5'-cap are added to mRNA.
 - Translation of mRNA can begin before transcription is complete.
 - mRNA is synthesized in the 3'-to-5' direction.
 - RNA polymerase binds at a promoter region upstream of the gene.
 - Mature mRNA is always precisely colinear to the gene from which it was transcribed.
- A family has two children, both of whom have a form of β -thalassemia. One child is almost nonsymptomatic, whereas the other requires frequent blood transfusion for his disease. The α - to β -globin ratio in the more severely affected child is most likely to be which one of the following?
 - 5:1
 - 2:1

- C. 1:1
 - D. 1:2
 - E. 1:5
6. Certain drugs can be used as antibiotics as they affect bacterial RNA polymerases, but not eukaryotic RNA polymerases. RNA polymerase is a key enzyme in the process of transcription, which can be best described by which one of the following?
 - A. The single-stranded RNA produced is complementary to one of the strands of double-stranded DNA.
 - B. The single-stranded RNA produced is identical to both of the strands of double-stranded DNA.
 - C. Eukaryotic genes are transcribed in the cytosol by three different RNA polymerases.
 - D. RNA polymerase cannot initiate new strand synthesis and must have a primer.
 - E. Eukaryotic genes are transcribed in the nucleus by three different DNA polymerases.
 7. Eukaryotic cells contain multiple RNA polymerases, which makes it difficult to block all RNA synthesis with one drug targeted to a specific polymerase. Which one of the following best describes properties of eukaryotic RNA polymerases?
 - A. Polymerase I produces most of the ribosomal RNA.
 - B. Polymerase II produces most of the transfer RNA.
 - C. Polymerase III produces most of the messenger RNA.
 - D. All three RNA polymerases have the same mechanism of action and bind to the same promoter sequences on DNA.
 - E. Enhancers identify the start point for transcription for all three polymerases.
 8. The production of mRNA in eukaryotic cells requires a large number of steps, and drugs targeted to any of these steps could block mRNA production. Which one of the following accurately describes a part of the process of producing mRNA from a eukaryotic gene?
 - A. The sense strand of DNA is the strand used by RNA polymerase during transcription.
 - B. The antisense DNA strand is identical to the RNA transcript except the DNA strand contains thymine and the RNA strand contains uracil.
 - C. The first RNA form produced contains both intron and exon sequences.
 - D. Mature mRNA contains a cap at the 5'-end, a poly(A) tail at the 3'-end, introns, and exons.
 - E. During processing in the nucleus of a precursor mRNA introns and exons are shuffled in sequence to produce the mature mRNA.
 9. Genetic abnormalities in DNA are transcribed into mRNA. This error then causes tRNA to utilize an incorrectly coded amino acid to produce a protein, which may then malfunction because of the alteration in primary structure of the synthesized protein. The tRNAs utilized for protein synthesis can be best described by which one of the following?
 - A. A specific tRNA can code for multiple different amino acids.
 - B. tRNA contains a codon site that binds with an anticodon of mRNA.
 - C. tRNA contains one specific binding site for both the sequence of three nucleotides in mRNA and the encoded amino acid.
 - D. One of the loops of tRNA contains the anticodon.
 - E. The D-loop contains the anticodon.
 10. A researcher wants to develop an antibiotic that targets histones and introns in bacteria and has applied for a grant. Why would the grant's physician/biochemist advisor advise against funding this grant application?
 - A. The proposed antibiotic would have no effect on bacteria but could harm human cells.
 - B. The proposed antibiotic would negatively affect both bacteria and human cells.
 - C. The proposed antibiotic would have no effect on either bacteria or human cells.
 - D. Bacteria have histones but do not have introns.
 - E. Bacteria have introns but do not have histones.
 11. A couple out on a hike in the woods picked some mushrooms to eat with their dinner that evening. About 24 hours after eating the mushrooms, they both developed nausea, vomited, and had bloody diarrhea. Upon going to the emergency department at the local hospital, they were eventually diagnosed with mushroom poisoning. The toxin they ingested was most likely affecting the transcription of which one of the following?
 - A. 18S and 28S ribosomal RNA genes
 - B. Transfer RNA genes
 - C. Genes of the mitochondrial genome
 - D. Messenger RNA
 - E. 5S ribosomal RNA genes

2. The sense strand of a bacterial gene has a partial sequence of - - ATGCCGTTATGGA - - . The corresponding region of an mRNA transcribed from this gene would be which one of the following?
- - ATGCCGTTATGGA - -
 - - AUGCCGUUAUGGA - -
 - - TCCATAACGGCAT - -
 - - UCCAUAACGGCAU - -
 - - AGGTATTGCCGTA - -
3. A young boy has been diagnosed with a β^+ -thalassemia intermediate, with hemoglobin levels of 7.1 g/dL (reference range is 12.0 to 16.0 g/dL). The reduction in functional hemoglobin levels could have occurred due to which of the mutations described below? Pick the one best answer.

	A Mutation in the Basal Promoter of the β-globin Gene	A Missense Mutation in the β-globin Gene	A Splice-site Mutation in the β-globin Gene	The Creation of a STOP Codon in Exon I of the β-globin Gene
A	Yes	No	Yes	Yes
B	Yes	Yes	No	No
C	Yes	No	Yes	No
D	No	Yes	No	No
E	No	No	Yes	Yes
F	No	Yes	No	Yes

4. Replication of the HIV genome is highly error-prone because of lack of proofreading activity of which of the following enzymes?
- DNA polymerase
 - RNA polymerase
 - Reverse transcriptase
 - DNA polymerase and RNA polymerase
 - DNA polymerase and reverse transcriptase
 - RNA polymerase and reverse transcriptase
5. Transfer RNA is a key component for protein synthesis and contains a significant number of bases that are modified posttranscriptionally. Based on the text, which one of the following bases is the one that is most frequently modified?
- A
 - T
 - C
 - G
 - U

ANSWERS TO REVIEW QUESTIONS

1. **The answer is B.** The transcript that is produced is copied from the DNA template strand, which must be

of the opposite orientation from the transcript. So the 5'-end of the template strand should base-pair with the 3'-end of the transcript, or the G. Thus, CGTACGGAT would base-pair with the transcript and would represent the template strand.

2. **The answer is A. Catherine T.** weighs 50 kg, and if 0.1 mg/kg body weight is the LD₅₀, then for her, 5 mg of toxin would bring her to the LD₅₀. Because one mushroom contains 7 mg of the toxin, ingesting just one mushroom could be fatal.
3. **The answer is C.** Enhancer sequences can be thousands of bases away from the basal promoter and still stimulate transcription of the gene. This is accomplished by looping of the DNA so that the proteins binding to the enhancer sequence (transactivators) can also bind to proteins bound to the promoter (coactivators). A promoter-proximal element is a DNA sequence nearby the promoter that can bind transcription factors that aid in recruiting RNA polymerase to the promoter region.
4. **The answer is D.** Both prokaryotes and eukaryotes require RNA polymerase binding to an upstream promoter element. Answer A applies only to eukaryotes; prokaryote mRNA is not capped, nor does it contain a poly(A) tail. Prokaryotes have no nucleus; thus, the 5'-end of an mRNA is immediately available for ribosome binding and initiation of translation (thus, B is incorrect). Answer C is incorrect overall; RNA synthesis, like DNA synthesis, is always in the 5'-to-3' direction. Answer E is incorrect because introns are present only in eukaryotic genes.
5. **The answer is A.** A β -thalassemia refers to a condition in which the α -chain of globin is produced in excess of the β -chain. The greater the ratio of α - to β - chain, the more severe the disease. Patients are usually asymptomatic at a ratio of 2:1, but once the ratio is greater than 2:1, symptoms will become evident. The reduction in β -globin synthesis can come about because of splicing mutations, promoter mutations, or point mutations within the coding regions of the β -globin gene.
6. **The answer is A.** The single-stranded RNA produced by transcription is identical in sequence to one (not both) of the DNA strands except that the RNA strand contains the base uracil in locations where the DNA strand contains thymine. The mRNA sequence is complementary to the template strand of the DNA. Eukaryotic genes are transcribed in the nucleus (not cytosol) by three different RNA polymerases (not DNA polymerases). RNA polymerase does not require a primer to initiate transcription, unlike DNA polymerase that does require a primer to initiate DNA replication.
7. **The answer is A.** The promoter region on the DNA identifies the start point of transcription for each gene. Enhancers are distal promoter elements that stabilize RNA polymerase binding to the promoter, but enhancers do not identify the initiation point for transcription. All of the RNA polymerases have the same mechanism of action but differ in which promoters they recognize (the sequence of promoters differs for each polymerase) because of the use of different accessory factors in forming the initiation complex. Polymerase I produces ribosomal RNA, polymerase II messenger RNA, and polymerase III transfer RNA in eukaryotic cells.
8. **The answer is C.** The sense (or coding) strand of DNA is identical to the mRNA produced, with the exception of the DNA containing thymine and the RNA containing uracil. The template (or antisense) strand of DNA is the strand that is used by RNA polymerase to produce a complementary RNA sequence to the template strand (thus, the antisense strand is complementary to the mRNA produced, and is not identical to it). The first RNA form produced by RNA polymerase is hnRNA, which contains both intron (noncoding) and exon (coding sequences) sequences. hnRNA is modified by the addition of a cap to the 5'-end, a poly(A) tail added to the 3'-end and all introns removed. During processing, the intron sequences are removed from the hnRNA to produce the mature mRNA.
9. **The answer is D.** tRNA contains a three-base sequence known as the anticodon that binds to a corresponding complementary codon on the mRNA. The amino acid is covalently linked to the tRNA at its 3'-end, which is distinct from the anticodon site. A particular tRNA only links to one amino acid, not multiple amino acids. In the cloverleaf structure of tRNA, one of the loops contains the anticodon, and that is distinct from the D-loop, which frequently contains dihydrouridine as an unusual base.
10. **The answer is A.** Bacteria do not have histones or introns but humans have both. The proposed antibiotic would have no effect on bacteria but could have a deleterious effect on human cells.
11. **The answer is D.** The couple were poisoned by α -amanitin, a toxin which primarily targets RNA polymerase II, which transcribes genes and produces mRNA. RNA polymerase I synthesizes the 18S and 28S ribosomal RNAs. RNA polymerase III synthesizes tRNA and 5S ribosomal RNA. A mitochondrial RNA polymerase synthesizes genes of the mitochondrial genome. These other RNA polymerases are not as affected by α -amanitin as is RNA polymerase II.
12. **The answer is B.** The mRNA has the same sequence and orientation as the sense strand of the DNA,

other than U replaces T in the sequence in the RNA.

13. **The answer is A.** The child is synthesizing more α -chains than β -chains, indicating a deficiency in β -chain synthesis. This could occur through a mutation in the promoter region of the β -chain, reducing the frequency of transcription initiation, or a mutation in a splice site such that an intron is not spliced out properly, leading to a misfolded and likely degraded form of the β -chain. A missense mutation in the coding region of the gene would likely produce a nonfunctional β -chain, but the ratio of α - to β -chain would not be altered, and it would not be classified as a thalassemia. The creation of a stop codon in the first exon would lead to a very short fragment of the β -chain being synthesized, which would likely be degraded, resulting in an imbalance in α - to β -chains and a thalassemia.
14. **The answer is F.** DNA polymerase has error-checking through proofreading but RNA polymerase and reverse transcriptase do not. Reverse transcriptase is required to convert the single-stranded RNA genome to a double-stranded DNA molecule (and errors could be introduced during this step). The double-stranded DNA is then integrated into the host genome, where RNA polymerase transcribes the viral DNA to produce viral RNA (a second step in which errors can be introduced into the genome due to the lack of error-checking by RNA polymerase).
15. **The answer is E.** Uracil is most often modified, as it is converted to pseudouridine, dihydrouracil, and thymine posttranscriptionally.

Translation: Synthesis of Proteins

Proteins are produced by the process of **translation**, which occurs on **ribosomes** and is directed by messenger RNA (**mRNA**). The genetic message encoded in DNA is first transcribed into mRNA, and the **nucleotide sequence** in the coding region of the mRNA is then translated into the **amino acid sequence** of the protein.

Translation of the Code. The portion of mRNA that specifies the amino acid sequence of the protein is read in **codons**, which are **sets of three nucleotides** that specify individual amino acids (Fig. 14.1). The codons on mRNA are read sequentially in the 5'-to-3' direction, starting with the **5'-AUG** (or "**start**" codon) that specifies **methionine** and sets the **reading frame** and ending with a **3'-termination** (or "**stop**") codon (**UAG, UGA, or UAA**). The protein is synthesized from its **N-terminus** to its **C-terminus**.

FIGURE 14.1. Binding of transfer RNA (tRNA) to a codon on messenger RNA (mRNA). The tRNA contains an amino acid at its 3'-end that corresponds to the codon on mRNA with which the anticodon of the tRNA can base-pair. Note that the codon-anticodon pairing is complementary and antiparallel.

Each amino acid is carried to the ribosome by an **aminoacyl-transfer RNA (tRNA)** (i.e., a tRNA with an amino acid covalently attached). **Base pairing** between the **anticodon** of the tRNA and the **codon** on the mRNA ensures that each amino acid is inserted into the growing polypeptide at the appropriate position.

Synthesis of the Protein. Initiation involves the formation of a complex containing the initial **methionyl-tRNA** bound to the AUG “start” codon of the **mRNA** and the “P” site of the **ribosome**. It requires guanosine triphosphate (**GTP**) and proteins known as **eukaryotic initiation factors (eIFs)**.

Elongation of the polypeptide involves **three steps**: (1) **binding** of an **aminoacyl-tRNA** to the “A” site on the ribosome, where it base-pairs with the second codon on the mRNA; (2) **formation** of a **peptide bond** between the first and second amino acids; and (3) **translocation**, movement of the mRNA relative to the ribosome, so that the third mRNA codon moves into the “A” site. These three **elongation steps** are **repeated** until a **termination** codon aligns with the site on the ribosome where the next aminoacyl-tRNA would normally bind. **Release factors** bind instead, causing the completed protein to be released from the ribosome.

After one ribosome binds and moves along the mRNA, translating the polypeptide, another ribosome can bind and begin translation. The complex of a single mRNA with multiple ribosomes is known as a **polysome**.

Folding and Modification and Targeting of the Protein. Folding of the polypeptide into its three-dimensional configuration occurs as the polypeptide is being translated. This process involves proteins called **chaperones**. **Modification** of amino acid residues in a protein occurs during or after translation. Proteins synthesized on **cytosolic ribosomes** are released into the cytosol or transported into mitochondria, peroxisomes, and the nucleus. Proteins synthesized on ribosomes attached to the **rough endoplasmic reticulum (RER)** are destined for lysosomes, cell membranes, or secretion from the cell. These proteins are transferred to the **Golgi complex**, where they are modified and **targeted** to their ultimate locations.

THE WAITING ROOM

Lisa N., a 4-year-old patient with β^+ -thalassemia intermedia (see Chapter 13), showed no improvement in her symptoms at her second visit. Her hemoglobin level was 7.3 g/dL (reference range for females, 12 to 16 g/dL).

The results of tests performed in the molecular biology laboratory show that **Jay S.** has an insertion in exon 11 of the α -chain of the hexosaminidase A gene, the most common mutation found in patients of Ashkenazi Jewish background who have Tay–Sachs disease. The hexosaminidase A gene encodes the α -chain for the hexosaminidase A protein. Hexosaminidase A, the enzyme activity that is lacking in **Jay S.**, can be assayed using a serum sample and a substrate that releases a fluorescent dye upon being hydrolyzed. When measuring enzyme activity, one needs to be careful to distinguish between hexosaminidase A activity and a closely related activity owing to hexosaminidase B. This is accomplished by differential heat inactivation of the sample (exposure of the sample to 50°C will inactivate hexosaminidase A activity but not hexosaminidase B activity). For prenatal screening, molecular techniques are the preferred method because of their sensitivity and the limited amount of sample available (see Chapter 17).

Jay S. is a 9-month-old male infant of Ashkenazi Jewish parentage. His growth and development were normal until age 5 months, when he began to exhibit mild, generalized muscle weakness. By 7 months, he had poor head control, slowed development of motor skills, and was increasingly inattentive to his surroundings. His parents also noted unusual eye movements and staring episodes. On careful examination of his retinae, his pediatrician observed a “cherry red” spot within a pale macula. The physician suspected Tay–Sachs disease and sent samples of his whole blood to the molecular biology–genetics laboratory.

Paul T. returned to his physician’s office after 5 days of azithromycin therapy (see Chapter 11) feeling significantly better. The sputum sample from his previous visit had been cultured. The results confirmed that

his respiratory infection was caused by *Streptococcus pneumoniae* and that the organism was sensitive to penicillin, macrolides (e.g., erythromycin, clarithromycin), tetracycline, and other antibiotics.

Edna R., a 25-year-old junior medical student, brings her healthy 4-month-old daughter, **Beverly**, to the pediatrician for her second diphtheria, pertussis, and tetanus (DPT, acellular pertussis) immunization, along with immunizations for pneumococcal, inactivated polio, haemophilus influenzae, and rotavirus. **Edna R.** tells the doctor that her great great aunt had died of diphtheria during an epidemic many years ago.

I. The Genetic Code

Transcription, the transfer of the genetic message from DNA to RNA, and **translation**, the transfer of the genetic message from the nucleotide language of nucleic acids to the amino acid language of proteins, both depend on base pairing. In the late 1950s and early 1960s, molecular biologists attempting to decipher the process of translation recognized two problems. The first involved decoding the relationship between the language of the nucleic acids and the language of the proteins, and the second involved determining the molecular mechanism by which translation between these two languages occurs.

Twenty different amino acids are commonly incorporated into proteins, and therefore the protein alphabet has 20 characters. The nucleic acid alphabet, however, has only four characters, corresponding to the four nucleotides of mRNA (A, G, C, and U). If two nucleotides constituted the code for an amino acid, then only 4^2 or 16 amino acids could be specified. Therefore, the number of nucleotides that code for an amino acid has to be at least three, providing 4^3 or 64 possible combinations or **codons**, more than required, but not excessive.

Scientists set out to determine the specific codons for each amino acid. In 1961, Marshall Nirenberg produced the first crack in the genetic code (the collection of codons that specifies all the amino acids found in proteins). He showed that poly(U), a polynucleotide in which all the bases are uracil, produced polyphenylalanine in a cell-free protein-synthesizing system. Thus, UUU must be the codon for phenylalanine. As a result of experiments using synthetic polynucleotides in place of mRNA, other codons were identified.

The pioneering molecular biologists recognized that, because amino acids cannot bind directly to the sets of three nucleotides that form their codons, adapters are required. The adapters were found to be tRNA molecules. Each tRNA molecule contains an **anticodon** and covalently binds a specific amino acid at its 3'-end (see Chapters 11 and 13). The anticodon of a tRNA molecule is a set of three nucleotides that can interact with a codon on mRNA (see Fig. 14.1). In order to interact, the codon and anticodon must be complementary (i.e., they must be able to form base pairs in an antiparallel orientation). Thus, the anticodon of a tRNA serves as the link between an mRNA codon and the amino acid that the codon specifies.

Obviously, each codon present within mRNA must correspond to a specific amino acid. Nirenberg found that trinucleotides of known base sequence could bind to ribosomes and induce the binding of specific aminoacyl-tRNAs (i.e., tRNAs with amino acids attached covalently). As a result of these and the earlier experiments, the relationship between all 64 codons and the amino acids they specify (the entire genetic code) was determined by the mid-1960s (Table 14.1).

TABLE 14.1 The Genetic Code

FIRST BASE		SECOND BASE			THIRD BASE
(5')	U	C	A	G	(3')
U	Phe	Ser	Tyr	Cys	U
	Phe	Ser	Tyr	Cys	C
	Leu	Ser	Stop	Stop	A
	Leu	Ser	Stop	Trp	G
C	Leu	Pro	His	Arg	U
	Leu	Pro	His	Arg	C
	Leu	Pro	Gln	Arg	A
	Leu	Pro	Gln	Arg	G
A	Ile	Thr	Asn	Ser	U
	Ile	Thr	Asn	Ser	C
	Ile	Thr	Lys	Arg	A
	Met	Thr	Lys	Arg	G
G	Val	Ala	Asp	Gly	U
	Val	Ala	Asp	Gly	C
	Val	Ala	Glu	Gly	A
	Val	Ala	Glu	Gly	G

Three of the 64 possible codons (UGA, UAG, and UAA) terminate protein synthesis and are known as **stop** or **nonsense codons**. The remaining 61 codons specify amino acids. Two amino acids each have only one codon (AUG for methionine; UGG for tryptophan). The remaining amino acids have multiple codons.

A. The Code Is Degenerate Yet Unambiguous

Because many amino acids are specified by more than one codon, the genetic code is described as degenerate, which means that an amino acid may have more than one codon. However, each codon specifies only one amino acid, and the genetic code is thus unambiguous.

Inspection of a codon table shows that in most instances of multiple codons for a single amino acid, the variation occurs in the third base of the codon (see Table 14.1). Crick noted that the pairing between the 3'-base of the codon and the 5'-base of the anticodon does not always follow the strict base-pairing rules that he and Watson had previously discovered (i.e., A pairs with U, and G with C). This observation resulted in the **wobble hypothesis**.

At the third base of the codon (the 3'-position of the codon and the 5'-position of the anticodon), the base pairs can wobble. For example, G can pair with U, and A, C, or U can pair with the unusual base hypoxanthine (I) found in tRNA. Thus, three of the four codons for alanine (GCU, GCC, and GCA) can pair with a single tRNA that contains the anticodon 5'-IGC-3' (Fig. 14.2). If each of the 61 codons for amino acids required a distinct tRNA, cells would contain 61 tRNAs. However, because of wobble between the codon and anticodon, fewer than 61 tRNAs are required to translate the genetic code.

A. Codons for alanine

B. Base pairing of three alanine codons with anticodon IGC

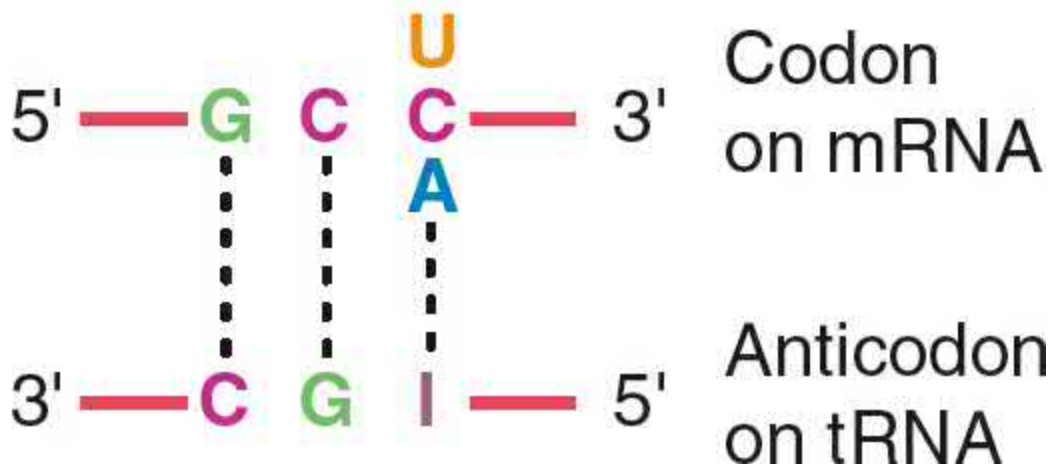

FIGURE 14.2. Base pairing of codons for alanine with 5'-IGC-3'. **A.** The variation is in the third base. **B.** The first three of these codons can pair with a transfer RNA (tRNA) that contains the anticodon 5'-IGC-3'. Hypoxanthine (I) is an unusual base found in tRNA that can form base pairs with U, C, or A. It is formed by the deamination of adenine. Hypoxanthine is the base attached to ribose in the nucleoside inosine. The single-letter abbreviation for hypoxanthine is I, referring to the nucleoside inosine.

All organisms studied so far use the same genetic code, with some rare exceptions. One exception occurs in human mitochondrial mRNA, in which UGA codes for tryptophan instead of serving as a stop codon, AUA codes for methionine instead of isoleucine, and CUA codes for threonine instead of leucine.

B. The Code Is Nonoverlapping

mRNA does not contain extra nucleotides, or punctuation, to separate one codon from the next, and the codons do not overlap. Each nucleotide is read only once. Beginning with a start codon (AUG) near the 5'-end of the

mRNA, the codons are read sequentially, ending with a stop codon (UGA, UAG, or UAA) near the 3'-end of the mRNA.

C. Relationship between mRNA and the Protein Product

The start codon (AUG) sets the reading frame, the order in which the sequence of bases in the mRNA is sorted into codons (Fig. 14.3). The order of the codons in the mRNA determines the sequence in which amino acids are added to the growing polypeptide chain. Thus, the order of the codons in the mRNA determines the linear sequence of amino acids in the protein.

FIGURE 14.3. Reading frame of messenger RNA (mRNA). **A.** For any given mRNA sequence, there are three possible reading frames (1, 2, and 3). **B.** An AUG near the 5'-end of the mRNA (the start codon) sets the reading frame for the translation of a protein from the mRNA. The codons are read in linear order, starting with this AUG. (The other potential reading frames are not used. They would give proteins with different amino acid sequences.)

II. Effects of Mutations

Mutations that result from damage to the nucleotides of DNA molecules or from unrepaired errors during replication (see Chapter 12) can be transcribed into mRNA and therefore can result in the translation of a protein with an abnormal amino acid sequence. Various types of mutations can occur, which have different effects on the encoded protein (Table 14.2).

TABLE 14.2 Types of Mutations		
TYPE	DESCRIPTION	EXAMPLE
Point	A single base change	
Silent	A change that specifies the same amino acid	CGA → CGG Arg → Arg
Missense	A change that specifies a different amino acid	CGA → CCA Arg → Pro
Nonsense	A change that produces a stop codon	CGA → UGA Arg → Stop
Insertion	An addition of one or more bases	
Deletion	A loss of one or more bases	

A. Point Mutations

Point mutations occur when only one base in DNA is altered, producing a change in a single base of an mRNA codon. There are three basic types of point mutations: silent mutations, missense mutations, and

nonsense mutations. Point mutations are said to be “silent” when they do not affect the amino acid sequence of the protein. For example, a codon change from CGA to CGG does not affect the protein because both of these codons specify arginine (see Table 14.1). In **missense mutations**, one amino acid in the protein is replaced by a different amino acid. For example, a change from CGA to CCA causes arginine to be replaced by proline. A nonsense mutation causes the premature termination of a polypeptide chain. For example, a codon change from CGA to UGA causes a codon for arginine to be replaced by a stop codon, so the synthesis of the mutant protein terminates at this point.

Silent point mutations can also lead to disease if they create a new splice site during mRNA processing. Hutchinson–Gilford Progeria syndrome (HGPS), a premature aging disorder, can result from a mutation in the lamin A gene (*LMNA* gene) in which the base at position 1,824 in the gene is altered from a cytosine to a thymine. This single nucleotide change does not alter the amino acid sequence (the codon indicated a glycine before the change and indicates a glycine after the change), but it does create a cryptic splice site in exon 11, which gives rise to a prelamin A that is missing 50 amino acids. The loss of these amino acids interferes with posttranslational processing of the protein, and disruption of the nuclear membrane, telomere dysfunction, chromatin remodeling defects, and epigenetic alterations.

Sickle cell anemia is caused by a missense mutation. In each of the alleles for β -globin, **Will S.**'s DNA has a single base change (see Chapter 6). In the sickle cell gene, GTG replaces the normal GAG. Thus, in the mRNA, the codon GUG replaces GAG and a valine residue replaces a glutamate residue in the protein. The amino acid change is indicated as E6V; the normal glutamate (E) at position 6 of the β -chain has been replaced by a valine (V).

B. Insertions, Deletions, and Frameshift Mutations

An **insertion** occurs when one or more nucleotides are added to DNA. If the insertion does not generate a stop codon, a protein with more amino acids than normal could be produced.

When one or more nucleotides are removed from DNA, the mutation is known as a **deletion**. If the deletion does not affect the normal start and stop codons, a protein with fewer than the normal number of amino acids could be produced.

A **frameshift mutation** occurs when the number of inserted or deleted nucleotides is not a multiple of three (Fig. 14.4). The reading frame shifts at the point where the insertion or deletion begins. Beyond that point, the amino acid sequence of the protein translated from the mRNA differs from the normal protein.

FIGURE 14.4. A frameshift mutation. The insertion of a single nucleotide (the A in the dotted red box) causes the reading frame to shift so that the amino acid sequence of the protein translated from the mRNA is different after the point of insertion. A similar effect can result from the insertion or deletion of nucleotides if the number inserted or deleted is not a multiple of three.

III. Formation of Aminoacyl-tRNA

A tRNA that contains an amino acid attached covalently to its 3'-end is called an **aminoacyl-tRNA** and is considered to be charged. Aminoacyl-tRNAs are named both for the amino acid and the tRNA that carries the amino acid. For example, the tRNA for alanine (tRNA^{Ala}) acquires alanine to become alanyl-tRNA^{Ala}. A particular tRNA recognizes only the AUG start codon that initiates protein synthesis and not other AUG codons that specify insertion of methionine within the polypeptide chain. This initiator methionyl-tRNA^{Met} is denoted by the subscript “i” in methionyl-tRNA_i^{Met}.

One type of thalassemia is caused by a nonsense mutation. Codon 17 of the β -globin chain is changed from UGG to UG. This change results in the conversion of a codon for a tryptophan residue to a stop codon. Other types of thalassemia are caused by deletions in the globin genes. Patients have been studied who have large deletions in either the 5' or the 3' coding region of the β -globin gene, removing almost one-third of the DNA sequence.

Is it possible that **Lisa N.** has either a nonsense mutation in codon 17 or a large deletion of the β -globin gene?

A nonsense mutation at codon 17 would cause premature termination of translation. A nonfunctional peptide containing only 16 amino acids would result, producing a β^0 -thalassemia if the mutation occurred in both alleles. A large deletion in the coding region of the gene could also produce a truncated protein. If **Lisa N.** has a nonsense mutation or a large deletion, it could only be in one allele. The mutation in the other allele must be milder because she produces some normal β -globin. Her hemoglobin is 7.3 g/dL, typical of thalassemia intermedia (a β^+ -thalassemia).

Amino acids are attached to their tRNAs by highly specific enzymes known as aminoacyl-tRNA synthetases. Twenty different synthetases exist, one for each amino acid. Each synthetase recognizes a particular amino acid and all of the tRNAs that carry that amino acid.

The formation of the ester bond that links the amino acid to the tRNA by an aminoacyl-tRNA synthetase is an energy-requiring process that occurs in two steps. The amino acid is activated in the first step when its carboxyl group reacts with adenosine triphosphate (ATP) to form an enzyme-aminoacyl-adenosine monophosphate (AMP) complex and pyrophosphate (Fig. 14.5). The cleavage of a high-energy bond of ATP in this reaction provides energy, and the subsequent cleavage of pyrophosphate by a pyrophosphatase helps to drive the reaction by removing one of the products. In the second step, the activated amino acid is transferred to the 2'- or 3'-hydroxyl group (depending on the type of aminoacyl-tRNA synthetase that catalyzes the reaction) of the ribose connected to the 3'-terminal A residue of the tRNA, and AMP is released (recall that all tRNAs have a CCA added to their 3'-end posttranscriptionally). The energy in the aminoacyl-tRNA ester bond is subsequently used in the formation of a peptide bond during the process of protein synthesis. The aminoacyl-tRNA synthetase provides the first error-checking step in preserving the fidelity of translation. The enzymes check their work, and if the incorrect amino acid has been linked to a particular tRNA, the enzyme will remove the amino acid from the tRNA, and try again utilizing the correct amino acid.

FIGURE 14.5. Formation of aminoacyl-tRNA. The amino acid is first activated by reacting with ATP. The amino acid is then transferred from the aminoacyl-AMP to tRNA. AMP, adenosine monophosphate; ATP, adenosine triphosphate; P_i, inorganic phosphate; PP_i, pyrophosphate; tRNA, transfer RNA.

Some aminoacyl-tRNA synthetases use the anticodon of the tRNA as a recognition site as they attach the amino acid to the hydroxyl group at the 3'-end of the tRNA (Fig. 14.6). However, other synthetases do not use the anticodon but recognize only bases located at other positions in the tRNA. Nevertheless, insertion of the amino acid into a growing polypeptide chain depends solely on the bases of the anticodon, through complementary base pairing with the mRNA codon.

FIGURE 14.6. Some aminoacyl-tRNA synthetase recognition sites on tRNA. Each aminoacyl-tRNA synthetase is specific for certain tRNA, which it “recognizes” by binding the sequences of nucleotides called recognition sites, shown in green. In some cases the anticodon is a recognition site, in others it is not. This is true for human tRNAs as well as for those shown here. *E. coli*, *Escherichia coli*; tRNA, transfer RNA.

IV. Process of Translation

Translation of a protein involves three steps: **initiation**, **elongation**, and **termination**. It begins with the formation of the initiation complex. Subsequently, synthesis of the polypeptide occurs by a series of elongation steps that are repeated as each amino acid is added to the growing chain (Fig. 14.7). Termination occurs where the mRNA contains an in-frame stop codon, and the completed polypeptide chain is released.

FIGURE 14.7. Overview of the process of translation. (1) Once a transfer RNA (tRNA) has donated its amino acid to the growing polypeptide chain (which itself is still linked to a tRNA), it is released from the mRNA. (2) A new aminoacyl-tRNA binds to the correct codon in the mRNA to donate its amino acid to the growing polypeptide chain.

A. Initiation of Translation

In eukaryotes, initiation of translation involves the formation of an **initiation complex** composed of methionyl-tRNA_i^{Met}, mRNA, and a ribosome (Fig. 14.8). Methionyl-tRNA_i^{Met} (also known as Met-tRNA_i^{Met}) initially forms a complex with the protein eIF2, which binds GTP. This complex then binds to the small (40S) ribosomal subunit with the participation of eIF3. eIF3 also participates in preventing the premature association of the 60S ribosomal subunit with the pre initiation complex. The cap at the 5'-end of the mRNA binds to components of the eIF4 complex, eIF4F, known as the cap-binding complex. eIF4F is a complex comprising eIF4E, eIF4A, and eIF4G. The mRNA, in association with the cap-binding complex, then binds to the eIFs-Met-tRNA_i^{Met}-40S ribosome complex. In a reaction that requires hydrolysis of ATP (because of the helicase activity of an eIF subunit), this complex unwinds a hairpin loop in the mRNA and scans the mRNA until it locates the AUG start codon (usually the first AUG in the mRNA). GTP is hydrolyzed, the initiation factors (IFs) are released, and the large ribosomal (60S) subunit binds. The ribosome is now complete. It contains one small and one large subunit, and it has three binding sites for tRNA, known as the **P (peptidyl)**, **A (aminoacyl)**, and **E (ejection)** sites. During initiation, Met-tRNA_i^{Met} binds to the ribosome at the P site, which is located initially at the start codon for translation. Eukaryotes also contain a Kozak consensus sequence which is recognized by the ribosome as the translational start site (the sequence is A or G – CCAUGG, where the purine base is three bases upstream of the AUG start codon). The Kozak sequence aids in defining the initial AUG codon for translation. Loss of this sequence reduces the efficiency of translational initiation.

FIGURE 14.8. Initiation of protein synthesis. This is a simplified version of translational initiation as many more initiation factors and steps are required. A site, aminoacyl site on the ribosome; ADP, adenosine diphosphate; ATP, adenosine triphosphate; E site, free transfer RNA (tRNA) ejection site (the A, P, and E sites or portions of them are indicated by dashed lines); eIF, eukaryotic initiation factor; GDP, guanosine diphosphate; GTP, guanosine triphosphate; *Met*, methionyl; mRNA, messenger RNA; P_i , inorganic phosphate; P site, peptidyl site on the ribosome.

The initiation process differs for prokaryotes and eukaryotes (Table 14.3). In bacteria, the initiating methionyl-tRNA is formylated, producing a formyl-methionyl-tRNA_f^{Met} that participates in the formation of the initiation complex (Fig. 14.9). Only three IFs are required to generate this complex in prokaryotes, compared with the dozen or more required by eukaryotes. The ribosomes also differ in size. Prokaryotes have 70S ribosomes, composed of 30S and 50S subunits, and eukaryotes have 80S ribosomes, composed of 40S and 60S subunits. Unlike eukaryotic mRNA, bacterial mRNA is not capped. Identification of the initiating AUG triplet in prokaryotes occurs when a sequence in the mRNA (known as the Shine–Dalgarno sequence) binds to a complementary sequence near the 3'-end of the 16S ribosomal RNA (rRNA) of the small ribosomal subunit.

TABLE 14.3 Differences between Eukaryotes and Prokaryotes in the Initiation of Protein Synthesis

	EUKARYOTES	PROKARYOTES
Binding of mRNA to small ribosomal subunit	Cap at 5'-end of mRNA binds eIFs and 40S ribosomal subunit containing tRNA _f ^{Met} . mRNA is scanned for AUG start codon within the Kozak consensus sequence	Shine–Dalgarno sequence upstream of initiating AUG binds to complementary sequence in 16S rRNA
First amino acid	Methionine	Formyl-methionine
Initiation factors	eIFs (12 or more)	IFs (3)
Ribosomes	80S (40S and 60S subunits)	70S (30S and 50S subunits)

eIF, eukaryotic initiation factor; IF, initiation factor; mRNA, messenger RNA; rRNA, ribosomal RNA; tRNA_f^{Met}, initiator methionyl-tRNA.

FIGURE 14.9. Bacterial tRNA containing formyl-methionine. The initial methionine is not formylated in eukaryotic protein synthesis. tRNA, transfer RNA.

Initiation of translation is also regulated at the level of the IFs. For example, insulin, an anabolic hormone, stimulates general protein synthesis by activating the initiation factor eIF4E. Normally, eIF4E is bound to an inhibitor protein, designated 4E-binding protein (4E-BP). When insulin binds to its cell surface receptor, it initiates an intracellular sequence of events resulting in phosphorylation of 4E-BP. Phosphorylated 4E-BP no longer binds to eIF4E, and eIF4E is now free to participate in the initiation of protein synthesis.

Similarly, eIF2 is a regulator of the initiation step in protein synthesis. When it is phosphorylated, it is inactive, and protein synthesis cannot begin. Conditions such as starvation, heat shock, and viral infection result in phosphorylation of eIF2 by a specific kinase.

The regulation of globin synthesis by heme in reticulocytes illustrates the role of eIF2 in the regulation of translation. Reticulocytes, which are the precursors of red blood cells, synthesize the oxygen-carrying hemoglobin molecules from the globin polypeptide chains and the Fe-binding pigment, heme. In the absence of heme, the rate of initiation of globin synthesis decreases. Heme acts by inhibiting the phosphorylation of the initiation factor eIF2. Thus, eIF2 is active in the presence of heme, and globin synthesis is initiated.

And finally, both eIF2 and elongation factor 1 (EF1) are types of heterotrimeric G proteins (see Chapter 10). They dramatically change their conformation and actively form complexes when they bind GTP but become inactive and dissociate when they hydrolyze this GTP to guanosine diphosphate (GDP). GTP can then displace the bound GDP to reactivate the eIF2 or the EF1.

B. Elongation of Polypeptide Chains

After the initiation complex is formed, addition of each amino acid to the growing polypeptide chain involves

binding of an aminoacyl-tRNA to the A site on the ribosome, formation of a peptide bond, and translocation of the peptidyl-tRNA to the P site (Fig. 14.10). The peptidyl-tRNA contains the growing polypeptide chain.

FIGURE 14.10. Elongation of a polypeptide chain. (1) Binding of valyl-tRNA^{Val} to the A site. (2) Formation of a peptide bond. (3) Translocation. (4) Ejection of the free tRNA. After step 4, step 1 is repeated using the aminoacyl-tRNA for the new codon in the A site. Steps 2, 3, and 4 follow. These four steps keep repeating until termination occurs. A site, aminoacyl site; EF, elongation factor; E site, free transfer RNA ejection site; GDP, guanosine diphosphate; GTP, guanosine triphosphate; mRNA, messenger RNA; P_i, inorganic phosphate; P site, peptidyl site; tRNA, transfer RNA.

Many antibiotics that are used to combat bacterial infections in humans take advantage of the differences between the mechanisms for protein synthesis in prokaryotes and eukaryotes. For example, streptomycin binds to the 30S ribosomal subunit of prokaryotes. It interferes with initiation of protein synthesis and causes misreading of mRNA. Streptomycin, however, was not used to treat **Paul T.** because it can cause permanent hearing loss. Its use is therefore confined mainly to the treatment of tuberculosis or other infections that do not respond adequately to other antibiotics. Another example is tetracycline, which binds to the 30S ribosomal subunit of prokaryotes and inhibits the binding of aminoacyl-tRNA to the A site of the ribosome.

1. Binding of Aminoacyl-tRNA to the A Site

When Met-tRNA_i (or a peptidyl-tRNA) is bound to the P site, the mRNA codon in the A site determines which aminoacyl-tRNA will bind to that site. An aminoacyl-tRNA binds when its anticodon is antiparallel and complementary to the mRNA codon. In eukaryotes, the incoming aminoacyl-tRNA first combines with eEF1A containing bound GTP before binding to the mRNA-ribosome complex. eEF1A is similar to the α -subunit of a heterotrimeric G-protein, in that it contains GTPase activity (see Chapter 10). When the aminoacyl-tRNA-eEF1A-GTP complex binds to the A site, GTP is hydrolyzed to GDP as the ribosome activates the GTPase activity of eEF1A. This prompts dissociation of eEF1A-GDP from the aminoacyl-tRNA ribosomal complex, thereby allowing protein synthesis to continue. The binding of the appropriate aminoacyl-tRNA to the A site comprises the second error-checking step in protein synthesis. If an improper aminoacyl-tRNA is brought to the A site, the ribosomal activation of the GTPase of eEF1A does not occur, and the complex will leave the binding site, along with the aminoacyl-tRNA. Only when the GTP is hydrolyzed can eEF1A release the aminoacyl-

tRNA and dissociate from the complex.

 The antibiotic levofloxacin (a quinolone) inhibits two bacterial enzymes: DNA gyrase and topoisomerase IV. The bacterium causing **Paul T.**'s infection was found to be sensitive to levofloxacin, and this could have been used in place of azithromycin.

Once released, the free eEF1A-GDP binds with the eEF1B α , which accelerates the replacement of bound GDP with GTP (Fig. 14.11). Thus, eEF1A-GTP is ready to bind another aminoacyl-tRNA molecule and to continue protein synthesis.

FIGURE 14.11. Recycling of eEF1A in eukaryotes. eEF1A contains a GTPase activity, which is activated upon binding to the ribosome. Guanosine triphosphate (GTP) is hydrolyzed, and eEF1A is released from the ribosome, binding to eEF1B α . eEF1B α is a guanine nucleotide exchange factor and accelerates the substitution of GTP for the guanosine diphosphate (GDP) on eEF1A. Once this occurs, eEF1A is ready for another round of translation. In prokaryotes, eEF1A corresponds to EF-Tu, and the protein corresponding to eEF1B α is EF-Ts. A site, aminoacyl site; EF, elongation factor; E site, free transfer RNA ejection site; P_i, inorganic phosphate; P site, peptidyl site.

The process of elongation is very similar in prokaryotes, except that the corresponding factor for eEF1A is named EF-Tu and the associating EFs are called EF-Ts instead of eEF1B α .

 The macrolide antibiotics (e.g., erythromycin, clarithromycin, azithromycin) bind to the 50S ribosomal subunit of bacteria and inhibit translocation. Azithromycin was used to treat **Paul T.** because he had taken it previously without difficulty. It has less serious side effects than many other antibiotics and can be used as an alternative drug in patients, such as **Paul T.** who are allergic to penicillin. After 2 weeks of therapy, **Paul T.** recovered from his infection.

2. Formation of a Peptide Bond

In the first round of elongation, the amino acid on the tRNA in the A site forms a peptide bond with the methionine on the tRNA in the P site. In subsequent rounds of elongation, the amino acid on the tRNA in the A site forms a peptide bond with the peptide on the tRNA in the P site (see Fig. 14.10). Peptidyl transferase, which is not a protein but the rRNA of the large ribosomal subunit, catalyzes the formation of the peptide bond. The tRNA in the A site now contains the growing polypeptide chain, and the tRNA in the P site is uncharged (i.e., it no longer contains an amino acid or peptide).

Chloramphenicol is an antibiotic that interferes with the peptidyl transferase activity of the 50S ribosomal subunit of bacteria. It was not used to treat **Paul T.** because it is very toxic to humans, partly because of its effect on mitochondrial protein synthesis.

3. Translocation

Translocation in eukaryotes involves another G-protein, elongation factor eEF2 (EF-G in prokaryotes) that complexes with GTP and binds to the ribosome, causing a conformational change that moves the mRNA and its base-paired tRNAs with respect to the ribosome. The uncharged tRNA moves from the P site to the E site. It is released from the ribosome when the next charged tRNA enters the A site. The peptidyl-tRNA moves into the P site, and the next codon of the mRNA occupies the A site. During translocation, GTP is hydrolyzed to GDP, which is released from the ribosome along with the EF (see Fig. 14.10).

Diphtheria is a highly contagious disease caused by a toxin secreted by the bacterium *Corynebacterium diphtheriae*. Although the toxin is a protein, it is not produced by a bacterial gene, but by a gene brought into the bacterial cell by an infecting bacteriophage.

Diphtheria toxin is composed of two protein subunits. The B-subunit binds to a cell surface receptor, facilitating the entry of the A-subunit into the cell. In the cell, the A-subunit catalyzes a reaction in which the ADP-ribose (ADPR) portion of nicotinamide adenine dinucleotide (NAD) is transferred to eEF2 (ADP-ribosylation). In this reaction, the ADPR is attached covalently to a posttranslationally modified histidine residue, known as diphthamide. ADP-ribosylation of eEF2 inhibits protein synthesis, leading to cell death. Children, including **Edna R.**'s daughter, should be immunized against this often fatal disease at an early age unless there is a contraindication.

C. Termination of Translation

The three elongation steps are repeated until a termination (stop) codon moves into the A site on the ribosome. Because no tRNAs with anticodons that can pair with stop codons normally exist in cells, release factors bind to the ribosome instead, causing peptidyl transferase to hydrolyze the bond between the peptide chain and tRNA. The newly synthesized polypeptide is released from the ribosome, which dissociates into its individual subunits, releasing the mRNA.

Protein synthesis requires a considerable amount of energy. Formation of each aminoacyl-tRNA requires the equivalent of two high-energy phosphate bonds because ATP is converted to AMP and pyrophosphate, which is cleaved to form two inorganic phosphates. As each amino acid is added to the growing peptide chain, two GTPs are hydrolyzed, one at the step involving eEF1A and the second at the translocation step. Thus, four high-energy bonds are cleaved for each amino acid of the polypeptide. In addition, energy is required for initiation of synthesis of a polypeptide chain and for synthesis from nucleoside triphosphate precursors of the mRNA, tRNA, and rRNA involved in translation.

V. Polysomes

As one ribosome moves along the mRNA, producing a polypeptide chain, a second ribosome can bind to the vacant 5'-end of the mRNA. Many ribosomes can simultaneously translate a single mRNA, forming a complex known as a polysome, or polyribosome (Fig. 14.12). A single ribosome covers approximately 80 nucleotides of mRNA. Therefore, ribosomes are positioned on mRNA at intervals of approximately 100 nucleotides. The growing polypeptide chains attached to the ribosomes become longer as each ribosome moves from the 5'-end toward the 3'-end of the mRNA.

FIGURE 14.12. A polysome. The complex of messenger RNA (mRNA) and multiple ribosomes, each of which is producing a polypeptide chain, is called a polysome.

Currently, because of misperceptions of vaccine side effects, some parents are not having their children immunized. The decrease in the incidence of infectious diseases in the United States has led to complacency. Anyone who remembers the summertime fear of poliomyelitis in the 1940s and 1950s realizes that immunizations are a blessing that should be available to all children. This has been reinforced by several outbreaks, including the measles outbreak at Disneyland, California, in December 2014. Between January 1, 2019 and October 1, 2019, there were 1,249 reports of measles cases in the United States, in which 75% of the cases were in the state and city of New York; 89% of those contracting measles were unvaccinated.

VI. Processing of Proteins

Nascent polypeptide chains (i.e., polypeptides that are in the process of being synthesized) are processed. As they are being produced, they travel through a tunnel in the ribosome, which can hold roughly 30 amino acid residues. As polymerization of the chain progresses, the amino acid residues at the *N*-terminal end begin to emerge from this protected region within the ribosome and to fold and refold into the three-dimensional conformation of the polypeptide. Proteins bind to the nascent polypeptide and mediate the folding process. These mediators are called **chaperones** (they are members of the heat-shock family of proteins; see Chapter 7) because they prevent improper interactions from occurring. Formation of disulfide bond between cysteine residues is catalyzed by protein disulfide isomerases and may also be involved in producing the three-dimensional structure of the polypeptide.

VII. Posttranslational Modifications

After proteins emerge from the ribosome, they may undergo **posttranslational modifications**. The initial methionine is removed by specific proteases; methionine is not the *N*-terminal amino acid of all mature proteins. Subsequently, other specific cleavages that convert proteins to more active forms (e.g., the conversion of proinsulin to insulin) also may occur. In addition, amino acid residues within the peptide chain can be modified enzymatically to alter the activity or stability of the proteins, direct it to a subcellular compartment, or

prepare it for secretion from the cell.

Amino acid residues are modified enzymatically by the addition of various types of functional groups (Table 14.4). For example, the *N*-terminal amino acid is sometimes **acetylated**, and methyl groups can be added to lysine residues (**methylation**). These changes alter the charge on the protein. Proline and lysine residues can be modified by **hydroxylation**. In collagen, hydroxylation leads to stabilization of the protein. **Carboxylations** are important, especially for the function of proteins involved in blood coagulation. Formation of γ -carboxyglutamate allows these proteins to chelate Ca^{2+} , a step in clot formation. Fatty acids or other hydrophobic groups (e.g., prenyl groups) anchor the protein in membranes (**fatty acylation** and **prenylation**). An adenosine diphosphate (ADP)-ribose group can be transferred from NAD^+ to certain proteins (**ADP-ribosylation**). The addition and removal of phosphate groups, which bind covalently to serine, threonine, or tyrosine residues, serve to regulate the activity of many proteins (e.g., the enzymes of glycogen degradation and regulators of gene transcription, **phosphorylation**). **Glycosylation**, the addition of carbohydrate groups, is a common modification that occurs mainly on proteins that are destined to be secreted or incorporated into lysosomes or cellular membranes.

VIII. Targeting of Proteins to Subcellular and Extracellular Locations

Many proteins are synthesized on polysomes in the cytosol. After they are released from ribosomes, they remain in the cytosol, where they carry out their functions. Other proteins synthesized on cytosolic ribosomes enter organelles such as mitochondria or nuclei. These proteins contain amino acid sequences called **targeting sequences** or **signal sequences** that facilitate their transport into a certain organelle. Another group of proteins are synthesized on ribosomes bound to the RER. These proteins are destined for secretion or incorporation into various subcellular organelles (e.g., lysosomes, endoplasmic reticulum [ER], Golgi complex) or cellular membranes, including the plasma membrane. Proteins that enter the RER as they are being synthesized have signal peptides near their *N*-termini that do not have a common amino acid sequence. However, they do contain several hydrophobic residues and are 14 to 30 amino acids in length (Fig. 14.13). A **signal recognition particle (SRP)** binds to the ribosome and to the signal peptide as the nascent polypeptide emerges from the tunnel in the ribosome and translation ceases. When the SRP subsequently binds to an SRP receptor (docking protein) on the RER, translation resumes, and the polypeptide begins to enter the lumen of the RER. The signal peptide is removed by the signal peptidase, and the remainder of the newly synthesized protein enters the lumen of the RER. These proteins are transferred in small vesicles to the Golgi complex.

FIGURE 14.13. Synthesis of proteins on the rough endoplasmic reticulum (RER). (1) Translation of the protein begins in the cytosol. (2) As the signal peptide emerges from the ribosome, a signal recognition particle (SRP) binds to it and to the ribosome and inhibits further synthesis of the protein. (3) The SRP binds to the SRP receptor in the RER membrane, docking the ribosome on the RER. (4) The SRP is released and protein synthesis resumes. (5) As the signal peptide moves through a pore into the RER, a signal peptidase removes the signal peptide. (6) Synthesis of the nascent protein continues, and the completed protein is released into the lumen of the RER.

The Golgi complex serves to process the proteins it receives from the RER and to sort them so that they are delivered to their appropriate destinations (Fig. 14.14). Processing, which can be initiated in the ER, involves glycosylation, the addition of carbohydrate groups, and modification of existing carbohydrate chains. Sorting signals permit the delivery of proteins to their target locations. For example, glycosylation of enzymes destined to become lysosomal enzymes results in the presence of a mannose 6-phosphate residue on an oligosaccharide attached to the enzyme. This residue is recognized by the mannose 6-phosphate receptor protein, which incorporates the enzyme into a clathrin-coated vesicle. The vesicle travels to endosomes and is eventually incorporated into lysosomes. Other proteins containing a KDEL (lys–asp–glu–leu) sequence at their carboxyl terminal are returned to the ER from the Golgi. Proteins with hydrophobic regions can embed in various membranes. Some proteins, whose sorting signals have not yet been determined, enter secretory vesicles and travel to the cell membrane, where they are secreted by the process of exocytosis.

FIGURE 14.14. Fate of proteins synthesized on the rough endoplasmic reticulum (RER). Proteins synthesized on ribosomes attached to the ER travel in vesicles to the *cis* face of the Golgi complex. After the membranes fuse, the proteins enter the Golgi complex. Structural features of the proteins determine their fate. Some remain in the Golgi complex, and some return to the RER. Others bud from the *trans* face of the Golgi complex in vesicles. These vesicles can become lysosomes or secretory vesicles, depending on their contents. Secretory proteins are released from the cell when secretory vesicles fuse with the cell membrane (exocytosis). Proteins with hydrophobic regions embedded in the membrane of secretory vesicles become cell membrane proteins. See Chapter 10 for descriptions of the endoplasmic reticulum, Golgi complex, lysosomes, and the cell membrane, and also for an explanation of the process of exocytosis.

 I-cell disease (mucopolipidosis II) is an inherited disorder of protein targeting. Lysosomal proteins are not sorted properly from the Golgi to the lysosomes, and lysosomal enzymes end up being secreted from the cell. This is because of a mutation in the enzyme *N*-acetylglucosamine phosphotransferase, which is a required first step for attaching the lysosomal targeting signal, mannose 6-phosphate, to lysosomal proteins. Thus, lysosomal proteins cannot be targeted to the lysosomes, and these organelles become clogged with materials that cannot be digested, destroying overall lysosomal function. This leads to a lysosomal storage disease of severe consequence, with death before the age of 8 years.

CLINICAL COMMENTS

 **Lisa N.** has a β^+ -thalassemia classified clinically as β -thalassemia intermedia. She produces an intermediate amount of functional β -globin chains (her hemoglobin is 7.3 g/dL; normal is 12 to 16 g/dL). In β^0 -thalassemia, little or none of the hemoglobin β -chain is produced. β -Thalassemia intermedia is usually the result of two different mutations (one that mildly affects the rate of synthesis of β -globin and one that severely affects its rate of synthesis), or, less frequently, homozygosity for a mild mutation in the rate of synthesis, or a complex combination of mutations. The mutations that cause the thalassemias have been studied extensively, and some are summarized in Table e-14.1.  For each of these mutations, the student should now be able to explain why the mutation results in a β^+ - or β^0 -thalassemia.

 **Jay S.** The molecular biology–genetics laboratory’s report on **Jay S.**’s white blood cells indicated that he had a deficiency of hexosaminidase A caused by a defect in the gene encoding the α -subunit of this enzyme (variant B, Tay–Sachs disease). Hexosaminidases are lysosomal enzymes that are necessary for the normal degradation of glycosphingolipids, such as the gangliosides. Gangliosides are found in high concentrations in neural ganglia, although they are produced in many areas of the nervous system. When the activity of these degradative enzymes is absent or subnormal, partially degraded gangliosides accumulate in lysosomes in various cells of the central nervous system, causing a wide array of neurologic disorders known collectively as gangliosidoses. When the enzyme deficiency is severe, symptoms appear within the first 3 to 5 months of life. Eventually, symptoms include upper and lower motor neuron deficits, visual difficulties that can progress to blindness, seizures, and increasing cognitive dysfunction. By the second year of life, the patient may regress to a completely vegetative state, often succumbing to bronchopneumonia caused by aspiration or an inability to cough.

 **Edna R.** With the availability of diphtheria toxoid as part of the almost universal DPT immunization practiced in the United States, fatalities owing to infection by the gram-positive bacillus *Corynebacterium diphtheriae* are rare. Most children, as is the case with **Edna R.**’s daughter **Beverly R.**, are immunized. In unimmunized individuals, however, symptoms are caused by a bacterial exotoxin encoded by a phage that infects the bacterial cells. The toxin enters human cells, inhibiting protein synthesis and, ultimately, causing cell death. The most common symptoms are sore throat, fever, and malaise, but complications related to cardiac and nervous system involvement are the major cause of morbidity and mortality. Patients for whom a definitive diagnosis of diphtheria is established are treated with equine diphtheria antitoxin and antibiotics.

 **Paul T.**’s use of the antibiotic azithromycin effectively cleared up his pneumonia caused by *Streptococcus pneumoniae*. His physician released **Paul T.** with no further follow-up appointments necessary.

BIOCHEMICAL COMMENTS

Antibiotics That Inhibit Protein Synthesis. The processes of translation on bacterial ribosomes and the cytoplasmic ribosomes of eukaryotic cells have many similarities, but there are a number of subtle differences. Antibiotics act at steps at which these differences occur, and different antibiotics target each of the major steps of protein synthesis (Table 14.5). Therefore, these compounds can be used selectively to prevent bacterial protein synthesis and inhibit bacterial proliferation, while having little or no effect on human cells. Caution must be exercised in their use, however, because some of the antibiotics affect human mitochondria, which have a protein-synthesizing system similar to that of bacteria. Another problem with these drugs is that bacteria can become resistant to their action. Mutations in genes that encode the proteins or RNA of bacterial ribosomes can cause resistance. Resistance also results when bacteria take up plasmids that carry genes for the inactivation of the antibiotic. Because of the widespread and often indiscriminate use of antibiotics, strains of bacteria are rapidly developing that are resistant to all known antibiotics. Examples of antibiotics are described below.

TABLE 14.5 Inhibitors of Protein Synthesis in Prokaryotes

ANTIBIOTIC	MODE OF ACTION
Streptomycin	Binds to the 30S ribosomal subunit of prokaryotes, thereby preventing the formation of the initiation complex. It also causes misreading of mRNA.
Tetracycline	Binds to the 30S ribosomal subunit and inhibits binding of aminoacyl-tRNA to the A site.
Chloramphenicol	Binds to the 50S ribosomal subunit and inhibits peptidyl transferase.
Erythromycin	Binds to the 50S ribosomal subunit and prevents translocation.

mRNA, messenger RNA; tRNA, transfer RNA.

Streptomycin. Streptomycin inhibits translation initiation by binding to three proteins and probably the 16S rRNA of the 30S ribosomal subunit of bacteria. Abnormal initiation complexes, known as streptomycin monosomes, accumulate. Streptomycin can also cause misreading of mRNA, resulting in premature termination of translation or the incorporation of incorrect amino acids into polypeptide chains that have already been initiated. The use of this antibiotic is limited because it causes ototoxicity that can result in loss of hearing.

Tetracycline. Tetracycline binds to the 30S ribosomal subunit of bacteria and prevents an aminoacyl-tRNA from binding to the A site on the ribosome. This effect of the drug is reversible; thus, when the drug is removed, bacteria resume protein synthesis and growth, resulting in a rekindling of the infection. Furthermore, tetracycline is not absorbed well from the intestine, and its concentration can become elevated in the contents of the gut, leading to changes in the intestinal flora. Because it has been used to treat human infections and has been added to animal feed to prevent animal infections, humans have had extensive exposure to tetracycline. As a result, resistant strains of bacteria have developed.

Chloramphenicol. Chloramphenicol binds to the 50S ribosomal subunit of bacteria and prevents binding of the amino acid portion of the aminoacyl-tRNA, effectively inhibiting peptidyl transferase action. This antibiotic is rarely used, usually only for certain extremely serious infections when there are no alternative treatments. Chloramphenicol readily enters human mitochondria, where it inhibits protein synthesis. Cells of the bone marrow often fail to develop in patients treated with chloramphenicol, and use of this antibiotic has been linked to fatal blood dyscrasias, including aplastic anemia.

Erythromycin. Erythromycin and the other macrolide antibiotics bind to the 50S ribosomal subunit of bacteria near the binding site for chloramphenicol. They prevent the translocation step, the movement of the peptidyl-tRNA from the A to the P site on the ribosome. Because the side effects are less severe and more readily reversible than those of many other antibiotics, the macrolides are often used to treat infections in persons who are allergic to penicillin, an antibiotic that inhibits bacterial cell-wall synthesis. However, bacterial resistance to erythromycin is increasing. Therefore, its close relative, azithromycin, is often used.

KEY CONCEPTS

- ◆ Translation is the process of translating the sequence of nucleotides in mRNA to an amino acid sequence of a protein.
- ◆ Translation proceeds from the amino to the carboxyl terminus, reading the mRNA in the 5'-to-3' direction.
- ◆ Protein synthesis occurs on ribosomes.
- ◆ The mRNA is read in codons, sets of three nucleotides that specify individual amino acids.
- ◆ AUG, which specifies methionine, is the start codon for all protein synthesis.
- ◆ Specific stop codons (UAG, UGA, and UAA) signal when the translation of the mRNA is to end.
- ◆ Amino acids are linked covalently to tRNA by the enzyme aminoacyl-tRNA synthetase, creating charged tRNA.
- ◆ Charged tRNAs base-pair with the codon via the anticodon region of the tRNA.
- ◆ Protein synthesis is divided into three stages: initiation, elongation, and termination.
- ◆ Multiprotein factors are required for each stage of protein synthesis.
- ◆ Proteins fold as they are synthesized.
- ◆ Specific amino acid side chains may be modified after translation by a process known as posttranslational modification.
- ◆ Mechanisms within eukaryotic cells specifically target newly synthesized proteins to different compartments in the cell.
- ◆ Table 14.6 summarizes the diseases discussed in this chapter.

TABLE 14.6 Diseases Discussed in Chapter 14

DISORDER OF CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
β -thalassemia	Genetic	Lisa N. has β -thalassemia intermedia, indicating that the β -globin gene product is produced at reduced levels as compared to the α -globin gene product. This can happen by a variety of mutations.
Tay–Sachs disease	Genetic	Mutation in a gene encoding a lysosomal enzyme, leading to loss of lysosomal function and death at an early age for the patient.
Pneumonia	Environmental	Although rifampin was used to treat the bacterial infection previously (acting on bacterial RNA polymerase), the mechanism of other antibiotics which target prokaryotic protein synthesis is also discussed.
Diphtheria, pertussis	Environmental	Diphtheria toxin catalyzes the ADP-ribosylation of eEF2, a necessary factor for eukaryotic protein synthesis. This results in cell death. Vaccination against pertussis antigens will prevent infection.
I-cell disease	Genetic	Mutation in posttranslational processing leads to mistargeting of enzymes destined for the lysosomes. Disease leads to lysosomal dysfunction and early death.
Hutchinson–Gilford Progeria syndrome	Genetic	An example of a silent mutation in terms of amino acid substitution, but the single nucleotide change creates an alternative splice site that leads to a loss of 50 amino acids from the precursor lamin A protein. This leads to altered posttranslational processing and the symptoms of a premature aging disease.

ADP, adenosine diphosphate.

REVIEW QUESTIONS—CHAPTER 14

1. Antibiotics can target differences in the processing of the genetic code between bacteria and humans. In the readout of the genetic code in prokaryotes, which one of the following processes acts before any of the others?
 - A. tRNA_i alignment with mRNA
 - B. Termination of transcription

- C. Movement of the ribosome from one codon to the next
 D. Recruitment of termination factors to the A site
 E. Export of mRNA from the nucleus
2. Genetic mutations can be simulated in laboratory situations. tRNA charged with cysteine can be chemically treated so that the amino acid changes its identity to alanine. If some of this charged tRNA is added to a protein-synthesizing extract that contains *all* the normal components required for translation, which of the following statements represents the most likely outcome after adding an mRNA that has both Cys and Ala codons in the normal reading frame?
- A. Cysteine would be added each time the alanine codon was translated.
 B. Alanine would be added each time the cysteine codon was translated.
 C. The protein would have a deficiency of cysteine residues.
 D. The protein would have a deficiency of alanine residues.
 E. The protein would be entirely normal.
3. Human and bacterial DNA differ in the organization of genetic information. A series of eukaryotic gene sequences (coding sequences) is given below. Based on this portion of the sequence, which gene could produce a protein that contains 300 amino acids and has a phenylalanine residue near its *N*-terminus? The phenylalanine codons (5'-to-3') are UUU and UUC.
- A. 5'-CCATGCCATTTGCATCA-3'
 B. 5'-CCATGCCATTTGCATGA-3'
 C. 5'-CCATGCCAATTTGCATC-3'
 D. 5'-CCATCCCATTTGCATAA-3'
 E. 5'-CCATCCCATTTGCATCA-3'
4. A drug is being designed to block eukaryotic translation. Which of the following would be an appropriate target for the drug? Choose the one best answer.

	N-Formyl-Methionine Linked to tRNA	The Nuclear Ribosomal Complex	Enzymes Necessary for Splicing	The Initiator tRNA for Methionine	An Enzyme Involved in 5'-Cap Formation
A	Yes	Yes	No	No	Yes
B	Yes	No	Yes	No	No
C	Yes	Yes	Yes	No	Yes
D	No	No	No	Yes	No
E	No	Yes	Yes	Yes	No
F	No	No	No	Yes	Yes

5. A gene has undergone a mutation in which a certain codon has been altered, through a single nucleotide change, into a phe codon. Which one of the following amino acids could the original codon code for?
- A. Pro
 B. Leu
 C. Gly

- D. Asn
 - E. Arg
 - F. Trp
6. A mutation in a gene has led to the generation of a nonsense codon in the corresponding protein. If this is caused by a single nucleotide change, the original codon may have coded for which one of the following amino acids?
 - A. Gly
 - B. Pro
 - C. Phe
 - D. Asn
 - E. Trp
 7. Which type of mutation leads to sickle cell anemia? Choose the one best answer.
 - A. Silent
 - B. Nonsense
 - C. Insertion
 - D. Deletion
 - E. Missense
 8. The creation of a stop codon in DNA often leads to a deleterious condition. If a mutation in DNA caused a “stop” codon TAG to be created on the coding strand between the TATA box and the transcription initiation site, what would be the most likely outcome?
 - A. No effect
 - B. Loss of transcription
 - C. Loss of translation
 - D. A shorter protein
 - E. A mistake in splicing
 9. A temperature-sensitive variant of *Escherichia coli* was discovered, which had a complete loss of protein synthetic ability after about five generations of growth at the nonpermissive temperature. Analysis of the components required for protein synthesis indicated that mRNA synthesis (transcription) still occurred at the nonpermissive temperature, and the mRNA produced had normal half-lives. The transcription of rRNA and tRNA was also normal, as was ribosome structure. A potential protein in which loss of activity at the nonpermissive temperature would lead to these findings is which one of the following?
 - A. A spliceosome protein
 - B. A tRNA modifying enzyme
 - C. The capping protein
 - D. Poly A polymerase
 - E. A nuclear mRNA export protein
 0. A new patient, recently admitted to the hospital, has contracted diphtheria. A family history indicates the patient had never been vaccinated against this pathogen. Protein synthesis in the patient’s cells is inhibited owing to which one of the following?
 - A. An inhibition of RNA polymerase II activity
 - B. An inhibition of peptidyl transferase activity
 - C. An inhibition of the assembly of the translation initiation complex
 - D. An inhibition of the translocation step of protein synthesis
 - E. An inhibition of the termination of protein synthesis
 1. An 8-month-old male exhibited coarse facial features, scoliosis, and an unusually short neck. He was lagging in both neuronal and motor skills. Fibroblasts cultured from the child were shown to secrete enzymes that would normally be found in the lysosome. Enzymes targeted for other organelles were not found to be secreted from the cell. A potential enzyme defect in this child could be which one of the following?
 - A. Inability to transfer vesicles from the endoplasmic reticulum to the Golgi
 - B. Inappropriate glycosylation of lysosomal enzymes
 - C. Loss of signal peptidase activity in the endoplasmic reticulum
 - D. Loss of the signal recognition particle receptor
 - E. Loss of signal sequence for lysosomal proteins
 2. A bacterial cell has obtained a mutation that is expressed at 42°C, but not at 25°C (a temperature-sensitive mutation). The mutation is in the aminoacyl-tRNA synthetase which recognizes methionine and tRNA^{met}.

The mutation allowed the enzyme to charge the tRNA^{met} with either met or *N*-formyl-methionine (f-met). When protein synthesis was studied at 42°C in this cell line, which one of the following would you expect to observe?

- A. Full-length proteins with a mixture of methionine and f-met
 - B. Full-length proteins with all methionine, and no f-met
 - C. Full-length proteins with all f-met, and no methionine
 - D. No effect on translation
 - E. Very limited translation
3. Shiga toxin is produced by certain *Escherichia coli* strains, and such bacteria can be introduced to humans through contaminated food. Once the active subunit of the toxin is inside cells, it halts protein synthesis by acting as a glycosylase and removing a specific adenine base from the 28S rRNA of the 60S large ribosomal subunit. Protein synthesis is inhibited in the cell owing to which one of the following?
- A. Blocking of the “A” Site of the ribosome
 - B. Blocking of the “P” Site of the ribosome
 - C. Loss of peptidyl transferase activity
 - D. Loss of Shine–Dalgarno base pairing
 - E. Loss of the translocation step
4. A bacterial strain was isolated, which contained a mutation that created a stop codon in the reading frame for gene X. The scientist who isolated this strain then looked for secondary mutations (outside of gene X) which would restore gene X activity. Such a mutation could be which one of the following?
- A. A mutation converting the normal stop codon to one that encodes an amino acid
 - B. A mutation in a tRNA such that it inserts an amino acid in response to a stop codon
 - C. A mutation in rRNA so that translation begins at a different initiating AUG
 - D. A mutation in the promoter for gene X which increases transcription of gene X
 - E. A mutation in the promoter for gene X which reduces transcription of gene X
5. Hutchinson–Gilford progeria (a premature aging disease) is caused by a mutation in the lamin A gene (C1824T, the nucleotide at position 1,842 in the gene, a cytidine, is replaced by a thymidine). The change in nucleotide leads to a G608G mutation; the DNA has been changed, but the altered codon still encodes glycine. As such, this should be a silent mutation, but instead, a serious disease occurs. Why might this be the case?
- A. A new splice site is created in the initial mRNA transcript.
 - B. An existing splice site is lost in the initial mRNA transcript.
 - C. Levels of gly-tRNA^{gly} are too low to support translation.
 - D. The initiation of translation is decreased.
 - E. The initiation of translation is increased.

ANSWERS TO REVIEW QUESTIONS

1. **The answer is A.** It is important to note that the question is asking about prokaryotic mechanisms. In prokaryotes, there is no nucleus (thus, E cannot be correct), and translation begins before transcription is terminated (coupled translation–transcription, thus B is incorrect). Therefore, before the ribosome can move from one codon to the next (translocation), or the protein synthesis machinery terminates (via termination factors), the initiating tRNA must bind and align with the mRNA to initiate translation, indicating that answer A is the first step of the choices listed that must occur.
2. **The answer is C.** Because the extract contains all normal components, the Cys-tRNA charged with alanine will compete with Cys-tRNA charged with cysteine for binding to the cysteine codons. Thus, the protein will have some alanines put in the place of cysteine, leading to a deficiency of cysteine residues. Answer A is incorrect because the tRNA recognizes the cysteine codon, not the alanine codon. Answer B is incorrect because of the competition mentioned above.
3. **The answer is A.** In order to answer this question, one first needs to find the start codon, AUG in mRNA, ATG in DNA. Bases 3 to 5 in the sequence contain this element. Next, the sequence needs to specify a phenylalanine residue near the amino terminus, which is UUU or UUC in mRNA, or TTT or TTG in DNA, but these sequences need to be in frame with the initiating methionine codon. The last element to look for is the absence of a premature stop codon, as this protein is 300 amino acids long. There is no stop sequence in the remaining bases of this piece of DNA. For answer B, the last three bases of this sequence

are TGA, which in mRNA would be UGA, and this is an in-frame stop signal. This sequence would not give rise to a protein that contained 300 amino acids. For answer C, the TTT in that sequence (bases 10 to 12) are not in frame with the initiating methionine, indicating that there is not a phenylalanine near the amino terminus in the protein encoded by this sequence. For answers D and E, there are no ATG sequences, indicating that the initiating methionine is absent and that this stretch of DNA cannot code for the amino terminal end of a protein.

4. **The answer is F.** *N*-formyl-methionine is used for the initiation of prokaryotic protein synthesis, but not eukaryotic protein synthesis. In eukaryotes, the mRNA is processed within the nucleus, and then exported into the cytoplasm before ribosomes can bind to it, so there is no nuclear mRNA-ribosome complex formed. Splicing occurs in the nucleus, but splicing errors will not alter translation. Eukaryotic translation requires an initiator tRNA for methionine, so if that tRNA were unavailable there would be no eukaryotic translation occurring. The cap on eukaryotic mRNA is necessary for appropriate IF binding to allow the charged initiator tRNA and ribosomes to bind to the mRNA. In the absence of cap formation, eukaryotic translation would be inhibited.
5. **The answer is B.** The codons for phe are UUC and UUU. Leucine has six codons, and single nucleotide changes in four of those codons would result in a phe codon. This is not the case for pro, gly, asn, or arg codons; to convert those codons to a phe codon, two nucleotide changes are required. Answering this question required consultation with the genetic code.
6. **The answer is E.** A nonsense codon is the conversion of a codon to a stop codon. The stop codons are UGA, UAG, and UAA. The codon for trp is UGG, which can be converted to UGA or UAG with a single nucleotide change. None of the other amino acid codons, with a single nucleotide change, can be converted into a stop codon.
7. **The answer is E.** A single mutation of one amino acid (valine for glutamate) causes sickle cell anemia. This change specifies a different amino acid (missense). A silent mutation specifies the same amino acid and has no consequence unless RNA splicing is altered by the mutation. A nonsense mutation is a change to a stop codon. An insertion is an addition of at least one base within the DNA. A deletion is a loss of at least one base in the DNA sequence. Sickle cell anemia could also be considered a point mutation because only a single base is changed which codes for a different amino acid.
8. **The answer is A.** There is no coding sequence between the TATA box (the promoter region where RNA polymerase binds) and the transcription initiation site, so the presence of a TAG in the DNA will not affect protein synthesis. In fact, the RNA corresponding to this sequence (UAG) will not even be synthesized, as the transcription initiation site occurs after this sequence in the DNA. The introns and exons are not affected by this mutation, and splicing will occur normally. Thus, the mRNA produced would be of normal size and would produce a normal-sized protein.
9. **The answer is B.** All tRNA molecules have the nucleotides CCA added to the 3'-end of the tRNA after it has been transcribed. The ribose on the 3'-terminal adenine is the one that accepts amino acids, to form aminoacyl-tRNA. The absence of this A residue would prevent the charging of the tRNA molecules, which would lead to the cessation of all protein synthesis. It would require a number of generations of growth such that any functional enzyme produced would have been degraded after that many generations. Spliceosomes are eukaryotic-specific, as bacterial genes do not contain introns that need to be spliced from the initial transcript. Prokaryotic RNA is not capped, nor are poly(A) tails added to each mRNA, as in eukaryotic cells. Prokaryotes do not contain a nucleus.
10. **The answer is D.** Diphtheria toxin catalyzes the ADP-ribosylation of eEF2, thereby inhibiting the activity of this factor, which is required for the translocation step of protein synthesis. The toxin does not affect RNA polymerase II, the peptidyl transferase activity of the large ribosomal subunit, the initiation complex required for ribosome assembly, or the termination steps of protein synthesis.
11. **The answer is B.** The cells lack UDP-*N*-acetylglucosamine 1-phosphotransferase, a necessary enzyme to add a mannose 6-phosphate residue to lysosomal proteins, and which is the targeting signal which directs proteins with this tag to the lysosome. Lacking the appropriate signaling marker the enzymes are secreted from the cell, rather than binding to the mannose 6-phosphate receptor protein and targeted to lysosomes. An inability to transfer vesicles from the endoplasmic reticulum to the Golgi apparatus would block all protein secretion. A loss of signal peptidase activity in the endoplasmic reticulum would affect all targeted proteins, not just lysosomal proteins, and would alter the folding of the protein such that multiple enzymatic defects would be evident, across all compartments of the cell. If the signal recognition particle receptor was defective, or absent, there would be no targeted protein synthesis in cells, affecting all organelles, not just the lysosomes. Additionally, the level of secreted proteins would be reduced. The

signal sequence for lysosomal proteins is a part of the gene for each different lysosomal protein. A single mutation would not be able to cause all lysosomal proteins to lose their signal sequence.

12. **The answer is E.** When f-met is incorporated into the middle of the protein it stops further protein synthesis, as the N-terminal is blocked by the formyl group and cannot participate in peptide bond formation. Thus, limited translation will occur as some tRNA^{met} will be charged with methionine or f-met, and whenever f-met is incorporated into the protein translation will stop. It is unlikely that full-length proteins will be synthesized owing to the incorporation of f-met into the coding region of the protein.
13. **The answer is C.** The 28S rRNA contains the peptidyl transferase activity of eukaryotic ribosomes, and losing the A base destroys that activity. The 28S rRNA is not utilized for defining the “A” or “P” Sites of the ribosome. Because Shiga toxin affects eukaryotic cells there is no Shine–Dalgarno sequence in eukaryotic mRNA. The translocation step in eukaryotic translation requires EFs, but not the rRNA components of the ribosomes.
14. **The answer is B.** A mutation within a tRNA molecule such that the anticodon base pairs with a stop codon (called a suppressor tRNA) would insert the amino acid charged to this tRNA into proteins whenever a stop codon is encountered. Such a tRNA could be tolerated in the cell as there are release factors that can compete for binding of the tRNA to stop codons, so while overall protein synthesis may be reduced sufficient levels of protein are synthesized to allow the cell to grow. Altering the rate at which the gene is transcribed (answers D and E) would not overcome the presence of a stop codon within the gene. If translation began at a different AUG (answer C), the reading frame of the protein would be altered, and a dysfunctional protein would be produced. Because the question asks for a secondary mutation outside of gene X answer A cannot be correct, as that mutation would be occurring within gene X. It also would not fix the problem of the internal stop codon, as opposed to the normal stop codon after the C-terminal of the protein.
15. **The answer is A.** A new splice site is created, which leads to the loss of about a third of the protein, leading to a mistargeted and dysfunctional protein. Recall that the invariant regions in mRNA that surround a splice site are AGGU at the 5'-end, and AGG at the 3'-end. In DNA this would be AGGT and AGG. The mutation alters an AGGC region to AGGT and creates a new splice site in the initial mRNA transcript which removes a significant amount of coding RNA from the transcript, producing a truncated lamin A molecule that has lost its function. Because the base C is not part of the recognition sequences for splicing, an existing splice site is not lost in the initial mRNA transcript (answer B). The mutation also does not alter the rate at which translation occurs (ribosome binding to the mRNA), as the mutation is in the middle of the protein and is not affecting the initiation of translation. Levels of charged tRNA^{gly} would not be altered by a mutation in the lamin A gene (answer C).

Regulation of Gene Expression

Gene expression, the generation of a protein or RNA product from a particular gene, is controlled by complex mechanisms. Normally, only a fraction of the genes in a cell are expressed at any time. Gene expression is regulated differently in prokaryotes and eukaryotes.

Regulation of Gene Expression in Prokaryotes. In **prokaryotes**, gene expression is regulated mainly by controlling the **initiation of gene transcription**. Sets of genes that encode proteins with related functions are organized into **operons**, and each operon is under the control of a **single promoter** (or regulatory region). Regulatory proteins called **repressors** bind to the promoter and inhibit the binding of RNA polymerase (**negative control**), whereas **activator proteins** facilitate RNA polymerase binding (**positive control**). Repressors are controlled by nutrients or their metabolites and are classified as **inducers** or corepressors. Regulation also may occur through **attenuation of transcription**.

Eukaryotes: Regulation of Gene Expression at the Level of DNA. In eukaryotes, activation of a gene requires changes in the state of chromatin (**chromatin remodeling**) that are facilitated by **acetylation of histones and methylation of bases**. These changes in DNA determine which genes are available for transcription.

Regulation of Eukaryotic Gene Transcription. Transcription of specific genes is regulated by proteins (called **specific transcription factors** or **transactivators**) that bind to **gene regulatory sequences** (called **promoter-proximal elements, response elements, or enhancers**) that activate or inhibit assembly of the basal transcription complex and RNA polymerase at a TATA box or similar regulatory element. These specific transcription factors, which may bind to DNA sequences some distance from the promoter, interact with coactivators or corepressors that bind to components of the basal transcription complex. These protein factors are said to work in “**trans**”; the DNA sequences to which they bind are said to work in “**cis**.”

Other Sites for Regulation of Eukaryotic Gene Expression. Regulation also occurs during the **processing** of RNA, during RNA **transport** from the nucleus to the cytoplasm, and at the level of **translation** in the cytoplasm. Regulation can occur simultaneously at multiple levels for a specific gene, and many factors act in concert to stimulate or inhibit the expression of a gene.

THE WAITING ROOM

Charles F., a 68-year-old man, complained of fatigue, loss of appetite, and a low-grade fever. An open biopsy of a lymph node indicated the presence of non-Hodgkin lymphoma, follicular type. Computed tomography and other noninvasive procedures showed a diffuse process with bone marrow involvement. He is receiving multidrug chemotherapy with R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone).

Many of the drugs used by **Charles F.** inhibit the proliferation of cancer cells in various ways. Doxorubicin (adriamycin) is a large, nonpolar molecule synthesized by fungi that intercalates between DNA bases, inhibiting replication and transcription and forming DNA with single- and double-stranded breaks. Vincristine binds to tubulin and inhibits formation of the mitotic spindle, thereby preventing cell division. Cyclophosphamide is an alkylating agent that damages DNA by covalently attaching alkyl groups to DNA bases. Rituximab is an anti-CD20 antibody that specifically targets B-cells (including the tumor

cells) for destruction (a form of immunotherapy). Prednisone is a steroid hormone, whose effect on cancer cells is not exactly understood, but it is also given to help manage the side effects of the other agents.

Mannie W. is a 56-year-old man who complains of weight loss related to a decreased appetite and increased fatigue. He notes discomfort in the left upper quadrant of his abdomen. On physical examination, he is noted to be pale and to have ecchymoses (bruises) on his arms and legs. His spleen is markedly enlarged.

Initial laboratory studies show a hemoglobin of 10.4 g/dL (normal, 13.5 to 17.5 g/dL) and a leukocyte (white blood cell) count of 106,000 cells/mm³ (normal, 4,500 to 11,000 cells/mm³). The majority of the leukocytes are granulocytes (white blood cells arising from the myeloid lineage), some of which have an “immature” appearance. The percentage of lymphocytes in the peripheral blood is decreased. A bone marrow aspiration and biopsy show the presence of an abnormal chromosome (the Philadelphia chromosome) in dividing marrow cells.

Ann R., who has anorexia nervosa, has continued on an almost meat-free diet (see Chapters 1, 3, 9, and 10). She now appears emaciated and pale. Her hemoglobin is 9.7 g/dL (normal = 12 to 15 g/dL), her hematocrit (volume of packed red cells) is 31% (reference range for women, 36% to 46%), and her mean corpuscular volume (the average volume of a red cell) is 70 femtoliters (fL; 1 fL is 10⁻¹⁵ L) (reference range = 80 to 100 fL). These values indicate an anemia that is microcytic (small red cells) and hypochromic (light in color, indicating a reduced amount of hemoglobin per red cell). Her serum ferritin (the cellular storage form of iron) was also subnormal. Her plasma level of transferrin (the iron transport protein in plasma) is higher than normal, but its percentage saturation with iron is below normal. This laboratory profile is consistent with changes that occur in an iron deficiency state.

The measurement of iron in the blood needs to account for iron associated with hemoglobin, free iron, and iron bound to its carrier protein, transferrin. When a physician orders a determination of serum iron, the order refers to ferric iron (Fe³⁺) bound to transferrin and not the ferrous iron (Fe²⁺) bound to circulating hemoglobin (which may be present in the plasma as a result of occasional red-cell lysis). Measurement of ferric iron has been adapted to automated spectrophotometric analysis. In most cases, the samples are acidified to remove the ferric ion from transferrin. The iron is then reduced to the ferrous state by a reducing agent (such as ascorbic acid), and the level of iron is determined by its binding to a dye that changes color when ferrous ion binds to it.

The total iron-binding capacity (TIBC) is determined by adding ferric ion to the sample to saturate all transferrin-binding sites in the sample. Excess iron (free iron, not bound to transferrin) is precipitated by treatment with MgCO₃, and the precipitate is removed by centrifugation. The resulting soluble sample is then analyzed for Fe³⁺ as described previously. By comparing the levels of Fe³⁺ bound both before and after saturation, one can determine what percentage of transferrin contained bound iron. For a woman between the ages of 16 and 40 years, the percentage saturation should be in the range of 20% to 50%. **Ann R.**'s iron saturation is below this normal range, indicating an iron deficiency.

I. Gene Expression Is Regulated for Adaptation and Differentiation

Virtually all cells of an organism contain identical sets of genes. However, at any given time, only a small number of the total genes in each cell are expressed (i.e., generate a protein or RNA product). The remaining genes are inactive. Organisms gain a number of advantages by regulating the activity of their genes. For example, both prokaryotic and eukaryotic cells adapt to changes in their environment by turning the expression of genes on and off. Because the processes of RNA transcription and protein synthesis consume a considerable amount of energy, cells conserve fuel by making proteins only when they are needed.

In addition to regulating gene expression to adapt to environmental changes, eukaryotic organisms alter the expression of their genes during development. As a fertilized egg becomes a multicellular organism, different kinds of proteins are synthesized in varying quantities. In the human, as the child progresses through adolescence and then into adulthood, physical and physiologic changes result from variations in gene expression and, therefore, of protein synthesis. Even after an organism has reached the adult stage, regulation of gene expression enables certain cells to undergo differentiation to assume new functions.

II. Regulation of Gene Expression in Prokaryotes

Prokaryotes are single-celled organisms and therefore require less complex regulatory mechanisms than multicellular eukaryotes (Fig. 15.1). The most extensively studied prokaryote is the bacterium *Escherichia coli*,

an organism that thrives in the human colon, usually enjoying a symbiotic relationship with its host. Based on the size of its genome (4×10^6 base pairs), *E. coli* should be capable of making several thousand proteins. However, under normal growth conditions, *E. coli* synthesizes only about 600 to 800 different proteins. Thus, many genes are inactive, and *E. coli* will only synthesize those genes that generate the proteins required for growth in that particular environment.

Prokaryote

FIGURE 15.1. *Escherichia coli* cell. In prokaryotes, DNA is not separated from the rest of the cellular contents by a nuclear

envelope; therefore, simultaneous transcription and translation occur in bacteria. Once a small piece of mRNA is synthesized, ribosomes bind to the mRNA and translation begins. mRNA, messenger RNA.

All *E. coli* cells of the same strain are morphologically similar and contain an identical circular chromosome (see Fig. 15.1). As in other prokaryotes, DNA is not complexed with histones, no nuclear envelope separates the genes from the contents of the cytoplasm, and gene transcripts do not contain introns. In fact, as messenger RNA (mRNA) is being synthesized, ribosomes bind and begin to produce proteins, so that transcription and translation occur simultaneously (known as coupled transcription–translation). The mRNA molecules in *E. coli* have a very short half-life and are degraded within a few minutes. mRNA molecules must be constantly generated from transcription to maintain synthesis of its proteins. Thus, regulation of transcription, principally at the level of initiation, is sufficient to regulate the level of proteins within the cell.

A. Operons

The genes encoding proteins are called **structural genes**. In the bacterial genome, the structural genes for proteins involved in performing a related function (such as the enzymes of a biosynthetic pathway) are often grouped sequentially into units called **operons** (Fig. 15.2, and see Fig. 13.6). The genes in an operon are coordinately expressed; that is, they are either all turned on or all turned off. When an operon is expressed, all of its genes are transcribed (refer to Chapter 13, Section III). A single polycistronic mRNA that codes for all the proteins of the operon is produced. This polycistronic mRNA contains multiple sets of start and stop codons that allow a number of different proteins to be produced from this single transcript at the translational level. Transcription of the genes in an operon is regulated by the **promoter**, which is located in the operon at the 5'-end, upstream from the structural genes.

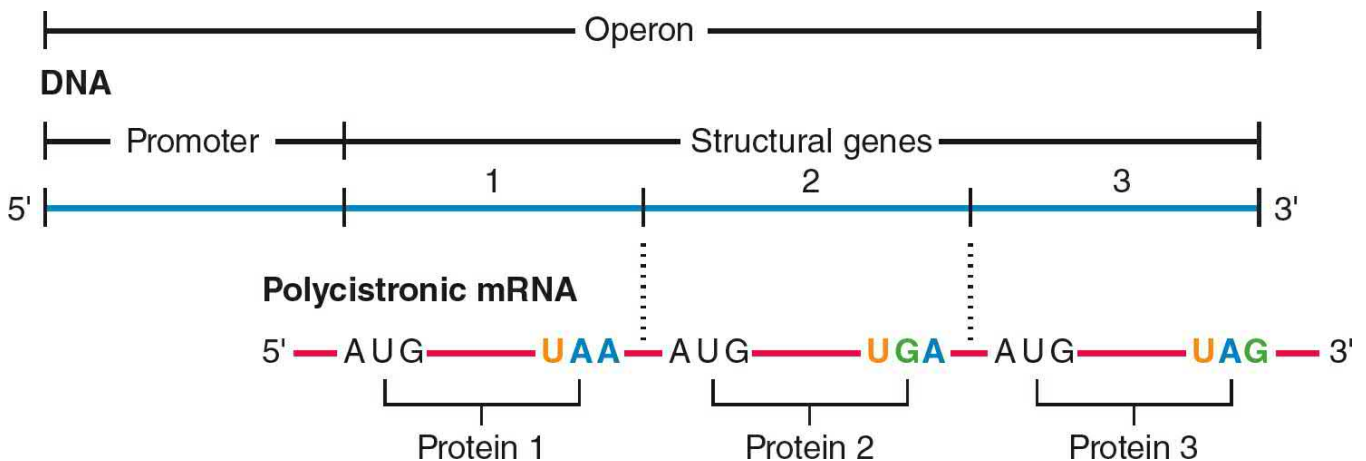

FIGURE 15.2. An operon. The structural genes of an operon are transcribed as one long polycistronic mRNA. During translation, different start (AUG) and stop (UAA, UGA, or UAG) codons lead to a number of distinct proteins being produced from this single mRNA. mRNA, messenger RNA.

B. Regulation of RNA Polymerase Binding by Repressors

In bacteria, the principal means of regulating gene transcription is through repressors, which are regulatory proteins that prevent the binding of RNA polymerase to the promoter and thus act on initiation of transcription (Fig. 15.3). In general, regulatory mechanisms such as repressors, which work through inhibition of gene transcription, are referred to as **negative control**, and mechanisms that work through stimulation of gene transcription are called **positive control**.

Repressors

FIGURE 15.3. Regulation of operons by repressors. When the repressor protein is bound to the operator (a DNA sequence adjacent to, or within, the promoter), RNA polymerase cannot bind, and transcription therefore does not occur. mRNA, messenger RNA.

The repressor is encoded by a regulatory gene (see Fig. 15.3). Although this gene is considered part of the operon, it is not always located near the remainder of the operon. Its product, the **repressor protein**, diffuses to the promoter and binds to a region of the operon called the **operator**. The operator is located within the promoter or near its 3'-end, just upstream from the transcription start point. When a repressor is bound to the operator, the operon is not transcribed because the repressor protein either physically blocks the binding of RNA polymerase to the promoter or prevents the RNA polymerase from initiating transcription. Two

regulatory mechanisms work through controlling repressors: induction (an inducer inactivates the repressor) and repression (a corepressor is required to activate the repressor).

1. Inducers

Induction involves a small molecule, known as an **inducer**, which stimulates expression of the operon by binding to the repressor and changing its conformation so that it can no longer bind to the operator (Fig. 15.4). The inducer is either a nutrient or a metabolite of the nutrient. In the presence of the inducer, RNA polymerase can therefore bind to the promoter and transcribe the operon. The key to this mechanism is that in the absence of the inducer, the repressor is active, transcription is repressed, and the genes of the operon are not expressed.

Inducers

Promoter

Protein C

FIGURE 15.4. An inducible operon. In the absence of an inducer, the repressor binds to the operator, preventing the binding of RNA polymerase. When the inducer is present, the inducer binds to the repressor, inactivating it. The inactive repressor no longer binds to the operator. Therefore, RNA polymerase can bind to the promoter region and transcribe the structural genes. mRNA, messenger RNA.

Consider, for example, induction of the ***lac* operon** of *E. coli* by lactose (Fig. 15.5). The enzymes for metabolizing glucose by glycolysis are produced constitutively; that is, they are constantly being made. If the milk sugar lactose is available, the cells adapt and begin to produce the three additional enzymes required for lactose metabolism, which are encoded by the *lac* operon. A metabolite of lactose (allolactose) serves as an inducer, binding to the repressor and inactivating it. Because the inactive repressor no longer binds to the operator, RNA polymerase can bind to the promoter and transcribe the structural genes of the *lac* operon, producing a polycistronic mRNA that encodes for the three additional proteins. However, the presence of glucose can prevent activation of the *lac* operon (see Section II.C). It is important to realize that the *lac* operon is expressed at very low levels (basal levels) even in the absence of inducer. Thus, even in the absence of lactose, a small amount of permease is present in the cellular membrane. Therefore, when lactose does become available in the environment, a few molecules of lactose are able to enter the cell and can be metabolized to allolactose. The few molecules of allolactose produced are sufficient to induce the operon. As the amount of permease increases, more lactose can be transported into the cell to be used as an energy source.

The *lac* operon

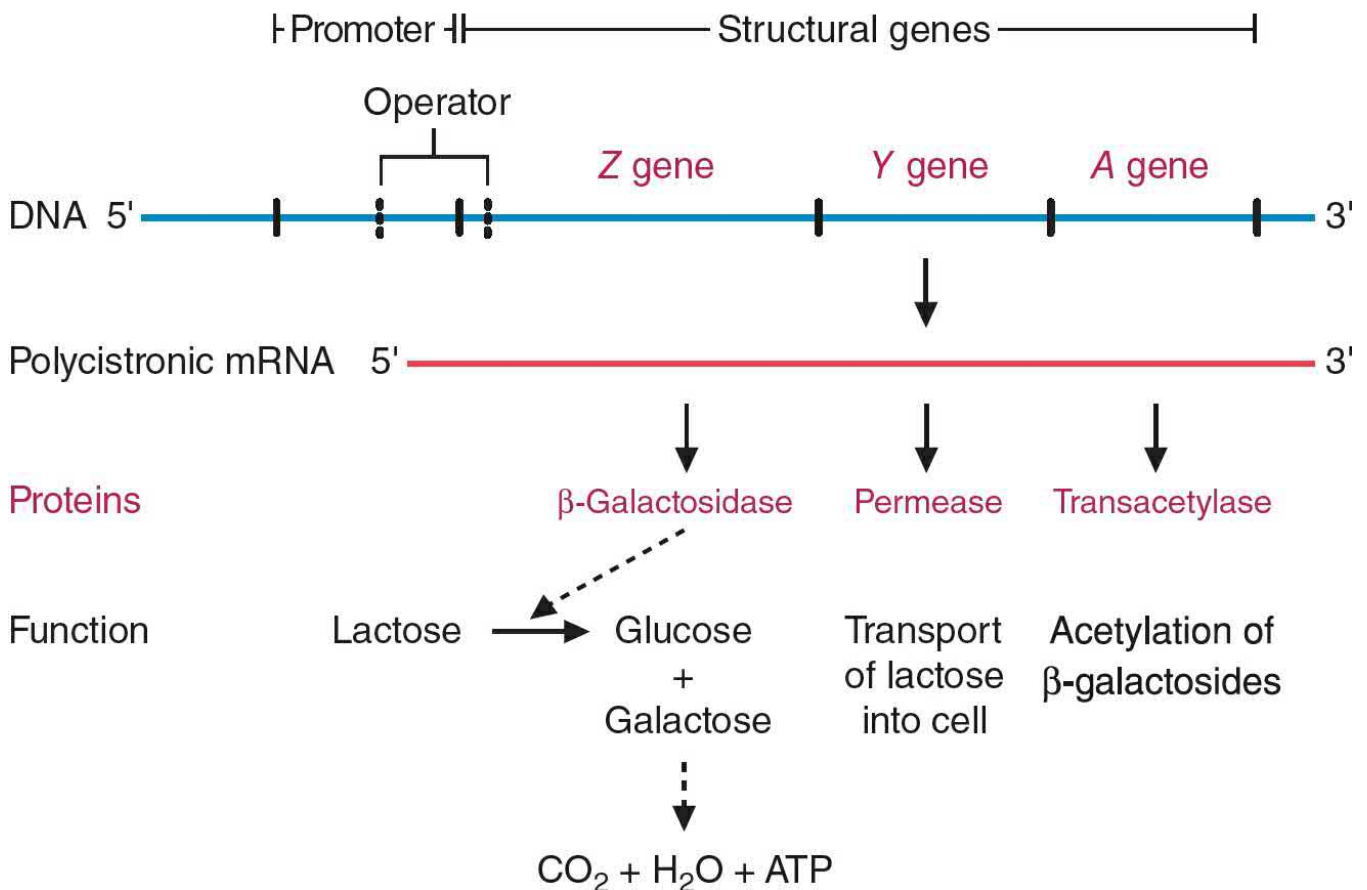

FIGURE 15.5. The protein products of the *lac* operon. Lactose is a disaccharide that is hydrolyzed to glucose and galactose by β-galactosidase (the product of the *lac* Z gene). Both glucose and galactose can be oxidized by the cell for energy. The permease (the product of the *lac* Y gene) enables the cell to take up lactose more readily. The A gene produces a transacetylase that acetylates β-galactosides. The function of this acetylation is not clear. The promoter binds RNA polymerase and the operator binds a repressor protein. Lactose is converted to allolactose, an inducer that binds the repressor protein and prevents it from binding to the operator. Transcription of the *lac* operon also requires activator proteins that are inactive when glucose levels are high. ATP, adenosine triphosphate; mRNA, messenger RNA.

2. Corepressors

In a regulatory model called **repression**, the repressor is inactive until a small molecule called a **corepressor** (a nutrient or its metabolite) binds to the repressor, activating it (Fig. 15.6). The repressor–corepressor complex then binds to the operator, preventing binding of RNA polymerase and gene transcription. Consider, for example, the *trp* operon, which encodes the five enzymes required for the synthesis of the amino acid tryptophan. When tryptophan is available, *E. coli* cells save energy by no longer making these enzymes. Tryptophan is a corepressor that binds to the inactive repressor, causing it to change conformation and bind to the operator, thereby inhibiting transcription of the operon. Thus, in the repression model, the repressor is inactive without a corepressor; in the induction model, the repressor is active unless an inducer is present.

Corepressors

FIGURE 15.6. A repressible operon. The repressor is inactive until a small molecule, the corepressor, binds to it. The repressor–corepressor complex binds to the operator and prevents transcription. mRNA, messenger RNA.

C. Stimulation of RNA Polymerase Binding

In addition to regulating transcription by means of repressors that inhibit RNA polymerase binding to promoters (negative control), bacteria regulate transcription by means of activating proteins that bind to the promoter and stimulate the binding of RNA polymerase (positive control). Transcription of the *lac* operon, for example, can be induced by allolactose only if glucose is absent. The presence or absence of glucose is communicated to the promoter by a regulatory protein named the **cyclic adenosine monophosphate (cAMP) receptor protein (CRP)** (Fig. 15.7). This regulatory protein is also called a **catabolite activator protein (CAP)**. A decrease in glucose levels increases levels of the intracellular second messenger cAMP by a mechanism that involves glucose transport into the bacteria. cAMP binds to CRP and the cAMP–CRP complex binds to a regulatory region of the operon, stimulating binding of RNA polymerase to the promoter and transcription. When glucose is present, cAMP levels decrease, CRP assumes an inactive conformation that does not bind to the operon, and the recruitment of RNA polymerase to the promoter is reduced, resulting in inhibition of transcription. Thus, the enzymes encoded by the *lac* operon are not produced if cells have an adequate supply of glucose, even if lactose is present at very high levels.

A. In the presence of lactose and glucose

B. In the presence of lactose and absence of glucose

FIGURE 15.7. Catabolite repression of stimulatory proteins. The *lac* operon is used as an example. **A.** The inducer allolactose (a metabolite of lactose) inactivates the repressor. However, because of the absence of the required coactivator, cAMP-CRP, no transcription occurs unless glucose is absent. **B.** In the absence of glucose, cAMP levels rise. cAMP forms a complex with the cAMP receptor protein. The binding of the cAMP-CRP complex to a regulatory region of the operon permits the binding of RNA polymerase to the promoter. Now the operon is transcribed, and the proteins are produced. cAMP, cyclic adenosine monophosphate; CRP, cAMP receptor protein; mRNA, messenger RNA.

D. Regulation of RNA Polymerase Binding by Sigma Factors

E. coli has only one RNA polymerase. Sigma factors bind to this RNA polymerase, stimulating its binding to certain sets of promoters, thus simultaneously activating transcription of several operons. The standard sigma factor in *E. coli* is σ^{70} , a protein with a molecular weight of 70,000 daltons (see Chapter 13). Other sigma

factors also exist. For example, σ^{32} helps RNA polymerase recognize promoters for the different operons that encode the heat-shock proteins. Thus, increased transcription of the genes for heat-shock proteins, which prevent protein denaturation at high temperatures, occurs in response to elevated temperatures.

E. Attenuation of Transcription

Some operons are regulated by a process that interrupts (attenuates) transcription after it has been initiated (Fig. 15.8). For example, high levels of tryptophan attenuate transcription of the *E. coli trp* operon, as well as repress its transcription. As mRNA is being transcribed from the *trp* operon, ribosomes bind and rapidly begin to translate the transcript. Near the 5'-end of the transcript are a number of codons for tryptophan. Initially, high levels of tryptophan in the cell result in high levels of Trp-tRNA^{Trp} and rapid translation of the transcript. However, rapid translation generates a hairpin loop in the mRNA that serves as a termination signal for RNA polymerase, and transcription terminates. Conversely, when tryptophan levels are low, levels of Trp-tRNA^{Trp} are low, and ribosomes stall at codons for tryptophan. A different hairpin loop forms in the mRNA that does not terminate transcription, and the complete mRNA is transcribed. Attenuation requires coupled transcription and translation, so this mechanism is not applicable to eukaryotic systems.

FIGURE 15.8. Attenuation of the *trp* operon. Sequences 2, 3, and 4 in the mRNA transcript can form base pairs (2 with 3 or 3 with 4) that generate hairpin loops. When tryptophan levels are low, the ribosome stalls at the adjacent Trp codons in sequence 1, the 2 to 3 loop forms, and transcription continues. When tryptophan levels are high, translation is rapid and the ribosome blocks formation of the 2 to 3 loop. Under these conditions, the 3 to 4 loop forms and terminates transcription.

The tryptophan, histidine, leucine, phenylalanine, and threonine operons are regulated, in part, by attenuation. Repressors and activators also act on the promoters of some of these operons, allowing the levels of these amino acids to be very carefully and rapidly regulated.

III. Regulation of Gene Expression in Eukaryotes

Multicellular eukaryotes are much more complex than single-celled prokaryotes. As the human embryo develops into a multicellular organism, different sets of genes are turned on and different groups of proteins are produced, resulting in differentiation into morphologically distinct cell types that are able to perform different functions. Even beyond development, certain cells within the organism continue to differentiate, such as those that produce antibodies in response to an infection, renew the population of red blood cells, and replace digestive cells that have been sloughed into the intestinal lumen. All of these physiologic changes are dictated by complex alterations in gene expression.

A. Regulation at Multiple Levels

Differences between eukaryotic and prokaryotic cells result in different mechanisms for regulating gene expression. DNA in eukaryotes is organized into the nucleosomes of chromatin, and genes must be in an active structure to be expressed in a cell. Furthermore, operons are not present in eukaryotes, and the genes that encode proteins that function together are usually located on different chromosomes. For example, the gene for α -globin is on chromosome 15, whereas the gene for β -globin is on chromosome 11. Thus, each gene needs its own promoter. In addition, the processes of transcription and translation are separated in eukaryotes by intracellular compartmentation (nucleus and cytosol, or endoplasmic reticulum [ER]) and by time (eukaryotic heterogeneous nuclear RNA [hnRNA], also known as pre-RNA) must be processed and translocated out of the nucleus before it is translated). Thus, regulation of eukaryotic gene expression occurs at multiple levels:

- DNA and the chromosome, including chromosome remodeling and gene rearrangement
- Transcription, primarily through transcription factors that affect binding of RNA polymerase to the promoter
- Processing of transcripts
- Initiation of translation and stability of mRNA

Once a gene is activated through chromatin remodeling, the major mechanism of regulating expression affects initiation of transcription at the promoter.

B. Regulation of Availability of Genes for Transcription

Once a haploid sperm and egg combine to form a diploid cell, the number of genes in human cells remains approximately the same. As cells differentiate, different genes are available for transcription. A typical nucleus contains chromatin that is condensed (heterochromatin) and chromatin that is diffuse (euchromatin) (see Chapter 11). The genes in heterochromatin are inactive, whereas those in euchromatin produce mRNA. Long-term changes in the activity of genes occur during development as chromatin goes from a diffuse to a condensed state or vice versa.

The cellular genome is packaged together with histones into nucleosomes, and initiation of transcription is prevented if the promoter region is part of a nucleosome. Thus, activation of a gene for transcription requires changes in the state of the chromatin, called **chromatin remodeling**. The availability of genes for transcription also can be affected in certain cells, or under certain circumstances, by **gene rearrangements**, **amplification**, or **deletion**. For example, during lymphocyte maturation, genes are rearranged to produce a variety of different antibodies. The term **epigenetics** is used to refer to changes in gene expression without altering the sequence of the DNA. Chromatin remodeling and DNA methylation are such changes that can be inherited and contribute to the regulation of gene expression.

1. Chromatin Remodeling

The remodeling of chromatin generally refers to the displacement of the nucleosome from specific DNA sequences so that transcription of the genes in that sequence can be initiated. This occurs through two different mechanisms. The first mechanism is by an adenosine triphosphate (ATP)-driven chromatin remodeling complex, which uses energy from ATP hydrolysis to unwind certain sections of DNA from the nucleosome

core. The second mechanism is by covalent modification of the histone tails through acetylation (Fig. 15.9). Histone acetyltransferases (HAT) transfer an acetyl group from acetyl coenzyme A (acetyl CoA) to lysine residues in the histone tails (the amino-terminal ends of histones H2A, H2B, H3, and H4) of the histone octamer. This reaction removes a positive charge from the ϵ -amino group of the lysine, thereby reducing the electrostatic interactions between the histones and the negatively charged DNA, making it easier for DNA to unwind from the histones. The acetyl groups can be removed by histone deacetylases (HDAC). Each histone has a number of lysine residues that may be acetylated and, through a complex mixing of acetylated and nonacetylated sites, different segments of DNA can be freed from the nucleosome. A number of transcription factors and coactivators contain histone acetyltransferase activity, which facilitates the binding of these factors to the DNA and simultaneous activation of the gene and initiation of its transcription.

FIGURE 15.9. Histone acetylation. CoA, coenzyme A; HAT, histone acetyltransferase; HDAC, histone deacetylase.

Alteration of gene expression is a common finding in cancer cells. Alterations in HAT or HDAC activity may contribute to

dysregulation of cellular proliferation in certain tumors. These alterations in HAT or HDAC activity are usually caused by mutations in transcription factors or coactivators, which have either enhanced or reduced their ability to recruit HATs or HDACs to a preinitiation complex at the promoter. HDACs have been shown to be excellent therapeutic targets for drugs that inhibit their activity. Some of these inhibitors display antiproliferative activity on a variety of human cancer cell lines and are currently in clinical trials.

2. Methylation of DNA

Cytosine residues in DNA can be methylated to produce 5-methylcytosine. The methylated cytosines are located in CG-rich sequences (called CG or CpG islands), which are often near or in the promoter region of a gene. In certain instances, genes that are methylated are less readily transcribed than those that are not methylated. For example, globin genes are more extensively methylated in nonerythroid cells (cells that are not a part of the erythroid, or red blood cell, lineage) than in cells in which these genes are expressed (such as erythroblasts and reticulocytes). Methylation is a mechanism for regulating gene expression during differentiation, particularly in fetal development.

Methylation has been implicated in genomic imprinting, a process that occurs during the formation of the eggs or sperm that blocks the expression of the gene in the fertilized egg. Males methylate a different set of genes than females. This sex-dependent differential methylation has been studied most extensively in two human disorders, Prader–Willi syndrome and Angelman syndrome. Both syndromes, which have very different symptoms, result from deletions of the same region of chromosome 15 (a microdeletion of <5 megabases in size). If the deletion is inherited from the father, Prader–Willi syndrome is seen in the child. If the deletion is inherited from the mother, Angelman syndrome is observed. A disease occurs when a gene that is in the deleted region of one chromosome is methylated on the other chromosome. The mother methylates different genes than the father, so different genes are expressed depending on which parent transmitted the intact chromosome. For example, for Prader–Willi syndrome, if genes 1, 2, and 3 are deleted in the paternal chromosome and gene 2 is methylated in the maternal chromosome, only genes 1 and 3 will be expressed. For Angelman syndrome, genes 1, 2, and 3 are deleted on the maternal chromosome and gene 1 is methylated on the paternal chromosome, so only genes 2 and 3 are expressed.

3. Gene Rearrangement

Segments of DNA can move from one location to another in the genome, associating with each other in various ways so that different proteins are produced (Fig. 15.10). The most thoroughly studied example of gene rearrangement occurs in cells that produce antibodies. Antibodies contain two light chains and two heavy chains, each of which contains both a variable region and a constant region (see Chapter 7, Section VIII, Fig. 7.19). Cells called B-cells make antibodies. In the precursors of B-cells, hundreds of V_H sequences,

approximately 20 D_H sequences, and approximately 6 J_H sequences are located in clusters within a long region of the chromosome (see Fig. 15.10). During the production of the immature B-cells, a series of recombinational events occur that joins one V_H , one D_H , and one J_H sequence into a single exon. This exon now encodes the variable region of the heavy chain of the antibody. Given the large number of immature B-cells that are produced, virtually every recombinational possibility occurs, so all VDJ combinations are represented within this cell population. Later in development, during the differentiation of mature B-cells, recombinational events join a VDJ sequence to one of the nine heavy-chain elements. When the immune system encounters an antigen, the one immature B-cell that can bind to that antigen (because of its unique manner of forming the VDJ exon) is stimulated to proliferate (clonal expansion) and to produce antibodies against the antigen.

FIGURE 15.10. Rearrangement of DNA. The heavy-chain gene from which lymphocytes produce immunoglobulins is generated by combining specific segments from among a large number of potential sequences in the DNA of precursor cells. The variable and constant regions of immunoglobulins (antibodies) are described in Chapter 7.

4. Gene Amplification

Gene amplification is not the usual physiologic means of regulating gene expression in normal cells, but it does occur in response to certain stimuli if the cell can obtain a growth advantage by producing large amounts of protein. In gene amplification, certain regions of a chromosome undergo repeated cycles of DNA replication. The newly synthesized DNA is excised and forms small, unstable chromosomes called **double minutes**. The double minutes integrate into other chromosomes throughout the genome, thereby amplifying the gene in the process. Normally, gene amplification occurs through errors during DNA replication and cell division and, if the environmental conditions are appropriate, cells containing amplified genes may have a growth advantage over those without the amplification.

 Although rearrangements of short DNA sequences are difficult to detect, microscopists have observed major rearrangements for many years. Such major rearrangements, known as translocations, can be observed in metaphase chromosomes under the microscope. **Mannie W.** has such a translocation, known as the Philadelphia chromosome because it was first observed in that city. The Philadelphia chromosome is produced by a balanced exchange between chromosomes 9 and 22. In this translocation, most of a gene from chromosome 9, the *c-abl* gene, is transferred to the *BCR* gene on chromosome 22. This creates a fused *BCR-abl* gene. The *c-abl* gene is a tyrosine kinase (see Chapter 10) and its regulation by the BCR promoter results in uncontrolled growth stimulation rather than differentiation in cells containing this translocation.

5. Gene Deletions

With a few exceptions, the deletion of genetic material is likewise not a normal means of controlling transcription, although such deletions do result in disease. Gene deletions can occur through errors in DNA replication and cell division and are usually noticed only if a disease results. For example, various types of cancers result from the loss of a good copy of a tumor-suppressor gene, leaving the cell with a mutated copy of the gene (see Chapter 17).

C. Regulation at the Level of Transcription

The transcription of active genes is regulated by controlling the assembly of the basal transcription complex containing RNA polymerase and its binding to distinct elements of the promoter, such as the TATA or Inr box (see Chapter 13). The basal transcription complex contains transcription factor (TFIID) (which binds to elements within the promoter, such as the TATA or Inr box), and other proteins called **general (basal) transcription factors** (such as TFIIA) that form a complex with RNA polymerase II. Additional transcription

factors that are ubiquitous to all promoters bind upstream at various sites in the promoter region. They increase the frequency of transcription and are required for a promoter to function at an adequate level. Genes that are regulated solely by these consensus elements in the promoter region are said to be constitutively expressed.

The control region of a gene also contains DNA regulatory sequences that are specific for that gene and may increase its transcription 1,000-fold or more (Fig. 15.11). Gene-specific transcription factors (also called transactivators or activators) bind to these regulatory sequences and interact with mediator proteins, such as coactivators. By forming a loop in the DNA, coactivators interact with the basal transcription complex and can activate its assembly at the initiation site on the promoter. These DNA regulatory sequences may be some distance from the promoter and may be either upstream or downstream of the initiation site.

FIGURE 15.11. The gene regulatory control region consists of the promoter region and additional gene regulatory sequences, including enhancers and HRE. In this case, a promoter containing a TATA box is shown. Gene regulatory proteins that bind directly to DNA (regulatory DNA-binding proteins) are usually called specific transcription factors or transactivators; they may be either activators or repressors of the transcription of specific genes. The specific transcription factors bind mediator proteins (coactivators or corepressors) that interact with the general transcription factors of the basal transcription complex. The basal transcription complex contains RNA polymerase and associated general transcription factors (TFII factors) and binds, in this case, to the TATA box of the promoter, initiating gene transcription. HRE, hormone response element.

Depending on the system, the terminology used to describe components of gene-specific regulation varies somewhat. For example, in the original terminology, DNA regulatory sequences called **enhancers** bound transactivators, which bound coactivators. Similarly, silencers bound corepressors. Hormones bound to hormone receptors, which bind to hormone response elements in DNA. Although these terms are still used, they are often replaced by more general terms such as **DNA regulatory sequences** and **specific transcription factors**, in recognition of the fact that many transcription factors activate one gene while inhibiting another or that a specific transcription factor may be changed from a repressor to an activator by phosphorylation.

Historically, non-Hodgkin lymphoma was treated with methotrexate, and it is still used in certain cases of lymphoma and other

malignancies. It inhibits cell proliferation by inhibiting dihydrofolate reductase. Dihydrofolate reductase reduces dihydrofolate to tetrahydrofolate, a cofactor required for the synthesis of thymine and purine nucleotides. Methotrexate resistance, however, was frequently observed in patients. Sometimes, rapidly dividing cancer cells treated with methotrexate amplify the gene for dihydrofolate reductase, producing hundreds of copies in the genome. These cells generate large amounts of dihydrofolate reductase, and normal doses of methotrexate are no longer adequate. Gene amplification is one of the mechanisms by which patients become resistant to a drug. Methotrexate is no longer utilized for the treatment of most non-Hodgkin lymphomas, having been supplanted by specific immunotherapy.

1. Gene-Specific Regulatory Proteins

The regulatory proteins that bind directly to DNA sequences are most often called **transcription factors** or **gene-specific transcription factors** (if it is necessary to distinguish them from the general transcription factors of the basal transcription complex). They also can be called **activators** (or **transactivators**), **inducers**, **repressors**, or **nuclear receptors**. In addition to their DNA-binding domain, these proteins usually have a domain that binds to mediator proteins (coactivators, corepressors, or TATA-binding protein-associated factors [TAFs]). Coactivators, corepressors, and other mediator proteins do not bind directly to DNA but generally bind to components of the basal transcription complex and mediate its assembly at the promoter. They can be specific for a given gene transcription factor or general and bind many different gene-specific transcription factors. Certain coactivators have histone acetyltransferase activity, and certain corepressors have HDAC activity. When the appropriate interactions among the transactivators, coactivators, and the basal transcription complex occur, the rate of transcription of the gene is increased (induction). The generation of acetylated histones in the region of the DNA in the gene to be transcribed attracts proteins that contain bromodomains. Proteins that bind to acetyl-lysine residues also attract a complex of proteins known as the chromatin remodeling engine. This engine utilizes the energy of ATP hydrolysis to slide DNA from nucleosomes and to free up regions of the DNA such that DNA-binding proteins can now bind, leading to the enhancement of transcription of this gene.

Some regulatory DNA-binding proteins inhibit (repress) transcription and may be called **repressors**. Repression can occur in a number of ways. A repressor bound to its specific DNA sequence may inhibit binding of an activator to its regulatory sequence. Alternatively, the repressor may bind a corepressor that inhibits binding of a coactivator to the basal transcription complex. The repressor may bind a component of the basal transcription complex directly. Some steroid hormone receptors that are transcription factors bind either coactivators or corepressors, depending on whether the receptor contains bound hormone. Furthermore, a particular transcription factor may induce transcription when it is bound to the regulatory sequence of one gene and may repress transcription when it is bound to the regulatory sequence of another gene.

2. Transcription Factors That Are Steroid Hormone/Thyroid Hormone Receptors

In the human, steroid hormones and other lipophilic hormones activate or inhibit transcription of specific genes through binding to nuclear receptors that are gene-specific transcription factors (Fig. 15.12A). The nuclear receptors bind to DNA regulatory sequences called **hormone response elements** and induce or repress transcription of target genes. The receptors contain a hormone (ligand)-binding domain, a DNA-binding domain, and a dimerization domain that permits two receptor molecules to bind to each other, forming characteristic homodimers or heterodimers. A transactivation domain binds the coactivator proteins that interact with the basal transcription complex. The receptors also contain a nuclear localization signal domain that directs them to the nucleus at various times after they are synthesized.

A. Domains of the steroid hormone receptor

B. Transcriptional regulation by steroid hormone receptors

FIGURE 15.12. Steroid hormone receptors. **A.** Domains of the steroid hormone receptor. The TAD binds coactivators; DBD binds to the hormone response element in DNA; LBD binds hormone; NLS is the nuclear localization signal; the dimerization sites are the portions of the protein involved in forming a dimer. The inhibitor-binding site binds heat-shock proteins and masks the nuclear localization signal. **B.** Transcriptional regulation by steroid hormone receptors. DBD, DNA-binding domain; GRE, glucocorticoid response element; GR, glucocorticoid receptor; HSP, heat-shock proteins; LBD, ligand-binding domain; TAD, transactivation domain.

In fragile X syndrome, a GCC triplet is amplified on the 5'-side of a gene (fragile X mental retardation 1, *FMR-1*) associated with the disease. This gene is located on the X chromosome. The disease is named for the finding that when cells containing this triplet repeat expansion are cultured in the absence of folic acid (which impairs nucleotide production and hence the replication of DNA), the X chromosome develops single- and double-strand breaks in its DNA. These were termed fragile sites. It was subsequently determined that the *FMR-1* gene was located in one of these fragile sites. A normal person has about 30 copies of the GCC triplet, but in affected individuals, thousands of copies can be present. This syndrome, which is a common form of inherited intellectual developmental disorder, affects about 1 in 4,000 males and 1 in 8,000 females worldwide.

Various members of the steroid hormone/thyroid hormone receptor family work in different ways. The **glucocorticoid receptor**, which binds the steroid hormone cortisol, resides principally in the cytosol bound to heat-shock proteins. As cortisol binds, the receptor dissociates from the heat-shock proteins, exposing the nuclear localization signal (see Fig. 15.12B). The receptors form homodimers that are translocated to the nucleus, where they bind to the hormone response elements (glucocorticoid response elements [GRE]) in the DNA control region of certain genes. The transactivation domains of the receptor dimers bind mediator proteins, thereby activating transcription of specific genes and inhibiting transcription of others.

Other members of the steroid hormone/thyroid hormone family of receptors are also gene-specific transactivation factors but generally form heterodimers that bind constitutively to a DNA regulatory sequence

in the absence of their hormone ligand and repress gene transcription (Fig. 15.13). For example, the **thyroid hormone receptor** forms a heterodimer with the retinoid X receptor (RXR) that binds to thyroid hormone response elements and corepressors (including one with HDAC activity), thereby inhibiting expression of certain genes. When thyroid hormone binds, the receptor dimer changes conformation and the transactivation domain binds coactivators, thereby initiating transcription of the genes.

FIGURE 15.13. Activity of the TR-RXR in the presence and absence of thyroid hormone (T_3). HAT, histone acetyltransferase; HDAC, histone deacetylase; TR-RXR, thyroid hormone receptor–retinoid receptor dimer.

The RXR, which binds the retinoid 9-*cis*-retinoic acid, can form heterodimers with at least eight other nuclear receptors. Each heterodimer has a different DNA-binding specificity. This allows the RXR to participate in the regulation of a wide variety of genes and to regulate gene expression differently, depending on the availability of other active receptors.

3. Structure of DNA-Binding Proteins

Several unique structural motifs have been characterized for specific transcription factors. Each of these proteins has a distinct recognition site (DNA-binding domain) that binds to the bases of a specific sequence of nucleotides in DNA. Four of the best-characterized structural motifs are zinc fingers, b-zip proteins (including leucine zippers), helix-turn-helix, and helix-loop-helix.

Zinc-finger motifs (commonly found in the DNA-binding domain of steroid hormone receptors) contain a bound zinc chelated at four positions with either histidine or cysteine in a sequence of approximately 20 amino acids (Fig. 15.14). The result is a relatively small, tight, autonomously folded domain. The zinc is required to maintain the tertiary structure of this domain. Eukaryotic transcription factors generally have two to six zinc-finger motifs that function independently. At least one of the zinc fingers forms an α -helix containing a nucleotide recognition signal, a sequence of amino acids that fits specifically into the major groove of DNA (Fig. 15.15A).

FIGURE 15.14. Zinc fingers of the estrogen receptor. In each of the two zinc fingers, one zinc ion is coordinated with four cysteine residues, shown in red. The region labeled α -helix with NRS forms an α -helix that contains a nucleotide recognition signal (NRS). This signal consists of a sequence of amino acid residues that bind to a specific base sequence in the major groove of DNA. Regions enclosed in boxed arrows participate in rigid helices.

FIGURE 15.15. Interaction of DNA-binding proteins with DNA. **A.** Zinc-finger motifs consist of an α -helix and a β -sheet in which four cysteine and/or histidine residues coordinately bind a zinc ion. The nucleotide recognition signal (contained within the α -helix) of at least one zinc finger binds to a specific sequence of bases in the major groove of DNA. **B.** Leucine-zipper motifs form from two distinct polypeptide chains. Each polypeptide contains a helical region in which leucine residues are

exposed on one side. These leucines form hydrophobic interactions with each other, causing dimerization. The remaining helices interact with DNA. **C.** Helix-turn-helix motifs contain three (or sometimes four) helical regions, one of which binds to DNA, whereas the others lie on top and stabilize the interaction. **D.** Helix-loop-helix motifs contain helical regions that bind to DNA like leucine zippers. However, their dimerization domains consist of two helices, each of which is connected to its DNA-binding helix by a loop.

As an example of zinc-finger transcription factors, two estrogen receptors combine to form a dimer that binds to a palindrome in the promoter region of certain genes (see Figs. 15.11 and 15.12). A palindrome is a sequence of bases that is identical on both the parallel and the antiparallel strand, and which could base-pair together. For example, the sequence 5'-ATCGCGAT-3' base-pairs with the sequence 3'-TAGCGCTA-5', which, when written in the 5'-to-3' direction, is ATCGCGAT. Each estrogen receptor is approximately 73 amino acids long and contains two zinc fingers. Each zinc is chelated to two cysteines in an α -helix and two cysteines in a β -sheet region. The position of the nucleotide recognition sequence in an α -helix keeps the sequence in a relatively rigid conformation as it fits into the major groove of DNA. The zinc finger that lies closest to the carboxyl terminal is involved in dimerization with the second estrogen receptor, thus inverting the nucleotide recognition sequence to match the other half of the palindrome. The dimer-palindrome requirement enormously enhances the specificity of binding, and, consequently, only those genes with the appropriate DNA sequences are affected. A wide variety of transcription factors contain the zinc-finger motif, including the steroid hormone receptors such as the estrogen and the glucocorticoid receptors. Other transcription factors that contain zinc-finger motifs include Sp1 and polymerase III transcription factor TFIIA (part of the basal transcription complex), which has nine zinc-finger motifs.

Leucine zippers also function as dimers to regulate gene transcription (see Fig. 15.15B). The leucine-zipper motif is an α -helix of 30 to 40 amino acid residues that contains a leucine every seven amino acids, positioned so that they align on the same side of the helix. Two helices dimerize so that the leucines of one helix align with the other helix through hydrophobic interactions to form a coiled coil. The dimers can be either homodimers or heterodimers (e.g., the transcription factor AP1 is a heterodimer whose subunits are coded by the *fos* and *jun* genes). The portions of the dimer adjacent to the zipper “grip” the DNA through basic amino acid residues (arginine and lysine) that bind to the negatively charged phosphate groups. This DNA-binding portion of the molecule also contains a nucleotide recognition signal.

In the **helix-turn-helix** motif, one helix fits into the major groove of DNA, making most of the DNA-binding contacts (see Fig. 15.15C). It is joined to a segment containing two additional helices that lie across the DNA-binding helix at right angles. Thus, a very stable structure is obtained without dimerization. An example of helix-turn-helix transcription factors is the homeodomain proteins (proteins that play critical roles in the regulation of gene expression during development).

Helix-loop-helix transcription factors are a fourth structural type of DNA-binding protein (see Fig. 15.15D). They also function as dimers that fit around and grip DNA in a manner geometrically similar to leucine-zipper proteins. The dimerization region consists of a portion of the DNA-gripping helix and a loop to another helix. Like leucine zippers, helix-loop-helix factors can function as either hetero- or homodimers. These factors contain regions of basic amino acids near the amino terminus and are also called **basic helix-loop-helix** (bHLH) proteins. Many of the transcription factors containing the helix-loop-helix motif are involved in cellular differentiation (such as myogenin in skeletal muscle, neurogenin in neurogenesis, and SCL/tal-1 in hematopoiesis and blood cell development).

4. Regulation of Transcription Factors

The activity of gene-specific transcription factors is regulated in several different ways. Because transcription factors must interact with a variety of coactivators to stimulate transcription, the availability of coactivators or other mediator proteins is critical for transcription factor function. If a cell upregulates or downregulates its synthesis of coactivators, the rate of transcription can also be increased or decreased. Transcription factor activity can be modulated by changes in the amount of transcription factor synthesized (see Section III.C.5), by binding a stimulatory or inhibitory ligand (such as steroid hormone binding to the steroid hormone receptors), and by stimulation of nuclear entry (illustrated by the glucocorticoid receptor). The ability of a transcription factor to influence the transcription of a gene is also augmented or antagonized by the presence of other transcription factors. For example, the thyroid hormone receptor is critically dependent on the concentration of the retinoid receptor to provide a dimer partner. Another example is provided by the phosphoenolpyruvate (PEP) carboxykinase gene, which is induced or repressed by a variety of hormone-activated transcription factors (see Section III.C.5). Frequently, transcription factor activity is regulated through phosphorylation.

In a condition known as androgen insensitivity, patients produce androgens (the male sex steroids), but target cells fail to respond to these steroid hormones because they lack the appropriate intracellular transcription factor receptors (androgen receptors). Therefore, the transcription of the genes responsible for masculinization is not activated. A patient with this condition has an XY (male) karyotype (set of chromosomes) but has external characteristics of a female. External male genitalia do not develop, but testes are present, usually in the inguinal region or abdomen.

Growth factors, cytokines, polypeptide hormones, and a number of other signal molecules regulate gene transcription through phosphorylation of specific transcription factors by receptor kinases. Examples include STAT proteins, which are transcription factors phosphorylated by cytokine receptors, and SMAD proteins, which are transcription factors phosphorylated by serine/threonine kinase receptors such as the transforming growth factor- β (TGF- β) receptor (see Chapter 10).

Before the advent of specifically targeted monoclonal antibody therapy, the cytokine interferon was used to treat tumors of blood cell origin. Interferons, cytokines produced by cells that have been infected with a virus, bind to the cytokine family of cell surface receptors. When an interferon binds, JAK (a receptor-associated tyrosine kinase) phosphorylates a STAT transcription factor (see Chapter 10). The phosphorylated STAT proteins are released from the JAK–receptor complex, dimerize, enter the nucleus, and bind to specific gene regulatory sequences. Different combinations of phosphorylated STAT proteins bind to different sequences and activate transcription of a different set of genes. One of the genes activated by interferon produces the oligonucleotide 2'-5'-oligo(A), which is an activator of a ribonuclease. This RNase degrades mRNA, thus inhibiting synthesis of the viral proteins required for its replication. In addition to stimulating degradation of mRNA, interferon leads to the phosphorylation of eIF2 α (a necessary factor for protein synthesis), which inactivates the eIF2 α complex. This enables interferon to prevent the synthesis of viral proteins.

In addition to antiviral effects, interferons were shown to have antitumor effects. The mechanisms of the antitumor effects are not well understood but are probably likewise related to stimulation of specific gene expression by STAT proteins. Interferon- α , produced by recombinant DNA technology, had been used in the past to treat patients such as **Charles F.** who have certain types of nodular lymphomas, and patients such as **Mannie W.** who have chronic myelogenous leukemia. As targeted therapy became available to reduce the side effects of treatments, interferon therapy was reduced in scope.

Nonreceptor kinases, such as protein kinase A, also regulate transcription factors through phosphorylation. Many hormones generate the second messenger **cAMP**, which activates **protein kinase A**. Activated protein kinase A enters the nucleus and phosphorylates the transcription factor CREB (**cAMP response element–binding protein**). CREB is constitutively bound to the DNA response element CRE (**cAMP response element**) and is activated by phosphorylation. Other hormone signaling pathways, such as the mitogen-activated protein (MAP) kinase pathway, also lead to the phosphorylation of CREB (as well as many other transcription factors).

5. Multiple Regulators of Promoters

The same transcription factor inducer can activate transcription of many different genes if the genes each contain a common response element. Furthermore, a single inducer can activate sets of genes in an orderly, programmed manner (Fig. 15.16). The inducer initially activates one set of genes. One of the protein products of this set of genes can then act as a specific transcription factor for another set of genes. If this process is repeated, the net result is that one inducer can initiate a series of events that results in the activation of many different sets of genes.

Regulatory protein

FIGURE 15.16. Activation of sets of genes by a single inducer. Each gene in a set has a common DNA regulatory element, so one regulatory protein can activate all the genes in the set. In the example shown, the first regulatory protein stimulates the transcription of genes *A* and *B*, which have a common DNA regulatory sequence in their control regions. The protein product of gene *B* is itself a transcriptional activator, which in turn stimulates the transcription of genes *E*, *F*, and *G*, which likewise contain common response elements. mRNA, messenger RNA.

An example of a transcriptional cascade of gene activation is observed during adipocyte (fat cell) differentiation. Fibroblast-like cells can be induced to form adipocytes by the addition of dexamethasone (a steroid hormone), cAMP-elevating agents, and insulin to the cells. These factors induce the transient expression of two similar transcription factors named C/EPB- β and C/EPB- δ . The names stand for CCAAT enhancer-binding protein, and β and δ are two forms of these factors that recognize CCAAT sequences in DNA. The C/EPB transcription factors then induce the synthesis of yet another transcription factor, named the peroxisome proliferator-activated receptor γ (PPAR- γ), which forms heterodimers with RXR to regulate the expression of yet another transcription factor, C/EPB- α . The combination of PPAR- γ and C/EPB- α then leads to the expression of adipocyte-specific genes.

An individual gene contains many different response elements and enhancers, and genes that encode different protein products contain different combinations of response elements and enhancers. Thus, each gene

does not have a single, unique protein that regulates its transcription. Rather, as different proteins are stimulated to bind to their specific response elements and enhancers in a given gene, they act cooperatively to regulate expression of that gene (Fig. 15.17). Overall, a relatively small number of response elements and enhancers and a relatively small number of regulatory proteins generate a wide variety of responses from different genes.

FIGURE 15.17. A simplified view of the regulatory region of the *PEPCK* gene. Boxes represent various response elements in the 5'-flanking region of the gene. Not all elements are labeled. Regulatory proteins bind to these DNA elements and stimulate or inhibit the transcription of the gene. This gene encodes the enzyme PEPCK, which catalyzes a reaction of gluconeogenesis (the pathway for production of glucose) in the liver. Synthesis of the enzyme is stimulated by glucagon (by a cAMP-mediated process), by glucocorticoids, and by thyroid hormone. Synthesis of PEPCK is inhibited by insulin. cAMP, cyclic adenosine monophosphate; CRE, cAMP response element; GRE, glucocorticoid response element; IRE, insulin response element; PEPCK, phosphoenolpyruvate carboxykinase; TRE, thyroid hormone response element.

D. Posttranscriptional Processing of RNA

After the gene is transcribed (i.e., posttranscription), regulation can occur during processing of the RNA transcript (hnRNA) into the mature mRNA. The use of alternative splice sites or sites for the addition of the poly(A) tail (polyadenylation sites) can result in the production of different mRNAs from a single hnRNA and, consequently, in the production of different proteins from a single gene.

1. Alternative Splicing and Polyadenylation Sites

Processing of the primary transcript involves the addition of a cap to the 5'-end, removal of introns, and polyadenylation (the addition of a poly(A) tail to the 3'-end) to produce the mature mRNA (see Chapter 13). In certain instances, the use of alternative splicing and polyadenylation sites causes different proteins to be produced from the same gene. For example, genes that code for antibodies are regulated by alterations in the splicing and polyadenylation sites, in addition to undergoing gene rearrangement (Fig. 15.18). At an early stage of maturation, pre-B-lymphocytes produce immunoglobulin M (IgM) antibodies that are bound to the cell membrane. Later, a shorter protein (immunoglobulin D [IgD]) is produced that no longer binds to the cell membrane, but rather is secreted from the cell.

FIGURE 15.18. Production of a membrane-bound antibody (immunoglobulin M [IgM]) and a smaller secreted antibody (immunoglobulin D [IgD]) from the same gene. Initially, the lymphocytes produce a long transcript that is cleaved and polyadenylated after the second stop codon. The intron that contains the first stop codon is removed by splicing between the 5'- and 3'-splice sites. Therefore, translation ends at the second stop codon, and the protein contains a hydrophobic exon at its C-terminal end that becomes embedded in the cell membrane. After antigen stimulation, the cells produce a shorter transcript by using a different cleavage and polyadenylation site. This transcript lacks the 3'-splice site for the intron, so the intron is not removed. In this case, translation ends at the first stop codon. The IgD antibody does not contain the hydrophobic region at its C-terminus, so it is secreted from the cell. IgD, immunoglobulin D; mRNA, messenger RNA.

2. RNA editing

In some instances, RNA is “edited” after transcription. Although the sequence of the gene and the primary transcript (hnRNA) are the same, bases are altered or nucleotides are added or deleted after the transcript is synthesized, so the mature mRNA differs in different tissues (Fig. 15.19). This leads to the synthesis of proteins with different activities in those tissues.

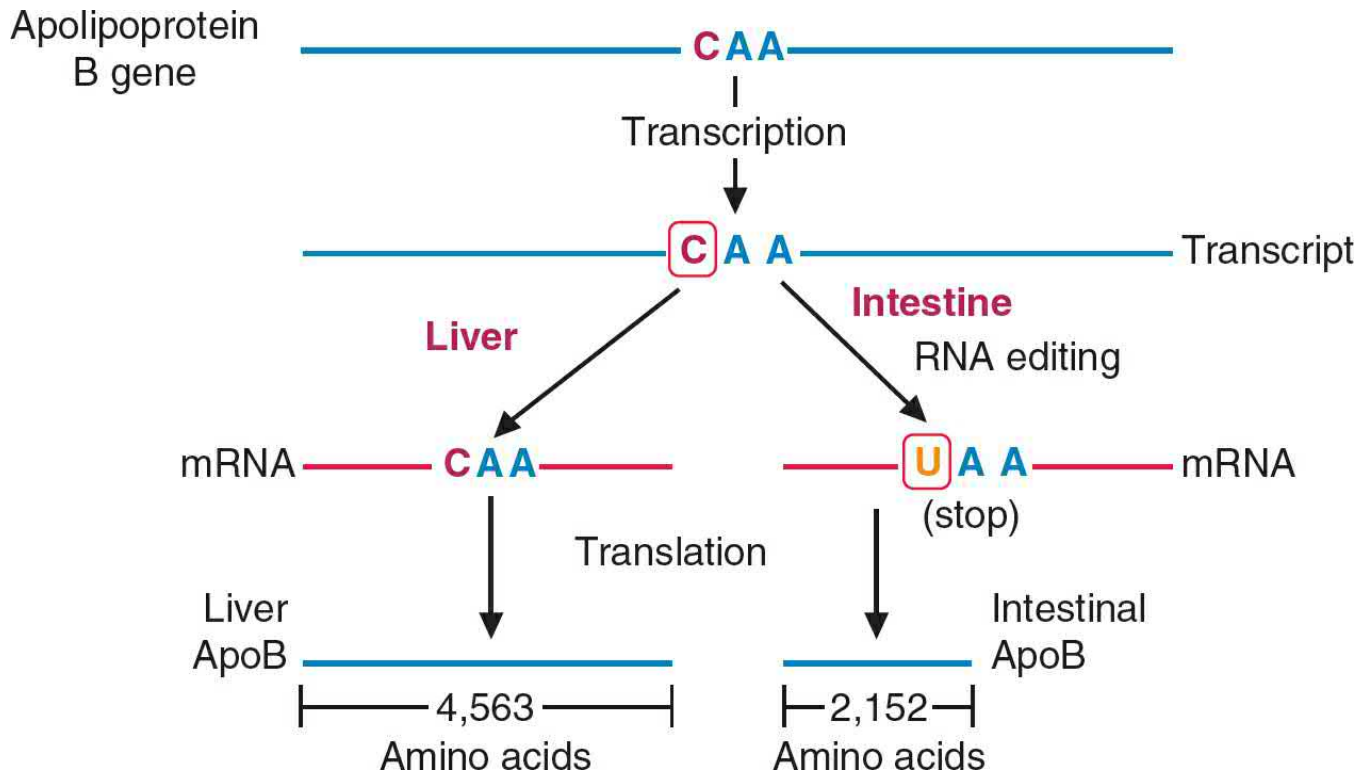

FIGURE 15.19. RNA editing. In liver, *ApoB* gene produces a protein that contains 4,563 amino acids. In intestinal cells, the same gene produces a protein that contains only 2,152 amino acids. Conversion of a C to a U (through deamination) in the RNA transcript generates a stop codon in the intestinal mRNA. Thus, the protein produced in the intestine (named apoB-48) is only 48% of the length of the protein produced in the liver (named apoB-100). ApoB, apolipoprotein B; mRNA, messenger RNA.

E. Regulation at the Level of Translation and the Stability of mRNA

Although the regulation of expression of most genes occurs at the level of transcription initiation, some genes are regulated at the level of initiation of translation, whereas others are regulated by altering the stability of the mRNA transcript.

1. Initiation of Translation

In eukaryotes, regulation of gene expression at the level of translation usually involves the initiation of protein synthesis by eukaryotic initiation factors (eIFs), which are regulated through mechanisms that involve phosphorylation (see Chapter 14, Section IV). For example, heme regulates the translation of globin mRNA in reticulocytes by controlling the phosphorylation of eIF2 α (Fig. 15.20). In reticulocytes (red blood cell precursors), globin is produced when heme levels in the cell are high but not when they are low. Because reticulocytes lack nuclei, globin synthesis must be regulated at the level of translation rather than at transcription. Heme acts by preventing phosphorylation of eIF2 α by a specific kinase (heme-regulated inhibitor kinase) that is inactive when heme is bound. Thus, when heme levels are high, eIF2 α is not phosphorylated and is active, resulting in globin synthesis. Similarly, in other cells, conditions such as starvation, heat shock, or viral infections may result in activation of a specific kinase that phosphorylates eIF2 α to an inactive form. Another example is provided by insulin, which stimulates general protein synthesis by inducing the phosphorylation of 4E-BP, a binding protein for eIF4E. When 4E-BP, in its nonphosphorylated state, binds eIF4E, the initiating protein is sequestered from participating in protein synthesis. When 4E-BP is phosphorylated as in response to insulin binding to its receptor on the cell surface, the 4E-BP dissociates from eIF4E, leaving eIF4E in the active form, and protein synthesis is initiated.

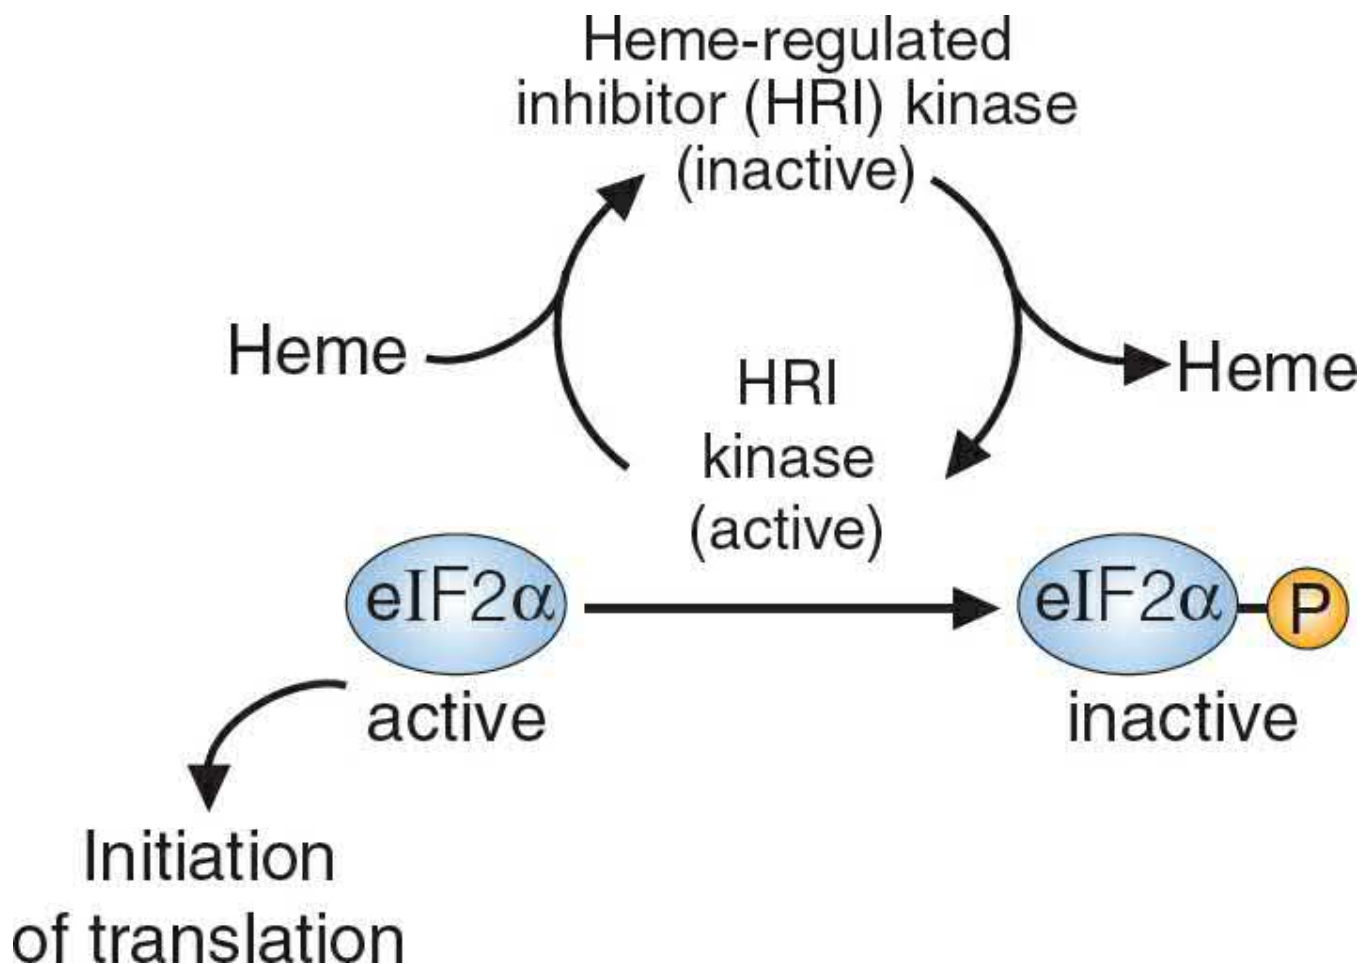

FIGURE 15.20. Heme prevents inactivation of eIF2 α . When eIF2 α is phosphorylated by heme-regulated inhibitor kinase, it is inactive, and protein synthesis cannot be initiated. Heme inactivates the heme-regulated inhibitor kinase, thereby preventing phosphorylation of eIF2 α and activating translation of the globin mRNA. eIF2, eukaryotic initiation factor; HRI, heme-regulated inhibitor.

A different mechanism for regulation of translation is illustrated by iron regulation of ferritin synthesis (Fig. 15.21). Ferritin, the protein involved in the storage of iron within cells, is synthesized when iron levels increase. The mRNA for ferritin has an iron response element (IRE), consisting of a hairpin loop near its 5'-end, which can bind a regulatory protein called the **iron response element-binding protein (IRE-BP)**. When IRE-BP does not contain bound iron, it binds to the IRE and prevents initiation of translation. When iron levels increase and IRE-BP binds iron, it changes to a conformation that can no longer bind to the IRE on the ferritin mRNA. Therefore, the mRNA is translated and ferritin is produced.

Ferritin synthesis

FIGURE 15.21. Translational regulation of ferritin synthesis. The mRNA for ferritin has an IRE. When the IRE-BP does not contain bound iron, it binds to IRE, preventing translation. When IRE-BP binds iron, it dissociates, and the mRNA is translated. IRE, iron response element; IRE-BP, iron response element-binding protein; mRNA, messenger RNA.

2. MicroRNAs

MicroRNAs (miRNAs) are small RNA molecules that regulate protein expression at a posttranscriptional level. An miRNA can either induce the degradation of a target mRNA or block translation of the target mRNA. In either event, the end result is reduced expression of the target mRNA.

miRNAs were first discovered in nematodes and have since been shown to be present in plant and animal cells. There are believed to be approximately 1,000 miRNA genes in the human genome, some of which are located within the introns of the genes they regulate. Other miRNA genes are organized into operons, such that certain miRNA families are produced at the same time. It is also evident that one miRNA can regulate multiple mRNA targets and that a particular mRNA may be regulated by more than one miRNA.

The biogenesis of miRNA is shown in Figure 15.22. miRNA is transcribed by RNA polymerase II and is capped and polyadenylated in the same manner as mRNA. The initial RNA product is designated the primary miRNA (pri-miRNA). The pri-miRNA is modified in the nucleus by an RNA-specific endonuclease named Drosha, in concert with a double-stranded RNA-binding protein named DGCR8/Pasha. The action of Drosha is to create a stem-loop RNA structure of about 70 to 80 nucleotides in length, which is the precursor miRNA (pre-miRNA). The pre-miRNA is exported from the nucleus to the cytoplasm (via the protein exportin-5), where it interacts with another RNA endonuclease named Dicer, and Dicer's binding partner transactivation response RNA-binding protein (TRBP). Dicer cleaves the pre-miRNA to mature miRNA (a double-stranded RNA with a two-nucleotide overhang at the ends). One of the strands of the miRNA (known as the guide strand) is incorporated into the RNA-induced silencing complex (RISC), while the other RNA strand (the passenger strand) is degraded. The major protein in RISC is known as argonaute. It is the RISC that will block translation of the target mRNA.

FIGURE 15.22. miRNA synthesis and action. miRNA genes are transcribed in the nucleus by RNA polymerase II, generating the primary miRNA, processed to a precursor miRNA (pre-miRNA), and then exported to the cytoplasm. In the cytoplasm, the pre-miRNA is further processed by a ribonuclease (Dicer), and resulting double-stranded miRNA is strand selected, with the guide strand (designated in *black*) entering the RISC. The guide strand of RISC targets the complex to the 3'-untranslated region of the target mRNA, leading to either degradation of the mRNA or an inhibition of translation. miRNA, microRNA; mRNA, messenger RNA; pre-miRNA, precursor miRNA; RISC, RNA-induced silencing complex.

The guide strand leads the RISC to the target mRNA, as the guide strand forms base pairs within a section of the 3'-untranslated region of the mRNA. If there is a high homology in base pairing, then argonaute, a ribonuclease, will degrade the mRNA. However, if the homology between the guide strand and the target mRNA is poor (owing to mismatches), then translation of the mRNA will be blocked.

The net result of miRNA expression is the loss of target mRNA translation. As miRNAs have multiple targets, and these targets will vary from tissue to tissue, an alteration in miRNA expression will have profound effects on gene expression within cells. As will be discussed in Chapter 17, tumors can result from the loss, or overexpression, of miRNA genes.

F. Transport and Stability of mRNA

Stability of an mRNA also plays a role in regulating gene expression because mRNAs with long half-lives can generate more protein than can those with shorter half-lives. The mRNA of eukaryotes is relatively stable (with half-lives measured in hours to days), although it can be degraded by nucleases in the nucleus or cytoplasm before it is translated. To prevent degradation during transport from the nucleus to the cytoplasm, mRNA is bound to proteins that help to prevent its degradation. Sequences at the 3'-end of the mRNA appear to be involved in determining its half-life and binding proteins that prevent degradation. One of these is the poly(A) tail, which protects the mRNA from attack by nucleases. As mRNA ages, its poly(A) tail becomes shorter.

The enzyme PEP carboxykinase (PEPCK) is required for the liver to produce glucose from amino acids and lactate. **Ann R.**, who has an eating disorder, needs to maintain a certain blood glucose level to keep her brain functioning normally. When her blood glucose levels drop, cortisol (a glucocorticoid) and glucagon (a polypeptide hormone) are released. In the liver, glucagon increases intracellular cAMP levels, resulting in activation of protein kinase A and subsequent phosphorylation of CREB. Phosphorylated CREB binds to its response element in DNA, as does the cortisol receptor. Both transcription factors enhance transcription of the *PEPCK* gene (see Fig. 15.17). Insulin, which is released when blood glucose levels rise after a meal, can inhibit expression of this gene, in part by leading to the dephosphorylation of CREB.

An example of the role of mRNA degradation in control of translation is provided by the transferrin receptor mRNA (Fig. 15.23). The transferrin receptor is a protein located in cell membranes that permits cells to take up transferrin, the protein that transports iron in the blood. The rate of synthesis of the transferrin receptor increases when intracellular iron levels are low, enabling cells to take up more iron. Synthesis of the transferrin receptor, like that of the ferritin receptor, is regulated by the binding of the IRE-BP to the IREs. However, in the case of the transferrin receptor mRNA, the IREs are hairpin loops located at the 3'-end of the mRNA and not at the 5'-end where translation is initiated. When the IRE-BP does not contain bound iron, it has a high affinity for the IRE hairpin loops. Consequently, IRE-BP prevents degradation of the mRNA when iron levels are low, thus permitting synthesis of more transferrin receptors so that the cell can take up more iron. Conversely, when iron levels are elevated, IRE-BP binds iron and has a low affinity for the IRE hairpin loops of the mRNA. Without bound IRE-BP at its 3'-end, the mRNA is rapidly degraded and the transferrin receptor is not synthesized.

Transferrin receptor synthesis

FIGURE 15.23. Regulation of degradation of the mRNA for the TfR. Degradation of the TfR mRNA is prevented by binding of the IRE-BP to IRE, which are hairpin loops located at the 3'-end of the transferrin receptor mRNA. When iron levels are high, IRE-BP binds iron and is not bound to the TfR mRNA. The TfR mRNA is rapidly degraded, preventing synthesis of the transferrin receptor. IRE, iron response element; IRE-BP, iron response element-binding protein; mRNA, messenger RNA; TfR, transferrin receptor.

CLINICAL COMMENTS

Charles F. Follicular lymphomas are the most common type of indolent non-Hodgkin lymphomas (about 20% to 35% of cases). Patients with a more aggressive course, as seen in **Charles F.**, die within 3 to 5 years after diagnosis if left untreated. In patients treated with multidrug chemotherapy (in this case, R-CHOP), a positive response rate of >90% has been reported, with approximately 50% of patients being alive without progression after 7 to 10 years.

Mannie W. has chronic myelogenous leukemia (CML), a hematologic disorder in which the proliferating leukemic cells are believed to originate from a single line of primitive myeloid cells. It is classified as one of the myeloproliferative disorders, and CML is distinguished by the presence of a specific cytogenetic abnormality of the dividing marrow cells known as the Philadelphia chromosome, found in >90% of cases. In most instances, the cause of CML is unknown, but the disease occurs with an incidence of around 1.5 per 100,000 population in Western societies.

Follicular lymphoma is one type of non-Hodgkin lymphoma. The most frequent form of non-Hodgkin lymphoma is diffuse large B-cell lymphoma. A study has recently shown that miRNA expression is different between these two different types of tumors and different from normal B-cells. miRNA “signatures” are being developed for different tumor types, with the ultimate goal being individualized therapy based on the miRNA expression profile in a particular tumor. For example, in follicular lymphoma (which is the disorder displayed by **Charles F.**), the majority of misexpressed miRNAs are overexpressed, whereas in diffuse large B-cell lymphoma these genes exhibit reduced expression. Therapeutic treatments are being developed to downregulate expression of the altered miRNAs in follicular lymphoma, which should alter overall gene expression in the tumor cells, and perhaps halt their runaway proliferation. Such approaches show promise as molecular medicine becomes an important tool in the physician’s arsenal for treating disease.

Ann R.’s iron stores are depleted. Normally, about 16% to 18% of total body iron is contained in ferritin, which contains a spherical protein (apoferritin) that is capable of storing as many as 4,000 atoms of iron in its center. When an iron deficiency exists, serum and tissue ferritin levels fall. Conversely, the levels of transferrin (the blood protein that transports iron) and the levels of the transferrin receptor (the cell surface receptor for transferrin) increase.

BIOCHEMICAL COMMENTS

Regulation of Transcription by Iron. A cell’s ability to acquire and store iron is a carefully controlled process. Iron obtained from the diet (with the aid of vitamin C for nonheme iron) is absorbed in the intestine and released into the circulation, where it is bound by transferrin, the iron transport protein in plasma. When a cell requires iron, the plasma iron–transferrin complex binds to the transferrin receptor in the cell membrane and is internalized into the cell. Once the iron is freed from transferrin, it then binds to ferritin, which is the cellular storage protein for iron. Ferritin has the capacity to store up to 4,000 molecules of iron per ferritin molecule. Both transcriptional and translational controls work to maintain intracellular levels of iron (see Figs. 15.21 and 15.23). When iron levels are low, the IRE-BP binds to specific hairpin structures on both the ferritin and transferrin receptor mRNAs. This binding event stabilizes the transferrin receptor mRNA so that it can be translated and the number of transferrin receptors in the cell membrane increased. Consequently, cells will take up more iron, even when plasma transferrin/iron levels are low. The binding of IRE-BP to the ferritin mRNA, however, blocks translation of the mRNA. With low levels of intracellular iron, there is little iron to store and less need for intracellular ferritin. Thus, the IRE-BP can stabilize one mRNA and block translation from a different mRNA.

Omnipotent stem cells in the bone marrow normally differentiate and mature in a highly selective and regulated manner, becoming red blood cells, white blood cells, or platelets. Cytokines stimulate differentiation of the stem cells into the lymphoid and myeloid lineages. The lymphoid lineage gives rise to B- and T-lymphocytes, which are white blood cells that

work together to generate antibodies for the immune response. The myeloid lineage gives rise to three types of progenitor cells: erythroid, granulocytic–monocytic, and megakaryocytic. The erythroid progenitor cells differentiate into red blood cells (erythrocytes), and the other myeloid progenitors give rise to nonlymphoid white blood cells and platelets. Various medical problems can affect this process. In **Mannie W.**, who has CML, a single line of primitive myeloid cells undergoes the event that leads to the Philadelphia chromosome being generated. This produces leukemic cells that proliferate abnormally, causing a large increase in the number of white blood cells in the circulation. The Philadelphia chromosome is a somatic translocation not found in the germ line. In **Lisa N.**, who has a deficiency of red blood cells caused by β^+ -thalassemia (see Chapter 14), differentiation of precursor cells into mature red blood cells is stimulated to compensate for the anemia.

What happens when iron levels rise? Iron will bind to the IRE-BP, thereby decreasing its affinity for mRNA. When the IRE-BP dissociates from the transferrin receptor mRNA, the mRNA becomes destabilized and is degraded, leading to fewer receptors being synthesized. Conversely, dissociation of the IRE-BP from the ferritin mRNA allows that mRNA to be translated, thereby increasing intracellular levels of ferritin and increasing the capacity of the cell for iron storage.

Why does anemia result from iron deficiency? When an individual is deficient in iron, the reticulocytes do not have sufficient iron to produce heme, the required prosthetic group of hemoglobin. When heme levels are low, eIF2 α (see Fig. 15.20) is phosphorylated and becomes inactive. Thus, globin mRNA cannot be translated because of the lack of heme. This results in red blood cells with inadequate levels of hemoglobin for oxygen delivery and in anemia.

Ann R. has a hypochromic anemia, which means that her red blood cells are pale because they contain low levels of hemoglobin. Because of her iron deficiency, her reticulocytes do not have sufficient iron to produce heme, the required prosthetic group of hemoglobin. Consequently, eIF2 α is phosphorylated in her reticulocytes and cannot activate initiation of globin translation.

KEY CONCEPTS

- ◆ Prokaryotic gene expression is primarily regulated at the level of initiation of gene transcription. In general, there is one protein per gene.
 - ◆ Sets of genes that encode proteins with related functions are organized into operons.
 - ◆ Each operon is under the control of a single promoter.
 - ◆ Repressors bind to the promoter to inhibit RNA polymerase binding.
 - ◆ Activators facilitate RNA polymerase binding to the repressor.
- ◆ Eukaryotic gene regulation occurs at several levels.
 - ◆ At the DNA structural level, chromatin must be remodeled to allow access for RNA polymerase, which is accomplished, in part, by proteins with histone acetyltransferase activity.
 - ◆ Transcription is regulated by transcription factors that either enhance or restrict RNA polymerase access to the promoter.
 - ◆ Transcription factors can bind to promoter-proximal elements, certain response elements, or enhancer regions that are a great distance from the promoter.
 - ◆ Coactivators (mediator proteins) bind to the transactivation domains of transcription factors to enhance the assembly of the basal transcription complex.
 - ◆ RNA processing (including alternative splicing), transport from the nucleus to the cytoplasm, and translation are also regulated in eukaryotes.
 - ◆ miRNA expression alters translation of expressed mRNAs.
- ◆ Diseases discussed in this chapter are found in Table 15.1.

TABLE 15.1 Disease Discussed in Chapter 15

DISORDER OF CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
Non-Hodgkin lymphoma, follicular type	Both	Treatment with multiple drugs, all targeted to inhibiting cell proliferation, but through different mechanisms. DNA synthesis is targeted, as is tubulin action (to block cell division). DNA damage is induced, and thymidine synthesis is also blocked to inhibit further DNA replication.
CML	Both	More than 90% of CML arises owing to the generation of the Philadelphia chromosome, which is created by an exchange

		of genetic material between chromosomes 9 and 22. This translocation creates a unique fusion protein (BCR- <i>abl</i>), which facilitates uncontrolled proliferation of cells which express this fusion protein.
Anorexia nervosa	Both	The patient's poor diet has led to a hypochromic anemia owing to low iron levels. This leads to a reduction of expression of serum and tissue ferritin, but an increase of expression of the transferrin protein and the transferrin receptor.
Angelman and Prader–Willi syndrome	Genetic	The use of base methylation, within promoter regions, to regulate gene expression. The methylation of key bases within the promoter leads to nonexpression of the gene and forms the basis for imprinting. This is an example of epigenetic modification of gene expression.
Fragile X disease	Genetic	A significant number of triplet repeat expansions within a gene may lead to dysfunction of the protein product, leading to disease. In fragile X, impairment of cognitive function is the primary symptom, caused by expansions in the <i>FMR-1</i> gene on the X chromosome.
Androgen insensitivity	Genetic	Lack of androgen receptors, leading to default female sexual characteristics. The patient produces androgens but cannot respond to them. These patients have an XY genotype but female sexual characteristics.

CML, chronic myelogenous leukemia.

REVIEW QUESTIONS—CHAPTER 15

- Bacteria can coordinately express a number of genes simultaneously. Which one of the following explains why several different proteins can be synthesized from a typical prokaryotic mRNA?
 - Any of the three reading frames can be used.
 - There is redundancy in the choice of codon/tRNA interactions.
 - The gene contains several operator sequences from which to initiate translation.
 - Alternative splicing events are commonly found.
 - Many RNAs are organized in a series of consecutive translational cistrons.
- E. coli* will only express genes for lactose metabolism when lactose is present in the growth medium. In *E. coli*, under high-lactose, high-glucose conditions, which one of the following could lead to maximal transcription activation of the *lac* operon?
 - A mutation in the *lac I* gene (which encodes the repressor)
 - A mutation in the CRP-binding site leading to enhanced binding
 - A mutation in the operator sequence
 - A mutation leading to enhanced cAMP levels
 - A mutation leading to lower binding of repressor
- Expression of the lactose operon in *E. coli* can be quite complex. A mutation in the *lac I* (repressor) gene of a “noninducible” strain of *E. coli* resulted in an inability to synthesize any of the proteins of the *lac* operon. Which one of the following provides a rational explanation?
 - The repressor has lost its affinity for the inducer.
 - The repressor has lost its affinity for the operator.
 - A *trans*-acting factor can no longer bind to the promoter.
 - The CRP protein is no longer being made.
 - Lactose feedback inhibition becomes constitutive.
- Many transcription factors, which act as dimers, bind to palindromic sequences in their target DNA. Which one of the following double-stranded DNA sequences shows perfect dyad symmetry (the same sequence of bases on both strands)?
 - GAAGTCTAGTCGC
 - GGCATCGCGATGCC
 - TAATCGGAACCAAT
 - GCAGATTTTAGACG

E. TGACCGGTGACCGG

5. Transcription factors can be activated in a number of ways, as well as inhibited under certain conditions. Which one of the following describes a common theme in the structure of DNA-binding proteins?
 - A. The presence of a specific helix that lies across the major or minor groove of DNA
 - B. The ability to recognize RNA molecules with the same sequence
 - C. The ability to form multiple hydrogen bonds between the protein peptide backbone and the DNA phosphodiester backbone
 - D. The presence of zinc
 - E. The ability to form dimers with disulfide linkages
6. Altered eukaryotic DNA can lead to mutations; however, the alteration in DNA does not necessarily have to be within an exon. Which one of the following best represents an epigenetic alteration in DNA which could lead to altered gene regulation?
 - A. Deamination of C to U in DNA
 - B. Deamination of A to I in DNA
 - C. Methylation of C residues in DNA
 - D. Substitution of an A for a G in DNA
 - E. A simple base deletion in the DNA
7. An altered response to hormones can occur if the receptor contains a mutation. A nuclear receptor has a mutation in its transactivation domain, such that it can no longer bind to other transcription factors. Which one of the following is most likely to occur when this receptor binds its cognate ligand?
 - A. Inability to bind to DNA
 - B. Reduced ability to bind to DNA
 - C. Enhanced transcription of hormone-responsive genes
 - D. Reduced dimerization of hormone receptors
 - E. Reduced transcription of hormone-responsive genes
8. A patient presents with a β -thalassemia. Such a disorder could result from a mutation located in which of the following? Choose the one best answer.

	An Intron of the β-globin Gene	An Exon of the β-globin Gene	An Intron of the α-globin Gene	The Promoter Region of the β-globin Gene	The Promoter Region of the α-globin Gene
A	No	No	Yes	No	Yes
B	Yes	Yes	No	Yes	Yes
C	No	No	Yes	No	Yes
D	Yes	Yes	No	Yes	No
E	No	No	Yes	No	No
F	Yes	Yes	No	Yes	No

9. In response to foreign organisms, humans produce a variety of antibodies that can bind to the organism. In the production of human antibodies, which one of the following can cause the production of different proteins from a single gene?
 - A. Pretranscription processing of hnRNA

- B. Removal of introns from hnRNA
 - C. Addition of a cap to the 5'-end of hnRNA
 - D. Addition of a cap to the 3'-end of hnRNA
 - E. Alternative sites for synthesizing the poly(A) tail
0. A eukaryotic cell line grows normally at 30°C, but at 42°C its growth rate is reduced owing to iron toxicity. At the elevated temperature, the cell displays elevated free intracellular iron levels, coupled with high levels of transferrin receptor. Ferritin levels within the cell are extremely low at the elevated temperature. These results can be explained by a single-nucleotide mutation in which one of the genes for the following proteins?
- A. Transferrin
 - B. Ferritin
 - C. Transferrin receptor
 - D. IRE-BP
 - E. RNA polymerase
1. The bacterial arabinose operon was considered a model of positive regulation when first discovered (as compared with the lactose operon, which was considered a model of negative regulation). The regulatory protein in this operon is the araC protein, whereas the genes in the polycistronic mRNA are the ara B, A, and D genes. The operon is expressed in the presence of arabinose and the absence of glucose. A piece of evidence which indicated that the operon was exhibiting positive regulation would be which one of the following?
- A. Addition of arabinose led to an arabinose–araC complex.
 - B. Addition of glucose allowed the araC protein to bind to the ara operon promoter.
 - C. Deletion of the araC gene led to constitutive expression of the operon.
 - D. Deletion of the araC gene led to no expression of the operon.
 - E. Removing glucose from the cells released the araC protein from the ara operon promoter.
2. Regulation of eukaryotic gene expression is accomplished by which of the following? Choose the one best answer.

	<i>Coupled Transcription– Translation</i>	<i>miRNA Inhibition of Translation</i>	<i>Alternative Splicing</i>	<i>Modulation of HAT and HDAC Activities</i>
A	No	Yes	Yes	Yes
B	Yes	Yes	No	No
C	No	Yes	Yes	No
D	Yes	No	No	Yes
E	No	No	Yes	No
F	Yes	No	No	Yes

3. A eukaryotic cell line was exposed to mutagenic agents, and a variant was isolated which displayed properties of a transformed (cancer) cell. This could occur via which one of the following?
- A. Overexpression of an miRNA targeted to ras mRNA
 - B. Overexpression of the IRE-BP
 - C. Reduced expression of an miRNA targeted to ras mRNA
 - D. Reduced expression of a TFII transcription factor
 - E. Reduced expression of the IRE-BP
4. The looping of eukaryotic DNA is necessary to permit the participation of which region of DNA in regulating gene expression?

- A. Core promoter
 - B. Enhancers
 - C. miRNA binding sites
 - D. Promoter-proximal elements
 - E. TATA box
5. Steroid hormone receptors differ from cytokine receptors by which of the following? Choose the one best answer. A “yes” means they differ; a “no” means they do not differ.

	Intrinsic Tyrosine Kinase Activity	Cellular Location	Contains a Transactivation Domain	Contains a Ligand-binding Domain
A	Yes	No	No	Yes
B	Yes	Yes	No	No
C	Yes	No	No	No
D	No	Yes	Yes	Yes
E	No	No	Yes	Yes
F	No	Yes	Yes	No

ANSWERS TO REVIEW QUESTIONS

- The answer is E.** Many prokaryotic genes are organized into operons, in which one polycistronic mRNA contains the translational start and stop sites for a number of related genes. Although each gene within the mRNA can be read from a different reading frame, the reading frame is always consistent within each gene (thus, A is incorrect). Redundancy in codon/tRNA interactions has nothing to do with multiple cistrons within an mRNA (thus, B is incorrect). Operator sequences are in DNA and initiate transcription, not translation (thus, C is incorrect). Alternative splicing occurs only in eukaryotes (which have introns), not in prokaryotes (thus, D is incorrect).
- The answer is D.** In order to transcribe the *lac* operon, the repressor protein (*lac I* gene product) must bind allolactose and leave the operator region, and the cAMP–CRP complex must bind to the promoter for RNA polymerase to bind. Of the choices offered, only raising cAMP levels can allow transcription of the operon when both lactose and glucose are high. Raising cAMP, even though glucose is present, will allow the cAMP–CRP complex to bind and recruit RNA polymerase. Answers that call for mutations in the repressor (answers A and E) will not affect binding of cAMP–CRP. Mutations in the DNA (answers B and C) do not allow CRP binding in the absence of cAMP. For CRP to bind to the DNA in the absence of cAMP would require a mutation in the CRP gene, not in the *lac* operator region.
- The answer is A.** The repressor will bind to the operator and block transcription of all genes in the operon unless prevented by the inducer allolactose. If the repressor has lost its affinity for the inducer, it cannot dissociate from the operator and the genes in the operon will not be expressed (thus, E is incorrect). If the repressor has lost its affinity for the operator (answer B), then the operon would be expressed constitutively. Because the question states that there is a mutation in the *I* (repressor) gene, answer D is incorrect, and mutations in the *I* gene do not affect *trans*-acting factors from binding to the promoter, although the only other one for the *lac* operon is the CRP.
- The answer is B.** The sequence, if read 5'-to-3', is identical to the complementary sequence, also read 5'-to-3'. None of the other sequences fit this pattern.

5. **The answer is A.** All DNA-binding proteins contain an α -helix that binds to the major or minor groove in DNA. These proteins do not recognize RNA molecules (thus, B is incorrect), nor do they form bonds between the peptide backbone and the DNA backbone (thus, C is incorrect; if this were correct, how could there be any specificity in protein binding to DNA?). Only zinc fingers contain zinc, and dimers are formed by hydrogen bonding—not by disulfide linkages.
6. **The answer is C.** Epigenetic events include histone acetylation and DNA methylation—alterations to the DNA which do not involve altering the base-pairing characteristics of the DNA (or causing insertions or deletions within the DNA). Deamination of C or A residues (to U or I, respectively) will lead to altered base pairing when the DNA is replicated (methylation of C does not alter the base-pairing properties of the C). Substitution of one base for another also leads to an alteration in base-pairing properties.
7. **The answer is E.** The transactivation domain of the receptor is required to recruit other positive acting factors to the promoter region of the gene in order to enhance transcription. Lack of this domain, and reduced recruitment of coactivators, would lead to reduced transcription. The receptor would still be able to bind to DNA (i.e., through a different site on the receptor, the DNA-binding domain), although its affinity for DNA is not enhanced by lack of the transactivation domain. The transactivation domain is not related to the dimerization domain of hormone receptors.
8. **The answer is B.** A β -thalassemia refers to a disorder in which the number of α -globin chains exceeds that of the β -globin genes. This can occur because of a stop codon being introduced into an exon of the β -globin gene or loss of a splice site in the β -globin gene (which could occur in an intron or exon). An imbalance in chain synthesis could also occur because of a mutation in the β -globin gene promoter or in the α -globin gene promoter that enhanced α -globin synthesis relative to β -globin gene synthesis. A mutation in an intron of the α -globin gene would not lead to more α -globin protein than β -globin protein.
9. **The answer is E.** After the gene is transcribed (posttranscription), the use of alternative splice sites or sites for the addition of the poly(A) tail can result in different mRNAs (and therefore different proteins) from a single hnRNA. Introns are inert (noncoding) and would have no effect. Alternative splicing would remove exons, but all introns are removed from the hnRNA. The cap (on the 5'-end) is required for translation but would not alter the reading frame of the protein.
10. **The answer is D.** Ferritin is the cellular storage protein for iron. Transferrin is the transport protein for iron in plasma. The transferrin receptor binds the iron–transferrin complex for transport of iron into the cell. The synthesis of both the transferrin receptor and ferritin are controlled by the IRE-BP. At the low temperature, the IRE-BP binds to the 3'-end of the transferrin receptor mRNA, stabilizing the mRNA so that it can be translated to produce transferrin receptor proteins. When intracellular iron levels increase, the iron binds to IRE-BP, displacing the protein from the mRNA, which leads to degradation of the mRNA and reduced synthesis of the transferrin receptor. In a similar fashion, the IRE-BP binds to the 5'-end of the ferritin mRNA, blocking ferritin synthesis. When intracellular iron levels increase, the IRE-BP falls off the mRNA, and ferritin is synthesized to bind the intracellular iron and prevent free iron toxicity in the cell. In this cell line, the IRE-BP is mutated such that at the elevated temperature it cannot bind iron, meaning that the IRE-BP remains bound to the transferrin receptor and ferritin mRNA molecules. This leads to a lack of ferritin and overexpression of transferrin receptor in the membrane. The cell will accumulate iron but not have adequate ferritin for the iron to bind to, leading to elevated free iron levels in the cell.
11. **The answer is D.** Positive regulation would indicate that the *araC* gene would need to be present, and active, for the operon to be transcribed. This is opposed to negative regulation, which would indicate that the presence of the *araC* gene product would inhibit the expression of the arabinose operon. Thus, if one were to delete the *araC* gene from the operon a positive effector would be lost, and there would be no expression of the operon (whereas if the *lac I* gene were deleted, which is an example of negative regulation, there would be constitutive expression of the operon). If an experiment determined that arabinose binds to the *araC* protein (which it does), it could indicate either negative or positive regulation was occurring; it could not differentiate between the two. Similarly, a demonstration that the addition of glucose allowed the *araC* protein to either bind to the arabinose operon promoter or be released from the arabinose promoter would not distinguish between positive and negative regulation.
12. **The answer is A.** Eukaryotic gene regulation can occur through miRNA inhibition of translation (column 2), alternative splicing of the primary RNA (column 3), or modulation of HAT and HDAC activity, generating either euchromatin or heterochromatin. Coupled transcription–translation (column 1) only occurs in bacteria as they lack a nucleus and mRNA is immediately available for translation, even as the mRNA is continuing to be synthesized. The presence of a nucleus prevents coupled transcription–

translation from occurring in eukaryotic cells.

13. **The answer is C.** Overexpression of ras can lead to transformation (see Chapter 10), and a reduced expression of a miRNAs targeted to ras will lead to overexpression of ras and constitutive activation of the MAP kinase pathway. Overexpressing an miRNA targeted to ras would reduce ras levels and would not lead to transformation. Overexpressing the IRE-BP would affect iron homeostasis but would not lead to cancer (nor would reducing the expression of this protein). A reduced expression of a TFII transcription factor would reduce overall mRNA production, which does not lead to cancer.
14. **The answer is B.** Enhancers are DNA segments that can be located a considerable distance from the genes they regulate (either upstream or downstream of the transcription start site), so in order to regulate the promoter of the genes the DNA needs to loop so the enhancer region is physically close to the promoter region of the gene of interest. The core promoter is physically adjacent to the transcription start site, so looping is not required for that region of the DNA. Similarly, the TATA box, if present, is within the core promoter, and promoter-proximal elements are adjacent to the core promoter and do not require significant looping to allow transcription to occur. miRNA does not bind to promoter elements; miRNA molecules bind to targeted mRNA molecules in the cytoplasm.
15. **The answer is F.** Steroid hormone receptors do not contain intrinsic tyrosine kinase activity, and neither do cytokine receptors (cytokine receptors associate with a distinct JAK protein that contains the tyrosine kinase activity). Steroid hormone receptors are found in the cytoplasm or nucleus, whereas cytokine receptors are found in the plasma membrane. Steroid hormone receptors have a transactivation domain to allow them to interact with other proteins, whereas cytokine receptors do not have such a domain. Both receptors contain a ligand-binding domain.

Use of Recombinant DNA Techniques in Medicine

The rapid development of techniques in molecular biology is revolutionizing the practice of medicine. The potential uses of these techniques for the diagnosis and treatment of disease are vast.

Clinical Applications. **Polymorphisms**, inherited differences in DNA base sequences, are abundant in the human population, and many alterations in DNA sequences are associated with diseases. Tests for DNA sequence variations are more sensitive than many other techniques (such as enzyme assays) and permit recognition of diseases at earlier and, therefore, potentially more treatable stages. These tests can also identify carriers of inherited diseases so they can receive appropriate counseling. Because genetic variations are so distinctive, **DNA fingerprinting** (analysis of DNA sequence differences) can be used to determine family relationships or to help identify the perpetrators of a crime.

Techniques of molecular biology are used in the **prevention** and **treatment** of disease. For example, recombinant DNA techniques provide human insulin for the treatment of diabetes, factor VIII for the treatment of hemophilia, and vaccines for the prevention of hepatitis. Enzyme replacement therapy has been successful for a number of diseases, in part owing to the ability to produce large amounts of enzyme through recombinant DNA technology. Although treatment of disease by gene therapy is in the experimental phase of development, the possibilities are limited only by the human imagination and, of course, by ethical considerations. The ability to rapidly analyze the genome and **proteome** (all expressed proteins) of a cell enables different variants of a particular disease to be identified and treated appropriately.

Techniques. To recognize normal or pathologic genetic variations, DNA must be isolated from the appropriate source and adequate amounts must be available for study. Techniques for **isolating** and **amplifying** genes and studying and **manipulating** DNA sequences involve the use of **restriction enzymes, cloning vectors, polymerase chain reaction (PCR), gel electrophoresis, blotting onto nitrocellulose paper**, and the preparation of **labeled probes that hybridize** to the appropriate target DNA sequences. Techniques to analyze all expressed genes within a cell require **gene chip** assays, which can lead to a genetic profile of normal versus diseased cells. **Gene therapy** involves isolating normal genes and inserting them into diseased cells so that the normal genes are expressed, permitting the diseased cells to return to a normal state. Ablation of gene expression is possible using techniques based on **silencing RNA** (small interfering RNA [siRNA]) and the clustered regularly interspaced small palindromic repeats (CRISPR)/CRISPR-associated (Cas) DNA editing system. **CRISPR/Cas** can also be used to either repair existing mutations in the human genome or to replace genes in the human genome. Students should have a general understanding of recombinant DNA techniques to appreciate their current use and the promise they hold for the future. Rapid sequencing of DNA and complementary DNA (cDNA; next-generation sequencing) allows for rapid determination of mutations in the genome and changes in gene expression.

Edna R., a third-year medical student, has started working in the hospital blood bank two nights a week (see Chapter 14 for an introduction to **Edna R.** and her daughter, **Beverly R.**). Because she will be handling human blood products, she must have a series of hepatitis B vaccinations. She has reservations about having these vaccinations and inquires about the efficacy and safety of the vaccines currently in use.

CF is a disease caused by an inherited deficiency in the CFTR (cystic fibrosis transmembrane conductance regulator) protein, which is a chloride channel. In the absence of chloride secretion, thick mucus blocks the pancreatic duct, resulting in decreased secretion of digestive enzymes into the intestinal lumen. The resulting malabsorption of fat and other foodstuffs decreases growth and may lead to varying degrees of small-bowel obstruction. Liver and gallbladder secretions may be similarly affected. Eventually, atrophy of the secretory organs or ducts may occur. Thick mucus also blocks the airways, markedly diminishing air exchange and predisposing the patient to stasis of secretions, diminished immune defenses, and increased secondary infections. Defects in the CFTR chloride channel also affect sweat composition, increasing the sodium and chloride content of the sweat, thereby providing a diagnostic tool.

Susan F. is a 3-year-old Caucasian girl who has been diagnosed with cystic fibrosis (CF). Her growth rate has been in the 30th percentile over the last year. Since birth, she has had occasional episodes of spontaneously reversible and minor small-bowel obstruction. These episodes are superimposed on gastrointestinal symptoms that suggest a degree of dietary fat malabsorption, such as bulky, glistening, foul-smelling stools two or three times per day. She has experienced recurrent flare-ups of bacterial bronchitis/bronchiolitis in the last 10 months, each time caused by *Pseudomonas aeruginosa*. A quantitative sweat test was unequivocally positive (excessive sodium and chloride were found in her sweat on two occasions). Based on these findings, the pediatrician informed **Susan F.**'s parents that **Susan F.** probably has CF. A sample of her blood was sent to a DNA testing laboratory to confirm the diagnosis and to determine specifically which one of the many potential genetic mutations known to cause CF was present in her cells.

Victoria T. was a 21-year-old woman who was the victim of a rape and murder. Her parents had told police she had left her home and drove to the local convenience store. When she had not returned home an hour later, her father drove to the store, looking for **Victoria T.** He found her car still parked in front of the store and called the police. They searched the area around the store and found **Victoria T.**'s body in a wooded area behind the building. She had been sexually assaulted and strangled. Medical technologists from the police laboratory collected a semen sample from vaginal fluid and took samples of dried blood from under the victim's fingernails. Witnesses identified three men who spoke to **Victoria T.** while she was at the convenience store. DNA samples were obtained from these suspects to determine whether any of them was the perpetrator of the crime.

Isabel S.'s cough is slightly improved on a multidrug regimen for pulmonary tuberculosis, but she continues to have night sweats. She is tolerating her current human immunodeficiency virus (HIV) therapy well but complains of weakness and fatigue. The man with whom she has shared needles to inject drugs accompanies **Isabel S.** to the clinic and requests that he be tested for the presence of HIV.

I. Recombinant DNA Techniques

Techniques for joining DNA sequences into new combinations (**recombinant DNA**) were originally developed as research tools to explore and manipulate genes and to produce the gene products (protein). Now they are also being used to identify mutated genes associated with disease and to correct genetic defects. These techniques will soon replace many current clinical testing procedures. A basic appreciation of recombinant DNA techniques is required to understand how genetic variations among individuals are determined and how these differences can be used to diagnose disease. The first steps in determining individual variations in genes involve isolating the genes (or fragments of DNA) that contain variable sequences and obtaining adequate quantities for study. The human genome project has succeeded in sequencing the 3 billion bases of the human genome and can now be used as a template to discover and understand the molecular basis of disease.

A. Strategies for Obtaining Fragments of DNA and Copies of Genes

1. Restriction Fragments

Enzymes called **restriction endonucleases** enable molecular biologists to cleave segments of DNA from the genome of various types of cells or to fragment DNA obtained from other sources. A class II **restriction enzyme** is an endonuclease that specifically recognizes a short sequence of DNA, usually 4 to 6 base pairs (bp) in length, and cleaves a phosphodiester bond in both DNA strands within this sequence (Fig. 16.1). A key feature of class II restriction enzymes is their specificity. A restriction enzyme always cleaves at the same DNA sequence and cleaves only at that particular sequence. Most of the DNA sequences recognized by restriction enzymes are palindromes—that is, both strands of DNA have the same base sequence when read in a 5'-to-3' direction. The cuts made by these enzymes are usually “sticky” (i.e., the products are single stranded at the ends, with one strand overhanging the other, so they anneal with complementary sequences to the overhang). However, sometimes they are blunt (the products are double stranded at the ends, with no overhangs). Hundreds of restriction enzymes with different specificities have been isolated (Table e-16.1). 

FIGURE 16.1 Action of restriction enzymes. Note that the DNA sequence shown is a palindrome: each strand of the DNA, when read in a 5'-to-3' direction, has the same sequence. Cleavage of this sequence by *EcoRI* produces single-stranded (or "sticky") ends or tails. Not shown is an example of an enzyme that generates blunt ends (see Table e-16.1).

Restriction endonucleases were discovered in bacteria in the late 1960s and 1970s. These enzymes were named for the fact that bacteria use them to "restrict" the growth of viruses (bacteriophage) that infect the bacterial cells. They cleave the phage DNA into smaller pieces so the phage cannot reproduce in the bacterial cells. However, they do not cleave the bacterial DNA because its bases are methylated at the restriction sites by

DNA methylases. Restriction enzymes also restrict the uptake of DNA from the environment, and they restrict mating with nonhomologous species.

Restriction fragments of DNA can be used to identify variations in base sequence in a gene. However, they also can be used to synthesize a **recombinant DNA** (also called **chimeric DNA**), which is composed of molecules of DNA from different sources that have been recombined in vitro (outside the organism; e.g., in a test tube). The sticky ends of two unrelated DNA fragments can be joined to each other if they have sticky ends that are complementary. Complementary ends are obtained by cleaving the unrelated DNAs with the same restriction enzyme (Fig. 16.2). After the sticky ends of the fragments base-pair with each other, the fragments can be attached covalently by the action of DNA ligase.

FIGURE 16.2 Production of recombinant DNA molecules with restriction enzymes and DNA ligase. The dashes at the 5'- and 3'-ends indicate that this sequence is part of a longer DNA molecule.

Which one of the following sequences is most likely to be a restriction enzyme recognition sequence? All the sequences are written in standard notation, with the top strand going 5'-to-3', left to right.

- A. GTCCTG
CAGGAC
- B. TACGAT
ATGCTA
- C. CTGAG
GACTC
- D. ATCCTA
TAGGAT

In sickle cell anemia, the point mutation that converts a glutamate residue to a valine residue (GAG to GTG) occurs in a site

that is cleaved by the restriction enzyme *Mst*II (recognition sequence CCTNAGG, where N can be any base) within the normal β -globin gene. The sickle cell mutation causes the β -globin gene to lose this *Mst*II restriction site. Therefore, because **Will S.** is homozygous for the sickle cell gene, neither of the two alleles of his β -globin gene will be cleaved at this site by *Mst*II.

2. DNA Produced by Reverse Transcriptase

If messenger RNA (mRNA) transcribed from a gene is isolated, this mRNA can be used as a template by the enzyme reverse transcriptase (see Chapter 11, Biochemical Comments), which produces a DNA copy (cDNA) of the RNA. In contrast to DNA fragments cleaved from the genome by restriction enzymes, DNA produced by reverse transcriptase does not contain introns because mRNA, which has no introns, is used as a template. cDNA also lacks the regulatory regions of a gene as those sequences (promoter, promoter-proximal elements, and enhancers) are not transcribed into mRNA.

The answer is C. C follows the palindromic sequence CTNAG, where N can be any base. None of the other sequences is this close to a palindrome. Although most restriction enzymes recognize a "perfect" palindrome, in which the sequence of bases in each strand is the same, others may have intervening bases between the regions of identity, as in this example. Note also the specificity of the enzyme *Mst*II in Table e-16.1.

3. Chemical Synthesis of DNA

Automated machines can synthesize oligonucleotides (short molecules of single-stranded DNA) up to 150 nucleotides in length. These machines can be programmed to produce oligonucleotides with a specified base sequence. Although entire genes cannot yet be synthesized in one piece, appropriate overlapping pieces of genes can be made and then ligated together to produce a fully synthetic gene. Additionally, oligonucleotides can be prepared that will base-pair with segments of genes. These oligonucleotides can be used in the process of identifying, isolating, and amplifying genes.

B. Techniques for Identifying DNA Sequences

1. Probes

A probe is a single-stranded polynucleotide of DNA or RNA that is used to identify a complementary sequence on a larger single-stranded DNA or RNA molecule (Fig. 16.3). Formation of base pairs with a complementary strand is called **annealing** or **hybridization**. Probes can be composed of cDNA (produced from mRNA by reverse transcriptase), fragments of genomic DNA (cleaved by restriction enzymes from the genome), chemically synthesized oligonucleotides, or, occasionally, RNA.

FIGURE 16.3 Use of probes to identify DNA sequences. The probe can be either DNA or RNA.

The conditions of hybridization can be manipulated to provide different degrees of **stringency**. Stringency refers to how exact a match the probe must have to the DNA to which it is hybridizing for significant hybridization to occur. Low-stringency conditions allow a number of mismatches between the two nucleic acid strands to be tolerated (nonstandard base pairs); high stringency requires an exact match of the complementary sequences before hybridization can take place. Stringency can be manipulated by raising or lowering the temperature (increased temperature increases stringency) and raising or lowering the salt concentration in the

hybridization reaction (high salt concentration reduces the stringency because it negates the electrostatic repulsion between the phosphates in the DNA backbone of two mismatched DNA strands). Thus, a high-stringency hybridization (looking for an exact match) will be performed at high temperature and low salt concentrations.

To identify the target sequence, the probe must carry a **label** (see Fig. 16.3). If the probe has a radioactive label such as ^{32}P , it can be detected by autoradiography. An autoradiogram is produced by covering the material containing the probe with a sheet of X-ray film. Electrons (β -particles) emitted by disintegration of the radioactive atoms expose the film in the region directly over the probe. Several techniques can be used to introduce labels into these probes. Not all probes are radioactive. Some are chemical adducts (compounds that bind covalently to DNA) that can be identified by, for example, fluorescence microscopy.

2. Gel Electrophoresis

Gel electrophoresis is a technique that uses an electrical field to separate molecules on the basis of size. Because DNA contains negatively charged phosphate groups, it will migrate in an electrical field toward the positive electrode (Fig. 16.4). Shorter molecules migrate more rapidly through the pores of a gel than do longer molecules, so separation is based on length. Gels composed of polyacrylamide, which can separate DNA molecules that differ in length by only one nucleotide, are used to determine the base sequence of DNA. Agarose gels are used to separate longer DNA fragments that have larger size differences.

A. Electrophoresis

B. After electrophoresis and treatment with stain

FIGURE 16.4 Gel electrophoresis of DNA. **A.** DNA samples are placed into depressions (“wells”) at one end of a gel, and an electrical field is applied. The DNA migrates toward the positive electrode at a rate that depends on the size of the DNA molecules. As the gel acts as a sieve, shorter molecules migrate more rapidly than longer molecules. **B.** The gel is removed from the apparatus. The bands are not visible until techniques are performed to visualize them (see Fig. 16.6).

The bands of DNA in the gel can be visualized by various techniques. Staining with dyes such as ethidium bromide allows direct visualization of DNA bands under ultraviolet light. Specific sequences are generally detected using a labeled probe.

3. Detection of Specific DNA Sequences

To detect specific sequences, DNA is usually transferred to a solid support, such as a sheet of nitrocellulose

paper. For example, if bacteria are growing on an agar plate, cells from each colony will adhere to a nitrocellulose sheet pressed against the agar, and an exact replica of the bacterial colonies can be transferred to the nitrocellulose paper (Fig. 16.5). A similar technique is used to transfer bands of DNA from electrophoretic gels to nitrocellulose sheets. After bacterial colonies or bands of DNA are transferred to nitrocellulose paper, the paper is treated with an alkaline solution and then heated. Alkaline solutions denature DNA (i.e., separate the two strands of each double helix), and the heating fixes the DNA on the filter paper, such that it will not move from its position during the rest of the blotting procedure. The single-stranded DNA is then hybridized with a probe, and the regions on the nitrocellulose blot containing DNA that base-pairs with the probe are identified.

Agar plate with bacterial colonies

Press nitrocellulose paper onto the plate
Cells from each colony adhere to the paper

Nitrocellulose paper containing bacterial cells

Treat with alkali to disrupt cells and denature DNA, and heat to fix DNA in place

Add radioactive DNA probe for specific DNA sequences
Incubate, then wash to remove probe that has not hybridized

Probe hybridized to DNA

Perform autoradiography

Exposed areas of X-ray film

FIGURE 16.5 Identification of bacterial colonies containing specific DNA sequences. The autoradiogram can be used to identify bacterial colonies on the original agar plate that contain the desired DNA sequence. Note that an orientation marker is placed on the nitrocellulose and the agar plate so the results of the autoradiogram can be properly aligned with the original plate of bacteria.

E. M. Southern developed the technique, which bears his name, for identifying DNA sequences on gels. **Southern blots** are produced when DNA on a nitrocellulose blot of an electrophoretic gel is hybridized with a DNA probe. Molecular biologists decided to continue with this geographic theme as they named two additional techniques. **Northern blots** are produced when RNA on a nitrocellulose blot is hybridized with a DNA probe. A slightly different but related technique, known as a **Western blot**, involves separating proteins by gel electrophoresis and probing with labeled antibodies for specific proteins (Fig. 16.6).

FIGURE 16.6 Southern, Northern, and Western blots. For Southern blots, DNA molecules are separated by electrophoresis, denatured, transferred to nitrocellulose paper (by “blotting”), and hybridized with a DNA probe. For Northern blots, RNA is electrophoresed and treated similarly except that alkali is not used (first, because alkali hydrolyzes RNA, and second, because RNA is already single stranded). For Western blots, proteins are electrophoresed, transferred to nitrocellulose, and probed with a specific antibody.

Western blots were one of the early generation tests to determine whether an individual was infected with the HIV. Antibodies to HIV proteins in the blood are detected by using the blood to probe a nitrocellulose filter that has HIV proteins on it. A positive result would indicate that the blood contains antibodies to HIV proteins, indicating that the individual has been infected with HIV. Fourth- and fifth-generation tests utilize a different technique to determine whether antibodies to HIV proteins are present in the blood and whether the viral protein P24 is also present. Such tests performed on **Isabel S.**'s friend showed that he was HIV positive.

4. DNA Sequencing

The most common procedure for determining the sequence of nucleotides in a DNA strand was developed by Frederick Sanger and involves the use of dideoxynucleotides. Dideoxynucleotides (see Chapter 12) lack a 3'-hydroxyl group (in addition to lacking the 2'-hydroxyl group that is normally absent from DNA deoxynucleotides). Thus, once they are incorporated into a replicating DNA chain, the next nucleotide cannot add, and polymerization is terminated. In this procedure, only one of the four dideoxynucleotides (dideoxyadenosine triphosphate [ddATP], dideoxythymidine triphosphate [ddTTP], dideoxyguanosine triphosphate [ddGTP], or dideoxycytidine triphosphate [ddCTP]) is added to a tube containing all four normal deoxynucleotides, DNA polymerase, a primer, and the template strand for the DNA that is being sequenced (Fig. 16.7). As DNA polymerase catalyzes the sequential addition of complementary bases to the 3'-end, the dideoxynucleotide competes with its corresponding normal nucleotide for insertion. Whenever the dideoxynucleotide is incorporated, further polymerization of the strand cannot occur, and synthesis is terminated. Some of the chains will terminate at each of the locations in the template strand that is complementary to the dideoxynucleotide. Consider, for example, a growing polynucleotide strand in which adenine (A) should add at positions 10, 15, and 16. Competition between ddATP and dATP for each position results in some chains terminating at position 10, some at 15, and some at 16. Thus, DNA strands of varying lengths are produced from a template. The shortest strands are closest to the 5'-end of the growing DNA strand because the strand is synthesized in a 5'-to-3' direction.

A. Terminates with ddATP

B. If synthesis is terminated with:

If synthesis is terminated with:

FIGURE 16.7 The Sanger method of DNA sequencing. **A.** A reaction mixture contains one of the dideoxynucleotides, such as ddATP, and some of the normal nucleotides, dATP, which compete for incorporation into the growing polynucleotide chain. When a T is encountered on the template strand (position 10), some of the molecules will incorporate a ddATP and the chain will be terminated. Those that incorporate a normal dATP will continue growing until position 15 is reached, where they will incorporate either a ddATP or the normal dATP. Only those that incorporate a dATP will continue growing to position 16. Thus, strands of different lengths from the 5'-end are produced, corresponding to the position of a T in the template strand. **B.** DNA sequencing by the dideoxynucleotide method. Four tubes are used. Each one contains DNA polymerase, a DNA template hybridized to a primer, plus dATP, dGTP, dCTP, and dTTP. Either the primer or the nucleotides must have a radioactive or fluorescent label, so bands can be visualized on the gel. Only one of the four dideoxyribonucleotides (ddNTPs) is added to each tube. Termination of synthesis occurs where the ddNTP is incorporated into the growing chain. The template is complementary to the sequence of the newly synthesized strand. Automated DNA sequencers utilize fluorescent-labeled ddNTPs and a column to separate the oligonucleotides by size. As samples leave the column, their fluorescence is analyzed

to determine which base has terminated the synthesis of that fragment. dATP, deoxyadenosine triphosphate; dCTP, deoxycytidine triphosphate; ddATP, dideoxyadenosine triphosphate; ddCTP, dideoxycytidine triphosphate; ddGTP, dideoxyguanosine triphosphate; ddNTP, dideoxynucleotide triphosphate; ddTTP, dideoxythymidine triphosphate; dGTP, deoxyguanosine triphosphate; dTTP, deoxythymidine triphosphate.

Four separate reactions are performed, each with only one of the dideoxynucleotides present (ddATP, ddTTP, ddGTP, ddCTP), plus a complete mixture of normal nucleotides (see Fig. 16.7B). In each tube, some strands are terminated whenever the complementary base for that dideoxynucleotide is encountered. If these strands are subjected to gel electrophoresis, the sequence 5' → 3' of the DNA strand complementary to the template can be determined by “reading” from the bottom to the top of the gel, that is, by noting the lanes (A, G, C, or T) in which bands appear, starting at the bottom of the gel and moving sequentially toward the top.

5. Next-Generation DNA Sequencing

The original limitation in the traditional Sanger method of sequencing DNA was speed; it took an extended period of time to generate significant amounts of sequence data. Improvements in the speed of sequencing have led to next-generation sequencing, which allow for sequencing of an entire genome in <1 day.

This technique involves mechanical fractionation of the genome, followed by the addition of known sequences of DNA to the ends of the unknown DNA (Fig. 16.8). The fractionated DNA, with known ends, is added to a glass slide which contains bound DNA complementary to the added ends of the unknown DNA. The DNA samples are amplified (see the section on PCR in this chapter) and then sequenced using a primer that is complementary to the known sequence of DNA on the ends of the unknown DNA. Many thousands of pieces of DNA are sequenced simultaneously on the slide. In this case, one sequences the unknown fragments one nucleotide at a time. Each dNTP in the reaction mixture is linked to a different fluorophore as well as a chemical blocking agent at the 3'-hydroxyl group on the ribose. After the first nucleotide has been added to the primer, a computer analyzes the fluorescence of all the DNA sequences on the slide and stores the data. Chemicals are then added to remove both the blocking groups from the 3'-hydroxyl groups and the fluorophores from the nucleotides already incorporated into the DNA. DNA synthesis is then initiated to add the next base to the primer, and the process is repeated. This continues for up to 100 bases, such that 100-base-long sequences are stored in the computer for each piece of unknown DNA on the slide. The computer then analyzes these sequences, looks for overlaps in sequence, and can generate an entire sequence of the DNA being analyzed. Multiple variations of this procedure have been developed and are revolutionizing clinical testing.

FIGURE 16.8 A simplified depiction of next-generation sequencing. See text for details.

 One of the drugs used to treat HIV is didanosine, a nucleotide reverse transcriptase inhibitor (NRTI). This drug is a purine nucleoside composed of the base hypoxanthine linked to dideoxyribose. In cells, didanosine is phosphorylated to form a nucleotide that adds to growing DNA strands. Because dideoxynucleotides lack both 2'- and 3'-hydroxyl groups, DNA synthesis is terminated. Reverse transcriptase has a higher affinity for the dideoxynucleotides than does the cellular DNA polymerase, so the use of this drug will affect reverse transcriptase to a greater extent than the cellular enzyme. It is no longer used because of side effects.

 Noninvasive prenatal testing is based on next-generation sequencing and is used to determine, early in a pregnancy, if certain chromosomal abnormalities are present (trisomies or monosomies), as well as the sex of the fetus. Fetal DNA can be found in the mother's blood, and through analysis of the DNA, and determining chromosome ratios by sequencing, it can be determined whether multiple copies of a particular chromosome are present in the fetus. This is currently utilized only as a screening procedure; positive results require confirmation by an invasive technique, such as amniocentesis (see Chapter 18).

C. Techniques for Amplifying DNA Sequences

To study genes or other DNA sequences, adequate quantities of material must be obtained. It is often difficult to isolate significant quantities of DNA from the original source. For example, an individual cannot usually afford to part with enough tissue to provide the amount of DNA required for clinical testing. Therefore, the available quantity of DNA has to be amplified.

1. Cloning of DNA

The first technique developed for amplifying the quantity of DNA is known as **cloning** (Fig. 16.9). The DNA that you want to be amplified (the “foreign” DNA) is attached to a **vector** (a carrier DNA), which is introduced into a host cell that makes multiple copies of the DNA. The foreign DNA and the vector DNA are usually cleaved with the same restriction enzyme, which produces complementary sticky ends in both DNAs. The foreign DNA is then added to the vector. Base pairs form between the complementary single-stranded regions, and DNA ligase joins the molecules to produce a chimera or recombinant DNA. As the host cells divide, they replicate their own DNA, and they also replicate the DNA of the vector, which includes the foreign DNA.

FIGURE 16.9 Simplified scheme for cloning of DNA in bacteria. A plasmid is a specific type of vector, or carrier, which can contain inserts of foreign DNA of up to 2.0 kilobase pairs in size. For clarity, the sizes of the pieces of DNA are not drawn to scale (e.g., the bacterial chromosomal DNA should be much larger than the plasmid DNA).

If the host cells are bacteria, commonly used vectors are **bacteriophage** (viruses that infect bacteria),

plasmids (extrachromosomal pieces of circular DNA that are taken up by bacteria), or **cosmids** (plasmids that contain DNA sequences from the lambda bacteriophage). When eukaryotic cells are used as the host, the vectors are often retroviruses, adenoviruses, free DNA, or DNA coated with a lipid layer (liposomes). The foreign DNA sometimes integrates into the host-cell genome, or it exists as episomes (extrachromosomal fragments of DNA).

In the early studies on CF, DNA sequencing was used to determine the type of defect in patients. Buccal cells were obtained from washes of the mucous membranes of the mouth, DNA isolated from these cells was amplified by PCR, and DNA sequencing of the CF gene was performed. A sequencing gel for the region in which the normal gene differs from the mutant gene is shown here. What is the difference between the normal and the mutant CF gene sequence shown on the gel, and what effect would this difference have on the protein produced from this gene?

Host cells that contain recombinant DNA are called **transformed cells** if they are bacteria or **transfected** (or **transduced** if the vector is a virus) cells if they are eukaryotes. Markers in the vector DNA are used to identify cells that have been transformed, and probes for the foreign DNA can be used to determine that the host cells actually contain the foreign DNA. If the host cells containing the foreign DNA are incubated under conditions in which they replicate rapidly, large quantities of the foreign DNA can be isolated from the cells. With the appropriate vector and growth conditions that permit the expression of the foreign DNA, large quantities of the protein produced from this DNA can be isolated.

2. Libraries

Specific collections of DNA fragments are known as libraries. A **genomic library** is a set of host cells (or phage) that collectively contain all the DNA sequences from the genome of another organism. Thus, a genomic library contains promoter and intron sequences of every gene. A **cDNA library** is a set of host cells that collectively contain all the DNA sequences produced by reverse transcriptase from the mRNA obtained from cells (or tissue) of a particular type. Therefore, a cDNA library contains cDNA for all the genes expressed in that cell type, corresponding to the particular stage of differentiation of the cell when the mRNA was isolated. Because cDNA libraries are generated by reverse transcription of mRNA, promoter and intron sequences of genes are not present in those libraries.

The DNA fragments that are utilized to construct genomic libraries are much larger than those needed to construct cDNA libraries (for humans, a genomic library would need to represent all 3 billion bp in the haploid genome; the average mRNA is about 2,500 bases in size). Thus, different vectors are utilized to construct genomic libraries compared to cDNA libraries. Bacteriophage (which can handle up to 20 kilobase pairs [kb] of foreign DNA), bacterial artificial chromosomes (BACs; which can handle up to 150 kb of foreign DNA), and yeast artificial chromosomes (YACs; which can handle up to 1,000 kb of foreign DNA) are often used in the construction of genomic libraries. For cDNA libraries, plasmids (which can accept up to 2 kb of foreign DNA) are usually the vector of choice.

To clone a gene, a suitable probe must be developed (derived from either an amino acid sequence within a protein or from a similar DNA sequence obtained from another species); the library is then screened with the probe (utilizing techniques described previously) to find host cells that harbor DNA sequences complementary to the probe. Obtaining sufficient clones enable the complete cDNA, or gene, to be obtained and sequenced.

3. Polymerase Chain Reaction

The PCR is an in vitro method that can be used for the rapid production of very large amounts of specific segments of DNA. It is particularly suited for amplifying regions of DNA for clinical or forensic testing procedures because only a very small sample of DNA is required as the starting material. Regions of DNA can be amplified by PCR from a single strand of hair or a single drop of blood or semen.

First, a sample of DNA containing the segment to be amplified must be isolated. Large quantities of primers, the four deoxyribonucleoside triphosphates, and a heat-stable DNA polymerase are added to a solution in which the DNA is heated to separate the strands (Fig. 16.10). The primers are two synthetic oligonucleotides: one oligonucleotide is complementary to a short sequence in one strand of the DNA to be amplified and the other is complementary to a sequence in the other DNA strand. As the solution is cooled, the oligonucleotides form base pairs with the DNA and serve as primers for the synthesis of DNA strands by a heat-stable DNA polymerase (this polymerase is isolated from *Thermus aquaticus*, a bacterium that grows in hot springs). The process of heating, cooling, and new DNA synthesis is repeated many times until a large number of copies of the DNA is obtained. The process is automated, so each round of replication takes only a few minutes, and in 20 heating and cooling cycles, the DNA is amplified over a million-fold.

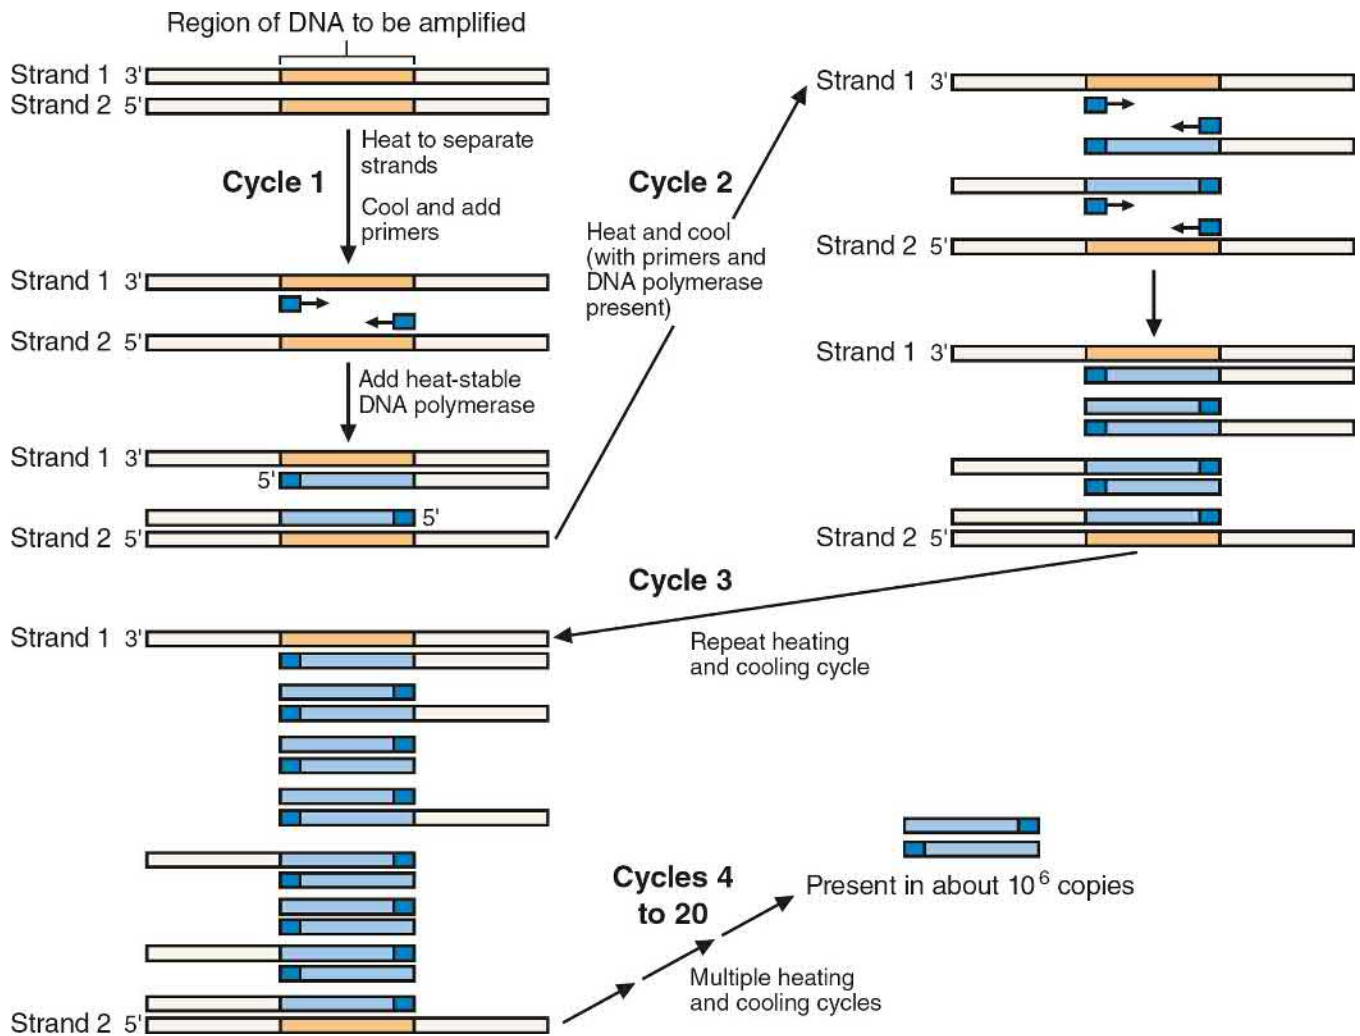

FIGURE 16.10 Polymerase chain reaction. Strand 1 and strand 2 are the original DNA strands. The short dark blue fragments are the primers. After multiple heating and cooling cycles, the original strands remain, but most of the DNA consists of amplified copies of the segment (shown in *lighter blue*) synthesized by the heat-stable DNA polymerase.

 Although only small amounts of semen were obtained from **Victoria T.**'s body, the quantity of DNA in these specimens could be amplified by PCR. This technique provided sufficient amounts of DNA for comparison with DNA samples from the three suspects.

 In individuals of northern European descent, 70% of the cases of CF are caused by a deletion of three bases in the CF gene. In the region of the gene shown on the gels, the base sequence (read from the bottom to the top of the gel) is the same for the normal and mutant gene for the first 6 positions, and the bases in positions 10 through 16 of the normal gene are the same as the bases in positions 7 through 13 of the mutant gene. Therefore, a three-base deletion in the mutant gene corresponds to bases 7 through 9 of the normal gene.

Loss of 3 bp (indicated by the dashes) maintains the reading frame, so only the single amino acid phenylalanine (F) is lost. Phenylalanine would normally appear as residue 508 in the protein. Therefore, the deletion is referred to as ΔF_{508} . The rest of

the amino acid sequence of the normal and the mutant proteins is identical.

II. Use of Recombinant DNA Techniques for Diagnosis of Disease

A. DNA Polymorphisms

Polymorphisms are variations among individuals of a species in DNA sequences of the genome. They serve as the basis for using recombinant DNA techniques in the diagnosis of disease. The human genome probably contains millions of different polymorphisms. Some polymorphisms involve **point mutations**, the substitution of one base for another, and are designated as single-nucleotide polymorphisms (SNPs). **Deletions** and **insertions** are also responsible for variations in DNA sequences. Some polymorphisms occur within the coding region of genes. Others are found in noncoding regions that are closely linked to genes involved in the cause of inherited disease, in which case they can be used as a marker for the disease. Because only about 1.5% of the human genome codes for genes, most polymorphisms are present in noncoding regions of the genome.

B. Detection of Polymorphisms

1. Restriction Fragment Length Polymorphisms

Occasionally, a point mutation occurs in a recognition site for one of the restriction enzymes. The restriction enzyme, therefore, can cut at this restriction site in DNA from most individuals but not in DNA from individuals with this mutation. Consequently, the restriction fragment that binds a probe for this region of the genome will be larger for a person with the mutation than for most members of the population. Mutations also can create restriction sites that are not normally present. In this case, the restriction fragment from this region of the genome will be smaller for a person with the mutation than for most individuals. These variations in the length of restriction fragments are known as **restriction fragment length polymorphisms (RFLPs)**.

In some cases, the mutation that causes a disease affects a restriction site within the coding region of a gene. However, in many cases, the mutation does not alter a restriction site within the gene of interest. However, an RFLP close to the gene may be discovered (tightly linked, i.e., physically close on the DNA molecule). This RFLP can still serve as a biologic marker for the disease. Both types of RFLPs can be used for genetic testing to determine whether an individual has the disease.

2. Detection of Mutations by Allele-Specific Oligonucleotide Probes

Other techniques have been developed to detect mutations because many mutations associated with genetic diseases do not occur within restriction enzyme recognition sites or cause detectable restriction fragment length differences when digested with restriction enzymes. For example, oligonucleotide probes (containing 15 to 20 nucleotides) can be synthesized that are complementary to a DNA sequence that includes a mutation. Different probes are produced for alleles that contain mutations and for those that have a normal DNA sequence. The region of the genome that contains the abnormal gene is amplified by PCR, and the samples of DNA are placed in narrow bands on nitrocellulose paper (“slot blotting”). The paper is then treated with the radioactive probe for either the normal or the mutant sequence. Appropriate manipulation of the hybridization conditions (e.g., high temperature and low salt concentration) will allow probes with only a one-base difference to distinguish between normal and mutant alleles, making this test a very sensitive technique. Autoradiograms indicate whether the normal or mutant probe has preferentially base-paired (hybridized) with the DNA—that is, whether the alleles are normal or mutated. Carriers, of course, have two different alleles: one that binds to the normal probe and one that binds to the mutant probe.

So how does one determine the DNA sequence of a gene that contains a mutation to develop specific probes to that mutation? First, the gene that causes the disease must be identified. This is done by a process known as positional cloning, which involves linking polymorphic markers to the disease. Individuals who express the disease will exhibit a specific subset of polymorphic markers, whereas individuals who do not express the disease will not express the same subset of polymorphic markers. Once such polymorphic markers are identified, identification of the disease gene can occur using these markers, in either of two ways. The first way is to use the polymorphic markers as probes to screen a human genomic library. This will identify pieces of human DNA that contain the polymorphic marker. These pieces of DNA can then be used as probes to expand the region of the genome surrounding this marker (chromosome walking). Potential genes within this region are identified (using data available from the sequencing of the human genome), and the sequence of bases within each gene is compared with the sequence of bases in the genes of individuals who have the disease. The one gene that shows an altered sequence in disease-carrying individuals compared with normal individuals is the tentative disease gene. The second method

to identify the disease gene is to screen the already sequenced human genome via database searching for genes near the identified polymorphic markers. Once identified, such genes would need to be sequenced in normal and afflicted individuals to identify the disease gene. Through the sequencing of genes from many people afflicted with the disease, the types of mutations that lead to this disease can be characterized and specific tests developed to determine whether individuals express these particular mutations.

3. Testing for Mutations by Polymerase Chain Reaction

If an oligonucleotide that is complementary to a DNA sequence containing a mutation is used as a primer for PCR, the DNA sample used as the template will be amplified only if it contains the mutation. If the DNA is normal (does not contain the mutation), the primer will not hybridize because of the one-base difference, and the DNA will not be amplified. This concept is extremely useful for clinical testing. In fact, a number of oligonucleotides, each specific for a different mutation and each containing a different label, can be used as primers in a single PCR. This procedure results in rapid and relatively inexpensive testing for multiple mutations.

4. Detection of Polymorphisms Caused by Repetitive DNA

Human DNA contains many sequences that are repeated in tandem a variable number of times at certain loci in the genome. These regions are called **highly variable regions** because they contain a **variable number of tandem repeats** (VNTR). Digestion with restriction enzymes that recognize sites that flank the VNTR region produces fragments containing these loci, which differ in size from one individual to another, depending on the number of repeats that are present. Probes used to identify these restriction fragments bind to or near the sequence that is repeated (Fig. 16.11).

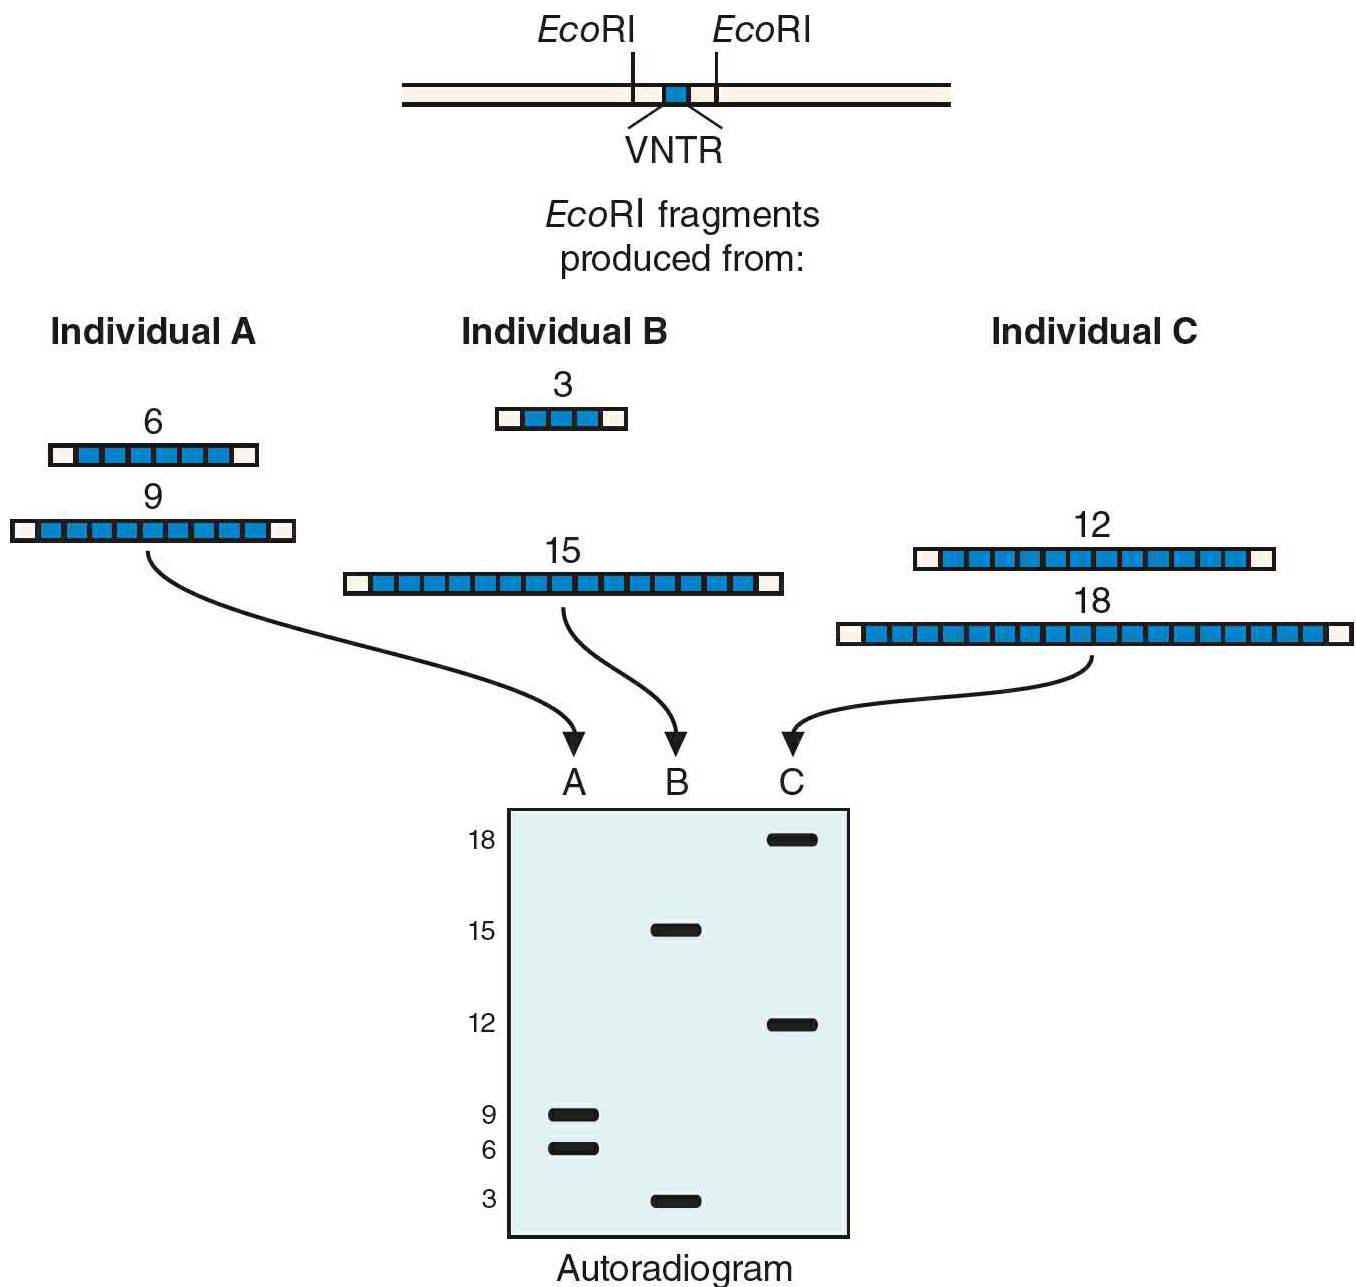

FIGURE 16.11 Restriction fragments produced from a gene with a VNTR. Each individual has two homologs of every somatic chromosome and thus two genes each containing this region with a VNTR. Cleavage of each individual's genomic DNA with a restriction enzyme produces two fragments containing this region. The length of the fragments depends on the number of repeats they contain. Electrophoresis separates the fragments, and a labeled probe that binds to the fragments allows them to be visualized. Each short blue block represents one repeat. VNTR, variable number of tandem repeats.

The restriction fragment patterns produced from these loci can be used to identify individuals as accurately as the traditional fingerprint. In fact, this restriction fragment technique has been called **DNA fingerprinting** and is gaining widespread use in forensic analysis. Family relationships can be determined by this method, and it can be used to help acquit or convict suspects in criminal cases.

 Testing for CF by DNA sequencing is time-consuming and expensive. Therefore, another technique that uses allele-specific oligonucleotide probes has been developed. **Susan F.** and her family were tested by this method. Oligonucleotide probes, complementary to the region where the three-base deletion is located, have been synthesized. One probe binds to the mutant (ΔF_{508}) gene and the other to the normal gene. DNA was isolated from **Susan F.**, her parents, and two siblings and amplified by PCR. Samples of the DNA were spotted on nitrocellulose paper, treated with the oligonucleotide probes, and the following results were obtained. (Dark spots indicate binding of the probe.)

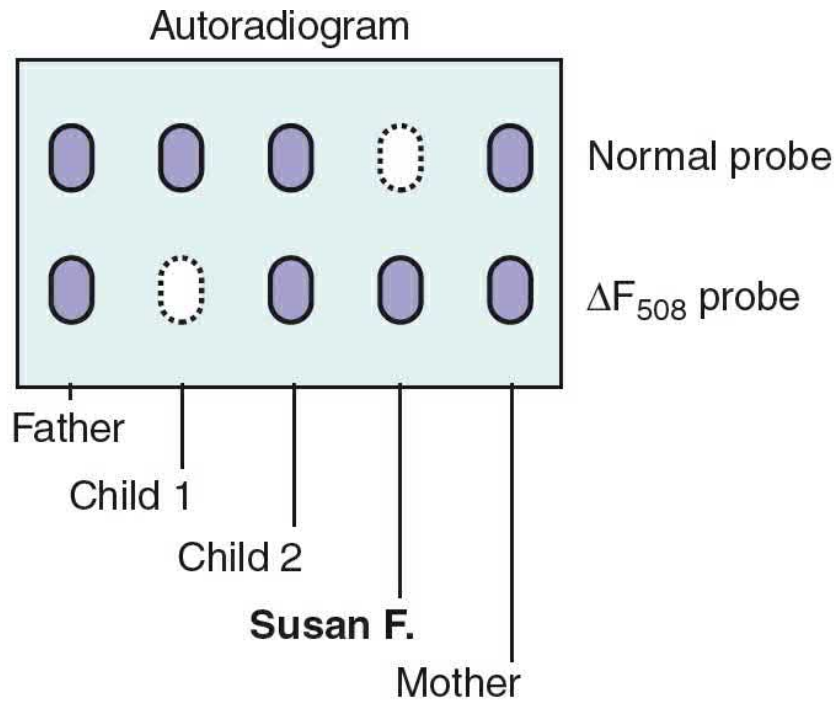

Which members of **Susan F.**'s family have CF, which are normal, and which are carriers?

Individuals who are closely related genetically will have restriction fragment patterns (DNA fingerprints) that are more similar than those who are more distantly related. Only monozygotic twins will have identical patterns.

5. Single-Nucleotide Polymorphisms

SNPs are the most common form of polymorphism in the human genome. To be considered a stable SNP in the population, the alteration in the base sequence must be present in 1% of the population. There are over 4 million SNPs in the human genome, occurring, on average, every 1,000 bp in the genome. SNPs are useful as genome markers because the majority of SNPs do not occur within genes. The pattern of SNPs can be used for DNA fingerprinting and for use in forensic analysis to locate ownership of biologic samples found at a crime scene. As the vast majority of SNPs do not occur in genes, their presence in the genome does not lead to disease. SNPs were not truly appreciated as genomic markers until the human genome was sequenced, and individual's genomes could be compared.

Identification of SNPs is accomplished by a technique known as primer extension, as indicated in Figure 16.12. Products of the reaction are detected by either fluorescence or mass spectrometry. Multiple reactions can be done simultaneously (multiplex) as long as the primers used for each SNP are of different sizes. In this case, the reaction products are separated by size using capillary electrophoresis, and the fluorescence associated with each product is determined. Specific patterns of SNPs have been associated with various disease genes and provide for a simple genetic test to determine whether an individual is a carrier for a particular genetic disorder or trait.

Which members of **Susan F.**'s family have CF, which are normal, and which are carriers?

FIGURE 16.12 Primer extension. Primers are designed to base-pair with the template up until the SNP, which extends one base beyond the 3'-end of the primer. Four dideoxy NTPs, each labeled with a different fluorophore, are added to the reaction, and the primer is extended by 1 nucleotide, which would be the complement of the SNP. The fluorescence of the extended primer then identifies the base at the location of the SNP. ddATP, dideoxyadenosine triphosphate; ddCTP, dideoxycytidine triphosphate; ddGTP, dideoxyguanosine triphosphate; ddTTP, dideoxythymidine triphosphate; NTP, nucleotide triphosphate; SNP, single-nucleotide polymorphisms.

Individuals to which both probes hybridize are carriers (as they contain one normal allele and one mutant allele). Thus, the father and mother are both carriers of the defective allele, as is one of the two siblings (Child 2). **Susan F.** has the disease (expressing only the mutant allele), and the other sibling (Child 1) is not a carrier for the disease (expressing only the normal allele).

The analysis of SNPs is the basis for genome-wide association studies (GWAS) in which a large number of SNPs are identified which track a particular disease. This technique has identified candidate genes for complex diseases, such as diabetes, cardiovascular disease, Parkinson disease, and Crohn disease. Such studies are being expanded to identify genes involved in drug responses to better treat patients with certain disorders.

6. DNA Chips (Microarrays)

Over the past 15 years, a technique has been developed that permits screening many genes simultaneously to determine which alleles of these genes are present in samples obtained from patients. The surface of a small chip is dotted with thousands of pieces of single-stranded DNA, each representing a different gene or segment of a gene. The chip is then incubated with a sample of a patient's DNA, and the pattern of hybridization is determined by computer analysis. The results of the hybridization analysis can be used, for example, to determine which one of the many known mutations for a particular genetic disease is the specific defect underlying a patient's problem. An individual's gene chip also may be used to determine which alleles of drug-metabolizing enzymes are present and, therefore, the likelihood of that individual having an adverse reaction to a particular drug.

Another use for a DNA chip is to determine which genes are being expressed in cells. If the mRNA from a tissue specimen is used to produce cDNA by reverse transcriptase, the cDNA will hybridize with only those genes being expressed in that tissue. In the case of a patient with cancer, this technique could be used to determine the classification of the cancer much more rapidly and more accurately than the methods traditionally used by pathologists. The treatment then could be tailored more specifically to the individual patient. This technique also can be used to identify the genes required for tissue specificity (e.g., the difference between a muscle cell and a liver cell) and differentiation (the conversion of precursor cells into the different cell types). Experiments using gene chips are helping us to understand differentiation and may open the opportunity to artificially induce differentiation and tissue regeneration in the treatment of disease.

The advent of next-generation sequencing has led to a technique known as RNA-SEQ, which enables an investigator to determine which mRNA is being expressed in a particular tissue and also how much mRNA is present in the cell. As an overview, mRNA is isolated from a cell, converted to cDNA, and the cDNA molecules sequenced using next-generation techniques. The intensity of the fluorescent signals during sequencing can quantitate the amount of starting cDNA, and comparing sequences obtained with genomic databases can identify the genes which have produced the mRNA under analysis. RNA-SEQ avoids using gene chips and does not restrict the results to only those genes that are represented on the gene chip.

As another example of the myriad uses of gene chips, a gene chip has been developed for the diagnosis of infectious disease. This gene chip contains 29,445 distinct oligonucleotides (60 bases long) that correspond to vertebrate viruses, bacteria, fungi, and parasites. Patient samples (nose aspirates, urine, blood, or tissue samples) are utilized as a source of RNA, which is converted to cDNA. Specific regions of the cDNA are amplified by PCR (the products of the PCR are fluorescent because of the incorporation of fluorescent primers in the procedure). Hybridization of the fluorescent probe with the chip allows identification of the infectious agent. The possibilities for gene chip applications in the future are virtually limitless.

The huge amount of information now available from the sequencing of the human genome and the results available from gene chip experiments have greatly expanded the field of bioinformatics. Bioinformatics can be defined as the gathering, processing, data storage, data analysis, information extraction, and visualization of biologic data. Bioinformatics also provides scientists with the capability to organize vast amounts of data in a manageable form that allows easy access and retrieval. Powerful computers are required to perform these analyses. As an example of an experiment that requires these tools, suppose you want to compare the effects of two different immunosuppressant drugs on gene expression in lymphocytes. Lymphocytes would be treated

with either nothing (the control) or with the drugs individually (experimental samples). RNA would be isolated from the cells during drug treatment and the RNA converted to fluorescent cDNA using the enzyme reverse transcriptase and a fluorescent nucleotide analog. The cDNA produced from your three samples would be used as probes for a gene chip containing DNA fragments from more than 5,000 human genes. The samples would be allowed to hybridize to the chips, and you would then have 15,000 results to interpret (the extent of hybridization of each cDNA sample with each of the 5,000 genes on the chip). Computers are used to analyze the fluorescent spots on the chips and to compare the levels of fluorescent intensity from one chip to another. In this way, you could group genes showing similar levels of stimulation or inhibition in the presence of the drugs and compare the two drugs with respect to which genes have had their levels of expression altered by drug treatment.

Gene chips have been used to answer the question of whether there are changes in gene expression during dieting.

Gene chips containing approximately 47,000 unique genes were utilized, and the probes were cDNA prepared from adipose tissue of control and calorie-restricted overweight women. Upon caloric restriction, 334 transcripts were upregulated, whereas 342 transcripts were reduced in expression, as compared with the control group. As expected, many of the genes corresponded to those involved in metabolism and metabolic regulation. Increased use of these techniques will, in the future, enable the development of pharmaceutical agents that specifically target transcripts involved in weight regulation, with the goal being the development and implementation of new and improved weight loss drugs.

Current methods for forensic analysis of DNA samples include SNPs or to take advantage of the presence of STRs in the DNA. The number of repeats differs among alleles, so an analysis of 8 to 16 STRs is usually sufficient for a statistically valid match. The DNA to be analyzed is amplified in a PCR reaction with all the primers (for all 8 to 16 STR regions) simultaneously (a process known as multiplexing). The primers are labeled with a fluorescent nucleotide, and they have been designed such that each STR amplification will yield a different-sized amplification product. After the PCR reaction has been completed, the fluorescent DNA samples are analyzed by size via capillary electrophoresis and a fluorescent detector. The sizes of the fragments are determined using time of elution from the column (and comparison to known size standards). If the multiplex PCR analyzed 8 STR regions, 16 different-sized bands (two alleles for each STR) can be generated from each individual donating DNA. These products are compared to the products obtained from the unknown sample, and matches, or nonmatches, can be determined. These procedures are now automated and very precise.

III. Use of Recombinant DNA Techniques for the Prevention and Treatment of Disease

A. Vaccines

Before the advent of recombinant DNA technology, vaccines were made exclusively from infectious agents that had been either killed or attenuated (altered so that they can no longer multiply in an inoculated individual). Both types of vaccines were potentially dangerous because they could be contaminated with the live infectious agent. In fact, in a small number of instances, the disease has actually been caused by vaccination. For the vaccine to be successful in preventing future infections, the human immune system must respond to the antigenic proteins on the surface of an infectious agent. The immune system is then prepared if the body is exposed to the infectious agent in the future. By recombinant DNA techniques, these antigenic proteins can be solely produced in large quantities, completely free of the infectious agent, and used in a vaccine. Thus, any risk of infection by the vaccine is eliminated. The first successful recombinant DNA vaccine to be produced was for the hepatitis B virus (HBV).

More recently, DNA vaccines have been utilized to achieve similar results. The theory behind DNA vaccines is to allow DNA to enter cells within a tissue, which then transcribe and translate the protein product encoded by the gene. This protein is an antigen from the organism against which antibody production is desired. The host then generates an immune response to the antigen, generating protection for the host. Although this therapy has been successful in rats, it has not yet evolved to the point of being successful in humans, perhaps as a result of insufficient cells accepting and expressing the DNA vaccine. Ongoing research is geared toward increasing the number of cells that receive the DNA, thereby enhancing immunogenicity.

B. Production of Therapeutic Proteins

1. Insulin and Growth Hormone

Recombinant DNA techniques are used to produce proteins that have therapeutic properties. One of the first such proteins to be produced was human **insulin**. Recombinant DNA corresponding to the A-chain of human

insulin was prepared and inserted into plasmids that were used to transform *Escherichia coli* cells. The bacteria then synthesized the insulin chain, which was purified. A similar process was used to obtain B-chains. The A- and B-chains were then mixed and allowed to fold and form disulfide bonds, producing active insulin molecules (Fig. 16.13). Insulin is not glycosylated, so there was no problem with differences in glycosyltransferase activity between *E. coli* and human cell types.

FIGURE 16.13 Production of human insulin in *E. coli*. Amp^R is the gene for ampicillin resistance. The presence of Amp^R allows bacterial cells that contain the vector to grow in the presence of ampicillin. Cells that lack the Amp^R gene die in the presence of ampicillin. Because *E. coli* cannot process preproinsulin, a synthetic scheme was developed whereby each individual chain of insulin was expressed, produced, and purified, and then the two chains were linked together in a test tube. *E. coli*, *Escherichia coli*.

Human growth hormone has also been produced in *E. coli* and is used to treat children with growth hormone deficiencies. Before the production of recombinant growth hormone, growth hormone isolated from cadaver pituitary tissue was used, which was in short supply.

The COVID-19 pandemic significantly accelerated the development of RNA vaccines. The virus that leads to COVID-19 is SARS-COV-2 (severe acute respiratory syndrome coronavirus 2). The virus contains an RNA genome, along with an RNA-dependent RNA polymerase that produces negative strands of the viral genome, and using the negative strand as a template, mRNA copies to be translated. The drug remdesivir inhibits RNA-dependent RNA polymerases and has been approved in the United States by the Food and Drug Administration (FDA) for the treatment of patients with COVID-19. The mRNA carried and produced by the virus encodes a number of proteins, one of which is the “spike” protein, a protein found on the surface of the intact virion. Accelerated research programs have analyzed the structure of the spike protein, and RNA molecules encoding the receptor-binding domain of the spike protein have been produced to utilize as an RNA vaccine. The RNA in the vaccine is produced using modified nucleosides to reduce the immunogenicity of the RNA and to improve stability of the RNA and translation of the mRNA. The modified RNA is encapsulated as a lipid nanoparticle, and upon injection into a vaccine recipient, the lipid nanoparticles will be encapsulated by cells, the RNA in the lipid particle translated, and the domain of the spike protein will be expressed and secreted by the cells. Once available to the immune system, the body develops antibodies against this domain of the spike protein such that if the individual is infected by the virus, the antibodies in the blood will disable the virus before it can do any harm. Preliminary results from clinical trials have indicated that the vaccines being developed are over 90% efficacious in protecting trial volunteers from becoming sick from viral infection.

2. Complex Human Proteins

More complex proteins have been produced in mammalian cell culture using recombinant DNA techniques. The gene for **factor VIII**, a protein involved in blood clotting, is defective in individuals with hemophilia. Before genetically engineered factor VIII became available, a number of hemophiliac patients died of acquired immune deficiency syndrome (AIDS) or hepatitis that they contracted from transfusions of contaminated blood or from factor VIII isolated from contaminated blood.

Tissue plasminogen activator (TPA) is a protease in the blood that converts plasminogen to plasmin. Plasmin is a protease that cleaves fibrin (a major component of blood clots), so administered TPA dissolves blood clots. Recombinant TPA, produced in mammalian cell cultures, can be administered immediately after symptoms of a stroke to dissolve the thrombi that occlude cerebral arteries and prevent oxygen from reaching the brain. It can also be used to treat other serious conditions caused by blood clots, including a heart attack and pulmonary embolism.

Hematopoietic growth factors also have been produced in mammalian cell cultures by recombinant DNA techniques. Erythropoietin can be used in certain types of anemias to stimulate the production of red blood cells. Colony-stimulating factors (CSFs) and interleukins (ILs) can be used after bone marrow transplants and after chemotherapy to stimulate white blood cell production and decrease the risk of infection. Recombinant β -interferon was the first drug known to decrease the frequency and severity of episodes resulting from the effects of demyelination in patients with multiple sclerosis.

DNA samples were obtained from each of the three suspects in **Victoria T.**'s rape and murder case, and these samples were compared with the victim's DNA by using DNA fingerprinting. Because **Victoria T.**'s sample size was small, PCR was used to amplify the regions containing the VNTRs. The results, using a probe for one of the repeated sequences in human DNA, are shown below to illustrate the process. For more positive identification, a number of different restriction enzymes and probes were used. The DNA from suspect 2 produced the same VNTR pattern as the DNA from the semen obtained from the victim. If the other restriction enzymes and probes corroborate this finding, suspect 2 can be identified by DNA fingerprinting as the rapist/murderer.

Chromosomal DNA

Digest with restriction endonucleases

DNA fragments

Amplify VNTR regions and separate fragments by gel electrophoresis

Denature and transfer DNA to nitrocellulose paper

Radioactive DNA probe

Incubate with probe, wash and perform autoradiography to observe labeled DNA bands

Lysosomal enzymes have been generated by recombinant DNA technology to treat lysosomal storage disorders. Examples include α -galactosidase, to treat Fabry disease; α -L-iduronidase, to treat mucopolysaccharidosis type 1 (Hurler syndrome); glucocerebrosidase to treat Gaucher disease; and acid α -galactosidase to treat Pompe disease. All of these serious disorders can be treated by regular enzyme infusions although treatment is required for the lifetime of the individual.

A method for producing human proteins that has proven to be successful involves transgenic animals. These animals (usually goat or sheep) have been genetically engineered to produce human proteins in the mammary gland and secrete them into milk. The gene of interest is engineered to contain a promoter that is only active in the mammary glands under lactating conditions. The vector containing the gene and promoter is inserted into the nucleus of a freshly fertilized egg, which is then implanted into a foster mother. The female animal progeny are tested for the presence of this transgene, and milk from the positive animals is collected. Large quantities of the protein of interest can then be isolated from the relatively small number of proteins present in milk.

C. Small Interfering RNA (SiRNA)

In a number of disorders, it would be advantageous to reduce the expression of a particular gene. This has, in the past, been very difficult to do, but a recently discovered series of reactions will allow this to occur, and the technique is already showing promise as a therapeutic tool. One way to reduce the expression of a particular protein is to reduce the level of mRNA within the cell that codes for the protein. This can occur by either specifically degrading this mRNA or by blocking translation from the mRNA of interest. It turns out that eukaryotic cells have a built-in system to silence gene expression via reduction of mRNA levels, a process known as gene silencing. Gene silencing comes about via the transcription of genes known as microRNAs (miRNA; see Chapter 15); the miRNAs are processed to form a small (21 to 24 bp) double-stranded RNA molecule. The double-stranded RNA is separated into single strands, and the strand that is complementary to a specific mRNA is guided to the mRNA, which is either degraded or inhibited from participation in translation, depending on the miRNA. If the miRNA pairing is exact with its target, mRNA degradation is initiated. If the miRNA pairing with the target is inexact, inhibition of translation results (see Fig. 15.22).

Since this expression-ablation pathway was first discovered, it has been shown that the introduction of chemically synthesized double-stranded RNA molecules into cells will generate siRNAs to inhibit the production of a cellular protein. Although this technique holds great promise for antiviral and anticancer therapies, a great deal of work still needs to be done to optimize the delivery of the double-stranded RNA to the target tissue and to optimize the stability of the agent. Alternative approaches include the induction, or inhibition, of certain miRNA genes.

This technique has been expanded such that DNA encoding small hairpin RNAs (shRNA) can be introduced into cells via appropriate vectors. The shRNA-encoding DNA sequences are transcribed by RNA polymerase II or III (depending on the promoter used), and the transcripts are processed as are miRNAs, such that the target mRNA of the shRNA is no longer translated. The use of shRNA in therapeutics has been targeted to certain cancers thus far, but significant technologic challenges (including delivery of the shRNA vector and control of expression of the shRNA gene) still need to be worked out before this type of therapy can be expanded to other diseases.

D. Genetic Counseling

One means of preventing disease is to avoid passing a pathogenic gene variant to offspring. If individuals are tested for genetic diseases, particularly members of families that are known to carry a pathogenic gene variant, genetic counselors can inform the individuals of their risks and options. With this information, people can decide in advance whether to have children.

When **Edna R.** began working with patients, she received the hepatitis B vaccine. The HBV infects the liver, causing severe damage. The virus contains a surface antigen (HBsAg) or coat protein for which the gene has been isolated. However, because the protein is glycosylated, it could not be produced in *E. coli*. (Bacteria, because they lack subcellular organelles, cannot produce glycosylated proteins.) Therefore, a yeast (eukaryotic) expression system was used that produced a glycosylated form of the protein. The viral protein, separated from the small amount of contaminating yeast protein, is used as a vaccine for immunization against HBV infection.

Screening tests based on the recombinant DNA techniques outlined in this chapter have been developed for

many inherited diseases. Although these tests are currently rather expensive, particularly if entire families have to be screened, the cost may be trivial compared with the burden of raising children with severe disabilities. Obviously, cost and ethical considerations must be taken into account, but recombinant DNA technology has provided individuals with the ability to make choices.

Screening can be performed on the prospective parents before conception. If they decide to conceive, the fetus can be tested for the genetic defect. In some cases, if the fetus has the defect, treatment can be instituted at an early stage, even in utero. For certain diseases, early therapy leads to a more positive outcome.

Dianne A. is using recombinant human insulin called lispro (Humalog) (see Chapter 6, Fig. 6.11). Lispro was genetically engineered so that lysine is at position 28 and proline is at position 29 of the B-chain (the reverse of their positions in normal human insulin). **Dianne A.** injects lispro right before each meal to help keep her blood sugars controlled. The switch of position of the two amino acids leads to a faster-acting insulin homolog. Lispro is absorbed from the site of injection much more quickly than other forms of insulin, and it acts to lower blood glucose levels much more rapidly than the other insulin forms. A long-acting form of insulin has also been produced by recombinant DNA technology.

E. Gene Therapy

The ultimate cure for genetic diseases is to introduce normal genes into individuals who have defective genes. Currently, gene therapy is being attempted in animals, cell cultures, and human subjects. Although it is possible, using the CRISPR/Cas system (see below), to replace the gene at its normal location in the genome, previous work has demonstrated that as long as the gene is expressed at the appropriate time and produces adequate amounts of the protein to return the person to a normal state, the gene does not have to integrate into a precise place in the genome. Sometimes the gene does not even have to be in the cells that normally contain it.

Historically, retroviruses were the first vectors used to introduce genes into human cells. Normally, retroviruses enter target cells, their RNA genome is copied by reverse transcriptase, and the double-stranded DNA copy is integrated into the host-cell genome (see Fig. 13.20). If the retroviral genes (e.g., *gag*, *pol*, and *env*) are first removed and replaced with the therapeutic gene, the retroviral genes integrated into the host-cell genome will produce the therapeutic protein rather than the viral proteins (Fig. 16.14). This process works only when the human host cells are undergoing division, so it has limited applicability. Other problems with this technique are that it can only be used with small genes (≤ 8 kb), and it may disrupt other genes because the insertion point is random, thereby possibly resulting in cancer.

Retroviral vector

FIGURE 16.14 Use of retroviruses for gene therapy. The retrovirus carries an RNA copy of the therapeutic gene into the cell. The endosome that contains the virus dissolves, and the RNA and viral reverse transcriptase are released. This enzyme copies the RNA, making a double-stranded DNA that integrates into the host-cell genome. Transcription and translation of this DNA (the therapeutic gene) produces the therapeutic protein. (The virus does not multiply because its genes were removed and replaced by the RNA copy of the therapeutic gene.)

Carrie S.'s fiancé decided to be tested for the sickle cell gene. He was found to have both the 1.3-kb and the 1.1-kb *MstII* restriction fragments that include a portion of the β -globin gene. Therefore, like **Carrie S.**, he also is a carrier for the sickle cell gene.

A defect in the adenosine deaminase (ADA) gene causes severe combined immunodeficiency syndrome (SCID). When ADA is defective, deoxyadenosine and dATP accumulate in rapidly dividing cells, such as lymphocytes, and prove toxic to these cells. Cells of the immune system cannot proliferate at a normal rate. When an appropriate donor is available, bone marrow transplantation can be performed in the first 3 months of life with a reasonable degree of success. Without this, children with SCID usually die at an early age because they cannot combat infections. To survive, they must be confined to a sterile, environmental “bubble.”

In 1990, a 4-year-old girl, for whom no donor was available, was treated with infusions of her own lymphocytes that had been treated with a retrovirus containing a normal ADA gene. Although she had not responded to previous therapy, she improved significantly after this attempt at gene therapy. This disease is still being treated with gene therapy in combination with replacement enzyme infusion.

Adenoviruses, which are natural human pathogens, can also be used as vectors. As in retroviral gene therapy, the normal viral genes required for the synthesis of viral particles are replaced with therapeutic genes. The advantages of using an adenovirus are that the introduced gene can be quite large (~36 kb), and infection does not require division of host cells. The disadvantage is that genes carried by the adenovirus do not integrate stably into the host genome, resulting in only transient expression of the therapeutic proteins (but preventing disruption of host genes and the complications that may arise from it). Thus, the treatment must be repeated periodically. Another problem with adenoviral gene therapy is that the host can mount an immune response to the pathogenic adenovirus, causing complications, including death.

To avoid the problems associated with viral vectors, researchers are employing treatment with DNA alone or with DNA coated with a layer of lipid (i.e., in liposomes). Adding a ligand for a receptor located on the target cells could aid the delivery of the liposomes to the appropriate host cells. Many problems still plague the field of gene therapy. In many instances, the therapeutic genes must be targeted to the cells where they normally function—a difficult task at present. Deficiencies in dominant genes are more difficult to treat than those in recessive genes, and the expression of the therapeutic genes often needs to be carefully regulated. Although the field is moving forward, progress has been slow.

Another form of SCID is X-linked and is known as X-SCID. This disease results from mutations in a common subunit protein of multiple cytokine receptors. The cDNA corresponding to this subunit was delivered to patient lymphocytes using a retroviral vector, and the success rate of reconstituting the immune system was high for patients who received this gene therapy. The enthusiasm concerning the treatment was tempered, however, by the development of leukemia in three of the patients who were part of the initial trial. Retroviruses randomly insert their DNA copy of their genome into the host chromosome. In the patients who developed leukemia, it has been determined that the vector inserted near the *LMO2* gene, a known proto-oncogene (see Chapter 17). The insertional event triggered activation (or overexpression) of *LMO2*, leading to uncontrolled cell proliferation. Current research is now directed to attempt to target areas of insertion for vectors utilized in gene therapy.

F. The CRISPR/Cas System

A significant gene-editing system has been discovered in archaea and has been adapted to use for gene editing in many different species, with almost unlimited applications. The system was originally designed as a rudimentary immune system, such that the archaea could destroy any invading DNA from viruses or other pathogens. Use of this DNA editing system has enabled scientists to knock out or insert targeted genes in cells. This primitive immune system has been given the name CRISPR/Cas, for clustered regularly interspaced short palindromic repeats (CRISPR), and CRISPR-associated system (for Cas, and includes nucleases and helicases necessary to aid in the introduction of double-strand breaks in the target DNA). Within the clustered repeats of these regions of the archaeal genome were found DNA sequences from bacteriophage. If a similar phage were to infect the archaea, the host cell would use a defense mechanism that would recognize the invading DNA and degrade it using the combination of the CRISPR and Cas genes (Fig. 16.15).

FIGURE 16.15 The CRISPR/Cas system. A simplified version of this gene-editing system is depicted. A guide RNA is synthesized (which will guide the molecule to the DNA sequence to be edited) coupled to what is called a tracrRNA, which allows the RNA molecule to interact with the Cas9 protein (it is the Cas9 protein that does the editing). The guide RNA directs the complex to the appropriate region of the genome (which needs to be adjacent to a PAM sequence, for protospacer adjacent motif, which is recognized by the complex such that DNA cleavage can occur). Once situated, the complex makes a double-strand break in the DNA, which can be repaired by either homologous recombination (to replace the gene or introduce a specific mutation) or nonhomologous end joining (to create a nonfunctional gene). See chapter 18 for more details on homologous recombination and nonhomologous end joining. Cas, CRISPR-associated; CRISPR, clustered regularly interspaced small palindromic repeats. sgRNA, single guide RNA; CrRNA, CRISPR RNA; tracrRNA, trans-activating RNA.

 The use of CRISPR/Cas has enabled strains of mosquitoes to be created that would render females unable to breed and would have the potential to eliminate certain strains of mosquitoes (e.g., those that carry the malaria parasite) from existence. However, is this an ethical concern of using the technology—destroying a species from existence? Chinese scientists have successfully altered the β -globin gene in nonviable human embryos as a test to see if thalassemia can be treated with CRISPR/Cas technology. These early experiments have demonstrated that there are still technical issues concerning nonspecific gene integration to work out, but the potential for this technique is enormous. Another Chinese scientist performed CRISPR/Cas editing on viable human embryos, inactivating the CCR5 membrane receptor on T-cells. The CCR5 receptor is a coreceptor for HIV to enter T-cells. Loss of expression of CCR5 would reduce the possibility of HIV infection. The embryos were implanted into a woman and brought to term, leading to twin girls with genetically altered genomes. Although the scientist in question had good intentions, he was sentenced to a 3-year jail term for his work, which has not been approved either ethically or scientifically. There are significant ethical issues associated with altering the human genome before birth. Recently, CRISPR/Cas was utilized on a live patient with the rare disorder Leber congenital amaurosis, which leads to blindness owing to a mutation in the *CEP290* gene. A genetically modified virus, containing appropriate CRISPR/Cas sequences to alter the *CEP290* gene, was injected into a cohort of patients for a clinical trial. The individuals will be followed to see if vision returns or if the disorder becomes worse because of the treatment. Thus, although the medical implications for this technique are endless, it is not clear that the ethical issues will not be as easily resolved as the scientific technique.

Scientists have used the specificity of this system to successfully alter genes in cultured cells, either by knocking them out (destroying their ability to code for a functional protein) or by replacing the gene with a modified one. The possibilities that CRISPR/Cas technology offers are limitless, but limits are placed on its use owing to ethical and societal concerns.

G. Transgenic Animals

The introduction of normal genes into somatic cells with defective genes corrects the defect only in the treated individuals, not in their offspring. To eliminate the defect for future generations, the normal genes must be introduced into the germ cell line (the cells that produce sperm in males or eggs in females). Experiments with animals indicate that gene therapy in germ cells is feasible. Genes can be introduced into fertilized eggs from

which transgenic animals develop, and these transgenic animals can produce apparently normal offspring.

In fact, if the nucleus isolated from the cell of one animal is injected into the enucleated egg from another animal of the same species and the egg is implanted in a foster mother, the resulting offspring is a “clone” of the animal from which the nucleus was derived. Clones of sheep and pigs have been produced, and similar techniques could be used to clone humans. Obviously, these experiments raise many ethical questions that will be difficult to answer.

Adenoviral vectors have been used in an aerosol spray to deliver normal copies of the *CFTR* gene to cells of the lung. Some cells took up this gene, and the patients experienced moderate improvement. However, stable integration of the gene into the genome did not occur, and cells affected by the disease other than those in the lung (e.g., pancreatic cells) did not benefit. Nevertheless, this approach marked a significant forward step in the development of gene therapy. Adenoviral vectors were also used in an attempt to treat ornithine transcarbamylase deficiency (a disorder of nitrogen metabolism). In this trial, a volunteer died of a severe immune response to the adenoviral vector. This unfortunate result has led to a reevaluation of the safety of viral vectors for gene therapy and the procedures developed for informed consent for clinical trials.

IV. Proteomics

The techniques described previously have concentrated on nucleic acid manipulation, but there have also been rapid advances in analyzing all proteins expressed by a cell at a particular stage of development. The techniques are sophisticated enough to allow comparisons between two different samples, such as normal cells and cancer cells from the same tissue. An abbreviated view of this technique is shown in Figure 16.16. Proteins from the two different cell types (A and B) are isolated and labeled with different fluorescent dyes. The proteins are then separated by two-dimensional gel electrophoresis (the first dimension, or separation, is by charge, and the second dimension is by size), which generates a large number of spots that can be viewed under a fluorescent imaging device, each of these spots corresponding to an individual protein. A computer aligns the spots from the two samples and can determine, by the level of fluorescence expressed at each protein spot, whether a protein has been upregulated or downregulated in one sample compared to the other. Proteins whose expression levels change can then be identified by sensitive techniques involving protein mass spectrometry.

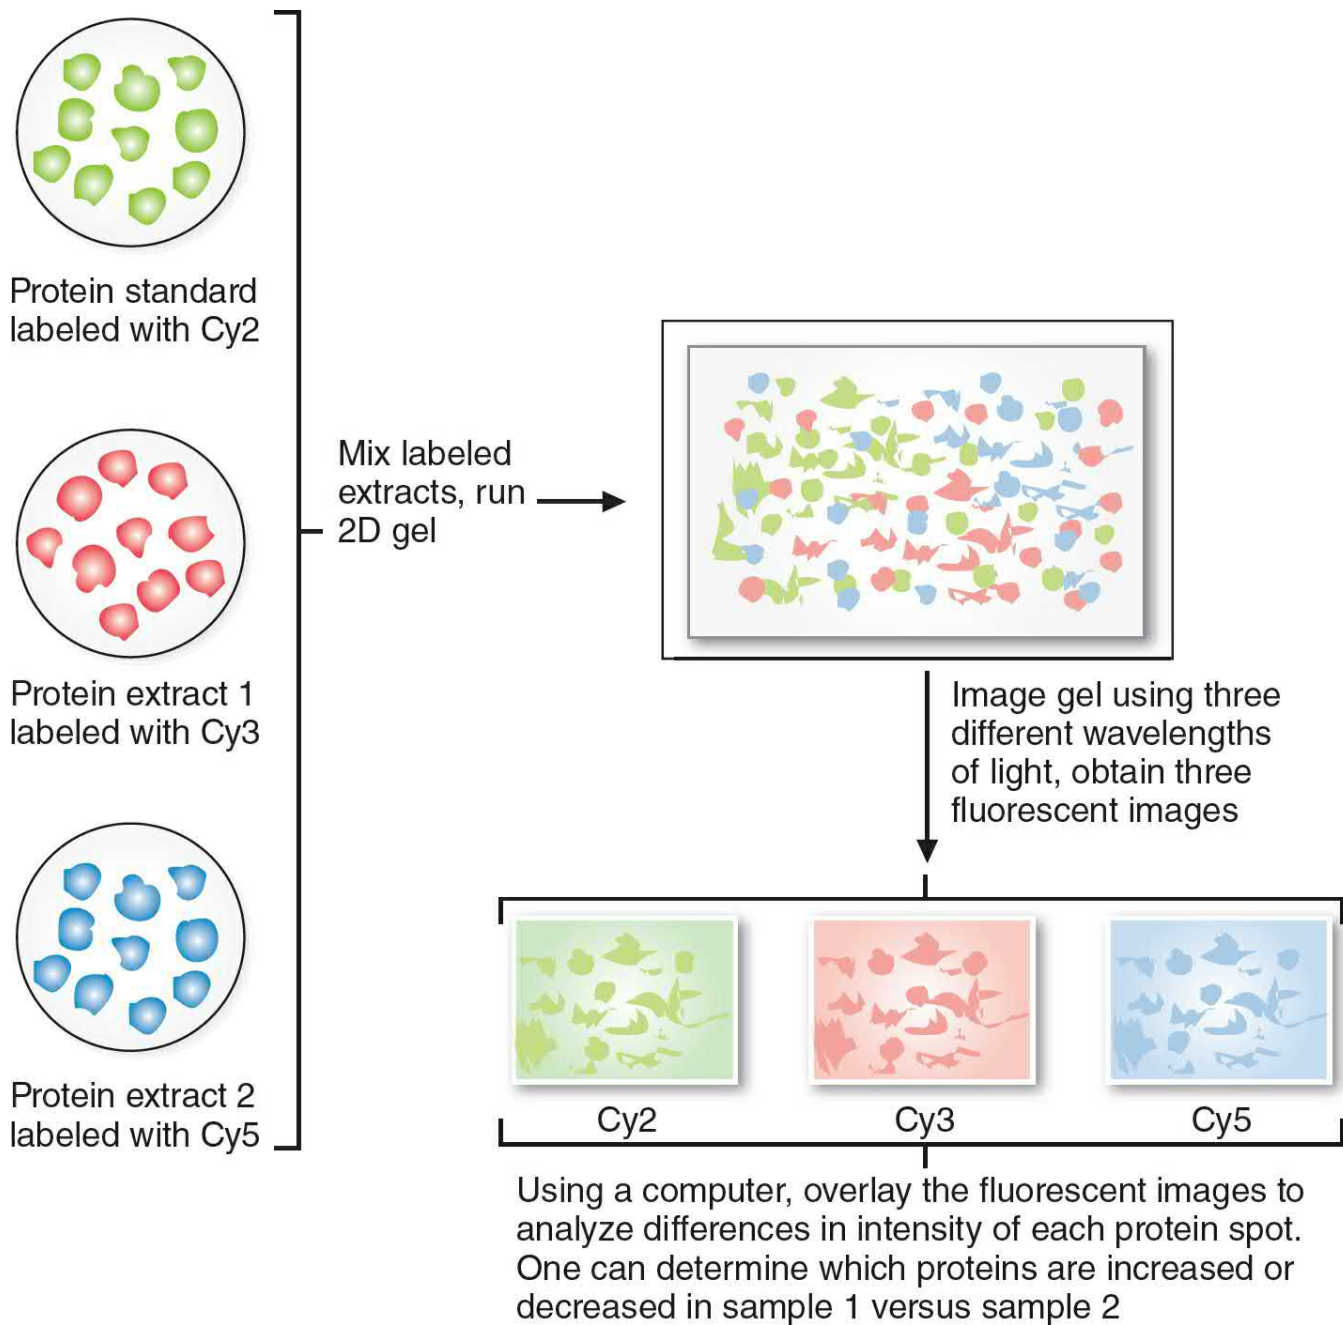

FIGURE 16.16 Using proteomics to determine whether a protein is upregulated or downregulated. See text for more details.

The proteomics approach holds great promise in molecularly fingerprinting particular tumors and for discovering novel targets for drug development that are only expressed in the cancerous state. A physician's knowledge of the markers expressed by a particular tumor should allow for specific drug regimes to be used; no longer will one treatment be the norm for a particular tumor. Depending on a patient's proteome, treatments for the patient's specific tumor can be devised and prescribed.

CLINICAL COMMENTS

Edna R. In reading about the development of the hepatitis B vaccine, **Edna R.** learned that the first vaccine available for HBV, marketed in 1982, was a purified and "inactivated" vaccine containing HBV virus that had been chemically killed. The virus was derived from the blood of known HBV carriers. Later, "attenuated" vaccines were used, in which the virus remained live but was altered so that it no longer multiplied in the inoculated host. Both the inactivated and the attenuated vaccines are potentially dangerous because they can be contaminated with live infectious HBV.

The most common CF mutation is a 3-bp deletion that causes the loss of phenylalanine at position 508 ($\Delta 508$; the Δ indicates deletion). This mutation is present in the gene of more than 70% of CFTR patients. The defective protein is synthesized in the endoplasmic reticulum but is misfolded. It is, therefore, not transported to the Golgi but is degraded by a proteolytic enzyme complex called the proteasome. Other mutations responsible for CF generate an incomplete mRNA because of premature stop signals, frameshifts, or abnormal splice sites, or create a CFTR channel in the membrane that does not function properly. Recently approved drugs to treat CF are molecular chaperones, which safely chaperone the misfolded CFTR protein to the plasma membrane, as opposed to intracellular protein degradation, which often occurs with misfolded proteins. If the protein is inserted into the membrane, partial function of the CFTR protein is restored, reducing the symptoms found in the patient.

The modern “subunit” vaccines, first marketed in 1987, were made by recombinant DNA techniques described earlier in this chapter. Because this vaccine consists solely of the viral surface protein or antigen to which the immune system responds, there is no risk for infection with HBV.

Susan F. CF is a genetically determined autosomal recessive disease that can be caused by a variety of mutations within the CF gene located on chromosome 7. **Susan F.** was found to have a 3-bp deletion at residue 508 of the CF gene (the mutation present in approximately 85% of Caucasian patients with CF in the United States). This mutation is generally associated with a more severe clinical course than many other mutations that cause the disease. However, other genes and environmental factors may modify the clinical course of the disease, so it is not currently possible to counsel patients accurately about prognosis based on their genotype.

CF is a relatively common genetic disorder in the United States, with a carrier rate of approximately 5% in Caucasians. The disease occurs in approximately 1 per 3,200 Caucasian births (1 per 17,000 in African Americans and 1 per 31,000 in Asian Americans).

Victoria T. DNA fingerprinting represents an important advance in forensic medicine. Before the development of this technique, identification of criminals was far less scientific. The suspect in the rape and murder of **Victoria T.** was arrested and convicted mainly based on the results of DNA fingerprint analysis.

This technique has been challenged in some courts based on technical problems in statistical interpretation of the data and sample collection. It is absolutely necessary for all the appropriate controls to be run, including samples from the victim’s DNA as well as the suspect’s DNA. Another challenge to the fingerprinting procedure has been raised because PCR is such a powerful technique that it can amplify minute amounts of contaminating DNA from a source unrelated to the case.

What are the statistical issues relating to DNA fingerprinting? Through the analysis of a large number of individuals of different ethnicities, one can determine the frequency of a particular DNA polymorphism within that distinct population. By matching 8 to 16 polymorphisms (using multiplexed PCR for polymorphic STRs or primer extension for SNPs) from DNA at the crime scene with DNA from a suspect, one can determine the odds of that match happening by chance. For example, let us assume that a suspect’s DNA was compared with DNA found at the crime scene for four unique polymorphisms within the suspect’s ethnic group. The frequency of polymorphism A in that population is 1 in 20; of polymorphism B, 1 in 30; of polymorphism C, 1 in 50; and of polymorphism D, 1 in 100. The odds of the suspect DNA matching the DNA found at the crime scene for all four polymorphisms would be the product of each individual probability or $(1/20) \times (1/30) \times (1/50) \times (1/100)$. This comes out to a 1 in 3 million chance that an individual would have the same polymorphisms in their DNA as that found at the crime scene. The question left to the courts is whether the 1 in 3 million matches is sufficient to convict the suspect of the crime. Given that there may be 30 million individuals in the United States within the same ethnic group as the suspect, there would then be 10 people within the country who would match the DNA polymorphisms found at the scene of the crime. Can the court be sure that the suspect is the correct individual? Clearly, the use of DNA fingerprinting is much clearer when a match is not made, for that immediately indicates that the suspect was not at the scene of the crime.

BIOCHEMICAL COMMENTS

Mapping of the Human Genome. The Human Genome Project began in 1990, and by the summer of 2000, the entire human genome had been mapped. This feat was accomplished in far less than the expected time, as a result of both cooperative and competitive interactions of laboratories in the private as well as public sectors.

The human genome contains $>3 \times 10^9$ (3 billion) bp. A large percentage of this genome (<95%) does not code for the amino acid sequences of proteins or for functional RNA (such as ribosomal [rRNA] rRNA or transfer RNA [tRNA]) but is composed of repetitive sequences, introns, and other noncoding elements of

unknown function. The human genome is estimated to contain only about 20,000 to 25,000 genes; however, significantly more proteins are produced than there are genes. This arises from alternative splicing and various posttranslational modifications. Further analysis of the proteome may prove to be more informative than the genome.

Analysis of the genome has led to the identification of a large number of SNPs, which refer to a single-nucleotide change within a given DNA sequence as compared between individuals. For such a change to be considered an SNP (as opposed to a random mutation), the polymorphism must be present within 1% of the population. SNPs are plentiful in the human genome, occurring every 1000 bp. SNPs are therefore useful tools for mapping disease genes within the chromosome. SNPs are also being used in place of short tandem repeat sequences (STRs) in forensic DNA analysis.

When identification of a wayward gene is announced on the morning news, the average citizen may expect a cure for the genetic disease to be available that evening. Although knowledge of the chromosomal location and the sequence of genes will result in the rapid development of tests to determine whether an individual carries a defective gene, the development of a treatment for the genetic disease caused by the defective gene is not that easy or that rapid. As outlined in the section on gene therapy, many technical problems need to be solved before gene therapy becomes common. In addition to solving the molecular puzzles involved in gene therapy, we will have to deal with many difficult ethical as well as technical questions.

Is it appropriate to replace defective genes in somatic cells to relieve human suffering? Many people may agree with this goal. But there is a related question: is it appropriate to replace defective genes **in the germ cell line** to relieve human suffering? Fewer people may agree with this goal. Genetic manipulation of somatic cells affects only one generation; these cells die with the individual. Germ cells, however, live on, producing each successive generation.

The techniques developed to explore the human genome could be used for many purposes. What are the limits for the application of the knowledge gained by advances in molecular biology? Who should decide what the limits are, and who should serve as the “genetic police”? If we permit experiments that involve genetic manipulation of the human germ cell line, however nobly conceived, could we, in our efforts to “improve” ourselves, genetically engineer the human race into extinction?

KEY CONCEPTS

- ◆ Techniques for isolating and amplifying genes and studying and manipulating DNA sequences are currently being used in the diagnosis, prevention, and treatment of disease.
- ◆ These techniques require an understanding of the following tools and processes:
 - ◆ Restriction enzymes
 - ◆ Cloning vectors
 - ◆ PCR
 - ◆ Dideoxy DNA sequencing
 - ◆ Gel electrophoresis
 - ◆ Nucleic acid hybridization
 - ◆ Expression vectors
 - ◆ Primer extension
 - ◆ The CRISPR/Cas gene-editing system
- ◆ Recombinant DNA molecules produced by these techniques can be used as diagnostic probes, in gene therapy, or for the large-scale production of proteins for the treatment of disease.
- ◆ Identified genetic polymorphisms, inherited differences in DNA base sequences between individuals, can be utilized for both diagnosis of disease and the generation of an individual’s molecular fingerprint.
- ◆ Genetic treatment of disease is possible, using either gene therapy or gene ablation techniques. Technical difficulties currently restrict the widespread use of these treatments.
- ◆ Proteomics is the study of proteins expressed by a cell. Differences in protein expression between normal and cancer cells can be used to identify potential targets for future therapy.
- ◆ Diseases discussed in this chapter are summarized in Table 16.1.

TABLE 16.1 Diseases Discussed in Chapter 16

DISORDER OR CONDITION	GENETIC OR ENVIRONMENTAL	COMMENTS
-----------------------	--------------------------	----------

Cystic fibrosis	Genetic	Cystic fibrosis is caused by a mutation in the CFTR protein, which is a chloride channel. The most common mutation in the <i>CFTR</i> gene is $\Delta 508$, a triplet deletion that removes codon 508 from the primary sequence. The disease leads to pancreatic duct blockage as well as clogged airways.
Hepatitis B	Environmental	Vaccine development for hepatitis B using molecular genetic techniques to produce recombinant virus proteins
Sickle cell disease	Genetic	The development of genetic testing for sickle cell disease is based on understanding the base change in DNA that leads to the disease, which leads to loss of a restriction endonuclease site in the genome.

CFTR, cystic fibrosis transmembrane conductance regulator.

REVIEW QUESTIONS—CHAPTER 16

- Many molecular techniques utilize electrophoresis of DNA fragments. Electrophoresis resolves double-stranded DNA fragments based on which one of the following?
 - Sequence
 - Molecular weight
 - Isoelectric point
 - Frequency of CTG repeats
 - Secondary structure
- Restriction enzymes can recognize, for the most part, a four-base sequence, a six-base sequence, or an eight-base sequence. If a restriction enzyme recognizes a six-base sequence, how frequently, on average, will this enzyme cut a large piece of DNA?
 - Once every 16 bases
 - Once every 64 bases
 - Once every 256 bases
 - Once every 1,024 bases
 - Once every 4,096 bases
- A forensic scientist is preparing to sequence some DNA found on a victim's clothing. Which one of the following sets of reagents will the technician require in order to carry out the Sanger technique for DNA sequencing? (The lists are not meant to be all-inclusive.)
 - Deoxyribonucleotides, Taq polymerase, DNA primer
 - Dideoxyribonucleotides, deoxyribonucleotides, template DNA
 - Dideoxyribonucleotides, DNA primer, reverse transcriptase
 - Two DNA primers, template DNA, Taq polymerase
 - mRNA, dideoxynucleotides, reverse transcriptase
- Certain diseases, such as fragile X syndrome, are caused by an expansion of triplet repeats within the gene. Which of the following sets of techniques would best enable a rapid determination if such a repeat were present within a gene? Choose the one best answer.
 - PCR, RFLP analysis, but not SNP analysis
 - PCR, RFLP analysis, and SNP analysis
 - RFLP analysis, but not PCR or SNP analysis
 - PCR, but not RFLP analysis or SNP analysis
 - SNP analysis, but not PCR or RFLP analysis
- The best method to determine whether albumin is transcribed in the liver of a mouse model of hepatocarcinoma is which one of the following?
 - Genomic library screening
 - Genomic Southern blot
 - Tissue Northern blot
 - Tissue Western blot

- E. VNTR analysis
6. Individuals metabolize drugs at different rates because of polymorphisms within the drug-metabolizing genes. Which one of the following may be sufficient for testing the presence of such a polymorphism?
 - A. Southern blots, PCR, SNP determinations, but not Northern blots
 - B. Southern blot, PCR, SNP determinations, and Northern blots
 - C. Southern blot, SNP determinations, Northern blot, but not PCR
 - D. Southern blot, Northern blot, PCR, but not SNP determinations
 - E. SNP determinations, but not Northern blot, Southern blot, or PCR
 7. A scientist has cloned the cDNA for a particular gene and wants to analyze tissue expression of the gene by Northern blot analysis. She is surprised to see three positive bands in liver samples but only one band in all other tissues examined. A potential explanation for this finding is which one of the following?
 - A. Liver contains three genes for this particular protein.
 - B. RNA editing
 - C. Posttranslational modifications
 - D. Loss of a restriction endonuclease recognition site in the liver gene
 - E. Alternative splicing
 8. A scientist is attempting to understand the difference in gene expression between a prostate cancer cell and a noncancer prostate cell. A gene chip experiment has identified 245 potential genes as being upregulated in the cancer cell line as compared to the noncancer cell line. Confirmation of this result can be obtained utilizing which one of the following techniques?
 - A. Southern blot
 - B. Northern blot
 - C. SNP analysis
 - D. RFLP analysis
 - E. PCR
 9. When an individual has a test to determine if they have been infected with HIV (the virus that causes AIDS), a Western blot has been used in the past for confirmation purposes. For the Western blot test, which one of the following samples is run through the polyacrylamide gel, the contents of which will be transferred to filter paper for the blotting technique?
 - A. Patient DNA cut with restriction enzymes
 - B. A sample of the patient's blood
 - C. Patient RNA prepared from DNA extracted from red blood cells
 - D. Antibodies against HIV proteins
 - E. Purified HIV proteins
 10. The isolation and use of restriction endonucleases has allowed for a proliferation of techniques to generate recombinant DNA. Which of the following can describe recombinant DNA? Choose the one best answer.

	Recombinant DNA Always Refers to One DNA Molecule Derived from Two or More Different Species	Recombinant DNA Techniques Can Be Used to Generate Therapeutic Proteins	Bacteriophages Were the Source of the First Restriction Enzymes Isolated	Recombinant DNA Has Allowed for Different Types of Insulin to Be Produced, Some Fast Acting, Some Slow Acting	The Use of Gene Therapy Requires the Production of Recombinant DNA Molecules
A	Yes	No	Yes	No	Yes
B	Yes	No	No	No	No
C	Yes	No	Yes	Yes	Yes
D	No	Yes	No	Yes	No
E	No	Yes	No	Yes	Yes
F	No	Yes	Yes	No	No

1. A unique pattern of five SNPs in the human genome has been shown, through GWAS, to be associated with a particular disease. Testing of individuals to see if they contain this pattern of SNPs can be carried out most efficiently by which one of the following techniques?
 - A. CRISPR/Cas
 - B. Northern blot

- C. Primer extension
 - D. Southern blot
 - E. Western blot
2. Genetic techniques that could ablate the expression of a targeted gene include which of the following?
Choose the one best answer.

	CRISPR/ Cas	Primer Extension	Next- generation Sequencing	Small Hairpin RNA	Southern Blot
A	Yes	Yes	No	No	No
B	Yes	No	No	Yes	No
C	Yes	No	No	Yes	Yes
D	No	Yes	Yes	Yes	Yes
E	No	No	Yes	No	No
F	No	Yes	Yes	No	Yes

3. A scientist is studying individuals who express a certain disease. The scientist has a DNA probe to a region of the chromosome linked to the putative disease gene. The scientist can then examine the DNA of individuals with the disease by Southern blot after digesting the DNA with a particular restriction enzyme and compare the results with that of a control individual who is known not to express the disease. The results are shown in the gel below. The differences in the size of the DNA fragments observed are most likely owing to which of the following in this region of the genome?

Control

Patient 1

Patient 2

Patient 3

- A. Deletion
- B. DNA methylation
- C. miRNA expression
- D. SNP

E. VNTR

4. The readout from a Sanger dideoxynucleotide sequencing gel, from the bottom (positive pole) to the top (negative pole) of the gel, corresponds to which one of the following?
 - A. The cloned piece of unknown DNA in the 5'-to-3' direction
 - B. The cloned piece of unknown DNA in the 3'-to-5' direction
 - C. The complement of the cloned piece of DNA in the 5'-to-3' direction
 - D. The complement of the cloned piece of DNA in the 3'-to-5' direction
 - E. The mRNA which would be synthesized from the cloned piece of DNA read in the 5'-to-3' direction
 - F. The mRNA which would be synthesized from the cloned piece of DNA read in the 3'-to-5' direction
5. Major differences between a cDNA library and a genomic library include which of the following? Choose the one best answer.

	Contains Promoter Regions	Contains Exons	Contains Introns	Contains Enhancer Regions
A	cDNA	cDNA	cDNA	cDNA
B	cDNA	Genomic	Genomic	Genomic
C	cDNA	cDNA	cDNA	Genomic
D	Genomic	Genomic	Genomic	cDNA
E	Genomic	cDNA	cDNA	cDNA
F	Genomic	Genomic	Genomic	Genomic

ANSWERS TO REVIEW QUESTIONS

1. **The answer is B.** All DNA fragments are negatively charged and will migrate toward the positive electrode. The only difference between the fragments is their size, and the smaller fragments will move faster than the larger fragments because of their ability to migrate through the gel at a faster rate.
2. **The answer is E.** The enzyme recognizes six bases, and the probability that the correct base is in each position is 1 in 4, so the overall probability is $(\frac{1}{4})^6$ or 1 in 4,096 bases.
3. **The answer is B.** The Sanger technique requires both deoxyribonucleotides and dideoxynucleotides and a template DNA. It does not use Taq polymerase (which is for PCR) nor does it need reverse transcriptase (which is required for producing cDNA from RNA).
4. **The answer is A.** PCR experiments, using primers that flank the repeat area, can determine the number of repeats in a gene as compared to a gene with no or few repeats (the PCR product would be larger for a region containing multiple repeats as compared to a region with few repeats). Similarly, using restriction endonuclease recognition sites that flank the repeat, one will see RFLPs, the length of the restriction fragment being dependent on the number of repeats in the gene. SNP analysis, however, examines SNPs, not multiple triplet repeats, and would not be a suitable method for determining a region of the genome that contained multiple triplet nucleotide repeats. Most individuals will have a certain number of repeats, and PCR and RFLP will enable expanded repeat regions to be distinguished from small repeat regions relatively easily.
5. **The answer is C.** A Northern blot allows one to determine which genes are being transcribed in a tissue at the time of mRNA isolation. The mRNA is run on a gel, transferred to filter paper, and then analyzed with a probe. If albumin is being transcribed, then a probe for albumin should give a positive result in the Northern blot. A library screening will not indicate if a particular gene is being transcribed nor will a

Southern blot. Those techniques will only allow one to determine that the gene is present in the genome. A Western blot analyzes protein content, not mRNA content. Analysis of VNTRs does not provide information about whether a gene is transcribed.

6. **The answer is A.** A polymorphism in the DNA may lead to altered restriction sites, which would be detected by Southern blots. The polymorphism, if it involved expansion of repeat sequences, would be detectable by Southern blots or PCR across the expanded region. Polymorphisms may be as small as a single-nucleotide difference, which would be detectable by SNP analysis. Northern blots are examining the transcript from the genes and would be the least likely technique to provide information concerning the polymorphism. The polymorphism may not be expressed within the exons of the genes, so a Northern blot would not show an extended or truncated mRNA. SNPs would also not be evident in Northern blots.
7. **The answer is E.** Certain primary transcripts have the capability to be spliced in an alternative fashion, depending upon the composition of the spliceosome in the tissues. In this case, the liver can splice in three ways, creating three different-sized transcripts, whereas all other tissues only splice in one way, creating just a single size of the transcript. As the genome is constant for all tissues, if the liver contained three genes for this transcript, the other tissues would as well. RNA editing will alter one base in a transcript but does not alter the overall size of the transcript. Posttranslational modifications occur to proteins after they are synthesized but not to RNA molecules (that would be posttranscriptional modifications). The loss of a restriction endonuclease recognition site within the liver gene would not alter the overall size of the transcript because this would be a mutation in the DNA. It is possible that this change created one alternative splicing event but not the three that are observed via the Northern blot.
8. **The answer is B.** If 245 genes are being upregulated in the cancer cells as compared to the normal cells, the mRNA levels for those 245 genes should be increased in the cancer cells as compared to the nontumor cells. One can therefore perform Northern blots, using cDNA corresponding to the genes as probes, of RNA from nontumor and tumor cells to determine whether mRNA levels actually do increase after transformation. A Southern blot will not show the expression of genes, just that the gene is present in the cells. SNP analysis will determine polymorphisms in DNA but cannot determine gene expression levels. Similarly, RFLP looks at differences in DNA structure but not at gene expression levels. PCR analyzes DNA as well, not gene expression. (Reverse transcription-polymerase chain reaction [RT-PCR], however, in which the mRNA is converted to DNA by reverse transcriptase, can determine mRNA levels between two different samples.)
9. **The answer is E.** The Western blot is used to determine whether a patient contains antibodies against HIV proteins in their blood (which would mean they are infected by HIV). To make this determination, purified HIV proteins are run through a polyacrylamide gel, transferred to filter paper, and the filter paper is blotted with a sample of the patient's blood. If the patient has antibodies to the HIV proteins in their blood, these antibodies will bind to the filter and can be detected by second antibodies, which recognize human antibodies and contain a fluorescent tag for detection. This test does not use DNA or RNA in the gel (a Western blot is the running of proteins through a gel), nor is the patient's blood run through a gel or antibodies to HIV proteins.
10. **The answer is E.** Restriction endonucleases were discovered in bacteria, and they are used to protect the bacteria from invasion by foreign DNA. Recombinant DNA refers to the generation of a piece of DNA from two other pieces of DNA in a test tube, and the DNA can be from the same or different species. Recombinant DNA techniques have been used to generate therapeutic proteins (such as factor VIII, growth hormone, and insulin). The use of recombinant DNA techniques has also allowed variants of therapeutic proteins to be synthesized (such as long- and short-acting variants of insulin). Gene therapy requires the use of recombinant DNA techniques to generate a gene, with appropriate promoter regions, to deliver to cells that have an inability to normally produce the protein encoded by the recombinant DNA.
11. **The answer is C.** SNPs, or single-nucleotide polymorphisms, reflect a difference in a single nucleotide between genomes at the same location in the genome. These are most easily detected by running multiple different primer extension reactions simultaneously, in which the primers used are of different lengths so they can be separated and analyzed by capillary electrophoresis. Each primer will be labeled with a fluorescent dideoxynucleotide, which identifies the SNP. If the appropriate fluorescent-tagged primers are generated in the test, the individual will be identified as containing the pattern of SNPs associated with the disease. CRISPR/Cas is utilized to alter DNA sequences and not to determine the SNP composition of a genome. Western blot analysis detects proteins expressed in a cell, but as SNPs can be in noncoding regions of a genome, protein analysis cannot be associated with the disease being studied. Northern blots analyze RNA separated by size in agarose gels, but as SNPs are not often within genes, such analysis

cannot detect a particular SNP pattern. Southern blots analyze DNA separated by size and can potentially detect SNPs, but it is difficult to design probes to detect a single-nucleotide difference in DNA samples. Primer extension is a much more powerful technique than Southern blot to detect an SNP.

12. **The answer is B.** Both shRNA and CRISPR/Cas techniques can ablate gene expression: CRISPR/Cas at the gene level and shRNA at the transcription/translation level. Primer extension detects SNPs but does not alter gene expression. Next-generation sequencing allows the rapid sequencing of the genome but does not ablate gene expression. Southern blotting allows for the identification of DNA fragments but will not alter gene expression.
13. **The answer is E.** VNTR, or variable number of tandem repeats, could potentially expand a restriction endonuclease fragment, generating an RFLP in this region of the genome. The individual without the disease (Control in the figure) shows a small number of tandem repeats (with the smallest size fragment). The patients with the disease (patients 1, 2, and 3) show an expansion of this region, with larger fragments and slower migrating fragments in the gel. If a deletion led to the disease, the patient's DNA fragments would be smaller than the control DNA. A SNP is a change in a single nucleotide in the genome, and as such would not show variability in restriction fragment size among patients with the disease (because the difference between DNA samples is just a single nucleotide). Even if the mutated allele led to the loss, or gain, of a restriction site, then all the patients would show the same polymorphism and same size restriction fragment. However, what is observed is differing sizes of restriction fragments from each patient with the disease. Southern blots are not utilized to determine alterations in DNA methylation or miRNA expression.
14. **The answer is C.** An unknown piece of single-stranded DNA is placed into a vector, and when using the appropriate primer, DNA is synthesized using dideoxy technology, with the cloned DNA as the template. Thus, the complement of the cloned DNA will be synthesized and read out on the gel which is produced. The 5'-end of the newly synthesized DNA will be the smallest piece of DNA produced, so reading the gel from the bottom to the top will give the sequence in the 5'-to-3' direction. mRNA is not involved in Sanger dideoxy DNA sequencing.
15. **The answer is F.** cDNA libraries are generated from mRNA that lacks promoter regions, introns, and enhancer regions (another regulatory region). A genomic library represents all aspects of DNA structure and includes promoter and enhancer regions, introns, and exons.

The Molecular Biology of Cancer

The term **cancer** applies to a group of diseases in which **cells grow abnormally** and form a **malignant tumor**. Malignant cells can invade nearby tissues and **metastasize** (i.e., travel to other sites in the body, where they establish secondary areas of growth). This aberrant growth pattern results from **mutations in genes that regulate proliferation, differentiation, and survival of cells** in a multicellular organism. Because of these genetic changes, cancer cells no longer respond to the signals that govern growth of normal cells (Fig. 17.1.)

Normal cells

Mutation in proto-oncogene or tumor-suppressor gene

Proliferation of mutated cell

Multiple mutations in proto-oncogenes; mutations in tumor-suppressor genes

Invasion of surrounding tissue

Invasion of blood vessel

Metastasis

FIGURE 17.1 Development of cancer. Accumulation of mutations in a number of genes results in transformation. Cancer cells change morphologically, proliferate, invade other tissues, and metastasize.

Oncogenes and Tumor-Suppressor Genes. The genes involved in the development of cancer are classified as **oncogenes** or **tumor-suppressor genes**. **Oncogenes** are mutated derivatives of normal genes (**proto-oncogenes**), which function to promote proliferation or cell survival. These genes can code for **growth factors, growth-factor receptors, signal transduction proteins, intracellular kinases, and transcription factors**. The process of transformation into a malignant cell may begin with a **gain-of-function** mutation in only one copy of a proto-oncogene. As the mutated cell proliferates, additional mutations can occur. **Tumor-suppressor genes** (normal growth-suppressor genes) encode proteins that **inhibit proliferation, promote cell death, or repair DNA**; both alleles need to be inactivated for transformation (**a loss of function**). Growth-suppressor genes have been called the guardians of the cell.

Cell-Cycle Suppression and Apoptosis. Normal cell growth depends on a balanced regulation of **cell-cycle** progression and **apoptosis** (programmed cell death) by proto-oncogenes and growth-suppressor genes. At **checkpoints** in the **cell cycle**, products of **tumor-suppressor genes** slow growth in response to signals from the cell's environment, including external growth-inhibitory factors, or to allow time for repair of damaged DNA, or in response to other adverse circumstances in cells. Alternatively, cells with damaged DNA are targeted for **apoptosis** so that they will not proliferate. Many growth-stimulatory pathways involving proto-oncogenes, and growth-inhibitory controls involving a variety of tumor-suppressor genes, converge to regulate the activity of some key protein kinases, the **cyclin-dependent kinases (CDKs)**. These kinases act to control progression at specific points in the cell growth cycle. Apoptosis is initiated by either **death-receptor activation** or intracellular signals leading to release of the **mitochondrial protein, cytochrome c**.

Mutations. Mutations in DNA that give rise to cancer may be **inherited** or may be caused by **chemical carcinogens, radiation, viruses**, and by **replication errors** that are not repaired. A cell population must accumulate **multiple mutations** for transformation to malignancy.

Treatment. Cancer has been treated through a variety of approaches, including surgery, chemotherapy, and most recently molecular analysis of an individual's cancer cells such that a personalized treatment plan can be developed. Molecular techniques (as described in the previous chapter) are more frequently being used to attack cancer at the molecular level.

THE WAITING ROOM

Mannie W. has chronic myelogenous leukemia (CML), a disease in which a single line of myeloid cells in the bone marrow proliferates abnormally, causing a large increase in the number of nonlymphoid white blood cells (see Chapter 15). His myeloid cells contain the abnormal Philadelphia chromosome, which increases their proliferation. He has recently complained of pain and tenderness in various areas of his skeleton, possibly stemming from the expanding mass of myeloid cells within his bone marrow. He also reports a variety of hemorrhagic signs, including bruises (ecchymoses), bleeding gums, and the appearance of small red spots (petechiae caused by release of red cells into the skin).

Patients with leukemia can experience a variety of hemorrhagic (bleeding) manifestations caused by a decreased number of platelets. Platelets are small cells that initiate clot formation at the site of endothelial injury. Because of the uncontrolled proliferation of white cells within the limited space of the marrow, the normal platelet precursor cells (the megakaryocytes) in the marrow are “squeezed” or crowded and fail to develop into mature platelets. Consequently, the number of mature platelets (thrombocytes) in the circulation falls, and a thrombocytopenia develops. Because there are fewer platelets to contribute to clot formation, bleeding problems are common.

Michael T. was diagnosed with a poorly differentiated adenocarcinoma of the lung (see Chapter 12) after resection of a nodule very concerning for malignancy seen on a computed tomography (CT) scan of his chest.

He survived the surgery and was recovering uneventfully until 6 months later, when he complained of an increasingly severe right temporal headache. A CT scan of his brain was performed. Results indicated that the cancer, which had originated in his lungs, had metastasized to his brain.

Clark T. has had an intestinal adenocarcinoma resected, as well as several small metastatic nodules in his liver (see Chapter 11). He completed his second course of chemotherapy with 5-fluorouracil (5-FU) and oxaliplatin and had no serious side effects. He assured his physician at his most recent checkup that, this time, he intended to comply with any instructions his physicians gave him. He ruefully commented that he wished he had returned for regular examinations after his first colonoscopy.

Calvin A. returned to his physician after observing a brownish-black irregular mole on his forearm (see Chapter 12). His physician thought the mole looked suspiciously like a malignant melanoma, so referred him to a dermatologist, who performed an excision biopsy (surgical removal for cytological analysis).

I. Causes of Cancer

The term **cancer** applies to a group of diseases in which cells grow abnormally and form a malignant tumor. Malignant cells can invade nearby tissues and metastasize (i.e., travel to other sites in the body where they establish secondary areas of growth). This aberrant growth pattern results from mutations in genes that regulate proliferation, differentiation, and survival of cells in a multicellular organism. Because of these genetic changes, cancer cells no longer respond to the signals that govern growth of normal cells.

Malignant neoplasms (new growth, a tumor) of epithelial cell origin (including the intestinal lining, cells of the skin, and cells lining the airways of the lungs) are called carcinomas. If the cancer grows in a gland-like pattern, it is an adenocarcinoma. Thus, **Michael T.** and **Clark T.** have adenocarcinomas. **Calvin A.** had a carcinoma arising from melanocytes, which is technically a melanocarcinoma but is usually referred to as a melanoma.

Normal cells in the body respond to signals, such as cell–cell contact (contact inhibition), that direct them to stop proliferating. Cancer cells do not require growth-stimulatory signals, and they are resistant to growth-inhibitory signals. They are also resistant to apoptosis, the programmed cell death process whereby unwanted or irreparably damaged cells self-destruct. They have an infinite proliferative capacity and do not become senescent (i.e., they are immortalized). Furthermore, they can grow independent of structural support, such as the extracellular matrix (loss of anchorage dependence).

The study of cells in culture was, and continues to be, a great impetus for the study of cancer. Tumor development in animals can take months, and it was difficult to do experiments with tumor growth in animals. Once cells could be removed from an animal and propagated in a tissue culture dish, the onset of transformation (the normal cell becoming a cancer cell) could be seen in days.

Once cells were available to study, it was important to determine the criteria that distinguish transformed cells from normal cells in culture. Three criteria were established. The first is the requirement for serum in the cell culture medium to stimulate cell growth. Serum is the liquid fraction of clotted blood and contains many factors that stimulate cell proliferation. Transformed cells have, in general, a reduced requirement for serum: approximately 10% that is required for normal cells to grow. The second criterion is the ability to grow without attachment to a supporting matrix (anchorage dependence). Normal cells (such as fibroblasts or smooth muscle cells) require adherence to a substratum (in this case, the bottom of the plastic dish) and will not grow if suspended in a soft agar mixture. Transformed cells, however, have lost this anchorage dependence. The third and most stringent criterion used to demonstrate that cells are truly transformed is the ability of cells to form tumors when they are injected into mice that lack an immune system. Transformed cells will do so, whereas normal cells will not.

Drs. Michael Bishop and Harold Varmus demonstrated that cancer is not caused by unusual and novel genes, but rather by mutation within existing cellular genes, and that for every gene that causes cancer (an **oncogene**), there is a corresponding cellular gene, called the **proto-oncogene**. Although this concept seems straightforward today, it was a significant finding when it was first announced and, in 1989, Drs. Bishop and Varmus were awarded the Nobel Prize in Medicine.

Moles (also called nevi) are tumors of the skin. They are formed by melanocytes that have been transformed from highly

dendritic single cells interspersed among other skin cells to round oval cells that grow in aggregates or “nests.” Melanocytes produce the dark pigment melanin, which protects against sunlight by absorbing UV light. Additional mutations may transform the mole into a malignant melanoma.

A single cell that divides abnormally eventually forms a mass called a tumor. A tumor can be benign and harmless; the common wart is a benign tumor formed from a slowly expanding mass of cells. In contrast, a malignant neoplasm (malignant tumor) is a proliferation of rapidly growing cells that progressively infiltrate, invade, and destroy surrounding tissue. Tumors develop angiogenic potential, which is the capacity to form new blood vessels and capillaries. Thus, tumors can generate their own blood supply to bring in oxygen and nutrients. Cancer cells also can metastasize, separating from the growing mass of the tumor and traveling through the blood or lymph to unrelated organs, where they establish new growths of cancer cells.

The first experiments to show that oncogenes were mutant forms of proto-oncogenes in human tumors involved cells cultured from a human bladder carcinoma. The DNA sequence of the *ras* oncogene cloned from these cells differed from the normal *c-ras* proto-oncogene. Similar mutations were subsequently found in the *ras* gene of lung and colon tumors. **Clark T.**'s malignant polyp had a mutation in the *ras* proto-oncogene.

The transformation of a normal cell to a cancer cell begins with damage to DNA (base changes or strand breaks) caused by chemical carcinogens, UV light, viruses, or replication errors (see Chapter 12). Mutations result from the damaged DNA if it is not repaired properly or if it is not repaired before replication occurs. A mutation that can lead to transformation also may be inherited. When a cell with one mutation proliferates, this clonal expansion (proliferation of cells arising from a single cell) results in a substantial population of cells containing this one mutation, from which one cell may acquire a second mutation relevant to control of cell growth or death. With each clonal expansion, the probability of another transforming mutation increases. As mutations accumulate in genes that control proliferation, subsequent mutations occur even more rapidly, until the cells acquire the multiple mutations (in the range of four to seven) necessary for full transformation.

The transforming mutations occur in genes that regulate cellular proliferation and differentiation (proto-oncogenes), suppress growth (tumor-suppressor genes), target irreparably damaged cells for apoptosis, or repair damaged DNA. The genes that regulate cellular growth are called proto-oncogenes, and their mutated forms are called oncogenes. The term **oncogene** is derived from the Greek word “onkos,” meaning bulk or tumor. A transforming mutation in a proto-oncogene increases the activity or amount of the gene product (a gain-of-function mutation). Tumor-suppressor genes (normal growth-suppressor genes) and repair enzymes protect against uncontrolled cell proliferation. A transforming mutation in these protective genes results in a loss of activity or a decreased amount of the gene product.

In summary, cancer is caused by the accumulation of mutations in the genes involved in normal cellular growth and differentiation. These mutations give rise to cancer cells that are capable of unregulated, autonomous, and infinite proliferation. As these cancer cells proliferate, they impinge upon normal cellular functions, leading to the symptoms exhibited by individuals with the tumors.

II. Damage to DNA Leading to Mutations

A. Chemical and Physical Alterations in DNA

An alteration in the chemical structure of DNA, or of the sequence of bases in a gene, is an absolute requirement for the development of cancer. The function of DNA depends on the presence of various polar chemical groups in DNA bases, which are capable of forming hydrogen bonds between DNA strands or other chemical reactions. The oxygen and nitrogen atoms in DNA bases are targets for a variety of electrophiles (electron-seeking chemical groups). A typical sequence of events leading to a mutation is shown for dimethylnitrosamine in Figure 17.2. Chemical carcinogens (compounds that can cause transforming mutations) found in the environment and ingested in foods are generally stable lipophilic compounds that, like dimethylnitrosamine, must be activated by metabolism in the body to react with DNA (see also benz[*a*]pyrene, Action of Mutagens, Chapter 12, Section III.A, and Fig. 12.12). Many chemotherapeutic agents, which are designed to kill proliferating cells by interacting with DNA, may also act as carcinogens and cause new mutations and tumors while eradicating the old. Structural alterations in DNA also occur through radiation and through UV light, which causes the formation of pyrimidine dimers. More than 90% of skin cancers occur in sunlight-exposed areas. UV rays derived from the sun induce an increased incidence of all skin cancers, including squamous cell carcinoma, basal cell carcinoma, and malignant melanoma of the skin. The wavelength

of UV light that is most associated with skin cancer is UVB (280 to 320 nm), which forms pyrimidine dimers in DNA. This type of DNA damage is repaired by nucleotide excision repair pathways that require products of at least 20 genes. With excessive exposure to the sun, the nucleotide excision repair pathway is overwhelmed, and some damage remains unrepaired.

FIGURE 17.2 Mutations in DNA caused by nitrosamines. Nitrosamines are consumed in many natural products and are produced in the stomach from nitrites used as preservatives and secondary amines found in foods such as fish. They are believed to be responsible for the high incidence of gastric cancer in Japan and Iceland, where salt-preserved fish is a major dietary item. Nitrosamine metabolites methylate guanine (the transferred methyl group is shown in red).

Each chemical carcinogen or reactant creates a characteristic modification in a DNA base. The DNA damage, if not repaired, introduces a mutation into the next generation when the cell proliferates.

B. Gain-of-Function Mutations in Proto-oncogenes

Proto-oncogenes are converted to oncogenes by mutations in the DNA that cause a gain in function; that is, the protein can now function in the absence of the normal activating events. Several mechanisms that lead to the conversion of proto-oncogenes to oncogenes are known:

- Radiation and chemical carcinogens act (1) by causing a mutation in the regulatory region of a gene, increasing the rate of production of the proto-oncogene protein, or (2) by producing a mutation in the coding portion of the oncogene that results in the synthesis of a protein of slightly different amino acid composition capable of transforming the cell (Fig. 17.3A).

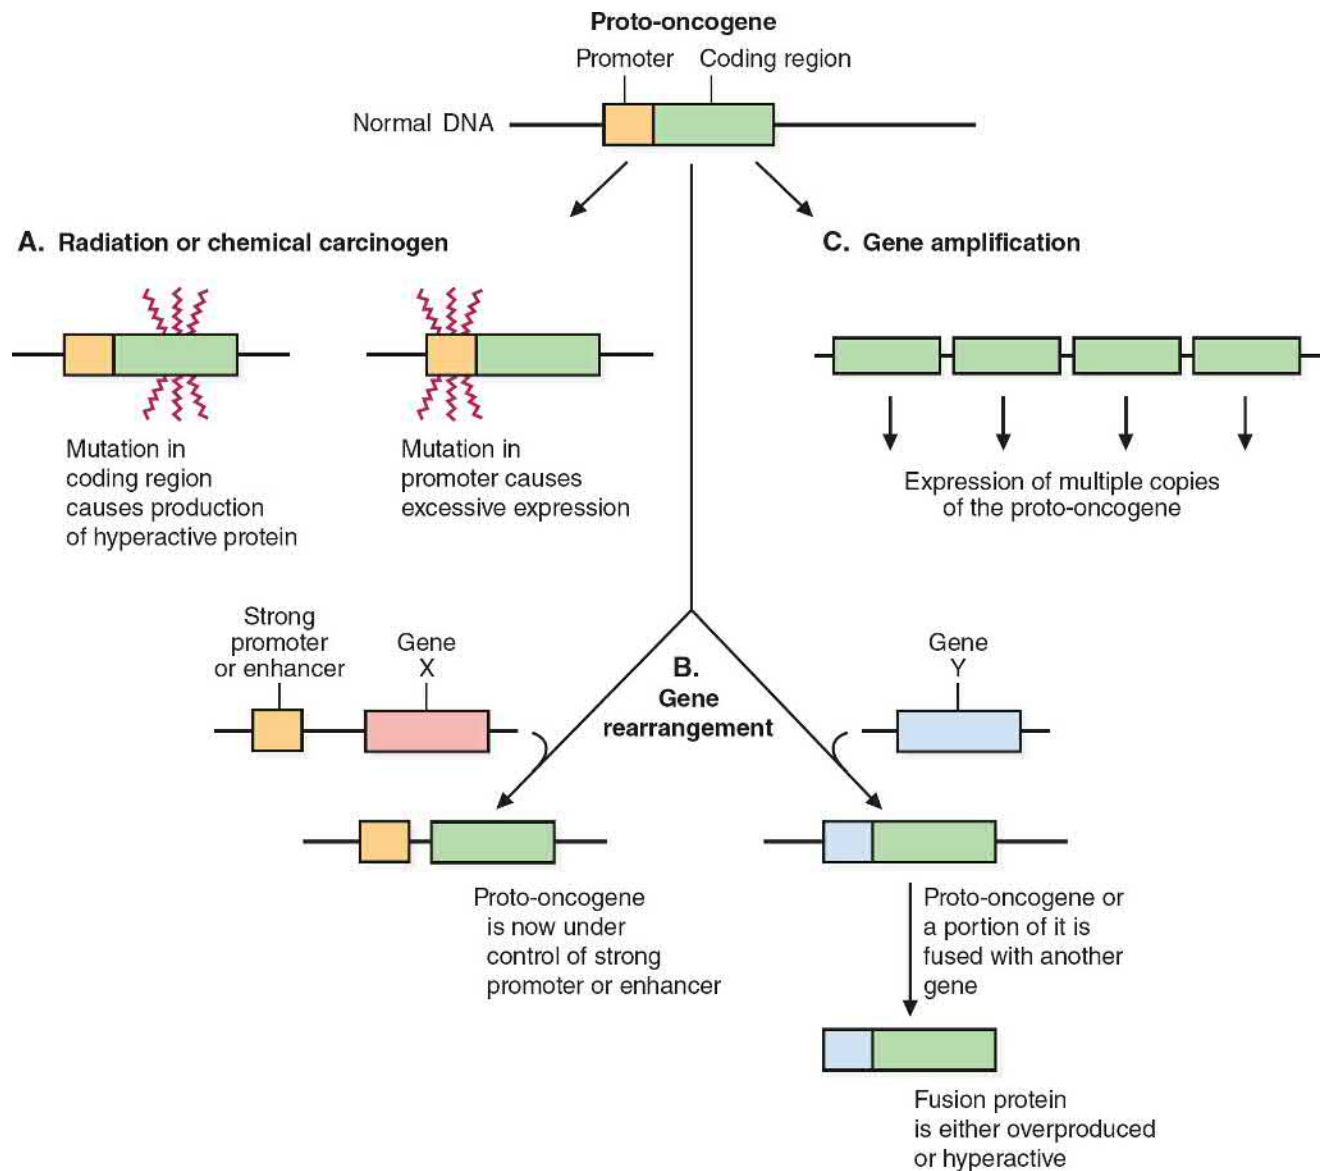

FIGURE 17.3 Transforming mutations in proto-oncogenes. **A.** Effect of radiation or chemical carcinogens on proto-oncogenes or their promoters. The mutations may be point mutations, deletions, or insertions. **B.** Gene rearrangements as caused by transposition or translocation of a proto-oncogene or proto-oncogene fragment. **C.** Amplification of a proto-

oncogene allows more protein to be produced.

- The entire proto-oncogene or a portion of it may be transposed or translocated, that is, moved from one position in the genome to another (see Fig. 17.3B). In its new location, the proto-oncogene may be under the control of a promoter that is regulated differently than the promoter that normally regulates this gene. This may allow the gene to be expressed in a tissue where it is not normally expressed or at higher-than-normal levels of expression. If only a portion of the proto-oncogene is translocated, it may be expressed as a truncated protein with altered properties, or it may fuse with another gene and produce a fusion protein containing portions of what are normally two separate proteins. The truncated or fusion protein may be hyperactive and cause inappropriate cell growth.
- The proto-oncogene may be amplified (see Fig. 17.3C), so that multiple copies of the gene are produced in a single cell. If more genes are active, more proto-oncogene proteins will be produced, increasing the growth rate of the cells. As examples, the oncogene N-myc (a cell proliferation transcription factor, related to c-myc) is amplified in some neuroblastomas, and amplification of the erb-B2 oncogene (a growth-factor receptor) is associated with several breast carcinomas.
- If an oncogenic virus infects a cell, its oncogene may integrate into the host-cell genome, permitting production of the abnormal oncogene protein. The cell may be transformed and exhibit an abnormal pattern of growth. Rather than inserting an oncogene, a virus may simply insert a strong promoter into the host-cell genome. This promoter may cause increased or untimely expression of a normal proto-oncogene.

Burkitt lymphoma is a B-cell malignancy, which usually results from a translocation between chromosomes 8 and 14. The translocation of genetic material moves the proto-oncogene transcription factor *c-myc* (normally found on chromosome 8) to another chromosome, usually chromosome 14. The translocated gene is now under the control of the promoter region for the immunoglobulin heavy-chain gene, which leads to inappropriate and overexpression of *c-myc*. The result may be uncontrolled cell proliferation and tumor development. All subtypes of Burkitt lymphoma contain this translocation. EBV infection of B-cells is also associated with certain types of Burkitt lymphoma.

The important point to remember is that transformation results from abnormalities in the normal growth-regulatory program caused by gain-of-function mutations in proto-oncogenes. However, loss-of-function mutations also occur in the tumor-suppressor genes, repair enzymes, or activators of apoptosis, and a combination of both types of mutations is usually required for full transformation to a cancer cell.

C. Mutations in Repair Enzymes

Repair enzymes are the first line of defense preventing conversion of chemical damage in DNA to a mutation (see Chapter 12, Section III.B). DNA repair enzymes are tumor-suppressor genes in the sense that errors repaired before replication do not become mutagenic. DNA damage is constantly occurring from exposure to sunlight, background radiation, toxins, and replication errors. If DNA repair enzymes are absent, mutations accumulate much more rapidly, and once a mutation develops in a growth-regulatory gene, a cancer may arise. As an example, inherited mutations in the tumor-suppressor genes *BRCA1* and *BRCA2* predispose women to the development of breast cancer (see Biochemical Comments at the end of this chapter). The protein products of these genes play roles in DNA repair, recombination, and regulation of transcription. A second example, HNPCC (**h**ereditary **n**onpolyposis **c**olorectal **c**ancer), was introduced in Chapter 12. It results from inherited mutations in enzymes involved in the DNA mismatch repair system.

Mannie W.'s bone marrow cells contain the Philadelphia chromosome, typical of chronic myelogenous leukemia (CML). The Philadelphia chromosome results from a reciprocal translocation between the long arms of chromosome 9 and 22. As a consequence, a fusion protein is produced that contains the N-terminal region of the Bcr protein from chromosome 22 and the C-terminal region of the Abl protein from chromosome 9. *Abl* is a proto-oncogene, and the resulting fusion protein (Bcr-Abl) has lost its regulatory region and is constitutively active, resulting in deregulated tyrosine kinase activity. When it is active, Abl stimulates the Ras pathway of signal transduction, leading to cell proliferation.

III. Oncogenes

Proto-oncogenes control normal cell growth and division. These genes encode proteins that are growth factors, growth-factor receptors, signal transduction proteins, transcription factors, cell-cycle regulators, and regulators of apoptosis (Table 17.1). (The name representing the gene of an oncogene is referred to in lowercase letters and italics [e.g., *myc*], but the name of the protein product is capitalized and italics are not used [e.g., *Myc*].)

The mutations in oncogenes that give rise to transformation are usually gain-of-function mutations; either a more active protein is produced or an increased amount of the normal protein is synthesized.

CLASS	PROTO-ONCOGENE	ACTIVATION MECHANISM	LOCATION	DISEASE
<i>Growth factors</i>				
Platelet-derived growth-factor β -chain	<i>sis</i>	Overexpression	Secreted	Glioma
Fibroblast growth factors	<i>int-2</i>	Amplification	Secreted	Fibrosarcoma Breast cancer Bladder cancer Melanoma

	<i>Myc</i>	Translocation	Nucleus	Burkitt lymphoma
		Amplification	Nucleus	Neuroblastoma, small-cell carcinoma of the lung
	<i>fos, jun</i>	Phosphorylation	Nucleus	Osteosarcoma, sarcoma
<i>Apoptosis regulators</i>				
	<i>Bcl-2</i>	Translocation	Mitochondria	Follicular B-cell lymphoma
<i>Cell-cycle regulators</i>				
Cyclins (example is Cyclin D)	<i>CcnD1</i>	Translocation	Nucleus	Lymphoma
		Amplification	Nucleus	Breast, liver, esophageal cancers
Cyclin-dependent kinase	<i>CDK4</i>	Amplification	Nucleus	Glioblastoma, sarcoma
		Point mutation	Nucleus	Melanoma

The table is not meant to be all-inclusive; only examples of each class of gene are presented.

MicroRNAs (miRNAs) can also behave as oncogenes. If a miRNA is overexpressed (increased function), it can act as an oncogene if its target (which would exhibit reduced expression under these conditions) is a protein, which is involved in inhibiting, or antagonizing, cell proliferation.

A. Oncogenes and Signal Transduction Cascades

All of the proteins in growth-factor signal transduction cascades are coded for by proto-oncogenes (Fig. 17.4).

FIGURE 17.4 Proto-oncogene sites for transforming mutations in growth-factor signaling pathways. (I) The amount of growth factor. (II) The receptor, which normally must bind the growth factor to dimerize and activate a kinase domain. (III) Signal transduction proteins. Some, such as PI 3-kinase, form second messengers. (IV) G-proteins, and their regulators, which are also signal transduction proteins. (V) Nonreceptor protein kinase cascades, which lead to phosphorylation of transcription factors. (VI) Nuclear transcription factors that are normally activated through phosphorylation or binding of a ligand.

 The gene for the human epidermal growth-factor receptor (*HER2*, *c-erbB-2*) is overexpressed in about 20% of breast cancer cases. Several drugs have been developed that recognize and blocks the receptor's action. The drug most studied, trastuzumab (Herceptin), has been shown to have survival benefits when used in combination with other chemotherapy. However, some tumors that overexpress *HER2* show resistance to herceptin. Thus, it appears that a complete genotyping of breast cancer cells is necessary (using the microarray or RNA-SEQ techniques described in Chapter 16) to develop an effective therapy for each patient with the disease, leading to personalized, individualized therapy.

1. Growth Factors and Growth-Factor Receptors

The genes for both growth factors and growth-factor receptors are proto-oncogenes.

Growth factors generally regulate growth by serving as ligands that bind to cellular receptors located on the plasma membrane (cell-surface receptors) (see Chapter 10). Binding of ligands to these receptors stimulates a signal transduction pathway in the cell that activates the transcription of certain genes. If too much of a growth factor or a growth-factor receptor is produced, the target cells may respond by proliferating inappropriately. Growth-factor receptors may also become oncogenic through translocation or point mutations in domains that affect binding of the growth factor, dimerization, kinase activity, or some other aspect of their signal transmission. In such cases, the receptor transmits a proliferative signal even though the growth factor normally required to activate the receptor is absent. In other words, the receptor is stuck in the “on” position.

2. Signal Transduction Proteins

The genes that encode proteins involved in growth-factor signal transduction cascades may also be proto-oncogenes. Consider, for example, the monomeric G-protein Ras. Binding of growth factor leads to the activation of Ras (see Fig. 10.17). When Ras binds guanosine triphosphate (GTP), it is active, but Ras slowly inactivates itself by hydrolyzing its bound GTP to guanosine diphosphate (GDP) and inorganic phosphate (P_i). This controls the length of time that Ras is active. Ras is converted to an oncogenic form by point mutations that decrease the activity of the GTPase domain of Ras, thereby increasing the length of time it remains in the active form.

Ras, when it is active, activates the serine–threonine kinase Raf (a mitogen-activated protein [MAP] kinase kinase kinase), which activates MEK (a MAP kinase kinase), which activates MAP kinase (Fig. 17.5). Activation of MAP kinase results in the phosphorylation of cytoplasmic and nuclear proteins, followed by increased transcription of the transcription-factor proto-oncogenes *myc* and *fos* (see below). Note that mutations in the genes for any of the proteins that regulate MAP kinase activity, as well as those proteins induced by MAP kinase activation, can lead to uncontrolled cell proliferation.

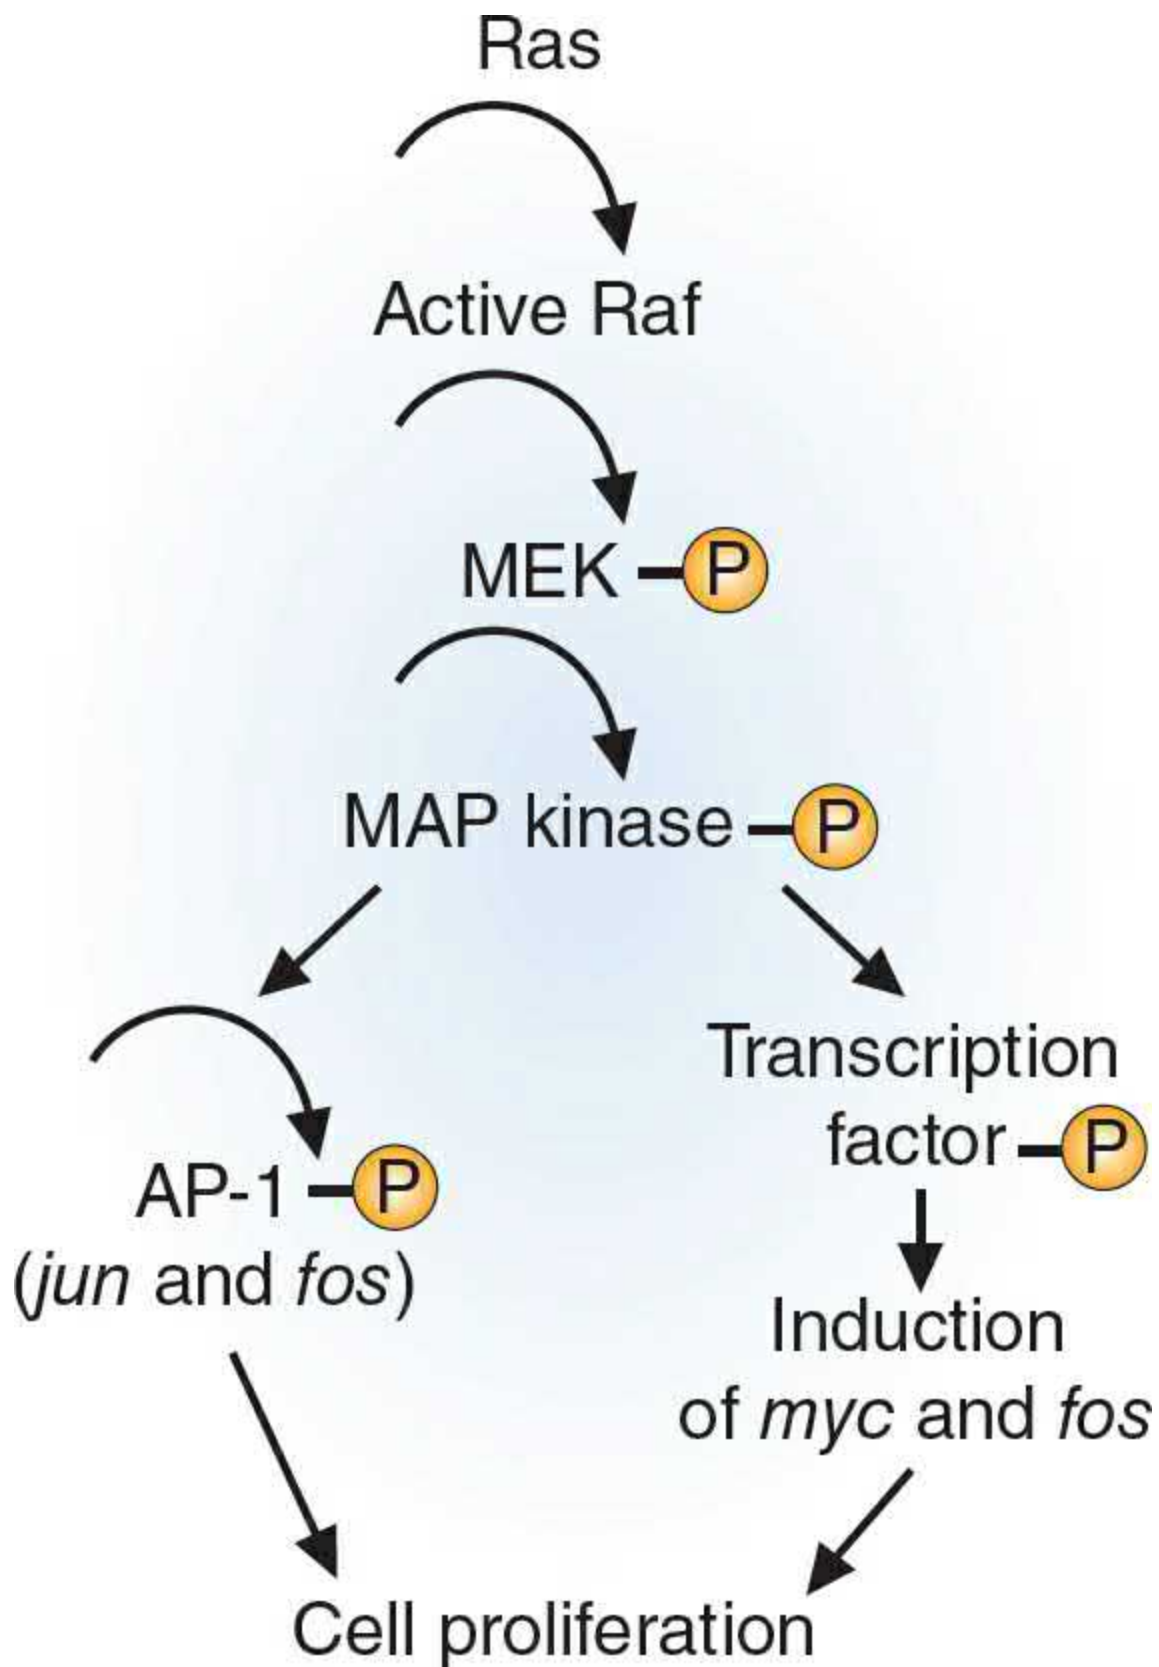

FIGURE 17.5 Phosphorylation cascade leading to activation of proto-oncogene transcription factors *myc*, *fos*, and *jun*.

3. Transcription Factors

Many transcription factors, such as Myc and Fos, are proto-oncoproteins (the products of proto-oncogenes). MAP kinase, in addition to inducing *myc* and *fos*, also directly activates the AP-1 transcription factor through phosphorylation (see Fig. 17.5). AP-1 is a heterodimer formed by the protein products of the *fos* and *jun*

families of proto-oncogenes. The targets of AP-1 activation are genes involved in cellular proliferation and progression through the cell cycle, as are the targets of the *myc* transcription factor. The synthesis of the transcription factor *c-myc* is tightly regulated in normal cells, and it is expressed only during the S phase of the cell cycle. In a large number of tumor types, this regulated expression is lost, and *c-myc* becomes inappropriately expressed or overexpressed throughout the cell cycle, driving cells continuously to proliferate.

The net result of alterations in the expression of transcription factors is the increased production of the proteins that carry out the processes required for proliferation.

B. Oncogenes and the Cell Cycle

Growth factors, hormones, and other messengers activate the growth of human cells, involving DNA replication and cell division in the cell cycle. These activators work through cyclins and CDKs that control progression from one phase of the cycle to another (Fig. 17.6). For quiescent cells to proliferate, they must leave G_0 and enter the G_1 phase of the cell cycle (see Chapter 12, Fig. 12.7). If the proper sequence of events occurs during G_1 , the cells enter the S phase and are committed to DNA replication and cell division. Similarly, during G_2 , cells make a commitment to mitotic division. CDKs are made continuously throughout the cell cycle but require binding of a specific cyclin to be active. Different cyclins made at different times in the cell-cycle control each of the transitions (G_1/S , S/G_2 , G_2/M).

FIGURE 17.6 Cyclin synthesis during different phases of the cell cycle.

The activity of the cyclin-CDK complex is further regulated through phosphorylation and through inhibitory proteins called **cyclin-dependent kinase inhibitors** (CKIs) (Fig. 17.7). CKIs slow cell-cycle

progression by binding and inhibiting the CDK–cyclin complexes. CDKs are also controlled through activating phosphorylation by CAK (cyclin-activating kinases) and inhibitory hyperphosphorylation kinases.

FIGURE 17.7 Cyclin-dependent kinase inhibitor (CKI) inhibition of cyclin/cyclin-dependent kinase (CDK) activity.

To illustrate the role of these proteins, consider some of the events that occur at the G_1/S checkpoint (Fig. 17.8). Because the cell is committed to DNA replication and division once it enters the S phase, multiple regulatory proteins are involved in determining whether the cell is ready to pass this checkpoint. These regulatory proteins include *cdk4* and *cdk6* (which are constitutively produced throughout the cell cycle), cyclin D (whose synthesis is induced only after growth-factor stimulation of a quiescent cell), the retinoblastoma gene product (Rb), and a class of transcription factors known collectively as E2F. In quiescent cells, Rb is complexed with E2F, resulting in inhibition of these transcription factors. Upon growth-factor stimulation, the cyclin Ds are induced (there are three types of cyclin D: D1, D2, and D3). They bind to *cdk4* and *cdk6*, converting them to active protein kinases. One of the targets of cyclin/cdk phosphorylation is the Rb protein. Phosphorylation of Rb releases it from E2F, and E2F is then free to activate the transcription of genes required for entry into S. The Rb protein is a tumor-suppressor gene (more below).

FIGURE 17.8 Control of the G_1/S transition in the cell cycle. The genes that encode cyclins and CDKs are oncogenes, and the gene that encodes the retinoblastoma protein (Rb) is a tumor-suppressor gene. CDK, cyclin-dependent kinase; CKI, cyclin-dependent kinase inhibitor.

The proteins induced by E2F include cyclin E, cyclin A, cdc25A (an activating protein phosphatase), and proteins required to bind at origins of replication to initiate DNA synthesis. The synthesis of cyclin E allows it to complex with cdk2, forming another active cyclin complex that retains activity into S phase (see Fig. 17.6). One of the major functions of the cyclin E1–cdk2 complex is hyperphosphorylation of the Rb protein, thereby keeping Rb in its inactive state. Cyclin A also complexes with cdk2, and it phosphorylates, and inactivates, the E2F family of transcription factors. This ensures that the signals are not present for extended periods of time. Thus, each phase of the cell cycle activates the next through cyclin synthesis. The cyclins are removed by regulated proteolysis.

In addition to sunlight and a pre-existing nevus, hereditary factors also play a role in the development of malignant melanoma. Ten percent of melanomas tend to run in families. Some of the suspected melanoma-associated genes include the tumor-suppressor gene *p16* (an inhibitor of cdk4) and CDK4. **Calvin A.** was the single child of parents who had died of a car accident in their 50s, and thus, a familial tendency could not be assessed.

Progression through the cell cycle is opposed by the CKIs (see Fig. 17.8). The CKIs regulating cyclin/cdk expression in the G_1 phase of the cell cycle fall into two categories: the Cip/Kip family and the INK4 family. The Cip/Kip family members (p21, p27, and p57) have a broad specificity and inhibit all cyclin–CDK complexes. The INK4 family, which consists of p15, p16, p17, and p19, are specific for the cyclin D–cdk4/6 family of complexes (**in**hibitors of cyclin-dependent **k**inase-**4**). The regulation of synthesis of different CKIs is complex, but some are induced by DNA damage to the cell and halt cell-cycle progression until the damage can be repaired. For example, the CKI p21 (a protein of 21,000 daltons) is a key member of this group that responds to specific signals to block cell proliferation. If the damage cannot be repaired, an apoptotic pathway is selected and the cell dies.

IV. Tumor-Suppressor Genes

Like the oncogenes, the tumor-suppressor genes encode molecules involved in the regulation of cell proliferation. Table 17.2 provides several examples. The normal function of tumor-suppressor proteins is generally to inhibit proliferation in response to certain signals such as DNA damage. The signal is removed when the cell is fully equipped to proliferate; the effect of the elimination of tumor-suppressor genes is to remove the brakes on cell growth. They affect cell-cycle regulation, signal transduction, transcription, and cell adhesion. The products of tumor-suppressor genes frequently modulate pathways that are activated by the products of proto-oncogenes.

CLASS	PROTEIN	LOCATION	ASSOCIATED DISEASES
Adhesion protein receptor	E-cadherin	Cell membrane	Stomach cancer
	Patched	Cell membrane	Basal cell carcinoma
	TGF- β receptor	Cell membrane	Colon cancer
Signal transduction	NF-1	Under cell membrane	Neurofibrosarcoma
	SMAD4/DPC	Cytoplasm/nucleus	Pancreatic and colorectal cancers
Transcription factor cell-cycle regulator	WT-1	Nucleus	Wilms tumor
	p16(INK4)	Nucleus	Melanoma, lung, pancreatic cancers
	Retinoblastoma	Nucleus	Retinoblastoma, sarcomas
Cell cycle/apoptosis	p53	Nucleus	Most cancers
DNA repair	BRCA 1	Nucleus	Breast cancer

Tumor-suppressor genes contribute to the development of cancer when both copies of the gene are inactivated. This is different from the case of proto-oncogene mutations because only one allele of a proto-oncogene needs to be converted to an oncogene to initiate transformation. As with the oncogenes, this is also applicable to miRNAs. If the expression of a particular miRNA is lost, the mRNA it regulates would be overexpressed, which could lead to enhanced cellular proliferation. Thus, miRNAs can be classified as either oncogenes (overexpression) or tumor suppressors (loss of function), depending upon the genes, which they regulate.

A. Tumor-Suppressor Genes That Regulate the Cell Cycle Directly

The two best-understood cell-cycle regulators that are also tumor suppressors are the retinoblastoma (*RB1*) and *p53* genes.

1. The Retinoblastoma (*RB*) gene

As discussed previously, the retinoblastoma gene (*RB* or *RB1*) product, Rb, functions in the transition from G₁ to S phase and regulates the activation of members of the E2F family of transcription factors (see Fig. 17.8). If an individual inherits a mutated copy of the *RB1* allele, there is a 100% chance of that individual developing retinoblastoma, because of the high probability that the second allele of *RB1* will gain a mutation (Fig. 17.9). This is considered familial retinoblastoma. Individuals who do not inherit mutations in *RB1*, but who develop retinoblastoma, are said to have sporadic retinoblastoma, and acquire two specific mutations, one in each *RB1* allele of the retinoblast, during their lifetime.

FIGURE 17.9 Mutations in the retinoblastoma (Rb) gene. **A.** Sporadic retinoblastoma. **B.** Familial retinoblastoma.

Inheritance of a mutation in *p53* leads to Li-Fraumeni syndrome, which is characterized by multiple types of tumors. Mutations in *p53* are present in more than 50% of human tumors. These are secondary mutations within the cell, and if *p53* is mutated, the overall rate of cellular mutation will increase because there is no *p53* to check for DNA damage, to initiate the repair of the damaged DNA, or to initiate apoptosis if the damage is not repaired. Thus, damaged DNA is replicated, and the frequency of additional mutations within the same cell increases remarkably.

2. *P53*, The Guardian of the Genome

The *p53* protein is a transcription factor that regulates the cell cycle and apoptosis, programmed cell death. Loss of both *p53* alleles is found in more than 50% of human tumors. *p53* acts as the “guardian of the genome” by halting replication in cells that have suffered DNA damage and targeting unrepaired cells to apoptosis.

In response to DNA-damaging mutagens, ionizing radiation, or UV light, the level of *p53* rises (Fig. 17.10, circle 1). *p53*, acting as a transcription factor, stimulates transcription of *p21* (a member of the Cip/Kip family of CKIs), as shown in Figure 17.10, circle 2. The *p21* gene product inhibits the cyclin–CDK complexes, which prevents the phosphorylation of Rb and release of E2F proteins. The cell is thus prevented from entering S phase. *p53* also stimulates the transcription of a number of DNA repair enzymes (including GADD45, growth arrest, and DNA damage) (Fig. 17.10, circle 3). If the DNA is successfully repaired, *p53* induces its own downregulation, through the activation of the *mdm2* gene. If the DNA repair was not successful, *p53* activates a number of genes involved in apoptosis, including *bax* (discussed below) and *insulin-like growth factor-binding protein 3* (*IGF-BP3*) (Fig. 17.10, circle 4). The IGF-BP3 protein product binds the receptor for insulin-like growth factor, which presumably induces apoptosis by blocking the anti-apoptotic signaling by growth factors, and the cell enters a growth factor deprivation mode.

FIGURE 17.10 p53 and cell-cycle arrest. Mechanisms that recognize DNA damage stop p53 degradation and modify the p53 protein (circle 1). p53 stimulates the transcription of p21 (circle 2) and GADD45 (circle 3). p21 blocks the cyclin/CDK phosphorylation of Rb, which continues to inhibit the E2F family of transcription factors, thereby blocking cell progression through the cell cycle. GADD45 allows the DNA damage to be repaired. If the damage is not repaired, apoptotic genes are activated (circle 4).

B. Tumor-Suppressor Genes That Affect Receptors and Signal Transduction

Tumor-suppressor genes may encode receptors, components of the signaling transduction pathway, or transcription factors.

1. Regulators of RAS

The Ras family of proteins is involved in signal transduction for many hormones and growth factors (see above) and is, therefore, oncogenic. The activity of these pathways is interrupted by GAPs (GTPase-activating proteins; see Chapter 9, Section III.C.2), which vary among cell types. Neurofibromin, the product of the tumor-suppressor gene *NF-1*, is a nervous system-specific GAP that regulates the activity of Ras in neuronal tissues. The growth signal is transmitted so long as the Ras protein binds GTP. Binding of NF-1 to Ras activates the GTPase domain of Ras, which hydrolyzes GTP to GDP, thereby inactivating Ras. Without a functional neurofibromin molecule, Ras is perpetually active.

 An inherited mutation in *NF-1* can lead to neurofibromatosis, a disease primarily of numerous benign, but painful, tumors of the nervous system. The movie *Elephant Man* was based on an individual who was believed to have this disease. Recent analysis of the patient's remains, however, indicates that he may have suffered from the rare Proteus syndrome, not neurofibromatosis.

2. Patched and Smoothened

A good example of tumor suppressors and oncogenes working together is provided by the coreceptor genes *patched* and *smoothened*, which encode the receptor for the hedgehog class of signaling peptides. (The strange names of some of the tumor-suppressor genes arose because they were first discovered in *Drosophila* [fruit fly], and the names of *Drosophila* mutations are often based on the appearance of a fly that expresses the mutation. Once the human homolog is found, it is given the same name as the *Drosophila* gene.) These coreceptors normally function to control growth during embryogenesis and illustrate the importance of maintaining a balance between oncogenes and tumor-suppressor genes. The Patched receptor protein inhibits Smoothened, its coreceptor protein. Binding of a hedgehog ligand to Patched releases the inhibition of Smoothened, which then transmits an activating signal to the nucleus, stimulating new gene transcription (Fig. 17.11). *Smoothened* is a proto-oncogene, and *patched* is a tumor-suppressor gene. If *patched* loses its function (definition of a tumor suppressor), then Smoothened can signal the cell to proliferate, even in the absence of a hedgehog signal. Conversely, if *smoothened* undergoes a gain-of-function mutation (definition of an oncogene), it can signal in the absence of the hedgehog signal, even in the presence of Patched. Inherited mutations in either *smoothened* or *patched* will lead to an increased incidence of basal cell carcinoma.

FIGURE 17.11 The Patched/Smoothened signaling system. **A.** In the absence of a hedgehog (HH) signal, Smoothened is inactive due to inhibition by the HH receptor Patched, and the GL1 transcription-factor complex acts as a repressor of transcription. **B.** When a ligand binds to the Patched receptor, the inhibition of Smoothened is repressed, leading to an activation of the GL1 complex, and active transcription of the target genes.

C. Tumor-Suppressor Genes That Affect Cell Adhesion

The cadherin family of glycoproteins mediates calcium-dependent cell–cell adhesion. Cadherins form intercellular complexes that bind cells together (Fig. 17.12A). They are anchored intracellularly by catenins,

which bind to actin filaments. Loss of E-cadherin (epithelial cell cadherin) expression may contribute to the ability of cancer cells to detach and migrate in metastasis. Individuals who inherit a mutation in E-cadherin (this mutation is designated CDH1) are sharply predisposed to developing diffuse-type gastric cancer.

A. Catenins and cadherins in cell attachment

B. β -Catenin and APC in gene transcription

FIGURE 17.12 A. Catenins and cadherins. E-cadherin molecules form intercellular, calcium-dependent homodimers with cadherins from another cell, resulting in cell–cell adhesion. The cytoplasmic portion of E-cadherin is complexed to a variety of catenins, which anchor the cadherin to the actin cytoskeleton. **B.** β -Catenin and APC in transcription. The APC complex activates β -catenin for proteolytic degradation. If APC is inactivated, β -catenin levels increase. It acts as a transcription factor that increases synthesis of *myc* and other genes that regulate cell-cycle progression.

The catenin proteins have two functions: In addition to anchoring cadherins to the cytoskeleton, they act as transcription factors (see Fig. 17.12B). β -Catenin also binds to a complex that contains the regulatory protein APC (adenomatous polyposis coli), which targets it for degradation. When the appropriate signal inactivates APC, β -catenin levels increase, and it travels to the nucleus, where it activates *myc* and *cyclin D1* transcription, leading to cell proliferation. APC is a tumor-suppressor gene. If it is inactivated, it cannot bind β -catenin and inhibit cell proliferation. Mutations in APC or proteins that interact with it are found in the vast majority of sporadic human colon cancer. Inherited mutations in APC lead to one of the most common forms of hereditary colon cancer, familial adenomatous polyposis (FAP).

D. Tumor-Suppressor Genes Linked to DNA Repair

Hereditary nonpolyposis colon cancer (HNPCC) and hereditary breast cancer both result from inherited mutations in genes involved in DNA repair.

1. Hereditary Nonpolyposis Colon Cancer

HNPCC is estimated to account for between 1% and 3% of all colon cancer cases. These syndromes are heterogenous, due, most likely, to the finding that mutations in any of five genes could lead to colon cancer. The disease genes include hMSH2, hMLH1, hPMS1, hPMS2, and hMSH6. These genes all play a role in DNA mismatch repair, and all act as tumor suppressors (a loss of function is required for the tumor to develop).

It is important to understand that the lack of a DNA mismatch repair enzyme actually does not directly lead to cancer (e.g., such as an activating mutation in *myc* would do). However, the lack of a functional mismatch repair system increases the frequency at which new mutations are introduced into somatic cells (particularly rapidly proliferating cells, such as the colonic epithelium), such that eventually, a mutation will result in a gene necessary for proper growth control. Once that mutation occurs, tumors can begin to develop.

2. Hereditary Breast Cancer

Five to ten percent of all breast cancer cases have been traced to inherited mutations in either one of two genes, *BRCA1* and *BRCA2*. *BRCA1* maps to chromosome 17 and acts as a tumor suppressor. The biochemical function of *BRCA1* is to participate in the response to DNA damage. *BRCA1* is phosphorylated by a variety of kinases, each of which is activated by a different form of DNA damage. *BRCA1* is primarily involved in repairing double-strand breaks in DNA, and in transcription-coupled repair. Once *BRCA1* is phosphorylated, it will signal for cell cycle arrest, to allow the DNA damage to be repaired.

Women who carry a *BRCA1* mutation have a 55% to 65% risk of developing breast cancer, and about a 40% risk of ovarian cancer, by the age of 70. Men who carry *BRCA1* mutations have been shown to have a slight increase in breast cancer and prostate cancer.

The other gene involved in hereditary breast cancer is *BRCA2*, located on chromosome 13. *BRCA2* is required for DNA double-strand break repair, which is usually caused by ionizing radiation. As such, loss of *BRCA2* activity is required for cancer to develop, classifying *BRCA2* as a tumor suppressor. *BRCA2* is also required for homologous recombination between sister chromatids during meiosis and mitosis. *BRCA2* mutations have also been linked to increased incidence of breast and ovarian cancer in women, and breast cancer and prostate cancer in men. *BRCA1* and *BRCA2* mutations account for about 20% to 25% of all hereditary breast cancer cases.

An understanding of the roles of *BRCA1* and *BRCA2* in repairing double-strand breaks in DNA has led to the development of poly-ADP-ribose polymerase (PARP-1) inhibitors for the treatment of *BRCA1*- or *BRCA2*-induced breast cancers. Double-strand break repair occurs either by homologous recombination (requiring the activities of *BRCA1* and *BRCA2* proteins) or through non homologous end joining (NHEJ), which is an error-prone process, due to trimming of the DNA ends before ligation (see Figs. 12.19 and 12.20).

Single-strand breaks in DNA are more common than double-strand breaks. The cellular mechanism for repairing single-strand breaks is dependent on PARP-1. PARP-1 produces large branched chains of poly (ADP-ribose) (derived from NAD^+) at the site of damage, which acts as a docking station for proteins involved in

repairing the single-strand break. Inhibiting PARP-1 would lead to an accumulation of single-strand breaks in the DNA.

PARP-1 inhibitors are effective in killing *BRCA1* or *BRCA2* mutated cells in that when single-strand breaks are not repaired, they often are converted to double-strand breaks when the replisome tries to replicate through the break. In a cell lacking *BRCA1* or *BRCA2* activity, the only way the DNA can be repaired is by NHEJ, which is an error-prone process. This leads to the cells accumulating a large number of mutations, eventually leading to cell death. Cells with functional *BRCA1* or *BRCA2* activity will not undergo that fate. Drugs that inhibit PARP-1 activity in cell culture are now in clinical trials, with very promising results. A PARP-1 inhibitor was approved by the FDA in 2018 for treatment of women with germline *BRCA* mutations who exhibited a particular subset of breast cancer. The PARP inhibitors have also been approved for the treatment of *BRCA* mutated ovarian cancers.

V. Cancer and Apoptosis

In the body, superfluous or unwanted cells are destroyed by a pathway called **apoptosis**, or programmed cell death. Apoptosis is a regulated energy-dependent sequence of events by which a cell self-destructs. In this suicidal process, the cell shrinks, the chromatin condenses, and the nucleus fragments. The cell membrane forms blebs (outpouches), and the cell breaks up into membrane-enclosed apoptotic vesicles (apoptotic bodies) containing varying amounts of cytoplasm, organelles, and DNA fragments. Phosphatidylserine, a lipid on the inner leaflet of the cell membrane, is exposed on the external surface of these apoptotic vesicles. It is one of the phagocytic markers recognized by macrophages and other nearby phagocytic cells that engulf the apoptotic bodies.

Apoptosis is a normal part of multiple processes in complex organisms: embryogenesis, the maintenance of proper cell number in tissues, the removal of infected or otherwise injured cells, the maintenance of the immune system, and aging. It can be initiated by injury, radiation, free radicals or other toxins, withdrawal of growth factors or hormones, binding of pro-apoptotic cytokines, or interactions with cytotoxic T-cells in the immune system. Apoptosis can protect organisms from the negative effects of mutations by destroying cells with irreparably damaged DNA before they proliferate. Just as an excess of a growth signal can produce an excess of unwanted cells, the failure of apoptosis to remove excess or damaged cells can contribute to the development of cancer.

A. Normal Pathways to Apoptosis

Apoptosis can be divided into three general phases: an initiation phase, a signal integration phase, and an execution phase. Apoptosis can be initiated by external signals that work through death receptors, such as tumor necrosis factor (TNF), or deprivation of growth hormones (Fig. 17.13). It can also be initiated by intracellular events that affect mitochondrial integrity (e.g., oxygen deprivation, radiation), and irreparably damaged DNA. In the signal integration phase, these **pro-apoptotic** signals are balanced against **anti-apoptotic** cell-survival signals by several pathways, including members of the **Bcl-2 family of proteins**. Apoptosis is only initiated when the signals from pro-apoptotic factors override the anti-apoptotic factors in the cell. The execution phase of apoptosis is carried out by proteolytic enzymes called **caspases**.

FIGURE 17.13 Major components in apoptosis. The release of cytochrome c from mitochondria, or activation of death receptors, can both lead to the initiation of apoptosis.

The human death-receptor family consists of the TNF-receptor 1, CD95, death receptor 3 (DD3), TNF-related apoptosis-inducing ligand receptor 1 (TRAIL-R1), and TRAIL-R2. Ligands for death receptors are TNF, CD95-ligand, TLIA (binds to DD3), and TRAIL. The ligands are produced by natural killer T-cells or macrophages.

1. Caspases

Caspases are cysteine proteases that cleave peptide bonds next to an aspartate residue. They are present in the cell as procaspases, zymogen-type enzyme precursors that are activated by proteolytic cleavage of the inhibitory portion of their polypeptide chain. The different caspases are generally divided into two groups according to their function: initiator caspases, which specifically cleave other procaspases, and execution caspases, which cleave other cellular proteins involved in maintaining cellular integrity (see Fig. 17.13). The initiator caspases are activated through two major signaling pathways: the death-receptor pathway and the mitochondrial integrity pathway. They activate the execution caspases, which cleave protein kinases involved in cell adhesion, lamins that form the inner lining of the nuclear envelope, actin and other proteins required for cell structure, and DNA repair enzymes. They also cleave an inhibitor protein of the endonuclease CAD (caspase-activated DNase), thereby activating CAD to initiate the degradation of cellular DNA. With destruction of the nuclear envelope, additional endonucleases (Ca^{2+} - and Mg^{2+} -dependent) also become activated.

2. The Death-Receptor Pathway to Apoptosis

The death receptors are a subset of TNF-1 receptors, which includes Fas/CD95, TNF-receptor 1 (TNF-R1), and death receptor 3 (DR3). These receptors form a trimer that binds TNF-1 or another death ligand on its external domain and binds adaptor proteins to its intracellular domain (Fig. 17.14). The activated TNF-receptor complex forms the scaffold for binding two molecules of procaspase 8 (or procaspase 10), which autocatalytically cleave each other to form active dimeric caspase 8 (or caspase 10). Caspases 8 and 10 are initiator caspases that activate execution caspases 3, 6, and 7. Caspase 3 also cleaves a Bcl-2 family member protein, Bid, to a form (tBid) that activates the mitochondrial integrity pathway to apoptosis.

FIGURE 17.14 The death-receptor pathway to apoptosis. The ligand (either a free ligand or a cell surface-associated protein from another cell) binds to the death receptor, which makes a scaffold for autocatalytic activation of caspase 8 (and sometimes 10). Active dimeric caspase 8 (and sometimes 10) cleaves apoptotic execution caspases directly. However, the pathway also

activates the Bcl-2 family member Bid, which acts on mitochondrial membrane integrity. tBid, truncated Bid.

3. The Mitochondrial Integrity Pathway to Apoptosis

Apoptosis is also induced by intracellular signals indicating that cell death should occur. Examples of these signals include growth factor withdrawal, cell injury, the release of certain steroids, and an inability to maintain low levels of intracellular calcium. All of these treatments, or changes, lead to release of cytochrome c from the mitochondria (Fig. 17.15). Cytochrome c is a necessary protein component of the mitochondrial electron transport chain that is loosely bound to the outside of the inner mitochondrial membrane. Its release initiates apoptosis.

FIGURE 17.15 The mitochondrial integrity pathway releases cytochrome c, which binds to apaf and forms a multimeric complex called the apoptosome. The apoptosome converts procaspase 9 to active caspase 9, an initiator caspase, which is released by the apoptosome into the cytosol. ATP, adenosine triphosphate.

In the cytosol, cytochrome c binds apaf (pro-apoptotic protease-activating factor). The apaf/cytochrome c complex binds caspase 9, an initiator caspase, to form an active complex called the **apoptosome**. The apoptosome, in turn, activates execution caspases (3, 6, and 7) by zymogen cleavage.

4. Integration of Pro- and Anti-apoptotic Signals by the BCL-2 Family of Proteins

The Bcl-2 family members are decision makers that integrate pro-death and anti-death signals to determine whether the cell should commit suicide. Both pro-apoptotic and anti-apoptotic members of the *Bcl-2* family exist (Table 17.3). Bcl-2 family members contain regions of homology, known as Bcl-2 homology (BH) domains. There are four such domains. The anti-apoptotic factors (known as guardians) contain all four domains (BH1 to BH4). The channel-forming pro-apoptotic factors (known as effectors) contain just three domains (BH1 to BH3), whereas the pro-apoptotic BH3 only family members (known as initiators) contain just one BH domain, BH-3.

Roughly 30 Bcl-2 family members are currently known. These proteins play tissue-specific as well as signal pathway-specific roles in regulating apoptosis. The tissue specificity is overlapping. For example, Bcl-2 is expressed in hair follicles, kidney, small intestines, neurons, and the lymphoid system, whereas Bcl-x is expressed in the nervous system and hematopoietic cells. BH-3 only proteins will interact with both the effectors to initiate apoptosis, or with the guardians, which blocks apoptosis.

The anti-apoptotic *Bcl-2*-type proteins (including Bcl-2, Bcl-xL, and Bcl-W) have at least two ways of antagonizing death signals. They insert into the outer mitochondrial membrane to antagonize channel-forming pro-apoptotic factors, thereby decreasing cytochrome c release. They may also bind cytoplasmic apaf so that it cannot form the apoptosome complex (Fig. 17.16).

FIGURE 17.16 Roles of the Bcl-2 family members in regulating apoptosis. Bcl-2, which is anti-apoptotic, binds Bid (or tBid) and blocks formation of channels that allow cytochrome c release from the mitochondria. Death signals result in activation of a BH3-only protein such as Bid, which can lead to mitochondrial pore formation, swelling, and release of cytochrome c. Bid binds to and activates the membrane ion-channel pro-apoptotic protein Bax, activating cytochrome c release, which binds to apaf and leads to formation of the apoptosome.

These anti-apoptotic Bcl-2 proteins are opposed by pro-apoptotic family members that fall into two categories: the effectors (ion channel-forming members) and the initiators (BH3-only members). The pro-death ion channel-forming members, such as Bax, are very similar to the anti-apoptotic family members, except that they do not contain the binding domain for apaf. They have the other structural domains, however, and when they dimerize with pro-apoptotic BH3-only members in the outer mitochondrial membrane, they form an ion channel that promotes cytochrome c release rather than inhibiting it (see Fig. 17.16). The pro-death BH3-only proteins (e.g., Bim and Bid) contain only the structural domain that allows them to bind to other Bcl-2 family members (the BH3 domain), and not the domains for binding to the membrane, forming ion channels, or binding to apaf. Their binding activates the pro-death family members and inactivates the anti-apoptotic members. When the cell receives a signal from a pro-death agonist, a BH3 protein-like Bid is activated (see Fig. 17.16). The BH3 protein activates Bax (an ion channel-forming pro-apoptotic channel member), which stimulates release of cytochrome c. Normally, Bcl-2 acts as a death antagonist by binding apaf and keeping it in an inactive state. However, at the same time that Bid is activating Bax, Bid also binds to Bcl-2, thereby disrupting the Bcl-2/apaf complex and freeing apaf to bind to released cytochrome c to form the apoptosome.

When *Bcl-2* is mutated and oncogenic, it is usually overexpressed, for example, in follicular lymphoma and CML. Overexpression of *Bcl-2* disrupts the normal regulation of pro- and anti-apoptotic factors and tips the balance to an anti-apoptotic stand. This leads to an inability to destroy cells with damaged DNA, such that mutations can accumulate within the cell. *Bcl-2* is also a multidrug-resistant transport protein and if it is overexpressed, it will block the induction of apoptosis by antitumor agents by rapidly removing them from the cell. Thus, strategies are being developed to reduce *Bcl-2* levels in tumors that overexpress it before initiating drug or radiation treatment.

B. Cancer Cells Bypass Apoptosis

Apoptosis should be triggered by a number of stimuli, such as withdrawal of growth factors, elevation of p53 in response to DNA damage, monitoring of DNA damage by repair enzymes, or release of TNF or other immune factors. However, mutations in oncogenes can create apoptosis-resistant cells.

One of the ways this occurs is through activation of growth-factor-dependent signaling pathways that inhibit apoptosis, such as the PDGF/Akt/BAD pathway. Nonphosphorylated BAD acts like Bid in promoting apoptosis (see Fig. 17.16). Binding of the platelet-derived growth factor to its receptor activates PI-3 kinase, which phosphorylates and activates the serine-threonine kinase Akt (protein kinase B, see Chapter 10, Section XII.B.3). Activation of Akt results in the phosphorylation of the pro-apoptotic BH3-only protein BAD, which inactivates it. The PDGF/Akt/BAD pathway illustrates the requirement of normal cells for growth-factor

stimulation to prevent cell death. One of the features of neoplastic transformation is the loss of growth-factor dependence for survival. The MAP kinase pathway is also involved in regulating apoptosis and sends cell-survival signals. MAP kinase kinase phosphorylates and activates another protein kinase known as RSK. Like Akt, RSK phosphorylates BAD and inhibits its activity. Thus, BAD acts as a site of convergence for the PI-3 kinase/Akt and MAP kinase pathways in signaling cell survival. Gain-of-function mutations in the genes that control these pathways, such as *ras*, create apoptosis-resistant cells.

C. MicroRNAs and Apoptosis

Recent work has identified a number of miRNAs, which regulate apoptotic factors. Bcl-2, for example, is regulated by at least 2 miRNAs, designated as miR-15 and miR-16. Expression of these miRNAs will control Bcl-2 (an anti-apoptotic factor) levels in the cell. If, for any reason, the expression of these miRNAs is altered, Bcl-2 levels will also be altered, promoting either apoptosis (if Bcl-2 levels decrease) or cell proliferation (if Bcl-2 levels increase). Loss of both of these miRNAs is found in 68% of chronic lymphocytic leukemia cells (CLL), most often due to a deletion on chromosome 13, band 14 on the long arm (q14). Loss of miR-15 and 16 expression would lead to an increase in Bcl-2 levels, favoring increased cell proliferation.

Other miRNA species have been identified, which regulate factors involved in apoptosis. miR-21 regulates the expression of the programmed cell death 4 gene (*PDCD4*). *PDCD4* is upregulated during apoptosis and functions to block translation. Loss of miR-21 activity would lead to cell death, as *PDCD4* would be overexpressed. However, overexpression of miR-21 would be anti-apoptotic, as *PDCD4* expression would be ablated.

The miR-17 cluster regulates the protein kinase B/akt pathway by modulating the levels of PTEN (the enzyme that converts PIP_3 to PIP_2), as well as the levels of the E2F family of transcription factors. An upregulation of miR-17, acting as an oncogene, would decrease PTEN levels such that cellular proliferation is favored over apoptosis, due to the constant activation of the akt pathway.

VI. Cancer Requires Multiple Mutations

Cancer takes a long time to develop in humans because multiple genetic alterations are required to transform normal cells into malignant cells (see Fig. 17.1). A single change in one oncogene or tumor-suppressor gene in an individual cell is not adequate for transformation. For example, if cells derived from biopsy specimens of normal cells are not already “immortalized,” that is, able to grow in culture indefinitely, addition of the *ras* oncogene to the cells is not sufficient for transformation. However, additional mutations in a combination of oncogenes, for example, *ras* and *myc*, can result in transformation (Fig. 17.17). Epidemiologists have estimated that four to seven mutations are required for normal cells to be transformed.

Metastasis

FIGURE 17.17 Possible steps in the development of colon cancer. The changes do not always occur in this order, but the most benign tumors have the lowest frequency of mutations, and the most malignant have the highest frequency.

Cells accumulate multiple mutations through clonal expansion. When DNA damage occurs in a normally proliferative cell, a population of cells with that mutation is produced. Expansion of the mutated population enormously increases the probability of a second mutation in a cell containing the first mutation. After one or more mutations in proto-oncogenes or tumor-suppressor genes, a cell may proliferate more rapidly in the presence of growth stimuli and with further mutations grow autonomously, that is, independent of normal growth controls. Enhanced growth increases the probability of further mutations. Some families have a strong predisposition to cancer. Individuals in these families have inherited a mutation or deletion of one allele of a tumor-suppressor gene, and as progeny of that cell proliferate, mutations can occur in the second allele, leading to a loss of control of cellular proliferation. These familial cancers include familial retinoblastoma, familial adenomatous polyps of the colon, and multiple endocrine neoplasia (MEN), one form of which involves tumors of the thyroid, parathyroid, and adrenal medulla (MEN type II).

Studies of benign and malignant polyps of the colon show that these tumors have a number of different genetic abnormalities. The incidence of these mutations increases with the level of malignancy. In the early stages, normal cells of the intestinal epithelium proliferate, develop mutations in the *APC* gene, and polyps develop (see Fig. 17.17). This change is associated with a mutation in the *ras* proto-oncogene that converts it into an active oncogene. Progression to the next stage is associated with a deletion or alteration of a tumor-suppressor gene on chromosome 5. Subsequently, mutations occur in chromosome 17, inactivating a gene that may be involved in cell adhesion, and in chromosome 17, inactivating the *p53* tumor-suppressor gene. The cells become malignant, and further mutations result in growth that is more aggressive and metastatic. This sequence of mutations is not always followed precisely, but an accumulation of mutations in these genes is found in a large percentage of colon carcinomas.

 **Michael T.** had been smoking for 40 years before he developed lung cancer. The fact that cancer takes so long to develop has made it difficult to prove that the carcinogens in cigarette smoke cause lung cancer. Studies in England and Wales show that cigarette consumption by men began to increase in the early 1900s. Followed by a 20-year lag, the incidence in lung cancer in men also began to rise. Women began smoking later, in the 1920s. As before, the incidence of lung cancer began to increase after a 20-year lag.

VII. At the Molecular Level, Cancer Is Many Different Diseases

More than 20% of the deaths in the United States each year are caused by cancer, with tumors of the lung, large intestine, and the breast being the most common (Fig. 17.18). Different cell types typically use different mechanisms through which they lose the ability to control their own growth. An examination of the genes involved in the development of cancer shows that a particular type of cancer can arise in multiple ways. For example, Patched and Smoothened are the receptor and coreceptor for the signaling peptide, sonic hedgehog. Either mutation of *smoothened*, an oncogene, or inactivation of *patched*, a tumor-suppressor gene, can give rise to basal cell carcinoma. Similarly, transforming growth factor β and its signal transduction proteins SMAD4/DPC are part of the same growth-inhibiting pathway, and either may be absent in colon cancer. Thus, treatments that are successful for one patient with colon cancer may not be successful in a second patient with colon cancer because of the differences in the molecular basis of each individual's disease (this now appears to be the case with breast cancer as well). Medical practice is now embracing personalized medicine, which requires identifying the molecular lesions involved in a particular disease and developing appropriate treatments accordingly. The use of proteomics, RNA-SEQ, and gene chip technology (see Chapter 16) to genotype tumor tissues, and to understand which proteins they express, will aid greatly in allowing patient-specific treatments to be developed and implemented.

**2014 Estimated cancer deaths, United States
percent distribution of sites by sex**

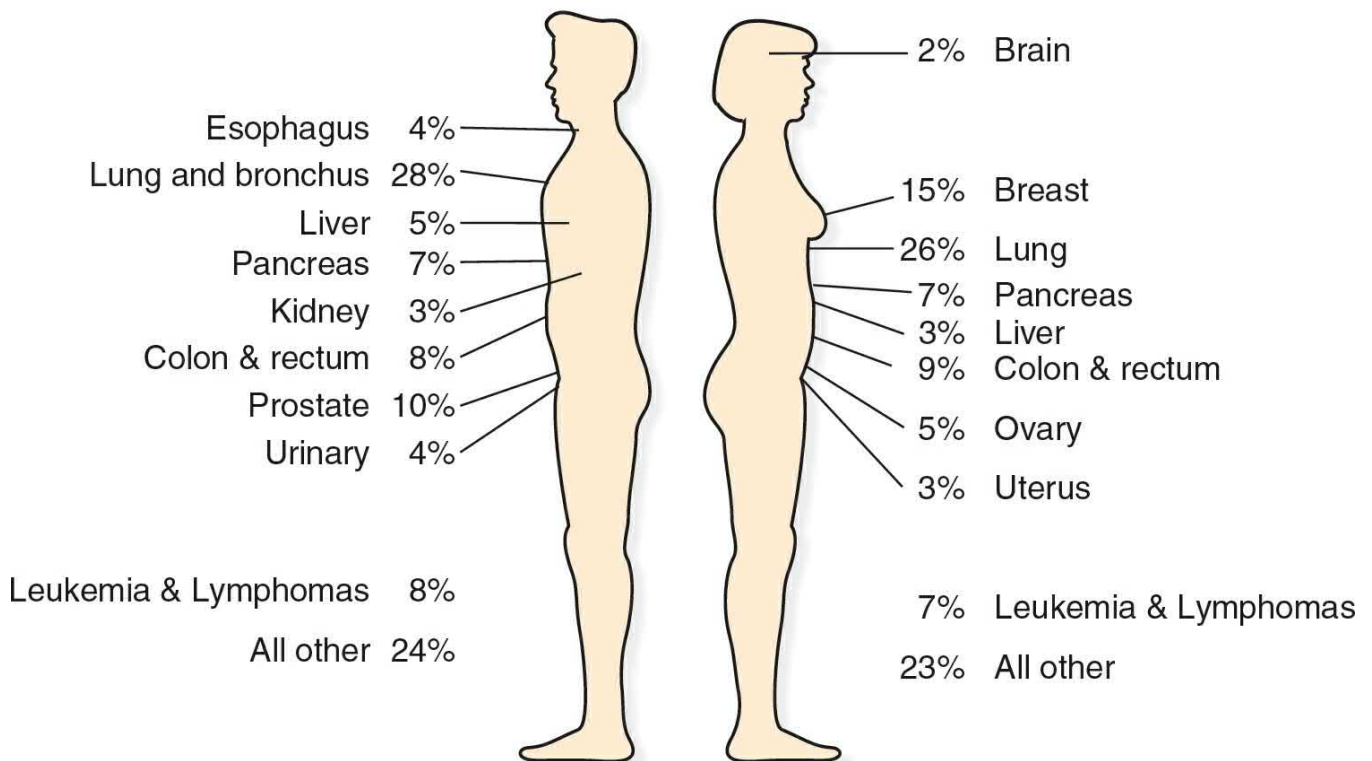

FIGURE 17.18 Estimated cancer deaths by site and sex. (Data from The American Cancer Society, Inc. *Cancer Facts and Figures*, 2019; www.cancer.org/research/cancerfactsstatistics/cancerfactsfigures2019/)

A treatment for CML based on rational drug design has been developed. The fusion protein Bcr-Abl is found only in transformed cells that express the Philadelphia chromosome and not in normal cells. Once the structure of Bcr-Abl was determined, the drug imatinib (Gleevec) was designed to specifically bind to and inhibit only the active site of the fusion protein and not the normal protein. Imatinib was successful in blocking Bcr-Abl function, thereby stopping cell proliferation, and in some cells inducing apoptosis, so the cells would die. Because normal cells do not express the hybrid protein, they were not affected by the drug. The problem with this treatment is that some patients suffered relapses, and when their Bcr-Abl proteins were studied, it was found that in some patients, the fusion protein had a single amino acid substitution near the active site that prevented imatinib from binding to the protein. Other patients had an amplification of the Bcr-Abl gene product. Other tyrosine kinase inhibitors (such as dasatinib and nilotinib) can also be used in treating CML if a resistance to Gleevec is encountered.

VIII. Viruses and Human Cancer

Three RNA retroviruses are associated with the development of cancer in humans: human T-lymphotrophic virus type 1 (HTLV-1), HIV, and hepatitis C. There are also DNA viruses associated with cancer, such as hepatitis B, Epstein-Barr virus (EBV), human papillomavirus (HPV), and Herpesvirus (HHV-8).

HTLV-1 causes adult T-cell leukemia. The HTLV-1 genome encodes a protein Tax, which is a transcriptional coactivator. The cellular proto-oncogenes *c-sis* and *c-fos* are activated by Tax, thereby altering the normal controls on cellular proliferation and leading to malignancy. Thus, *tax* is a viral oncogene without a counterpart in the host-cell genome.

Infection with HIV, the virus that causes acquired immunodeficiency disease (AIDS), leads to the development of neoplastic disease through several mechanisms. HIV infection leads to immunosuppression and, consequently, loss of immune-mediated tumor surveillance. Individuals with HIV are predisposed to non-Hodgkin lymphoma, which results from an overproduction of T-cell lymphocytes. The HIV genome encodes a protein, Tat, a transcription factor that activates transcription of the *interleukin-6* (IL-6) and *interleukin-10* (IL-10) genes in infected T-cells. IL-6 and IL-10 are growth factors that promote proliferation of T-cells, and thus, their increased production may contribute to the development of non-Hodgkin lymphoma. Tat can also be released from infected cells and act as an angiogenic (blood vessel-forming) growth factor. This property is thought to contribute to the development of Kaposi sarcoma.

DNA viruses also lead to human cancer, but by different mechanisms. Chronic hepatitis B infections will lead to hepatocellular carcinoma. A vaccine currently is available to prevent hepatitis B infections. EBV is associated with B- and T-cell lymphomas, Hodgkin disease, and other tumors. The EBV encodes a Bcl-2-like-protein that restricts apoptosis of the infected cell. HHV-8 has been associated with Kaposi sarcoma. Certain strains of papillomavirus are the major cause of cervical cancer, and a vaccine has been developed against those specific papillomavirus strains.

CLINICAL COMMENTS

Mannie W. The treatment of a symptomatic patient with CML whose white blood cell count is in excess of 50,000 cells/mL is initiated with a tyrosine kinase inhibitor (TKI). If one type is not tolerated or successful, another one is tried. In the past, both γ - and β -interferon had been used to treat CML, though this is rarely used now with the development of several TKIs. Hematopoietic stem cell transplantation is another option for treatment in specific patients.

Michael T. Surgical resection of the lung nodule with an attempt at cure was justified in **Michael T.**, who had a good prognosis with a T_1, N_0, M_0 staging classification preoperatively. Because of his history and the characteristics of the nodule, there was a high probability it was a malignant nodule and a preoperative PET (positron emission tomography) scan did not show obvious signs of metastasis.

The TNM system is a cancer staging system that standardizes the classification of tumors. The T stands for the size and extent of the primary tumor (the higher number stands for a larger and more extensive tumor), the N stands for the amount of regional lymph nodes that are affected by the tumor (again, the higher the number, the worse the prognosis), and M stands for the presence of metastasis (0 for none, 1 for the presence of metastatic cells).

Unfortunately, **Michael T.** developed a metastatic lesion in the right temporal cortex of his brain 6 months later. Because metastases were almost certainly present in other organs, his brain tumor was not treated surgically. In spite of palliative radiation therapy to the brain, he succumbed to his disease just 9 months after its discovery, an unusually virulent course for this malignancy. On postmortem examination, it was found that his body was riddled with metastatic disease.

Clark T. requires regular colonoscopies to check for new polyps in his intestinal tract. It is recommended he initially has a colonoscopy 1 year after the surgery and if no polyps are found, the next colonoscopy can be at 3 years. Because the development of a metastatic adenoma requires a number of years (because of the large numbers of mutations that must occur), frequent checks will enable new polyps to be identified and removed before malignant tumors develop.

Calvin A. The biopsy of **Calvin A.**'s excised mole showed that it was not malignant. The most important clinical sign of a malignant melanoma are changes in color or variation in color and irregular borders. Unlike benign (nondysplastic) nevi, melanomas exhibit striking variations in pigmentation, appearing in shades of black, brown, red, dark blue, and gray. Additional clinical warning signs of a melanoma are enlargement of a pre-existing mole, itching or pain in a pre-existing mole, or development of a new pigmented lesion during adult life. **Calvin A.** was advised to conduct a monthly self-examination, to have a clinical skin examination once or twice yearly, to avoid sunlight, and to use appropriate sunscreens.

Mutations associated with malignant melanomas include *ras* (gain of function in growth signal transduction oncogene), *p53* (loss of function of tumor-suppressor gene), *p16* (loss of function in cdk inhibitor tumor-suppressor gene), *cdk4* (gain of function in a cell-cycle progression oncogene), and cadherin/ β -catenin regulation (loss of regulation that requires attachment).

BIOCHEMICAL COMMENTS

A recently developed technique to specifically destroy tumor cells, and not normal cells, utilizes the body's own immune system to do so. The technique is known as **CAR-T (chimeric antigen receptor–T-cells) therapy**, in which an individual's T-cells are genetically modified in a lab, and then reinfused into the individual. The cells have been modified to recognize a cell-surface marker, which is specifically on tumor cells and not normal cells. The T-cells will bind to the tumor cells and destroy them. The treatment has been FDA approved for B-cell acute lymphoblastic leukemia (ALL) and large B-cell lymphoma, as well as CAR-T cell-induced cytokine release syndrome.

In order to understand how this is accomplished, some basic immunology needs to be discussed. A class of white blood cells are known as T-cells, and a second class of white blood cells are known as B-cells. The B-cells are the antibody-producing cells, and the T-cells play a role in cell-based immunity and in the activation of B-cells. For T-cells to recognize their targets, they express a protein named the T-cell receptor, which has a structure like a membrane-embedded antibody, with both variable and constant regions on the single antigen-binding site (Fig. 17.19). The T-cell receptor normally recognizes short peptide fragments on the surface of cells, and binding of the T-cell to the cell presenting the antigen will lead to the destruction of the cell containing the antigenic short peptide fragments.

FIGURE 17.19 The T-cell receptor contains a single antigen-binding domain composed of the variable domains of the α and β chains. Note that the receptor does not have the classic bivalent structure of an antibody as seen in Chapter 7.

With the advent of recombinant DNA technology, monoclonal antibody production, and next-generation sequencing, it has become possible to clone antibody genes, which recognize a particular antigen. If a tumor cell expresses a unique antigen, and the cDNA is available for the antibody, which recognizes the antigen, a chimeric T-cell receptor can be generated, which recognizes the antigen, rather than a short peptide fragment. In order to do this, normal T-cells from the patient are harvested and infected with a modified retrovirus that carries a gene that encodes a modified T-cell receptor, which recognizes the antigen of choice. The cells are expanded and then infused into the patient, where they will proliferate and target the cells to which the chimeric T-cells bind for destruction.

In order to have the T-cell receptor recognize more than just a short peptide fragment, a chimeric T-cell receptor is cloned, in which the variable region from an antibody, which recognizes CD19, is fused to the constant region of the receptor. The intracellular domain of the chimeric receptor is also modified to contain domains, which activate and enhance the T-cell response once the receptor has bound antigen. The chimeric receptor is produced using recombinant DNA technology, in which the cDNA from the variable region of an anti-CD19 antibody (obtained from a monoclonal cell line, which produces antibodies against CD19) is placed with the other domains of a functional T-cell receptor, replacing the variable region of the natural receptor. The nucleic acid construct is converted to RNA and placed within a retroviral vector. After introduction of the retroviral vector into the patient's T-cells, the T-cells are stimulated to proliferate (to increase the number of cells) and then, after depletion of the patient's T-cells, are infused into the patient. The CAR-T cells will take residence in the bone marrow and now produce T-cells, which recognize the cancer cells and will destroy them. This therapy has been shown to be highly effective in many patients, but potentially serious side effects can, and do, occur with this therapy.

CAR-T cell therapy has been most successful for B-cell malignancies (the antibody-producing immune

cells), as those cells express the surface marker CD19, whereas the stem cells for B-cell production do not express CD19. Thus, therapy with anti-CD19 CAR-T cells will destroy the tumor cells expressing CD19, but not the stem cells, which produce more B-cells.

The most severe side effect is called the cytokine release syndrome (cytokine storm), in which part of the normal response of T-cells binding to a target cell (the release of cytokines) is amplified such that excessive amounts of cytokines are secreted. This can lead to organ damage, particularly the lungs, and sometimes death. Individuals who undergo CAR-T therapy are carefully monitored and treated if symptoms of cytokine release syndrome appear (initially as a high fever a few days after the initiation of the therapy). Why some patients undergo this problem, and others do not, is not yet fully understood.

Targeted therapies will increase in the future as more is known about the molecular nature of tumors and should prove to be quite effective in specifically targeting the tumor cells with few side effects.

KEY CONCEPTS

- ◆ Cancer is the term applied to a group of diseases in which cells no longer respond to normal constraints on growth.
- ◆ Cancer arises due to mutations in the genome (either inherited or formed in somatic cells).
- ◆ The mutations that lead to cancer occur in certain classes of genes, including
 - ◆ Those that regulate cellular proliferation and differentiation
 - ◆ Those that suppress growth
 - ◆ Those that target cells for apoptosis
 - ◆ Those that repair damaged DNA
- ◆ Mutations that lead to cancer can be either gain-of-function mutations or loss of activity within a protein.
 - ◆ Gain-of-function mutations occur in proto-oncogenes, resulting in oncogenes.
 - ◆ Loss-of-function mutations occur in tumor-suppressor genes.
- ◆ Examples of proto-oncogenes are those involved in signal transduction and cell-cycle progression:
 - ◆ Growth factors and growth-factor receptors
 - ◆ Ras (a GTP-binding protein)
 - ◆ Transcription factors
 - ◆ Cyclins and proteins that regulate them
 - ◆ microRNAs, which regulate growth-inhibitory proteins
- ◆ Examples of tumor-suppressor genes include
 - ◆ Retinoblastoma (Rb) gene product, which regulates the G₁-to-S phase of the cell cycle
 - ◆ p53, which monitors DNA damage and arrests cell-cycle progression until the damage has been repaired
 - ◆ Regulators of *ras*
 - ◆ microRNAs that regulate growth-promoting signals
- ◆ Apoptosis, programmed cell death, leads to the destruction of damaged cells that cannot be repaired, and consists of three phases:
 - ◆ Initiation phase (external signals or mitochondrial release of cytochrome c)
 - ◆ Signal integration phase
 - ◆ Execution phase
- ◆ Apoptosis is regulated by a group of proteins of the Bcl-2 family, which consists of both pro- and anti-apoptotic factors.
- ◆ Cancer cells have developed mechanisms to avoid apoptosis.
- ◆ Multiple mutations are required for a tumor to develop in a patient, acquired over a number of years.
- ◆ Both RNA and DNA viruses can cause a normal cell to become transformed.
- ◆ Exploitation of DNA repair mechanisms may provide a novel means for regulating tumor cell growth.
- ◆ Genetically engineered patient T-cells can be utilized to treat certain types of tumors; early results are encouraging.
- ◆ The diseases discussed in this chapter are summarized in Table 17.4.

TABLE 17.4 Diseases Discussed in Chapter 17

DISEASE OR DISORDER	OR GENETIC	COMMENTS
Chronic myelogenous leukemia	Environmental	Chromosomal translocation leading to the novel Bcr-Abl protein being produced, leading to uncontrolled cell growth. Rational drug design has led to Bcr-Abl targeted agents, such as imatinib, which have a high rate of initial success in controlling tumor cell proliferation.
Lung adenocarcinoma	Environmental	Lung tumor, due to inhalation of mutagenic compounds over a number of years. Longitudinal data indicates a twenty-year lag from the initiation of smoking and a rise in cancer incidence in such individuals.
Intestinal adenocarcinoma	Both	Colon tumors may result from environmental insult, leading to mutations, or an inherited mutation in a tumor-suppressor gene, such as APC. Hereditary nonpolyposis colon cancer (HNPCC) is due to inherited mutations in proteins involved in DNA mismatch repair.
Melanoma	Environmental	Tumor of the melanocyte, leading to uncontrolled cell growth. Mutations associated with malignant melanomas include ras, p53, p16 (a regulator of cdk4), cdk4, and cadherin/ β -catenin regulation.
Burkitt lymphoma	Environmental	Disorder due to a chromosomal translocation, in this case chromosomes 8 and 14, leading to the transcription factor <i>myc</i> being moved from chromosome 8 to 14. This leads to inappropriate and overexpression of c-myc, leading to uncontrolled cell proliferation.
Li-Fraumeni syndrome	Genetic	An inherited mutation in the protein p53, which is responsible for protecting the genome against environmental damage. Loss of p53 activity will lead to an increased mutation rate, eventually leading to a mutation in a gene, which regulates cell proliferation.
Neurofibromatosis (NF-1)	Genetic	A mutation in a protein (neurofibromin-1), which regulates the GTPase activity of ras, which leads to numerous, benign tumors of the nervous system.

REVIEW QUESTIONS—CHAPTER 17

1. The *ras* oncogene in **Clark T.**'s malignant polyp differs from the *c-ras* proto-oncogene only in the region that encodes the N-terminus of the protein. This portion of the normal and mutant sequences is shown below:

	10	20	30
Normal	A T G A C G G A A T A T A A G C T G G T G G T G G T G G G C G C C G G C G G T		
Mutant	A T G A C G G A A T A T A A G C T G G T G G T G G T G G G C G C C G T C G G T		

This mutation is similar to the mutation found in the *ras* oncogene in various tumors. What type of mutation converts the *ras* proto-oncogene to an oncogene?

- A. An insertion that disrupts the reading frame of the protein
 - B. A deletion that disrupts the reading frame of the protein
 - C. A missense mutation that changes one amino acid within the protein
 - D. A silent mutation that produces no change in amino acid sequence of the protein
 - E. An early termination that creates a stop codon in the reading frame of the protein
2. The mechanism through which Ras becomes an oncogenic protein is which one of the following?
- A. Ras remains bound to GAP.
 - B. Ras can no longer bind cAMP.
 - C. Ras has lost its GTPase activity.
 - D. Ras can no longer bind GTP.
 - E. Ras can no longer be phosphorylated by MAP kinase.
3. The ability of a normal cell to become a cancer cell can occur via a variety of mechanisms. Which one of the

following best describes such a mechanism?

- A. Tumors arise via the acquisition of the ability to metabolize glucose at a faster rate than non-cancer cells.
 - B. Clonal expansion allows for a cell with a single mutation to become a cancer cell.
 - C. Mutations in proto-oncogenes can lead to uncontrolled cell growth.
 - D. Virtually all tumors arise via recombination events leading to the formation of unusual and novel genes.
 - E. Normal cellular oncogenes are mutated to proto-oncogenes, which leads to uncontrolled cellular proliferation.
4. Loss of both p53 protein alleles is found in more than 50% of human tumors. Which one of the following is a function of the p53 protein?
- A. Halting replication in cells that have suffered DNA damage
 - B. Targeting repaired cells to undergo apoptosis
 - C. Stimulating cyclin production
 - D. Stimulating CDK production
 - E. Stimulating phosphorylation of Rb
5. A tumor-suppressor gene is best described by which one of the following?
- A. A gain-of-function mutation leads to uncontrolled proliferation.
 - B. A loss-of-function mutation leads to uncontrolled proliferation.
 - C. When it is expressed, the gene suppresses viral genes from being expressed.
 - D. When it is expressed, the gene specifically blocks the G₁/S checkpoint.
 - E. When it is expressed, the gene induces tumor formation.
6. A tumor cell, due to accumulated mutations, constitutively expresses the akt pathway. Such cells bypass apoptosis due to which one of the following?
- A. Increased expression of cytochrome c
 - B. Phosphorylation of BH3-only domain-containing proteins
 - C. Phosphorylation of Bcl-2
 - D. Increased expression of apaf
 - E. Decreased expression of caspases
 - F. Phosphorylation of caspases
7. Inheriting a mutation in an enzyme necessary for DNA mismatch repair requires which one of the following to occur before a cell loses its ability to regulate its own proliferation?
- A. A mutation in BRCA1 or 2
 - B. A mutation in the PDGF receptor
 - C. A mutation on one p53 gene
 - D. A mutation in the ras gene
 - E. A mutation in the corresponding normal allele
8. A tumor was found in which altered expression of a miRNA led to uncontrolled cellular proliferation. If the target of this miRNA was the Myc protein, how best would this miRNA be characterized?
- A. As an oncogene
 - B. As a dominant-negative effector
 - C. As a tumor suppressor
 - D. As a factor, which upregulates its target
 - E. As a regulatory factor for an enzyme important in DNA repair
9. A 3-year-old girl is seen by a pediatric ophthalmologist due to reduced vision within her left eye. The doctor soon detects a mass growing within the eye, which is blocking her vision. Analysis of DNA from the girl's blood cells indicates a mutation in a tumor-suppressor gene, which, when mutated, most often leads to tumor formation within the eyes. Which one of the following is a description of how this tumor-suppressor gene regulates the cell cycle?
- A. It encodes a cyclin.
 - B. It encodes a CDK.
 - C. It encodes a CKI.
 - D. It encodes a protein that regulates the transition from G₀ to G₁ phase in the cell cycle.
 - E. It encodes a protein that regulates the transition from G₁ to S phase in the cell cycle.
10. An individual has been diagnosed with hereditary diffuse-type stomach cancer, in which rather than being located in one area of the stomach, the tumor is located in many areas of the stomach. A mutation in which one of the following proteins would lead to such a disorder?

- A. p53 protein
 - B. NF-1
 - C. rb gene
 - D. Cadherins
 - E. Caspases
1. The power and promise of CAR-T therapy is best described by which one of the following?
 - A. Increasing the immune response to pathogens while an individual is undergoing chemotherapy
 - B. Boosting the immune response to pathogens after treatment for cancer
 - C. Specifically targeting tumor cells for destruction without affecting non-tumor cells
 - D. Increasing antibody production to destroy tumor cells
 - E. Reducing growth-factor production by the tumor cells
 2. The drug methotrexate inhibits the enzyme dihydrofolate reductase (DHFR), which leads to a cell becoming functionally folate deficient such that DNA replication does not occur. Methotrexate was one of the first chemotherapeutic drugs developed, but tumor cells would gain resistance to the drug by overproducing DHFR. This could occur via which one of the following?
 - A. Upregulating inhibitory transcription factors, which bind to the promoter region of the DHFR gene
 - B. Enhancing the affinity of RNA polymerase for the promoter region of the DHFR gene
 - C. Reducing the number of copies of the DHFR gene in the tumor cell genome
 - D. Increasing the number of copies of the DHFR gene in the tumor cell genome
 - E. Deleting the promoter region for the DHFR genes
 3. The loss of expression of which one of the following would be expected to lead to enhanced cellular growth?
 - A. A growth-factor receptor
 - B. The ras protein
 - C. The MEK protein
 - D. A cyclin kinase inhibitor
 - E. The raf protein
 4. Assume a drug has been developed, which will bind to the patched coreceptor and prevent smoothed from interacting with patched. Another consequence of this drug would be which one of the following?
 - A. Inhibition of patched/smoothened-induced transcription
 - B. Stimulation of patched/smoothened-induced transcription
 - C. Increased binding of hedgehog to patched
 - D. Decreased binding of hedgehog to patched
 - E. There would be no other consequence
 5. The use of dideoxynucleotides as a treatment for HIV infection has proven to be beneficial. Why wouldn't such a treatment be as effective for inhibiting the growth of tumor cells?
 - A. The dideoxynucleotides cannot enter eukaryotic cells.
 - B. Dideoxynucleotides would not inhibit eukaryotic DNA replication.
 - C. Eukaryotic DNA polymerases have a reduced affinity for dideoxynucleotides as compared to reverse transcriptase.
 - D. Dideoxynucleotides are converted to deoxynucleotides by eukaryotic cells.
 - E. Dideoxynucleotides cannot be converted to deoxynucleotides in eukaryotic cells.

ANSWERS TO REVIEW QUESTIONS

1. **The answer is C.** The *ras* oncogene has a point mutation in codon 12 (position 35 of the DNA chain) in which T replaces G. This changes the codon from one that specifies glycine to one that specifies valine. Thus, there is a single amino acid change in the proto-oncogene (a valine for a glycine) that changes *ras* to an oncogene.
2. **The answer is C.** Ras, when it is oncogenic, has lost its GTPase activity and thus remains active for an extended time. Answer A is incorrect because GAP proteins activate the GTPase activity of Ras and this mutation would make Ras less active. cAMP does not interact directly with Ras (thus, B is incorrect), and if Ras could no longer bind GTP, it would not be active (hence, D is also incorrect). Ras is not phosphorylated by the MAP kinase (thus, E is incorrect).
3. **The answer is C.** Cancers develop from mutations in normal cellular genes (the proto-oncogenes) that

convert the genes to oncogenes. The oncogenes then alter cellular proliferation, as they are not regulated in the same way as their corresponding proto-oncogene. While a small number of tumors utilize recombination events to create a novel gene, this is not the usual mechanism for most tumors to develop. The proto-oncogenes need multiple mutations (4 to 7) for full transformation into oncogenes (clonal expansion of just a single mutation is usually not sufficient to form a tumor *in vivo*).

4. **The answer is A.** The p53 protein is a transcription factor that regulates the cell cycle and apoptosis. It has been named the “guardian of the genome” in that it halts DNA replication in cells that have suffered DNA damage and, if the damage is too difficult to repair, targets such cells for apoptosis. Repaired cells are not targeted for apoptosis by p53. The p53 protein stimulates production of proteins that inhibit cyclin–CDK complexes, which prevents the phosphorylation of Rb and stops cells from further replicating their DNA.
5. **The answer is B.** Tumor-suppressor genes balance cell growth and quiescence. When they are not expressed (via loss-of-function mutations), the balance shifts to cell proliferation and tumorigenesis (thus, A is incorrect). Answer C is incorrect because tumor-suppressor genes do not act on viral genes, answer D is incorrect because tumor-suppressor genes are not specifically targeted to just one aspect of the cell cycle, and answer E is incorrect because a loss of expression of tumor-suppressor genes leads to tumor formation, not expression of these genes.
6. **The answer is B.** Growth-factor deprivation can lead to apoptosis due to the action of BH3-only domain members of the Bcl-2 family of proteins. The BH3-only domain proteins dimerize with channel-forming proteins in the outer mitochondrial membrane, allowing cytochrome c to leave the mitochondria and bind to apaf, to form the apoptosome to initiate the apoptotic pathway. Growth factors, via activation of the akt/protein kinase B pathway, lead to the phosphorylation of the BH3-only domain proteins, and inactivate them, such that apoptosis is blocked. As the cell in question is always expressing active akt, the cell will be in a constant anti-apoptotic state. Increased expression of cytochrome c will not lead to apoptosis or cell growth; it will not affect cellular proliferation. Bcl-2 is an anti-apoptotic factor, but it is not phosphorylated by the akt pathway. Increased expression of apaf might lead to apoptosis if cytochrome c were released; its increased expression would not lead to uncontrolled cellular proliferation. Decreased expression of caspases would hinder apoptosis, but the akt pathway does not alter the expression level of these proteases. Caspases are also not phosphorylated by akt.
7. **The answer is E.** In order for a mutation in a DNA mismatch repair enzyme to be fully manifest, both alleles that code for this protein must be mutated; otherwise, 50% of the protein made would be functional, and that is often sufficient to allow for normal DNA repair. Mutating the corresponding normal allele would reduce the functional enzyme level to zero, and the lack of mismatch repair would eventually lead to mutations in genes involved in growth regulation, resulting in uncontrolled cellular proliferation. Mutations in BRCA1 or BRCA2 involve DNA repair of double-strand breaks, not mismatches. A mutation in the PDGF receptor may lead to transformation as a dominant oncogene, but does not affect mismatch repair. A mutation in a p53 gene would have no effect, as p53 is also a tumor-suppressor gene, and both copies of p53 would need to be mutated for a tumor to develop. A mutation in p53 would not, in combination with one mutation in a mismatch repair gene, lead to uncontrolled proliferation. A mutation in the ras gene, by itself, would lead to uncontrolled cellular proliferation as ras is a dominant oncogene, but the mechanism would not be by inability to repair DNA mismatches.
8. **The answer is C.** If *myc*, a proto-oncogene, is overexpressed, increased cell proliferation would result. One way *myc* could be overexpressed is if the miRNA regulating its expression were no longer expressed. In that case, *myc* mRNA levels would increase, and *myc* would be inappropriately expressed in the cell. For this to occur, the miRNA would have a loss of function, which is what defines a tumor-suppressor gene. The miRNA is downregulating, not upregulating, the expression of *myc*. A gain of function (such as overexpression of the miRNA) would define an oncogene. The miRNA is not acting as a dominant-negative effector, which is when one mutated copy of a protein (or RNA) interferes with the functioning of a functional protein produced by a normal allele. *Myc* is a transcription factor, and not an enzyme needed for DNA repair.
9. **The answer is E.** The girl has retinoblastoma, which is due to a mutation in the Rb gene, a tumor suppressor. The normal Rb protein binds to the E2F family of transcription factors, and when it does, transcription is inhibited. Phosphorylation of the Rb protein by cyclin–cdk complexes at the G1/S interface of the cell cycle inactivates Rb, phosphorylated Rb dissociates from E2F, and transcription is now initiated, allowing cells to enter the S phase of the cycle. Since the mutation is in a tumor-suppressor gene, a loss of function is leading to tumor growth. Loss of Rb function leads to constant E2F activity,

and the cell is always stimulated to proliferate (the checks and balances at the G1/S boundary are lost). Loss of function of a cyclin, or a CDK, would stop cell growth (mutations in those genes would need to be gain-of-function mutations in order for a tumor to form). The cyclin-dependent kinase inhibitors (CKIs) are inhibitors, and loss of their function could lead to tumor growth, but such mutations would not be specific for retinoblastoma, as mutations in the Rb protein are.

10. **The answer is D.** Cadherins are membrane-bound glycoproteins involved in intracellular adhesion. Loss of function of a specific cadherin (E-cadherin) allows cell migration within the stomach, due to the loss of intracellular adhesion. This allows tumor cells to leave their site of origin and move to other areas within the stomach (giving rise to the diffuse type of cancer found). p53 proteins and the Rb protein help regulate cell-cycle completion and cell reproduction, but do not regulate the ability of tumor cells to migrate. The protein produced by the NF-1 gene (neurofibromin) binds to Ras and activates its GTPase activity, thereby reducing the amount of time that Ras is in its active state. Caspases are cysteine proteases involved in the apoptotic response.
11. **The answer is C.** CAR-T (chimeric antigen receptor–T cells) therapy generates recombinant T-cells outside the body, which have been altered to produce a T-cell receptor that recognizes a particular antigen, or protein, on the tumor cell. When infused back into patients, these T-cells specifically bind to the tumor cells and initiate their destruction. Since only the tumor cells express this particular antigen, non-tumor cells are not affected by the treatment. CAR-T therapy is not designed to attack traditional pathogens, which may accumulate during chemotherapy. T-cells are involved in the cellular immune response, whereas B-cells produce soluble antibodies (thus, D is incorrect). CAR-T cells do not target growth-factor production by tumor cells, but rather the destruction of tumor cells through specific binding to such cells.
12. **The answer is D.** Methotrexate resistance occurs through gene amplification of the DHFR gene (similar to what is shown in Fig. 17.3). Multiple copies of the gene are produced, each transcriptionally active, such that the levels of methotrexate given to treat the cancer cannot inhibit all of the enzymes produced from the multiple genes. Resistance does not appear to occur due to changes in transcription of the multiple DHFR genes. Deleting the promoter region for the DHFR genes would result in reduced expression of DHFR, and would not lead to methotrexate resistance.
13. **The answer is D.** The loss of expression of a protein, which leads to enhanced cellular growth, is the hallmark of a tumor-suppressor gene. A gain of function within a protein, which leads to enhanced growth, is the definition of an oncogene. Losing expression of a growth-factor receptor, or ras activity, or functioning of the MEK protein, or the raf protein, would all lead to reduced cellular proliferation, as their activities are required for cell proliferation. Loss of function of a cyclin kinase inhibitor would keep the cyclin kinase active for longer than intended periods of time, and would lead to enhanced cellular proliferation. The cyclin-dependent kinase inhibitor genes fall into the classification of tumor-suppressor genes.
14. **The answer is B.** Patched normally binds to smoothened and inhibits smoothened activity. When the hedgehog signal binds to patched, the inhibition of smoothened is released, and smoothened initiates signaling leading to increased gene transcription. If patched is prevented from binding to smoothened by the use of a drug, smoothened will be able to initiate increased transcription in the absence of a hedgehog signal, which would lead to inappropriate gene transcription. There is not enough information given in the question to determine if hedgehog binding would be affected by the drug binding to patched.
15. **The answer is C.** The use of dideoxynucleotides is successful if the DNA polymerase utilizing them is efficient at recognizing them as substrates. Reverse transcriptase will utilize dideoxynucleotides at a greater rate than nuclear eukaryotic DNA polymerases, so the modified nucleotides will preferentially interfere with viral replication as opposed to cellular replication. Since tumor cells utilize nuclear eukaryotic DNA polymerases, as do non-tumor cells, both types of cells will be affected by the drug, and there would not be preferential destruction of the tumor cells as compared to normal cells. Additionally, mitochondrial DNA polymerase will utilize dideoxynucleotides, and contributes to the toxicity involved with treating patients with dideoxynucleotide analogs. Dideoxynucleotides do enter eukaryotic cells, and can inhibit eukaryotic DNA replication, albeit at a very low rate in the nucleus. Dideoxynucleotides cannot be reduced by cells to form normal deoxyribonucleotides.

An Introduction to Human Genetics

Human genetics is defined as the study of heredity and the variation in inherited characteristics, as they apply to humans. As discussed in Chapter 11, human DNA is spread across 46 chromosomes (23 inherited from the mother, and 23 inherited from the father). The autosomal chromosomes are numbered from 1 through 22, originally based on size (numbered from largest to smallest, with 1 being the largest and 22 the smallest, although recent data indicate that 21 is smaller than 22), and then X or Y, which are referred to as the sex chromosomes. Human somatic cells are diploid, with two copies of each autosomal chromosome (one from each parent) and two sex chromosomes—XX will be a female, XY a male. Women transmit their X chromosome to their children, while the father transmits either an X or a Y chromosome.

Genes are sequences of DNA on chromosomes that encode a functional product. An **allele** is a form of a gene present at a particular location (**locus**) on the chromosome. Since human cells are diploid, each locus is present as two alleles, which may or may not be identical to each other.

Mitosis is the process whereby a cell divides into two daughter cells such that each daughter cell contains the same number and kind of chromosomes as the parent cell. Human cells contain 46 chromosomes; during the phases of mitosis, the chromosomes are copied and the cell then divides, sending 46 chromosomes to each daughter cell.

Meiosis is the process whereby a cell produces four daughter cells, each with a haploid number of chromosomes (one-half the number possessed by the parent cell). Meiosis is utilized for the production of haploid germ cells (sperm and eggs).

Mendelian inheritance patterns include **autosomal dominant**, **autosomal recessive**, **X-linked dominant**, and **X-linked recessive**. An autosomal dominant mutation only needs to be present in one copy of a gene in the genome (it is dominant to the normal allele on the other chromosome) for the effects of the mutation to be evident. It is inherited 50% of the time from the parent with the disease. An autosomal recessive mutation means that for the disease to be manifest both alleles must contain a mutation, and each parent contributes one mutated allele to the fetus. The probability of inheriting an autosomal recessive disease is 25%, as there is a 1 in 2 chance that each parent will pass on the allele, and both events must occur for the child to inherit two mutant alleles (one-half times one-half is one-quarter). X-linked disorders are due to mutations in genes residing on the X chromosome. X-linked recessive disorders are inherited by males from carrier or affected females, and since males only contain one X chromosome they express the disease. X-linked dominant disorders are expressed by both males and females.

Failure of the chromosomes to sort appropriately during meiosis can lead to **nondisjunction** events, which allow germ cells with an abnormal number of individual chromosomes to be created (**aneuploidy**), and often leads to spontaneous abortion or disease. Gene dosage effects are important as over expression of genes can be detrimental, as can reduced expression of genes (due to fewer chromosomes carrying the allele). Also, during meiosis, chromosome structure can be altered, leading to **inversions**, **duplications**, **insertions**, **isochromosome** formation, **deletions**, and **translocations**.

Epigenetics refers to the mechanisms whereby genes can be expressed, or not expressed, in a heritable manner, without altering the DNA base sequence. Epigenetic events involve modifications to histones (acetylation, methylation, phosphorylation) and to DNA (primarily methylation of cytosine bases). **Imprinting** refers to altering the expression of an allele without altering the nucleotide

sequence of the allele. Imprinting is sex-specific as males and females imprint different alleles. The imprint remains throughout the life of the cell and its progeny. Imprinting is reset when gametes are produced.

The **Hardy–Weinberg equilibrium** allows one to determine estimates of **allele frequencies** in a general population, which can generate the frequency of heterozygotes in a population, as well as the frequency of those affected by a disease. It is best applied to autosomal and X-linked recessive disorders.

Multifactorial diseases (such as schizophrenia) involve significant interactions between multiple genes and **environmental factors**.

DNA structural abnormalities can also lead to disease. An example of such an abnormality is **triplet nucleotide repeat expansion** within or near certain genes. If the DNA expansion exceeds a certain size, disease can result; such diseases are inherited in an autosomal dominant fashion. **Anticipation** refers to an earlier onset of disease and more severe symptoms in members of later generations, which correlates with an increase in the number of triplet nucleotide repeats in successive generations.

Tumor suppressor genes (genes whose normal function is to block uncontrolled cellular proliferation), if analyzed through pedigrees, most often display an autosomal dominant pattern of inheritance, yet the molecular mechanism is recessive. The loss of a functional allele is known as **loss of heterozygosity** and occurs through a variety of mechanisms.

THE WAITING ROOM

 **Carrie S.**, **Will S.**'s 19-year-old sister, is considering marriage. Her growth and development have been normal, and she is free of symptoms of sickle-cell anemia. Because a younger sister, Amanda, was tested and found to have sickle-cell trait (expressing one normal β -globin gene, and one sickle β -globin gene), and because of **Will S.**'s repeated sickle-cell crises, **Carrie S.** wants to know whether she also has sickle-cell trait (see Chapters 6 and 7 for **Will S.**'s history). A hemoglobin electrophoresis is performed that shows the composition of her hemoglobin to be 58% HbA, 39% HbS, 1% HbF, and 2% HbA₂, a pattern consistent with the presence of sickle-cell trait. The hematologist who saw her in the clinic on her first visit is studying the genetic mutations of sickle-cell trait and asks **Carrie S.** for permission to draw additional blood for more sophisticated analysis of the genetic disturbance that causes her to produce HbS. **Carrie S.** informed her fiancé that she has sickle-cell trait and that she wants to delay their marriage until he is tested.

 **Martha W.** is one of five siblings who express symptoms of a very rare mitochondrial disorder MERRF (myoclonic epilepsy with ragged red fibers). Mitochondrial diseases occur due to mutations in the mitochondrial genome and display maternal inheritance. Because of heteroplasmy, the symptoms of MERRF vary widely among affected individuals, even in the same family. **Martha W.** has the mildest case of her siblings experiencing some muscle weakness and muscle twitching. Unfortunately, her other siblings have more severe symptoms and two of her siblings died in their teens from the disease. **Martha W.**'s mother also has a mild case of the disorder.

Martha W. has just recently married and would like children of her own, but knowing that as a woman with a mitochondrial disorder she will transmit the disease to all her children, she would like to do her best to prevent her children from inheriting her disease. A search on the internet leads her to a foreign clinic for a consultation with a doctor who claims to be able to help women with mitochondrial disorders have children without the disease.

I. Mendelian Inheritance Patterns

Humans are diploid organisms, meaning that each somatic cell contains two copies of each chromosome, one

from each parent. The cells contain 46 chromosomes (two copies of each autosomal chromosome, numbered from 1 through 22, and two sex chromosomes, which can be either XX or XY). As females are XX, the egg contains one copy each of chromosomes 1 through 22, and one X chromosome. Sperm contain one copy each of chromosomes 1 through 22, and either one X or one Y chromosome. Fertilization of an egg by a sperm will lead to a zygote with 46 chromosomes, which then develops into a fetus and then an infant.

The principle of independent assortment allows the calculation of probabilities concerning the transmission of a mutant allele through an extended family and is of great aid to genetic counselors in working with families in which a disease mutation is present.

Ploidy refers to the copy number of the chromosome complement in multiples of 23 chromosomes in human cells. Monoploid refers to a cell with just one copy of all chromosomes; diploid refers to two copies, and triploid (69 chromosomes) refers to cells with three copies of all chromosomes. Only diploid cells are viable. **Aneuploidy** refers to an abnormal number of individual chromosomes rather than a multiple of 23. Loss of a chromosome is considered aneuploidy (Turner syndrome, which is monosomy X [45 XO], is considered an aneuploid disorder), as is the gain of a chromosome (Down syndrome, trisomy 21 [47, XX, +21; 47, XY, +21], is an aneuploid disorder).

Determination of normal and abnormal chromosome structures is done by karyotype analysis (see figure below). Karyotypes are created by first arresting cells in mitotic metaphase, a stage at which the chromosomes are condensed and visible under the light microscope. Nuclei are isolated, placed on a microscope slide, and the chromosomes are stained. Microscopic images of the chromosomes are obtained, and the homologous chromosomes are paired. Through this type of analysis, translocations between chromosomes can be determined, as can trisomies and monosomies. As seen in the figure, this karyotype indicates a translocation between chromosomes 9 and 22 (a piece of chromosome 22 is now attached to chromosome 9; note the arrows in the figure). This is known as the Philadelphia chromosome, and it gives rise to Chronic myelogenous leukemia (CML), the disease exhibited by **Mannie W.** Translocations now often are identified using multicolored fluorescence in situ hybridization (FISH) probes that label each chromosome fully with a unique color.

Cellular division involves replication of the DNA within the nucleus of a cell and successful transfer of one intact copy of the duplicated genome to the daughter cells. This process is known as mitosis (see Chapter 10) and consists of a number of different stages during which the chromosomes are duplicated, condensed, and copies are sent to the appropriate daughter cells (Fig. 18.1). The generation of gametes (germ cells) requires the process of meiosis, in which the chromosomes are duplicated (making the cell tetraploid) and then a first meiotic division occurs in which two sister chromatids are sent into daughter cells (in mitosis the sister chromatids are split and go into different daughter cells). The second meiotic division splits the sister chromatids such that each germ cell gets a haploid number of chromosomes. An important principle is that of **independent assortment**, which states that during meiosis each chromosome in a pair is randomly sorted into a daughter cell. There is no linkage between chromosomes when they segregate during meiosis, thereby providing up to 2 to the 22nd power in combinations of chromosomes in the resulting gametes (excluding the sex chromosomes).

FIGURE 18.1 **A.** The process of mitosis. For simplicity, only four chromosomes are shown. Note that when the chromosomes separate to be passed to daughter cells (from 4N to 2N ploidy), the sister chromatids are separated during cell division to reach the diploid state. **B.** The steps of meiosis, in which a 2N cell increased ploidy to 4N, then decreases, via two meiotic divisions, back to 2N and finally to an N content of DNA. Note that in meiosis I, the 2N content of DNA consists of sister chromatids (basically identical chromosomes) that are separated in the second meiotic division to form cells with an N content of DNA. **C.** Crossing over during meiosis. Two pairs of sister chromatids can exchange genetic information before the first meiotic division. (Reprinted with permission from Gelehrter TD, Collins FS, Ginsburg D. *Principles of Medical Genetics*. 2nd ed. Williams & Wilkins; 1998. Figures 2.11 and 2.12.)

An important feature of meiosis 1 is that before metaphase 1, but after DNA replication, crossover of

genetic information occurs between paired homologous chromosomes. Such crossover events increase genetic diversity by altering the combination of genes on homologous chromosomes, which will be separated into two different cells during the second meiotic division. There are approximately 3 to 5 crossover events per chromosome during meiosis.

Chromosomes can be visualized by **karyotype**, which displays all of the chromosomes in a cell, obtained through a metaphase spread (Fig. 18.2). Alterations in karyotype (gain or loss of chromosomes, large insertions or deletions, and translocations), can be easily observed through this technique. Tumor cells often exhibit genomic instability and can have quite complicated karyotypes.

FIGURE 18.2 An example of a male karyotype (note the presence of an X and a Y chromosome). (Reprinted with permission from Lieberman MA, Ricer R. *BRS Biochemistry, Molecular Biology & Genetics*. 7th ed. Wolters Kluwer; 2020. Figure 10.1.)

II. Genes

Genes, the basic unit of heredity, reside at specific locations, known as **loci** (plural) or **locus** (singular), on a particular chromosome. The form of a gene at a given locus is an **allele**. The **homozygous** state refers to the two alleles being identical; the **heterozygous** state refers to the two alleles having a different nucleotide sequence, which may be caused by mutations. A **phenotype** refers to the observable traits of the individual, produced by the interaction of the individual's genes and the environment. **Genotype** refers to the genetic composition of the individual.

The ability to inherit a trait from a parent depends on two variables: a genetic component and an environmental component. Together they define **heritability**. A genetic component of 100% indicates no influence of the environment on the inheritance of the phenotype of the individual. A genetic component of 10% would indicate the major determinant of the phenotype is environmental rather than genetic.

Autosomal alleles are present as pairs within cells. If the alleles are different what determines which allele is expressed? This is determined by whether one allele is dominant, or recessive, to the other, or if they are codominant and equally expressed. A **dominant** trait is one that manifests itself even when an allele is in a heterozygous state (one example of this is a protein composed of subunits—having a mix of normal and altered subunits may render the entire complex inactive). **Codominant** traits are when both alleles in a heterozygous pair are expressed (one example is the blood group antigens, such that a person can express both an A antigen and a B antigen—type AB blood). A **recessive** trait is one that manifests only when the gene is in a homozygous state (an example is sickle-cell disease, where the disease is expressed when both alleles contain the same mutation, which produces an altered β subunit of hemoglobin). Recessive **X-linked traits** occur when a mutant allele is located on the X chromosome and will be expressed in males (since males only have one X chromosome), but not usually in females. Females with one mutant allele on an X chromosome are carriers of the disorder and do not express the disease if the nonmutated allele on the other X chromosome is dominant to the mutated allele. **X-linked traits** also can be dominant; if dominant then both males and females who inherit the mutant allele will express the trait.

Mutations in the *BRCA1* and *BRCA2* genes are associated with breast cancer; inheritance of a single mutated allele in either gene leads to an 80% probability that the woman will develop breast cancer during her lifetime. The penetrance of these alleles is 80%, not 100%; not every woman who inherits a mutation in *BRCA1* or *BRCA2* will develop breast cancer. This is in contrast to inheriting one mutated allele of the *APC* gene, which leads to colon cancer. The penetrance of mutations in the *APC* gene is 100%. Every individual who inherits such a mutation will develop colon cancer during their lifetime, usually in the third or fourth decade of life. In contrast, mutations in the *GBA* gene, which leads to Gaucher disease (a sphingolipidosis, see Chapter 32), can result in a variety of phenotypes (variable expressivity) depending, in part, on the location of the mutation and the presence of modifier alleles for *GBA* enzyme activity.

Not all individuals who inherit a mutant allele will necessarily express the phenotype of the disease. The term **penetrance** refers to the probability an individual will express a phenotype when inheriting a particular mutant allele. A penetrance of 100% means that everyone who inherits the mutant allele will express the disease. Penetrance can be <100% due to, in part, the nature of the mutation in the allele, epigenetic differences between individuals, or differences in modifier genes between individuals. Breast cancer, due to mutations in *BRCA1* or *BRCA2*, displays incomplete penetrance. **Variable expressivity** refers to the severity of the expressed phenotype caused by a mutant allele. Even if the penetrance of a particular mutant allele is 100%, the allele may lead to different phenotypes (variable expressivity) in members of the same family who inherit the allele. Variable expressivity is often caused by environmental influences and modifier genes that affect the phenotype. Marfan's syndrome and osteogenesis imperfecta are diseases that display variable expressivity.

III. Mutations

Alterations in a DNA sequence of an allele can give rise to a nonfunctional or unregulated gene product (see Chapter 15). Mutations can be classified in a variety of ways, as indicated in Table 18.1. All newborn infants are tested for genetic diseases, such as phenylketonuria (PKU), although the diseases tested for by newborn screening vary by state. Many genetic disorders require early treatment to prevent serious and irreversible consequences to the infant. The U.S. federal government has a recommended list of 35 disorders to be tested, but each state makes its own determination.

TABLE 18.1 Types of Mutations

TYPE OF MUTATION	DESCRIPTION	EXAMPLE
Point mutations	A change in one base of the DNA	Sickle-cell disease
Deletions	A loss of bases in the DNA	Cystic fibrosis ($\Delta F508$); infantile Tay–Sachs disease
Insertions	New DNA sequence added into the existing DNA	A form of Menkes disease (a disorder of copper metabolism)
Loss of a chromosome	Creates an aneuploid state	Turner syndrome
Extra copy of a chromosome	Trisomy for an autosomal chromosome leads to disease	Down syndrome
Trinucleotide repeats	Expansion of specific trinucleotide sequences in a gene can give rise to a disease	Huntington disease
Epigenetic	No alterations in base sequence but chemical modifications to the DNA and histones do occur (gain or loss of methylation and acetylation patterns, for example)	Angelman and Prader–Willi syndromes

For a listing of each state required genetic tests for newborns go to <http://www.babysfirsttest.org/newborn-screening/states>

IV. Inheritance Patterns

Mutations can be inherited, in Mendelian fashion, via autosomal dominant, autosomal recessive, and X-linked mechanisms. **Non-Mendelian inheritance** includes **mitochondrial disorders**, due to mutations in the mitochondrial genome. Each will be described below, along with examples of diseases transmitted via that mechanism.

A. Autosomal Dominant Inheritance

A sample pedigree of autosomal dominant inheritance is shown in Figure 18.3A along with the common symbols used in pedigrees (Fig. 18.3B). An affected individual most often has an affected parent (unless the affected individual is expressing a new mutation). The affected individuals are heterozygotes, as homozygosity for these traits is statistically very unlikely, and may be lethal in utero. An affected heterozygous parent has a 50% chance of passing the affected allele to their offspring. Transmission of the trait is sex-independent, and both sexes can express the disease.

A

B

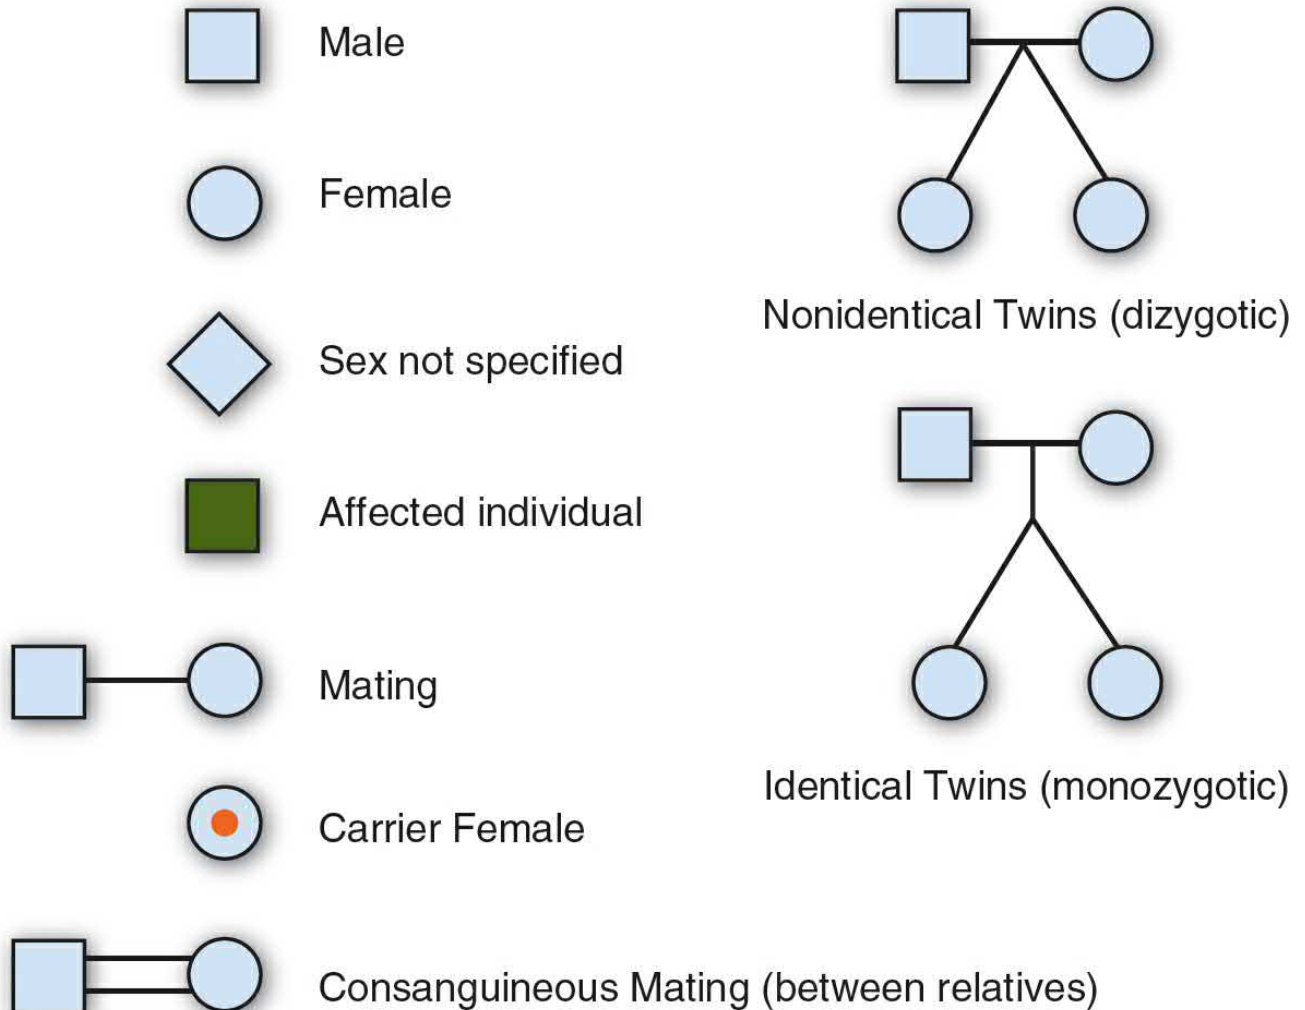

FIGURE 18.3 A. An autosomal dominant pedigree. The large “A” is the dominant mutant allele, and the small “a” is the wild type allele. The darkened boxes indicate the individuals with the disease. **B.** Common symbols used in pedigree analysis. (Reprinted with permission from Lieberman MA, Ricer R. *BRS Biochemistry, Molecular Biology & Genetics*. 7th ed. Wolters Kluwer; 2020. Figures 10.2 and 10.3.)

A Punnett square analysis will aid in calculating the probabilities of passing the altered allele to the children (Fig. 18.4). For an autosomal dominant pattern of inheritance 50% of the children will be affected, whereas 50% will not acquire the mutated gene (thus, there is a one in two chance of inheriting the mutated allele).

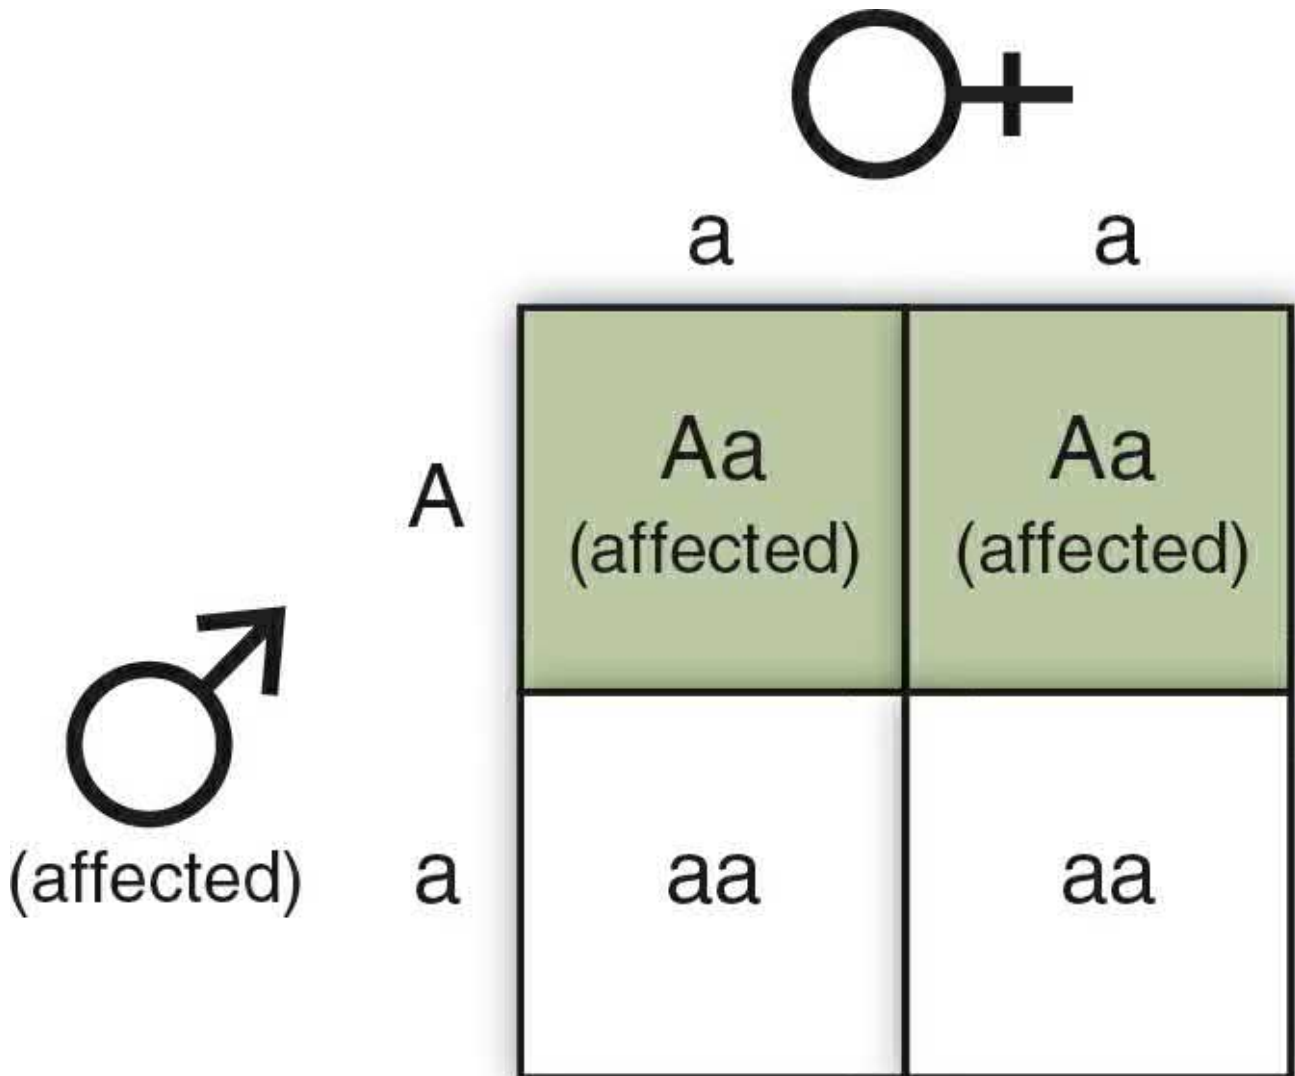

FIGURE 18.4 A Punnett square analysis of an autosomal dominant disorder. The disease gene is indicated by the uppercase “A.” Note that 50% of the offspring will inherit the disease, as any individual with at least one copy of the “A” allele will express the disease.

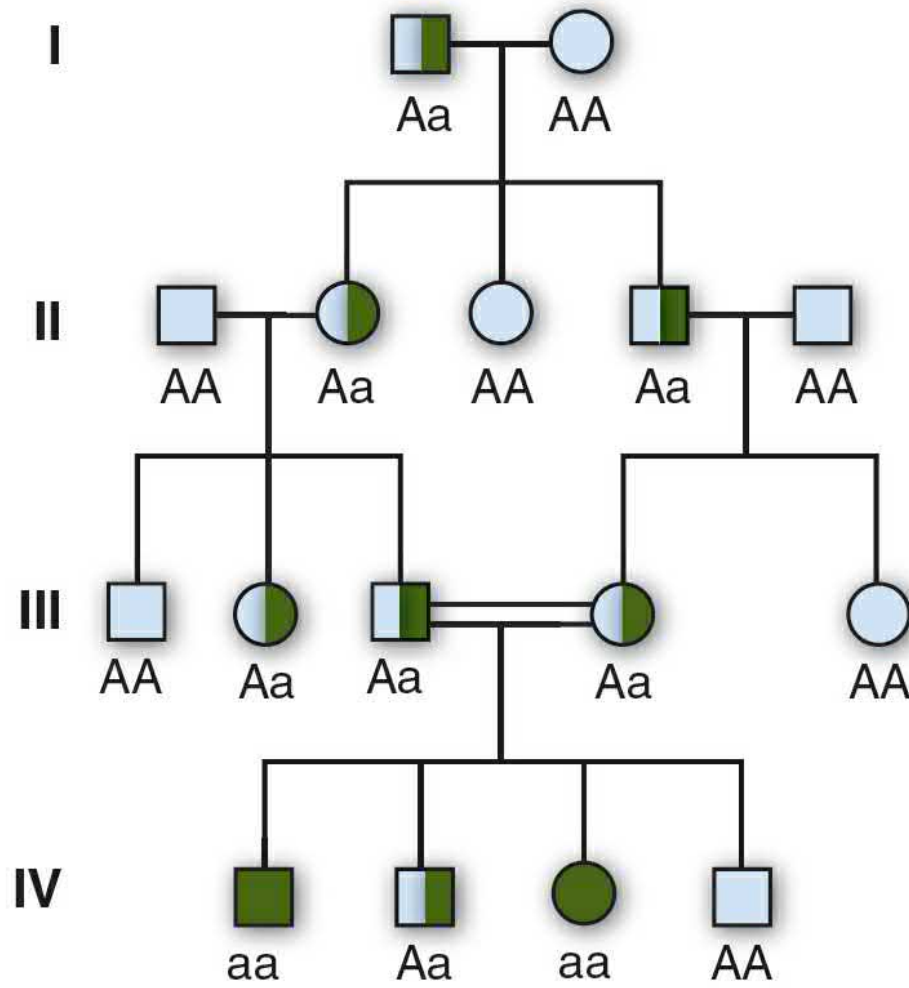

Examples of autosomal dominant disorders include **achondroplasia** (dwarfism, due to a mutation in an FGF receptor gene), **Huntington disease, type 2** (due to a triplet-repeat expansion in the *HTT* gene), **Marfan syndrome** (due to a mutation in the fibrous protein fibrillin) and **neurofibromatosis, type 1** (*NF-1*), due to mutations in the *NF-1* gene that encodes a GTPase-activating protein.

B. Autosomal Recessive Inheritance

A sample pedigree of autosomal recessive inheritance is shown in Figure 18.5A. Indications of autosomal recessive inheritance include both sexes being affected equally when inheriting the mutant alleles, that the transmission of the trait must occur from both parents, and that generations may be skipped in the expression of

the disease if all offspring are heterozygotes. Figure 18.5B displays a Punnett square analysis of autosomal recessive inheritance. Note that one in four children (25%) will be affected, and two in four children (50%) will be a carrier of the disease.

A

B

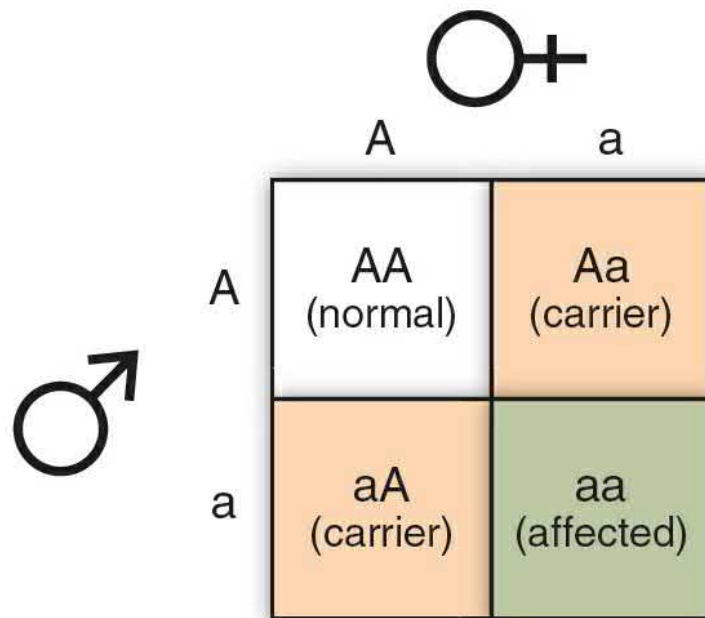

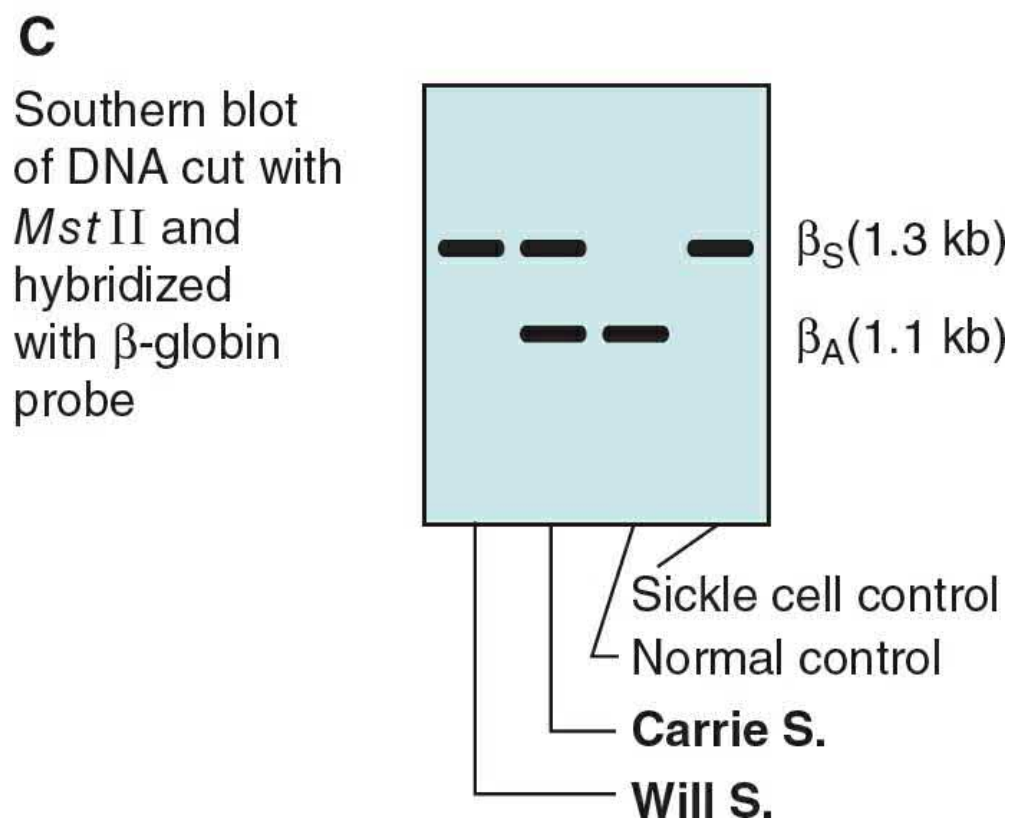

FIGURE 18.5 A. An autosomal recessive inheritance pedigree. The lowercase “a” reflects the disease allele; a person with the genotype aa will express the disease, whereas the genotype Aa designates a carrier of the disease. **B.** A Punnett square analysis of autosomal recessive inheritance. Note that one in four of the offspring will inherit both mutated alleles, and express the disease. (Reprinted with permission from Lieberman MA, Ricer R. *BRS Biochemistry, Molecular Biology & Genetics*. 7th ed. Wolters Kluwer; 2020. Figures 10.5 and 10.6.)

Examples of autosomal recessive disorders include **albinism** (which affects 1 in 20,000 live births and is due to a loss of melanocyte tyrosinase), **cystic fibrosis** (which affects 1 in 2,500 live births of individuals of northern European ancestry and is due to a mutation in the cystic fibrosis transmembrane conductance regulator [CFTR] protein), **phenylketonuria** (which affects 1 in 14,000 live births and is primarily due to phenylalanine hydroxylase deficiency) and **sickle-cell disease** (which can affect people with ancestors from parts of the world where malaria is/was common, and results from an E6V amino acid change in the b subunit of hemoglobin).

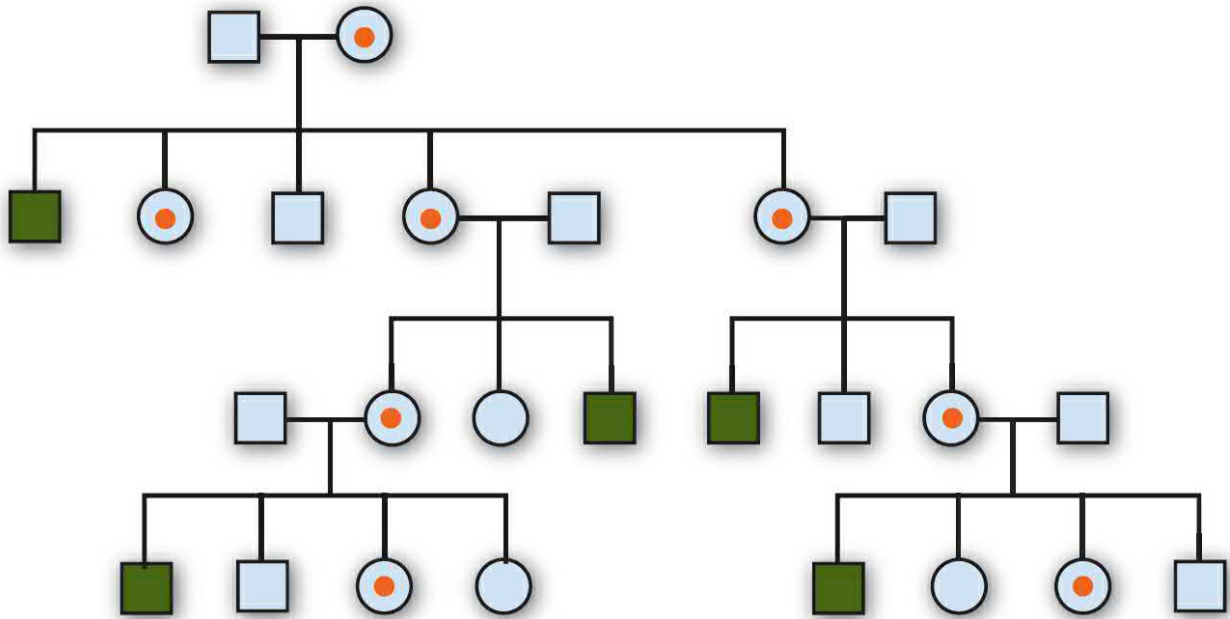

The mutation that causes sickle-cell anemia abolishes a restriction site for the enzyme *MstII* in the β -globin gene. The consequence of this mutation is that the restriction fragment produced by *MstII* that includes the 5'-end of the β -globin gene is larger (1.3 kb) for individuals with sickle-cell anemia than for normal individuals (1.1 kb). Analysis of restriction fragments provides a direct test for the mutation. In **Will S.**'s case (**Carrie S.**'s brother), both alleles for β -globin lack the *MstII* site and produce 1.3-kb restriction fragments; thus, only one band is seen in a Southern blot. Carriers have both a normal and a mutant allele. Therefore, their DNA will produce both the larger and the smaller *MstII* restriction fragments. When **Will S.**'s sister, **Carrie S.**, was tested, she was found to have both the small and the large restriction fragments, and her status as a carrier of sickle-cell anemia, initially made on the basis of protein electrophoresis, was confirmed.

C. X-linked Inheritance

X-linked inheritance refers to inheritance of mutant alleles on the X chromosome. Males are hemizygous for genes on the X chromosome, as males only have one copy of the X chromosome, while females have two copies of the X chromosome. For X-linked recessive disorders, there is no male-to-male transmission in a pedigree (Fig. 18.6A), and females are usually asymptomatic (for an exception see the **Lyon hypothesis**, below). Sons and daughters each have a 50% chance of inheriting the mutant allele from their mothers, but the sons will express the disease while the daughters will be carriers of the disease. The Punnett square analysis of X-linked recessive disorders is shown in Figure 18.6B.

A

B

FIGURE 18.6 **A.** A pedigree demonstrating X-linked recessive inheritance. Females with one defective allele are carriers of the disease. **B.** A Punnett square analysis of X-linked recessive allele transmission. In this case, the lowercase “x” refers to the X chromosome carrying the mutant allele. Partially shaded symbols indicate a carrier of the mutation, whereas fully shaded symbols indicate an individual who expresses the disease. (Reprinted with permission from Lieberman MA, Ricer R. *BRS*

1. Gene Dosage and the Lyon Hypothesis

The expression of genes on an extra chromosome copy (trisomy), or loss of expression of genes on a chromosome (monosomy, due to a chromosomal deletion) is detrimental for human development. All monosomies of an entire autosomal chromosome (chromosomes 1 to 22) are embryonic lethal, whereas trisomic conditions of chromosomes 13, 18, and 21 are tolerated to a limited extent, but trisomies of other chromosomes do not result in viable offspring. Monosomic X chromosomes give rise to viable female offspring, but they do exhibit a phenotype.

The X chromosome is about five times larger than the Y chromosome, and if females expressed all of the genes on both X chromosomes, they would express many genes much more highly than males. To compensate for this difference in gene expression from the sex chromosomes, and to keep gene dosage equal between the sexes, X-chromosome inactivation occurs when there is more than one X chromosome in a somatic cell. For females with 2 X chromosomes, one X chromosome in each cell is inactivated and condensed. The resulting chromosome copy is known as a **Barr body**. Inactivation is random as to the origin (maternal or paternal) of the chromosome (Fig. 18.7). While the Barr body is highly condensed a small region of the chromosome is transcriptionally active, to balance the level of transcription from a male's Y chromosome.

Once inactivation occurs, the same X chromosome remains inactivated in all progeny cells

FIGURE 18.7 The Lyon hypothesis. The dark bar represents the inactivated chromosomes. The Lyon hypothesis explains how equal numbers of active genes are maintained in males and females. Inactivation at the 16-cell stage is random. Once an X chromosome is inactivated in a cell, all subsequent daughter cells have the same pattern of X-inactivation. In the zygote, both maternal (X_m) and paternal (X_p) X chromosomes are active. (Reprinted with permission from Lieberman MA, Ricer R. *BRS Biochemistry, Molecular Biology & Genetics*. 7th ed. Wolters Kluwer; 2020. Figure 10.9.)

If a woman has the karyotype 48, XXXX, how many Barr bodies would be present in the nuclei of her cells?

Examples of X-linked recessive disorders include **hemophilia A** (1 in 4,000 to 1 in 5,000 live male births, due to a mutation in the *factor VIII* gene, necessary for normal blood clotting), **Duchenne muscular dystrophy** (1 in 3,500 live male births, due primarily to large deletions in the *DMD* gene), **red-green color blindness** (1 in 12 males of northern European ancestry, due to a mutation that compromises function of cone photoreceptors) and **ornithine transcarbamylase deficiency** (1 in 100,000 live births, the most common inborn error of the urea cycle).

Assume that a woman has a father with a recessive X-linked disease, and the woman is expressing some of the symptoms of the disease. Her mother is not a carrier for this disease. How might this occur?

2. X-linked Dominant Disorders

Women carrying an X-linked dominant disorder will express symptoms of the disease. Affected males will give the mutated allele to their daughters 100% of the time, but never to their sons (Fig. 18.8). Females may express less severe symptoms than males due to the presence of a corresponding nonmutated allele or potential inactivation of the mutant allele.

FIGURE 18.8 An example of X-linked dominant inheritance. The male in generation I has an X-linked dominant disease, and passes it to his daughter, but not his son. The daughter then passes the defective allele to one of her sons and to one daughter. (Reprinted with permission from Lieberman MA, Ricer R. *BRS Biochemistry, Molecular Biology & Genetics*. 7th ed. Wolters Kluwer; 2020. Figure 10.10.)

D. Mitochondrial Inheritance

Human mitochondria have a genome of 16,569 bp, which encodes a number of polypeptides and both rRNA and tRNA molecules. The proteins are needed for oxidative phosphorylation, and the rRNAs and tRNAs to synthesize the mitochondrial genome-encoded proteins within the mitochondria, although all ribosomal proteins and tRNA synthetases are encoded in nuclear DNA and must be imported into the mitochondria. Mutations in the mitochondrial genome can lead to defects in oxidative phosphorylation and reduction of energy production by mitochondria containing a mutated genome.

A cell has multiple copies of mitochondria, and **heteroplasmy** refers to the fact that some mitochondria contain normal genomes, and other mitochondria contain mutated genomes, within the same cell. **Homoplasmy** is the term used if all the mitochondria within the cell contain the same normal or mutated genome.

Examples of X-linked dominant disorders include **hypophosphatemic rickets** (due to mutations in the *PHEX* gene, with an incidence of 1/20,000 newborns) and **incontinentia pigmenti type 1** (this disease is often fatal in males, but not in females). The mutation in incontinentia pigmenti type 1 is in the *IKBKG* gene, whose product regulates a family of transcription factors. Incontinentia pigmenti type 1 is an extremely rare disease (about 1,200 individuals worldwide, including a dozen males).

Mitochondria are inherited from the mother (most of the mitochondria associated with the sperm are destroyed when they enter the egg), so mitochondrial inheritance is considered an example of maternal inheritance. A pedigree of mitochondrial inheritance is shown in Figure 18.9. The key features of a mitochondrially inherited disorder are the following:

FIGURE 18.9 An example of a pedigree demonstrating mitochondrial inheritance. (Reprinted with permission from Lieberman MA, Ricer R. *BRS Biochemistry, Molecular Biology & Genetics*. 7th ed. Wolters Kluwer; 2020. Figure 10.11.)

1. All children of an affected female will express the disease (100% penetrance), but there will be variable expressivity depending on the number of mutated mitochondria inherited by each child, and which organ systems contain the majority of mutated mitochondria.
2. The children of an affected male will most likely be unaffected.
3. The symptoms of the disease are manifest in tissues with a high energy requirement, such as the muscle and nervous system.

Each cell would have three Barr bodies, as only one X chromosome would be primarily transcriptionally active in each cell.

Inactivation of the X chromosome is random as to the origin (maternal or paternal) of the chromosome, but it is possible that in

this woman more X chromosomes from the mother were inactivated than from the father, which would then have the majority of cells expressing the X chromosome with the disease allele, and symptoms of the disease would appear.

The inheritance patterns described are summarized in Table 18.2.

TABLE 18.2 Summary of Inheritance Patterns (Pedigree Analysis)				
	FREQUENCY OF THE CHILD INHERITING THE TRAIT	SEX OF AFFECTED INDIVIDUALS	PEDIGREE PATTERNS IN FAMILIES	OTHER
Autosomal dominant	50%	Both	Vertical, no skipping of generations; transmission by the mother or father	Homozygosity is generally a genetic lethal; nuclear inheritance
Autosomal recessive	25%	Both	Horizontal, skipping of generations; mother and father each transmit a recessive allele	Both parents are obligate carriers; nuclear inheritance; Consanguinity may occur at some point in the pedigree
Sex-linked: X-linked recessive	50% for sons of a carrier female, and a 50% chance of a daughter being a carrier; 0% for sons of an affected male, although 100% of daughters are carriers	Males	Horizontal, do see skipping of generations	Absence of father to son transmission; heterozygous females are clinically normal but may be mildly affected depending on the skew of the X-chromosome inactivation; homozygous recessive females are overtly affected; nuclear inheritance
Sex-linked: X-linked dominant	50% sons affected, and 50% daughters affected if mother affected; 0% sons and 100% daughters affected if father affected	Both	Vertical, disease phenotype seen in generation after generation	Absence of father–son transmission, expression usually less severe in heterozygous females than in affected males; nuclear inheritance
Mitochondrial disorders	100% if mother has disease, 0% if father has disease	Both	Vertical, transmitted maternally	Absence of father to child transmission; a range of phenotypes is observed in affected females and males due to heteroplasmy; tissues with a high ATP requirement are more severely affected; extranuclear inheritance

V. Cytogenetics

Chromosomal abnormalities (alterations that traditionally are large enough to be seen under a microscope, although more recently can be observed using array-based comparative genomic hybridization) are responsible for a significant number of disorders, occurring with a frequency of 1/150 live births. Such chromosomal abnormalities are a leading cause of intellectual disability in children, as well as a leading cause of miscarriage (spontaneous abortion). Chromosomal abnormalities are seen in 50% of first-trimester miscarriages and in 20% of second-trimester miscarriages. To understand how such abnormalities can occur a review of mitosis and meiosis is needed.

Martha W. meets with the physician at the foreign clinic to discuss a procedure that would enable her to have children who do not express her mitochondrial disease. The physician explains that **Martha W.** would have to identify an egg donor from a woman without a mitochondrial disease. The doctor would harvest eggs from the donor, as well as from **Martha W.** The donor eggs would then have their nucleus removed, and the nucleus from one of **Martha W.**'s eggs would be inserted into the enucleated donor egg. This “hybrid” egg would contain **Martha W.**'s nuclear DNA, but the donor woman's mitochondrial DNA, which does not carry a mutation. The “hybrid” egg would be fertilized with sperm taken from **Martha W.**'s partner, and the fertilized egg then implanted into her uterus for embryonic and fetal growth.

A. Mitosis and Cell Division

As seen previously in Figure 18.1 mitosis is the process of cell division, in which the DNA is replicated (during the S phase of the cell cycle) and then during the M phase of the cell cycle cell division occurs. Recall that human cells contain 46 chromosomes, 22 pairs of autosomes (numbered 1 through 22), and 2 sex chromosomes (XX for women, XY for males). The diploid state is 46 chromosomes (a 2N content of DNA), while the haploid state is 23 chromosomes (with an N content of DNA). In mitosis each chromosome is replicated, leading to a 4N state, and then cell division creates two daughter cells containing a 2N content of DNA. During mitosis, at the 4N state, the sister chromatids are separated such that the two chromosomes of each pair end up in different daughter cells.

Results presented in a recent scientific paper (<https://www.pnas.org/content/115/51/13039>), using advanced sequencing

technology, suggest that paternal mitochondrial DNA can also be transmitted to the child in certain conditions, but the results are not universally accepted. Further research is necessary to determine if the initial result will hold true, and under what conditions such mitochondrial transfer can occur from father to child.

B. Meiosis and Gamete Formation

Meiosis is the process of converting 2N DNA content to the haploid (N) DNA content, which occurs during two meiotic divisions. The cell first replicates its DNA, creating a cell with a 4N content of DNA. In the first meiotic division, the cell divides such that each daughter cell receives a 2N content of DNA, but as opposed to mitosis, at the 2N stage each cell contains exact duplicates of each chromosome (the sister chromatids) except for regions where crossing over between homologous chromosomes occurred. In the second meiotic division (meiosis 2), the cell divides its DNA content again (without any DNA replication), separating the sister chromatids such that each cell receives a haploid (N) number of chromosomes.

Examples of mitochondrial disorders include **Leber’s hereditary optic neuropathy (LHON)**, due to a mutation in a protein-encoding gene, **myotonic epilepsy with ragged red fibers (MERRF)**, which is due to a mutation in a mitochondrial tRNA gene, **mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS)**, also due to a mutation in a different mitochondrial tRNA gene, and **Kearns–Sayre disease**, characterized by muscle weakness, cerebellar damage, and heart failure, due to a deletion of part of the mitochondrial genome.

C. Chromosome Structure and Nomenclature

Chromosomes contain **centromeres**, DNA segments where the homologous chromosomes are attached during cell division. The centromere is positioned in the middle of **metacentric** chromosomes; **submetacentric** chromosomes have the centromeres positioned between the middle of the chromosome and the tip of the chromosome; and **acrocentric** chromosomes have the centromeres located at the tips of the chromosomes.

The ends of the chromosomes are known as telomeres. The short arm of a chromosome is designated as the “p” arm, and the long arm as the “q” arm. Appropriate staining of chromosomes (both DNA and protein staining) yields banding patterns based on chromatin structure that can allow further subdivision of the chromosome into regions; for example, 14q32 refers to the second band in the third region (32) of the long arm (q) of chromosome 14.

The nomenclature utilized for karyotypes is summarized in Table 18.3.

TABLE 18.3 Chromosome and Karyotype Nomenclature

DESIGNATION	MEANING
1–22	Autosome numbers
X, Y	Sex chromosomes
P	Short arm of chromosome, petit
Q	Long arm of chromosome
Del	Deletion of chromosomal material
Der	Derivative, a structurally rearranged chromosome
Dup	Duplication of a part of a chromosome
Ins	Insertion of DNA into a chromosome
Inv	Inversion of the DNA within a chromosome
/	A designation to indicate mosaicism; cells of different genotypes within one individual. The first karyotype goes before the /; the second karyotype after the /.
T	Translocation; the regions which are translocated are described after the t symbol
Ter	Terminal (also seen as pter, or qter, when referring to the terminal end of a specific chromosome arm)
r	Ring chromosome (the two ends are joined to form a ring structure)
+ or –	Placed before the chromosome number, these symbols indicate either additions (+) or loss (–) of a whole chromosome; placed after the chromosome number, these symbols indicate gain or loss of a chromosome part, e.g., 5p– indicates loss of part of the short arm of chromosome 5; however, del (5p) is the preferred nomenclature for such a loss

Carrie S.'s fiancé decided to be tested for the sickle-cell gene. He was found to have both the 1.3-kb and the 1.1-kb *MstII* restriction fragments that include a portion of the β -globin gene. Therefore, like **Carrie S.** he also is a carrier for the sickle-cell gene.

One of **Martha W.**'s concerns about her procedure is that it may be possible that her child will still be born with a mitochondrial disorder. At what step of the procedure might mutant mitochondria be placed in the hybrid egg?

D. Abnormalities of Chromosome Number

Euploid refers to cells with a multiple of 23 chromosomes (23 is haploid, 46 is diploid, 69 is triploid, and 92 is tetraploid). Triploidy and tetraploidy are incompatible with human life. Aneuploid refers to conditions when the total chromosome number is not a multiple of 23. Aneuploidy involves primarily monosomies (one copy of one of the 23 chromosomes) or trisomies (three copies of one chromosome). Autosomal monosomies are always lethal in utero. Autosomal trisomies are often lethal with only a few exceptions (Table 18.4). Sex chromosome aneuploidies are better tolerated but can result in abnormalities.

TABLE 18.4 Major Chromosome Aneuploidy Syndromes Compatible with Live Births

SYNDROME	CHROMOSOMAL ABNORMALITY	MAJOR FEATURES
Patau syndrome	Trisomy 13	Cleft lip and palate, heart defects, severe central nervous system anomalies, polydactyly; occurs in 1 out of 16,000 live births, 90% die within 12 months
Edward syndrome	Trisomy 18	Low birth weight, heart defects, small abnormally shaped head; occurs in 1 out of 5,000 live births, 90% die within 12 months
Down syndrome	Trisomy 21	Hypotonia, characteristic facial features, developmental delay, intellectual disability, heart abnormalities, increased risk of leukemia; occurs in 1 out of 800 live births
Turner syndrome	Monosomy X	Short stature, amenorrhea, lack of secondary sex characteristics; occurs in 1 out of 2,500 live female births, more common in miscarriages and stillbirths
Klinefelter syndrome	XXY	Small testes, infertility, tall stature, learning problems; occurs in 1 out of 650 live male births
Triple-X	XXX	Learning disabilities, no major physical anomalies; occurs in 1 out of 1,000 live female births
XYY	XYY	Learning and behavioral problems in some individuals, occurs in 1 out of 1,000 live male births

Adapted with permission of John Wiley & Sons from Korf BR. *Human Genetics: A Problem-Based Approach*. 2nd ed. Blackwell Science; 2000; permission conveyed through Copyright Clearance Center, Inc.

Aneuploidy can arise by the process of **nondisjunction**. Nondisjunction is unequal chromosome sorting during meiosis I or II, such that the incorrect number of chromosomes is distributed to the daughter cells (one too many, or one too few). Such possibilities are shown in Figure 18.10 for the process of meiosis. If the appropriate chromosomal markers are available, one can determine whether a nondisjunction event occurred in meiosis I or II.

FIGURE 18.10 Examples of nondisjunction in meiosis I and II. (Adapted with permission from Gelehrter TD, Collins FS. *Principles of Medical Genetics*. Williams & Wilkins; 1990:165.)

E. Abnormalities of Chromosome Structure

Chromosome structure can be altered in a variety of ways. These include the following:

- **Inversions:** two breaks in a single chromosome and an inversion of genetic material between the breaks
- **Duplications:** part of a chromosome is duplicated and inserted into the same chromosome
- **Insertions:** a section of one chromosome is inserted into another chromosome, and usually does not lead to a loss of genetic material in the cell
- **Isochromosomes:** an abnormal centromere division of a metacentric chromosome can lead to chromosomes in which entire arms are lost, and the other arm is duplicated, such that an isochromosome can contain two p arms or two q arms derived from the same chromosome. The arms of the isochromosome are genetically identical.
- **Microdeletion syndromes** are syndromes with a consistent but complex phenotype associated with a small (<5 megabases) chromosomal deletion. **FISH** (fluorescent in situ hybridization) is often necessary to locate such microdeletions. A more sensitive genomic technique (array-based comparative genomic hybridization) can detect microdeletions that FISH cannot. A partial list of microdeletion syndromes is presented in Table 18.5.

TABLE 18.5 Partial Listing of Chromosome Microdeletion Syndromes

SYNDROME	FEATURES	DELETION
Langer–Giedion syndrome	Sparse hair, bulbous nose, cone-shaped epiphyses, cartilaginous exostoses, intellectual disability	8q24.1
WAGR	Wilms tumor, aniridia, genital, and renal anomalies	11p13
Retinoblastoma	Retinoblastoma, intellectual disability, dysmorphic facies	13q14.1
Prader–Willi	Hypotonia, eating disorder, obesity, mild to moderate intellectual disability	15q11.2-13 (paternal)
Angelman	Hypotonia, seizures, inappropriate laughter and happy	15q11.2-13 (maternal)

	demeanor, uncoordination; severe intellectual disability	
Miller–Dieker	Lissencephaly (smooth brain), dysmorphic facies; microcephaly; early death	17p13.3
Smith–Magenis	Characteristic facies, intellectual disability, delayed speech	17p11.2
Alagille	Biliary dysplasia, pulmonary stenosis, vertebral anomalies, dysmorphic facies	20p11
DiGeorge	Congenital heart defect, hypoplasia of parathyroid and thymus, facial anomalies; cleft palate	22q11.2
Wolf–Hirschhorn syndrome	Congenital heart defects; delayed growth; severe intellectual disability; characteristic facial features	4p16.3
Williams syndrome	Facial dysmorphism; cardiovascular disease; mild intellectual disability; endocrine abnormalities	7q11.23

Adapted from Korf BR. *Human Genetics: A Problem-Based Approach*. 2nd ed. Blackwell Science; 2000, Table 5-3; and from Dudek, RW. *BRS Genetics*. Lippincott Williams & Wilkins; 2009, Table 11-1.

- Translocations: there are two main types of translocations.

Reciprocal or balanced translocations (Fig. 18.11) occur when there are breaks in two different chromosomes and the material between the breaks is mutually exchanged. No genetic material is lost in a balanced reciprocal translocation. Individuals with balanced translocations usually are phenotypically normal, but gamete formation can be compromised, leading to multiple miscarriages upon conception due to fetal monosomies or trisomies. Offspring carrying an unbalanced translocation due to only one translocation chromosome in the gamete can be viable but usually carry congenital abnormalities.

Reciprocal translocation

FIGURE 18.11 A reciprocal translocation between chromosomes 3 and 21. In this case, a segment of chromosome 3 is now attached to chromosome 21, and a segment of chromosome 21 is attached to the long arm of chromosome 3. (Adapted with permission from Gelehrter TD, Collins FS. *Principles of Medical Genetics*. Williams & Wilkins; 1990:167.)

A When the nucleus from **Martha W.**'s egg is carefully removed, it is possible that some of **Martha W.**'s mitochondria are also removed and inserted into the enucleated donor egg. If the mutant mitochondria segregate together during development (an unlikely event, but statistically possible), it is possible that the child would have a mild case of the mitochondrial disorder inherited from the mother. Since the percentage of mutant mitochondria is very low in this case, the probability of the child expressing symptoms is also quite low; however, this is still a scientific gray area. There have been studies done with stem cells indicating that when two different populations of mitochondria are present within the same cell, one population may divide faster than the other, and "outcompete" the other population of mitochondria, which could lead to disease. This issue has not yet been resolved, as there have been very few studies on children born as a result of this procedure.

B Chromosomal translocations can lead to disease, particularly if a translocated gene is regulated inappropriately, or if a fusion protein is created on one of the translocated chromosomes. **Chronic myelogenous leukemia (CML)**, due to a translocation between chromosomes 9 and 22, creates the fusion protein bcr-abl, which is an unregulated tyrosine kinase and leads to uncontrolled cellular proliferation. This is the disease that **Mannie W.** expresses. Burkitt lymphoma, a translocation between chromosomes 8 and 14, leads to dysregulated myc expression, and uncontrolled cell proliferation.

Robertsonian translocations (Fig. 18.12) occur between two acrocentric chromosomes (13, 14, 15, 21, 22) in which the short arms (satellites) are lost and the long arms are fused between the two chromosomes. The loss of genes from the short arms does not cause a problem as the genes lost are primarily those for rRNA, which are present in multiple copies throughout the genome. Individuals carrying a Robertsonian translocation have 45 chromosomes and are phenotypically normal. As with reciprocal translocations, gamete formation can be compromised, leading to fetal monosomies or trisomies or unbalanced translocations.

Robertsonian translocation

FIGURE 18.12 An example of a Robertsonian translocation between chromosomes 14 and 21. (Adapted with permission from Gelehrter TD, Collins FS. *Principles of Medical Genetics*. Williams & Wilkins; 1990:168.)

F. Prenatal Cytogenetics

Cytogenetics is a useful tool for determining if a fetus is carrying a chromosomal abnormality. Indications for performing prenatal cytogenetics on a pregnant woman include advanced maternal age (>35 years), a family history of a child with a chromosomal disorder, or an abnormal chromosomal prenatal study of the parents. There are a number of methods for obtaining fetal cells such that a karyotype analysis can be done prenatally.

1. Amniocentesis

Amniocentesis is the most widely used method for prenatal diagnostics. It can be performed at 15 to 16 weeks of gestation. Fetal cells are recovered from amniotic fluid obtained using an ultrasound-guided needle inserted into the womb. The cells obtained are cultured and then processed for karyotype analysis. Since this is an invasive procedure, there is a 0.25% chance of pregnancy loss due to the procedure.

2. Chorionic Villus Sampling (CVS)

The advantage of **chorionic villus sampling** as compared to amniocentesis is that CVS can be performed earlier, at 10 to 12 weeks of gestation. In this procedure, a small sample of chorionic villi are obtained, which contains fetal cells. The cells are cultured, and a karyotype is determined. The risk of pregnancy loss in this procedure is also about 0.25%.

3. Cordocentesis

Cordocentesis is a procedure where umbilical cord blood is obtained after 18 weeks of gestation. Fetal cells are present in the sample and are cultured and analyzed for chromosomal content via karyotype analysis. There is a 1% to 2% chance of pregnancy loss with this procedure. Cordocentesis is also utilized for the detection of hematopoietic disorders.

4. Noninvasive Techniques

The advent of next-generation DNA sequencing and the discovery of cell-free fetal (cff) DNA in a pregnant woman's blood have led to the development of minimally invasive techniques for the determination of chromosome number in the fetus. Sequencing is done on the cff DNA using primers specific for each chromosome, and ratios of chromosome reads are compared to see if a chromosome is overrepresented (a trisomy) or underrepresented (a monosomy). Currently (as of 2020), this technique is considered a screening procedure, and not a confirmatory procedure. If a result is obtained suggesting a monosomy or trisomy through DNA sequencing, then a confirmatory technique, such as amniocentesis, is performed.

Another minimally invasive test used to screen for chromosomal or neural tube disorders is the "quad test." A blood sample is obtained from the pregnant woman between the 16th and 18th week of pregnancy and analyzed for the levels of four proteins: α -fetoprotein (AFP, made by the fetus); human chorionic gonadotropin (hCG, produced by the placenta); estriol (a form of estrogen produced by both the fetus and placenta); and inhibin A (a protein produced by the placenta and ovaries). Analysis of the levels of each protein can indicate an increased risk for a fetus with an open neural tube defect, or an increased risk for Down syndrome (trisomy 21). If abnormal results are obtained a confirmatory test (ultrasound and amniocentesis) are recommended.

VI. Population Genetics

One can analyze the frequency of alleles in defined populations and knowing these frequencies can make predictions of the probability of disease occurring in the general population. Such probability calculations are invaluable for the counseling of patients concerning the risk of transmitting a disease allele to their children. The Hardy–Weinberg equilibrium, which forms the basis for these calculations, is based on five assumptions for a large population (over 1,000 individuals). These five assumptions are random mating between individuals, fairly large populations, negligible mutation rate between the wild-type allele and the disease allele, negligible migration in and out of the population, and no selection, that is, all genotypes are viable and fertile.

The Hardy–Weinberg equilibrium considers two alleles at a locus, A and a. The combination aa represents a disease phenotype for an autosomal recessive disorder. Let p equal the frequency of allele A in the population,

and let q equal the frequency of allele a in the population. Since A and a are the only two possible alleles at this locus $p + q = 1$. Squaring this expression yields the Hardy–Weinberg equilibrium, $p^2 + 2pq + q^2 = 1$, where p^2 represents the frequency of AA homozygotes in the population (wild type), q^2 represents the frequency of aa homozygotes in the population (those expressing the autosomal recessive disease), and $2pq$ represents the frequency of carriers (heterozygotes) in the population.

The frequency of individuals of northern European ancestry with cystic fibrosis (CF) is 1 in 2,500. What is the carrier frequency for CF in that population?

Examples of complex trait disorders include **cardiovascular disease, cancer, asthma, emphysema, hypertension, type 2 diabetes, and birth defects.**

VII. Multifactorial Diseases (Complex Traits)

Multifactorial diseases result from the interaction of alleles at multiple loci (the genotype) with the environment; they are complex to study due to the gene interactions required to promote the observed phenotype (it is more than just an allele at one locus).

To understand multifactorial disease, the concepts of **risk** and **relative risk** are important to understand. Risk is the probability that a child will be born with a particular trait. Relative risk is the ratio of the risk of having the trait in the person being studied to the risk of having the trait in a random person in the population. The higher the relative risk, the greater is the chance that a couple will have a child with a particular trait. As an example, the risk of having a child with pyloric stenosis in the general population is 0.5%, but if one child in a family is born with pyloric stenosis the risk of having another child with pyloric stenosis is 5%, for a relative risk within that family of 10.

Environmental issues are important and are best observed with identical twins. For identical twins (same genotype), if one child is born with a cleft palate the chance of the other twin having a cleft palate is not 100% but is 40%. As the ratio of cleft palate to noncleft palate in the general population is 0.1%, the relative risk of a monozygotic twin exhibiting a cleft palate when the other does is 400 (40% divided by 0.1%). Since the genotype of the monozygotic twins is the same there must be significant environmental factors at play such that only 40% of monozygotic twins will both express a cleft palate.

In a simplistic way, one can view birth defects, or other complex traits, as requiring a certain number of variant alleles to accumulate for the affected individual to express the defect. Thus, if a couple has a child with a cleft palate, for example, their relative risk for a second child with a cleft palate is increased relative to the general population since it is known that the couple contains, between them, sufficient variant alleles to bring about this phenotype. Another form of birth defect, pyloric stenosis, is more frequently seen in males than females. This indicates, in a simple fashion, that females need to accumulate more variant alleles than males to express the disorder pyloric stenosis. Thus, if a mother has had pyloric stenosis as a child, the relative risk of her passing on the disorder to her son is greater than if the father had pyloric stenosis as a child, as the mother has a greater accumulation of variant alleles to have had pyloric stenosis as a child.

VIII. Triplet Nucleotide Repeat Expansions

A number of diseases result from a triplet nucleotide repeat expansion within a transcribed region of a gene. The number of repeats inherited correlates with the severity of the disease, leading to variable expressivity of the disease. The diseases are not necessarily 100% penetrant; individuals in a pedigree may inherit a triplet repeat but do not express the disease. Such individuals, however, can transmit the triplet repeat to their children, who may then express the disease. Within a pedigree, triplet-repeat disorders display an X-linked or autosomal dominant mode of inheritance.

In diseases that are due to triplet-repeat expansions, it has been observed that the length of the expansion increases with every generation, and the severity of the disease is worse in subsequent generations (earlier onset, with more severe symptoms). This phenomenon is known as **anticipation**. Nucleotide repeats tend to cause errors during DNA replication, and additional triplets can either be added or removed from this region during gamete formation.

Diseases due to triplet-repeat expansions include **myotonic dystrophy (DM), fragile X syndrome, Huntington chorea, spinocerebellar ataxia, and spino and bulbar muscular dystrophy.** DM is due to a CTG repeat in the three prime-untranslated regions of the gene, which encodes a protein kinase. Fifty or more copies of the repeat will lead to a mild

form of DM. Greater than 100 copies will lead to classical DM, and >1,000 copies will lead to congenital DM.

Triplet-repeat expansions during replication are thought to arise through a mechanism known as slipped strand mispairing or replication slippage. A simplified version of this process is shown in Figure 18.13. When DNA polymerase enters a region of repeats (whether they are dinucleotide or trinucleotide repeats) during replication, it is possible for DNA polymerase to slip off the DNA, allowing the newly replicated strand of DNA to form a hairpin loop, which causes a mispairing of bases. Continuation of replication leads to an expansion of bases on one of the replicated strands of DNA. DNA repair enzymes are also involved such that both strands of DNA acquire the extra bases and an expansion of the repeat. Triplet repeats become unstable when they reach a **threshold**, in which repeat lengths lower than the threshold do not usually increase in size, whereas repeat lengths greater than the threshold have a significantly higher rate of expansion.

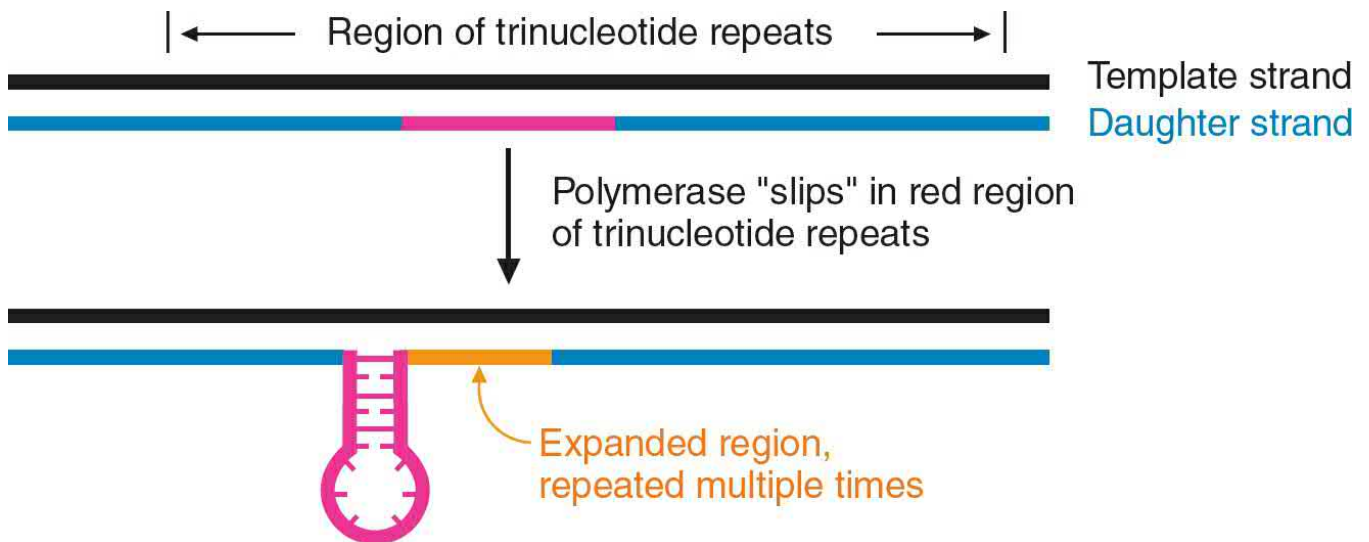

FIGURE 18.13 Strand slippage leading to an expansion of the number of triplet repeats, the biochemical basis of genetic anticipation.

To determine the size of the expansions in individuals within a pedigree, triplet-repeat lengths can be determined using Southern blot or PCR-based methods (using primers that surround the repeated regions). Such analyses have led to the conclusion that the larger the repeat, the earlier the age of onset of symptoms for the disorder.

 In fragile X syndrome, a GCC triplet is amplified on the 5'-side of a gene (fragile X mental retardation 1, *FMR-1*) associated with the disease. This gene is located on the X chromosome. The disease is named for the finding that when cells containing this triplet-repeat expansion are cultured in the absence of folic acid (which impairs nucleotide production and hence the replication of DNA) the X chromosome develops single- and double-strand breaks in its DNA. These were termed fragile sites. It was subsequently determined that the *FMR-1* gene was located in one of these fragile sites. A normal person has about 30 copies of the GCC triplet, but in affected individuals, thousands of copies can be present. This syndrome, which is a common form of inherited intellectual developmental disorder, affects about 1 in 3,500 males and 1 in 4,000 to 1 in 6,000 females worldwide.

IX. Imprinting

Imprinting refers to a modification of a gene's ability to be expressed via means other than changing the base sequence of the DNA (see Chapter 15), which is dependent upon the parental origin of the allele. Imprinting a gene arises through methylation of adenine or cytosine bases in the DNA through a complex enzyme system, and different alleles are imprinted by males and females. Such events can be reversed by demethylating systems in the cell.

 The frequency of individuals who are homozygous for the CF disease allele is $1/2,500$, so $q^2 = 1/2,500$, or $q = 1/50$ (the disease allele frequency). Since $p + q = 1$, $p = 49/50$, which will be approximated as 1. The carrier frequency (heterozygote frequency) is $2pq$, or $2 \times 1 \times 1/50$, or 1 in 25 individuals within this population.

The initial clue implicating nonequal expression of genes inherited from the mother or father was from studies with mice. Nuclear transplantation experiments were performed such that diploid zygotes were generated with either two copies of each paternal chromosome or two copies of each maternal chromosome (uniparental embryos). The finding that neither embryo was able to develop normally led to the hypothesis that there needed to be a balance of expression between maternally inherited and paternally inherited alleles for normal development to occur.

Imprintable alleles are transmitted in a Mendelian fashion, and imprinting is sex-specific (maternal imprinting versus paternal imprinting). Maternal imprinting refers to alleles that females modify (through methylation primarily) during gamete formation, which may never be expressed in their children, whereas paternal imprinting refers to the alleles that males modify during gamete formation, which may never be expressed in their children. For the purposes of this text, we will assume that the imprinting event has blocked the expression of the allele, although that is not universally true for all imprinted genes. Figure 18.14 displays examples of maternal and paternal imprinting in pedigrees (recall that maternal imprinting is being interpreted to mean that alleles are inactivated by the mother, whereas paternal imprinting is the inactivation of alleles by the father).

Maternal Imprinting pattern in which the paternal gene has a mutation.

Paternal Imprinting pattern in which the maternal gene has a mutation.

FIGURE 18.14 Idealized imprinting pedigrees, with the (*top*) pedigree an example of maternal imprinting, and the (*bottom*) pedigree an example of paternal imprinting. (Reprinted with permission from Lieberman MA, Ricer R. *BRS Biochemistry, Molecular Biology & Genetics*. 7th ed. Wolters Kluwer; 2020. Figure 10.15.)

To interpret a pedigree displaying maternal imprinting recall that when the eggs are formed certain alleles are marked (by methylation of certain bases), which leads to those genes not being expressed when the egg is

fertilized. The marked maternal genes remain repressed in all cells as the fetus develops (and through birth), and they are only reprogrammed in the germ cells of the offspring. The corresponding allele from the father is not inactivated during maternal imprinting, so for those genes inactivated maternally, the fetus is hemizygous for those alleles (only one functional allele, from the father). If the father carried an inactivating mutation in a maternally imprinted gene then the fetus would lack expression of the wild-type gene, and a disease may result. The probability of passing such a mutated allele to children would be 50% (the father has one normal gene and one mutated allele at the imprinted locus).

Examples of other diseases due to imprinting include certain types of cancer (**Wilms tumor** with maternally derived deletions on chromosome 11), **retinoblastoma** (the first mutation most often occurs on the paternal chromosome), and **Huntington chorea** (about 5% to 10% of paternally derived triplet-repeat expansions lead to symptoms that are not observed in maternally derived triplet-repeat expansions).

Classic examples of sex-dependent imprinting are Prader–Willi syndrome and Angelman syndrome. Both syndromes, which have very different symptoms, result from deletions of the same region of chromosome 15q (a microdeletion of <5 megabases in size). If the deletion is of paternal origin, Prader–Willi syndrome results; if the deletion is of maternal origin, Angelman syndrome results. As shown in the figure below the symptoms of the two diseases are quite distinct. These findings indicate that there are both maternally and paternally imprinted genes in this region of chromosome 15, and loss of a corresponding allele (through the deletion) can lead to disease, which differs depending on which genes are missing and/or inactivated (as depicted in the figure below). A disease occurs when a gene that is in the deleted region of one chromosome is methylated on the other chromosome. The mother's cells methylate different genes than the father's cells, so different genes are expressed depending on which parent transmitted the intact chromosome. For example, for Prader–Willi syndrome, if genes 1, 2, and 3 are deleted in the paternal chromosome and gene 2 is methylated in the maternal chromosome, only genes 1 and 3 will be expressed. For Angelman syndrome, genes 1, 2, and 3 are deleted on the maternal chromosome and gene 1 is methylated on the paternal chromosome, so only genes 2 and 3 are expressed.

X. Epigenetics

As indicated in Chapters 11 and 15, chemical modifications of histones and bases in DNA (see imprinting above) can alter gene expression. The histone modifications can be inherited, as can the base modifications. Histones can undergo a variety of modifications, such as acetylation, methylation, phosphorylation, sumoylation, and ubiquitination. Modifications of histones at a particular location (such as a specific lysine

residue) have been correlated with changes in gene expression. A histone code has been proposed in which the sequence of alterations in a histone can predict its effect on transcription (see Chapter 15). As will be detailed in Chapter 25, an inability to demethylate histones and DNA (due to the overproduction of 2-hydroxyglutarate, an α -ketoglutarate antagonist) leads to altered gene expression and uncontrolled cell proliferation.

While *Rb* was the example used to illustrate tumor repressors, these principles of loss of heterozygosity apply to all tumor suppressor genes (such as *p53*, *APC*, *BRCA1*, *BRCA2*, *NF1* [neurofibromas] and *NF2* [gives rise to acoustic neuromas], *WT1* [Wilms tumor], and *p16* [can give rise to melanomas]).

XI. The Genetics of Tumor Suppressors

Tumor suppressors are genes whose loss of expression can lead to tumor formation (see Chapter 17), yet the pedigree of such diseases exhibits a dominant type of transmission (Fig. 18.15). The example shown is retinoblastoma (*Rb*), which can be hereditary or sporadic. The sporadic variety accounts for 60% of the disease. The genetic locus is 13q14. Note in Figure 18.15 the autosomal dominant pattern of expression in the hereditary form of *Rb*, and that bilateral *Rb* predominates (osteosarcomas can also result); in contrast, the sporadic form is cancer in only one eye, and tumors are not found in other locations.

Hereditary

Sporadic

Bilateral retinoblastoma

Unilateral retinoblastoma

FIGURE 18.15 A pedigree analysis indicating both hereditary (*top*) and sporadic Rb (*bottom*). As indicated in the top pedigree hereditary Rb appears as a dominant trait in pedigrees, but at the molecular level, the individuals inherit one mutated copy of the Rb gene (a 50% probability) from their affected parent, and then undergo a loss of heterozygosity in the retinal cells, leading to tumor formation. There is a high probability that loss of heterozygosity will occur during the individual's lifetime. (Reprinted with permission from Lieberman MA, Ricer R. *BRS Biochemistry, Molecular Biology & Genetics*. 7th ed. Wolters Kluwer; 2020. Figure 10.17.)

In hereditary Rb (and other tumors due to tumor suppressors), one of the Rb alleles is already mutated in all cells, and, over time, there is a close to 100% chance that the corresponding normal allele will lose activity in the retina, leading to tumor formation. In sporadic Rb, both an initial mutation and the second event have to occur *de novo*, which makes these tumors less frequent, and not seen bilaterally (Fig. 18.16)

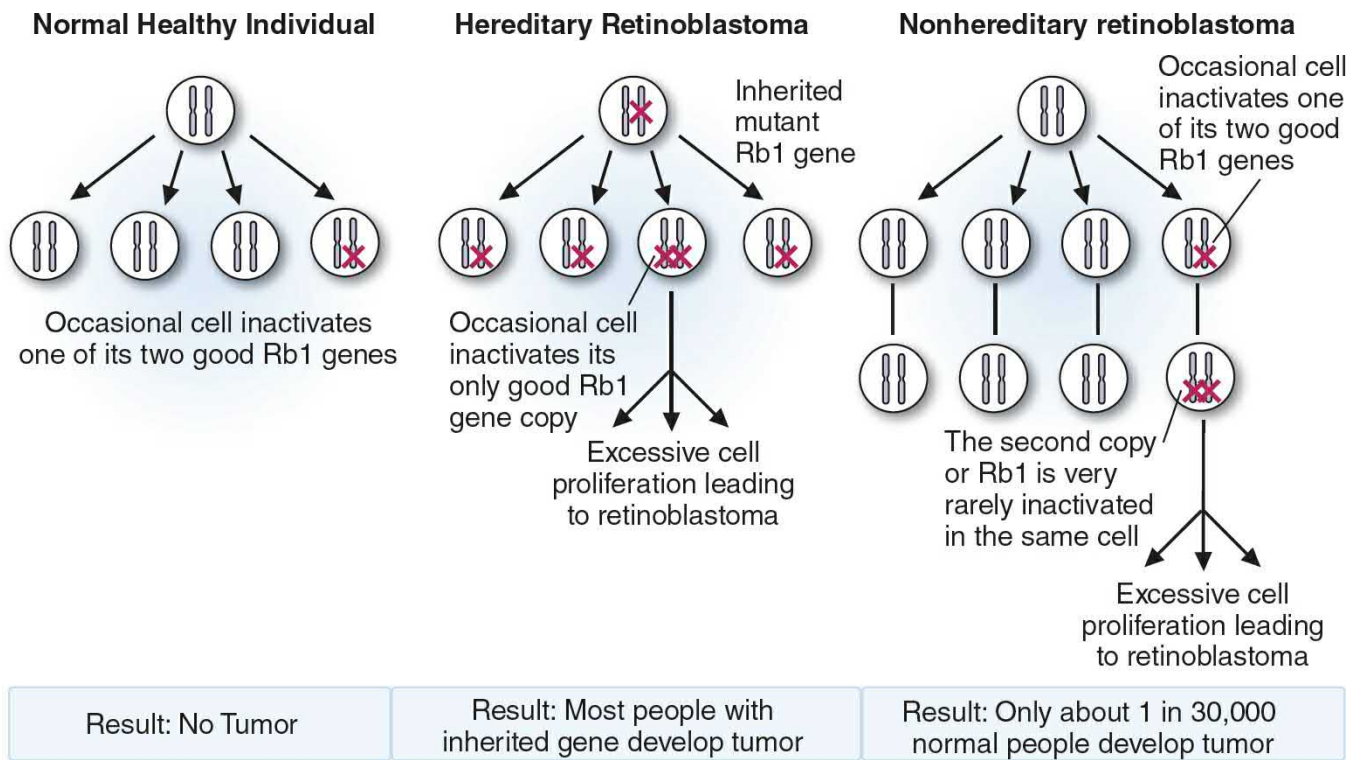

FIGURE 18.16 An illustration of the manner in which Rb mutations can lead to disease. Not the differences between hereditary and nonhereditary Rb transmission. (Reprinted with permission from Lieberman MA, Ricer R. *BRS Biochemistry, Molecular Biology & Genetics*. 7th ed. Wolters Kluwer; 2020. Figure 10.18.)

The Knudson two-hit model explained these results. A tumor develops when two events that together knock out both copies of a gene occur in the same cell lineage. Two rare events must occur to produce a sporadic tumor. A person who is born with the first mutation (an inherited mutation), however, needs to acquire only one additional mutation to develop a tumor.

The loss of the corresponding normal allele is known as **loss of heterozygosity**. This can occur in a variety of ways, as outlined in Table 18.6. The end result is the loss of function of the tumor suppressor gene, leading to uncontrolled cell proliferation and cancer.

TABLE 18.6 Events Leading to Loss of Heterozygosity	
EVENT	DESCRIPTION
Nondisjunction	Mitotic nondisjunction such that the chromosome containing the normal allele is lost during cell division
Nondisjunction followed by reduplication of the existing chromosome	Leads to two identical copies of the same chromosome, each of which contains the mutated allele
Mitotic recombination	Recombination during mitosis such that one cell now contains two copies of the mutated allele
Gene conversion	A mitotic event in which the genetic information from one chromosome is transferred

	to another chromosome, such that the cell now contains two copies of the mutated allele
Deletion	A deletion of the normal allele such that the cell is hemizygous at this locus, and only expresses the mutated allele
Point mutation	A mutation within the normal allele such that it loses function, leaving the cell with two nonfunctional alleles at this locus

CLINICAL COMMENTS

Carrie S. After learning the results of their tests for the sickle-cell gene, **Carrie S.** and her fiancé consulted a genetic counselor. The counselor informed them that, because they were both carriers of the sickle-cell gene, their chance of having a child with sickle-cell anemia was fairly high (~1 in 4). She told them that prenatal testing was available with fetal DNA obtained from cells by amniocentesis or chorionic villus sampling. If these tests indicated that the fetus had sickle-cell disease, abortion was a possibility. **Carrie S.** because of her religious background, was not sure that abortion was an option for her. But having witnessed her brother's sickle-cell crises for many years, she also was not sure that she wanted to risk having a child with the disease. Her fiancé also felt that, at 25 years of age, he was not ready to deal with such difficult problems. They mutually agreed to cancel their marriage plans.

Martha W. had an uncomplicated pregnancy and delivery, and the child does not appear to have any symptoms of a mitochondrial disorder. She and her partner have decided to only have the child tested for mitochondrial disorders if symptoms develop, so the child will not be tested to examine the degree of heteroplasmy in his/her cells, and if any tissues have a preponderance of mutated mitochondria as compared to normal mitochondria.

BIOCHEMICAL COMMENTS

With the advent of advanced techniques to alter genomes (such as the CRISPR-Cas gene-editing tool described in the previous chapter), scientists have been able to create genomes in which a recessive gene can be “driven” to increase in frequency in the population beyond that predicted by Mendelian genetics. This is known as a **gene drive**. One example of how a gene drive is being used to treat disease is with malaria. The life cycle of the malaria parasite requires a stage where they live in mosquitoes, who then transmit the malaria parasite to a human when the female mosquito feeds to support her pregnancy. Mosquitoes have been generated which contain a gene drive, which renders the female mosquitoes unable to reproduce. If the population loses all its females, then the mosquito population will drop significantly, and it will be more difficult for the malaria parasite to complete its life cycle.

So how does one engineer a gene drive? A gene drive will increase the probability of propagation of a certain allele in a population. With normal Mendelian genetics, a recessive mutated allele would have a 50% chance of being passed onto the next generation from a carrier parent. When a gene drive is introduced, this can approach 100%. The basic premise of the gene drive is to insert into the appropriate chromosome a CRISPR-Cas system adjacent to the mutated allele of interest. Guide DNA sequences are also inserted, which will target the CRISPR-Cas system to the normal gene on the homologous chromosome where a double-strand break will be created in the DNA. The cell will use homology-directed recombination (HDR) to repair the double-strand break, which will utilize the mutated allele as a template to synthesize DNA on the damaged chromosome. This will result in the cell now containing two mutated alleles (homozygous for the mutation), such that all progeny will inherit at least one mutant gene. Cells will also inherit the CRISPR-Cas system such that the gene drive is continued in successive generations. Over the span of a few generations, all progeny will be expressing the mutated allele and the frequency of homozygous females, carrying both mutated alleles, will increase and the mosquito population will decline due to the inability of those mosquitoes to breed. Environmentalists and scientists are discussing the ethical issues concerning the use of gene drives, which have the potential to eliminate a particular species from existence.

KEY CONCEPTS

- ◆ Human cells are diploid; half the chromosomes are from the mother, the other half from the father.
- ◆ Alleles reside at specific loci on chromosomes.
- ◆ Mutations are alterations in the allele sequence that can lead to disease.
- ◆ A karyotype displays all of the chromosomes of a cell.
- ◆ Mendelian inheritance can be classified as autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive.
- ◆ Mitochondrial inheritance is always from the mother.
- ◆ Nondisjunction events in meiosis can lead to aneuploidy, which often leads to disease.
- ◆ Gene dosage is important, as over expression, or under expression of alleles, due to trisomy or monosomy, can lead to disease.
- ◆ Abnormalities of chromosome structure include inversions, duplications, insertions, formation of isochromosomes, deletions, and translocations.
- ◆ Epigenetics refers to the mechanisms whereby genes can be expressed, or silenced, without necessarily altering the DNA base sequence, in an inheritable manner. Epigenetic changes involve modifications, usually methylation, of histones and of DNA bases.
- ◆ The Hardy–Weinberg equation allows one to make estimates of allele frequencies, and heterozygote frequencies, within a given population.
- ◆ Multifactorial diseases involve significant interactions between the genes and environmental factors.
- ◆ Triplet nucleotide repeat expansions in and around genes can lead to disease once the repeat length reaches a threshold. Anticipation refers to an increase in the number of triplet repeats in successive generations, which correlates with the severity of the disease in successive generations.
- ◆ Imprinting refers to altering the expression of an allele in a sex-dependent fashion without altering the nucleotide sequence of the allele. Males and females imprint alleles differently. The imprint remains throughout the life of the cell and its progeny. Imprinting is reset when germ cells are produced.
- ◆ Tumor suppressor alleles, analyzed through pedigrees, display a dominant pattern of inheritance, yet the molecular mechanism is recessive. The loss of a functional allele is known as loss of heterozygosity and occurs through a variety of mechanisms.
- ◆ The diseases discussed in this chapter are summarized in Table 18.7.

TABLE 18.7 Diseases Discussed in Chapter 18

DISEASE	COMMENTS
Achondroplasia, Huntington disease, type 2, hypercholesterolemia, Marfan syndrome, polycystic kidney disease, tuberous sclerosis, neurofibromatosis, type 1	Autosomal dominant inheritance pattern
Albinism, cystic fibrosis, phenylketonuria, hemochromatosis, sickle-cell disease	Autosomal recessive inheritance pattern
Hemophilia A, Duchenne muscular dystrophy, red-green color blindness, Alport syndrome, ornithine transcarbamoylase deficiency	X-linked recessive inheritance pattern
Hypophosphatemic rickets, incontinentia pigmenti type 1	X-linked dominant inheritance pattern
Leber's hereditary optic neuropathy, myoclonic epilepsy with ragged red fibers, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes, Kearns–Sayre disease	Mitochondrial inheritance pattern
Chronic myelogenous leukemia, Burkitt lymphoma	Disorders due to translocations
Cardiovascular disease, cancer, asthma, emphysema, hypertension, type 2 diabetes, birth defects	Multifactorial traits
Cleft palate, pyloric stenosis	Complex traits
Myotonic dystrophy, fragile X syndrome, Huntington chorea, spinocerebellar ataxia, spinal muscular dystrophy, bulbar muscular dystrophy	Triplet-repeat disorder syndromes
Prader–Willi syndrome, Angelman syndrome, Wilms tumor, retinoblastoma	Syndromes due to imprinting; may be caused by microdeletions or uniparental disomy for chromosome 15 (rare)

REVIEW QUESTIONS—CHAPTER 18

1. A woman has a brother with cystic fibrosis (both children have the same parents). She is engaged to a man who is a known carrier of cystic fibrosis. What is the probability that the woman and man would have a child that has cystic fibrosis?
 - A. 16.7%
 - B. 33%
 - C. 50%
 - D. 67%
 - E. 75%
 - F. 100%
2. The prevalence of a particular autosomal recessive disorder in a population is 1 in 360,000. What is the frequency of carriers in this population?
 - A. 1 in 360,000
 - B. 1 in 180,000
 - C. 1 in 600
 - D. 1 in 300
 - E. 1 in 150
3. When analyzing a pedigree to determine the mode of inheritance a characteristic that is unique to X-linked recessive inheritance would be which one of the following?
 - A. The absence of male-to-male transmission
 - B. The absence of female-to-female transmission
 - C. Only female-to-female transmission
 - D. The disease is only expressed in alternate generations
 - E. Multiple immediate family members cannot have the disease
4. The prevalence of an X-linked recessive disorder in the general population is 1 in 5,000 men. What fraction of women in this population are carriers for the mutant allele?
 - A. 1 in 5,000
 - B. 1 in 2,500
 - C. 1 in 1,250
 - D. 1 in 625
 - E. 1 in 312
5. A major difference between mitosis and the first meiotic division is which one of the following?
 - A. The mitotic division yields a cell with 46 chromosomes, whereas the first meiotic division yields cells with 23 chromosomes
 - B. The mitotic division yields a cell with 23 chromosomes, whereas the first meiotic division yields cells with 46 chromosomes
 - C. The mitotic division sends two sister chromatids into each daughter cell, whereas the first meiotic division separates the two sister chromatids into different cells
 - D. The mitotic division separates the two sister chromatids into two different daughter cells, whereas the first meiotic division sends two identical chromatids into the daughter cells
 - E. There is no difference in chromosome segregation between the first meiotic division and cell division in mitosis
6. Assume there are three distinct forms of an allele at a particular locus on chromosome 21, labeled A, B and C. The father contains one A and one B allele, while the mother has one B and one C allele. The parents have a child with trisomy 21, and an analysis of the child's karyotype indicates one B and two C alleles. The nondisjunction event that led to trisomy 21 occurred in which one of the following?
 - A. Paternal meiosis 1
 - B. Paternal meiosis 2
 - C. Maternal meiosis 1
 - D. Maternal meiosis 2
 - E. Paternal mitosis
 - F. Maternal mitosis
7. A phenotypically normal female, with a phenotypically normal male partner, has experienced three miscarriages and has not successfully continued a pregnancy to term (37 weeks). A potential explanation for

this observation could be which of the following? Choose the one best answer.

8. Alleles can be dominant, recessive, or codominant to the corresponding allele at the same locus on another chromosome. Which one of the following is an example of codominant alleles?
 - A. Sickle-cell anemia
 - B. Prader-Willi syndrome
 - C. Achondroplasia
 - D. Fragile X syndrome
 - E. Red-green color blindness
 - F. Blood type AB
9. The pedigree shown below is best explained by which one of the following?

- A. Autosomal recessive
 - B. Autosomal dominant
 - C. X-linked recessive
 - D. X-linked dominant
 - E. Mitochondrial
10. A phenotypically normal woman volunteered for a study in which karyotype analyses were done. Her karyotype was determined to be 48, XXXX. Females with Turner syndrome (45, X) have significant phenotypic properties associated with the loss of an X chromosome. Why does the woman who is 48, XXXX exhibit a normal phenotype?
 - A. Only the genes on 2 X chromosomes are expressed, as is the case for women who are 46, XX
 - B. The women's cells contain one Barr body
 - C. There is very little gene expression from any of her X chromosomes
 - D. The women's cells contain two Barr bodies
 - E. There is very little gene expression from 3 of the 4 X chromosomes

	Robertsonian Translocation in One Parent	Reciprocal Translocation in One Parent	A Microdeletion in One Parent	An Expanded Triplet-Repeat Region in One Parent
A	Yes	Yes	No	Yes
B	Yes	No	Yes	No
C	Yes	Yes	No	No
D	No	No	Yes	No
E	No	Yes	No	Yes
F	No	No	Yes	Yes

1. Prenatal cytogenetic screening has risks for procedure-induced fetal loss. Recent newer technologies, using noninvasive screening through maternal blood sampling, have been utilized to determine if definitive cytogenetic tests need to be ordered. Such noninvasive tests include screening for which of the following? Choose the one best answer.

	Cell-free Fetal DNA	Inhibin A	Human Chorionic Gonadotropin	Testosterone
A	Yes	Yes	Yes	Yes
B	Yes	No	No	No
C	Yes	Yes	Yes	No
D	No	No	No	Yes
E	No	Yes	Yes	No
F	No	No	No	Yes

2. Within the general population, the risk of exhibiting a certain multifactorial trait (trait X) is 0.2%. Within a given family the relative risk of a child exhibiting trait X is 200, based on the finding that they have previously had a child with this trait. What is the percentage probability that the child in the family will exhibit the trait?

 - 10%
 - 20%
 - 30%
 - 40%
 - 50%
3. A young family member has been diagnosed with myotonic dystrophy, a disease his father also expresses. The father first had symptoms of the disorder in his twenties, while the son is expressing symptoms at the age of 10. The patient's grandfather expressed symptoms of the disease in his fifties, much later than his son or grandchild. The earlier onset of disease in succeeding generations within a family is referred to as which one of the following?

 - X-linked recessive
 - Anticipation
 - Microdeletion
 - Autosomal recessive
 - Variable expressivity
 - Penetrance
4. A young boy has developed a tumor in one of his eyes, and a genetic analysis of the DNA in fibroblasts obtained from the patient indicated the inheritance of one mutated *rb* allele. Tumors develop when the normal *rb* allele is lost within a cell. The loss of the normal *rb* allele can happen by which of the following mechanisms? Choose the one best answer.

	Nondisjunction	Mitotic Recombination	Deletion	Point Mutation
A	No	No	No	Yes
B	No	Yes	No	No
C	No	No	No	No
D	Yes	Yes	Yes	Yes
E	Yes	No	Yes	Yes
F	Yes	Yes	Yes	No

5. Genetic imprinting and gene silencing, in which genes and associated chromatin are chemically modified, alters the ability of the genes to be expressed. Imprinting and silencing is dependent upon which of the following? Choose the one best answer.

	Sex of the Parent	Methylation Reactions	Histone Modifications	Modification of RNA Polymerase II
A	Yes	Yes	Yes	No
B	No	No	Yes	No
C	Yes	Yes	Yes	Yes
D	No	No	No	Yes
E	Yes	Yes	No	No
F	No	No	No	Yes

ANSWERS TO REVIEW QUESTIONS

- The answer is B.** The sister of the boy who has cystic fibrosis has a 2/3 chance of being a carrier (there are four genotypes available to her, one is homozygous wild type, one is homozygous for the disease allele, and two are carriers, one normal and one CF allele: since she does not express the disease there is a 2 in 3 chance she is a carrier, since one of the allele combinations can be eliminated). The fiancé of the sister is a carrier, so he has a 1 in 2 chance of passing the allele to a child. The woman has a 2 in 3 chance of passing the allele to her child. For the child to have the disease both parents have to transmit the mutated allele, so the probability is half times 2/3, or 1 in 3, which is 33.3%.
- The answer is D.** Using the Hardy–Weinberg equilibrium, $p^2 + 2pq + q^2 = 1$, the value of q^2 represents the frequency of individuals with the disease. So $q^2 = 1$ in 360,000, and $q = 1$ in 600. $2pq$ represents the

frequency of carriers in the population, and since $p + q = 1$, p is very close to one, and $2pq = 1$ times $1/600$, or $1/300$.

3. **The answer is A.** In a sex-linked recessive mode of inheritance, the disease allele is on the X chromosome, and since males only have one X chromosome, the disease will be expressed since the dominant, wild-type allele is not present in their cells. When males have male sons, they pass their Y chromosome to their son—never the X chromosome. So, the outstanding characteristic of X-linked recessive inheritance is the lack of male-to-male transmission. Females have 2 X chromosomes and always pass an X chromosome to their children, both male and female. Females who inherited the mutated allele from their mother will be carriers of the X-linked recessive disorder. The disease being expressed in alternate generations would fit an autosomal recessive mode of inheritance, while multiple family members having the disorder would fit an autosomal dominant mode of inheritance.
4. **The answer is B.** If 1 in 5,000 men express an X-linked recessive disorder then the gene frequency for that allele is 1 in 5,000 (since each male has one X chromosome). Females have 2 X chromosomes, so the frequency of carriers is 1 in 2,500 ($2pq$, where q is 1 in 5,000).
5. **The answer is D.** During mitosis, a cell goes from a diploid content of DNA to a $4n$ content of DNA. After DNA synthesis and chromosomal duplication, there are 46 pairs of sister chromatids, and when the cell divides the sister chromatids are split, and one chromatid goes into one daughter cell, and the other chromatid goes to the second daughter cell. In meiosis 1, a $2N$ content of DNA is duplicated to create a $4n$ content, and at this point, there are 46 pairs of sister chromatids. However, when the cell divides in meiosis 1, one pair of sister chromatids goes into one daughter cell, and the other pair of sister chromatids goes into the second daughter cell. It is in the second meiotic division that the identical sister chromatids are split and go into separate germ-line cells, which have a haploid number of chromosomes.
6. **The answer is D.** The child expresses one B and two C alleles on the three chromosome 21s. Since the father does not carry a C allele, the B allele must have come from dad. That means two identical C alleles came from mom, which would be a nondisjunction event in meiosis 2. If the nondisjunction event occurred in meiosis 1 then the child would have received a B and a C allele from mom, and their trisomy would be BBC instead of BCC.
7. **The answer is C.** A repeated history of miscarriages suggests that one of the parents is likely to have a chromosomal translocation, such as a Robertsonian or reciprocal translocation. While the person carrying the translocation is phenotypically normal, gamete formation can be comprised, leading to embryos containing monosomies or nonviable trisomies. Carriers of microdeletions or triplet-repeat expansions do not have trouble forming appropriate germ cells, and miscarriages are not likely to result from a parent carrying either of those types of mutations.
8. **The answer is F.** The AB blood type arises due to the expression of an enzyme encoded by the “A” allele, and the equal expression of an enzyme with a different specificity by the “B” allele. Both alleles are expressed equally, and the red blood cell membrane expresses carbohydrate chains extended by either the enzymes expressed by the A or B alleles. Sickle-cell anemia is an autosomal recessive trait, while Prader–Willi syndrome is due to a microdeletion inherited from the father. Achondroplasia is an autosomal dominant trait, while both fragile X syndrome and red-green color blindness are X-linked traits (fragile X is dominant, while color blindness is recessive).
9. **The answer is A.** The pedigree displays an autosomal recessive mode of inheritance. Keys to recognizing the mode of inheritance include the skipping of affected people in certain generations and consanguinity at some point in the pedigree. An X-linked recessive disorder would only show males with the disease, and an X-linked dominant disorder would show women with the disease in some of the skipped generations. An autosomal dominant mode of inheritance would also not typically display a skipping of generations. If this were a mitochondrial disorder, all of the children of a woman affected by the disease would be affected, which is not observed in the pedigree.
10. **The answer is E.** To balance gene dosage between males and females, in a diploid state, one X chromosome is inactivated and condensed into a Barr body, giving one fully functional X chromosome per cell, and one from which only a small amount of transcription occurs (on par with the Y chromosome in males). If a female has more than two X chromosomes, then one X chromosome stays intact, and the others are converted to Barr bodies. So for the patient in this question (48, XXXX), her cells contain three Barr bodies, so there is very little gene expression from those three X chromosomes. Monosomy X leads to phenotypic symptoms due to the loss of expression of a number of genes from the missing X chromosome, which would be a Barr body.
11. **The answer is C.** Noninvasive prenatal testing examines a number of items, which can be obtained from

the blood of a pregnant woman. Cell-free fetal DNA can be sequenced and monosomies or trisomies can be identified, and serum markers, such as inhibin A, human chorionic gonadotropin, and estriol can be measured to see if there is a risk for a neural tube defect, or trisomy 21. Measurement of testosterone levels is not part of the panel in noninvasive prenatal testing.

12. **The answer is D.** The relative risk is the ratio of the risk of a family member expressing the disease divided by the risk of a person in the general population having the disease. Since the relative risk was given as 200, and the risk of a person in the general population having the disease is 0.2%, the risk of a person in this family having the disease is 200 times 0.2% or 40%.
13. **The answer is B.** Myotonic dystrophy is caused by a triplet-repeat expansion within the *DM* gene; the more expansions the earlier the onset and more severe the disease is, and the expansions can increase in size when DNA replication occurs. This observation of increasing severity in future generations is known as anticipation. The expansion of the repeat region is due to DNA polymerase slippage, as shown in Figure 18.13. Penetrance refers to the percentage of individuals who inherit a mutated gene that expresses the disease, while variable expressivity refers to a variation of phenotypic symptoms for people who inherit the same mutated allele.
14. **The answer is D.** In hereditary retinoblastoma, children have inherited one mutated copy of the *rb* gene. In order for them to develop a tumor, the expression of the normal *Rb* gene (on the other chromosome) must be lost. This loss of expression is known as loss of heterozygosity (LOH). LOH can come about through a nondisjunction event, mitotic recombination converting the normal gene to a mutated gene, deletion of the normal gene, or a point mutation within the mutated gene.
15. **The answer is A.** Imprinting results from the methylation of bases in the DNA of a gene, leading to a loss of expression of that gene. Histone modifications (acetylation, phosphorylation, methylation) can also alter expression of a gene (either positively or negatively). Gene methylation is sex dependent—females methylate a different set of genes than males. Gene silencing does not come about via covalent modification of RNA polymerase II.

SECTION

IV

Carbohydrate Metabolism, Fuel Oxidation, and the Generation of Adenosine Triphosphate

Glucose is central to all of metabolism. It is the universal fuel for human cells and the source of carbon for the synthesis of most other compounds. Every human cell type uses glucose to obtain energy. The release of insulin and glucagon by the pancreas aids in the body's use and storage of glucose. Other dietary sugars (mainly fructose and galactose) are converted to glucose or intermediates of glucose metabolism.

Glucose is the precursor for the synthesis of an array of other sugars that are required for the production of specialized compounds such as lactose, cell surface antigens, nucleotides, or glycosaminoglycans. Glucose is also the fundamental precursor of noncarbohydrate compounds; it can be converted to lipids (including fatty acids, cholesterol, and steroid hormones), amino acids, and nucleic acids. Only those compounds that are synthesized from vitamins, essential amino acids, and essential fatty acids cannot be synthesized from glucose in humans.

All physiologic processes in living cells require energy transformation. Cells convert the chemical bond energy in foods into other forms, such as an electrochemical gradient across the plasma membrane, or the movement of muscle fibers in an arm, or assembly of complex molecules such as DNA. These energy transformations can be divided into three principal phases: (1) oxidation of fuels (fat, carbohydrate, and protein), (2) conversion of energy from fuel oxidation into the high-energy phosphate bonds of adenosine triphosphate (ATP), and (3) utilization of ATP phosphate bond energy to drive energy-requiring processes.

More than 40% of the calories in the typical diet in the United States are obtained from starch, sucrose, and lactose. These dietary carbohydrates are converted to glucose, galactose, and fructose in the digestive tract (Fig. IV.1). Monosaccharides are absorbed from the intestine, enter the blood, and travel to the tissues, where they are metabolized.

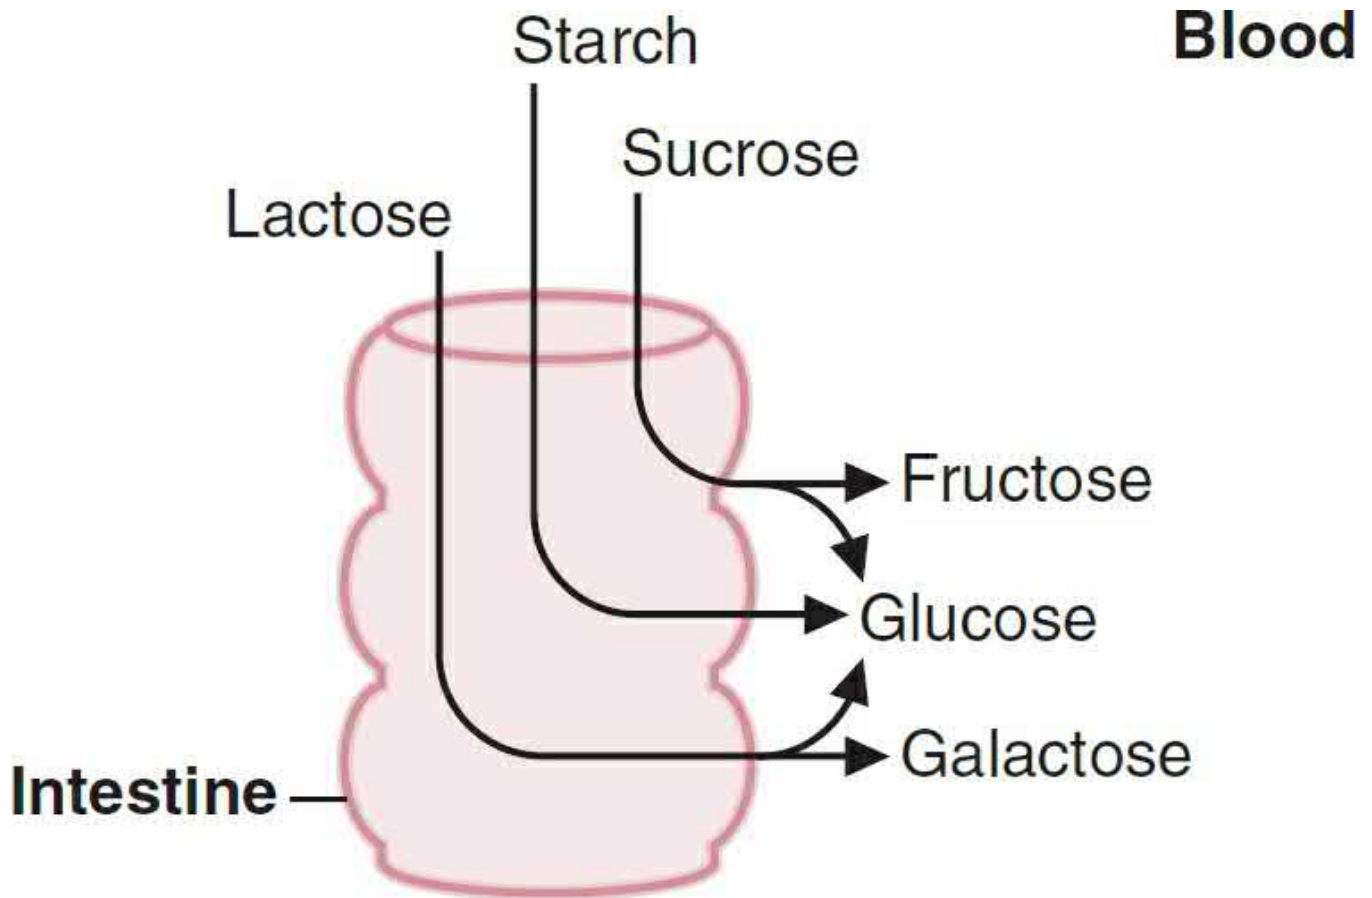

FIGURE IV.1 Overview of carbohydrate digestion. The major carbohydrates of the diet (starch, lactose, and sucrose) are digested to produce monosaccharides (glucose, fructose, and galactose), which enter the blood.

After glucose is transported into cells, it is phosphorylated by a hexokinase to form glucose 6-phosphate. Glucose 6-phosphate can then enter a number of metabolic pathways. The three that are common to all cell types are glycolysis, the pentose phosphate pathway, and glycogen synthesis (Fig. IV.2). In tissues, fructose and galactose are converted to intermediates of glucose metabolism. Thus, the fate of these sugars parallels that of glucose (Fig. IV.3).

FIGURE IV.2 Major pathways of glucose metabolism.

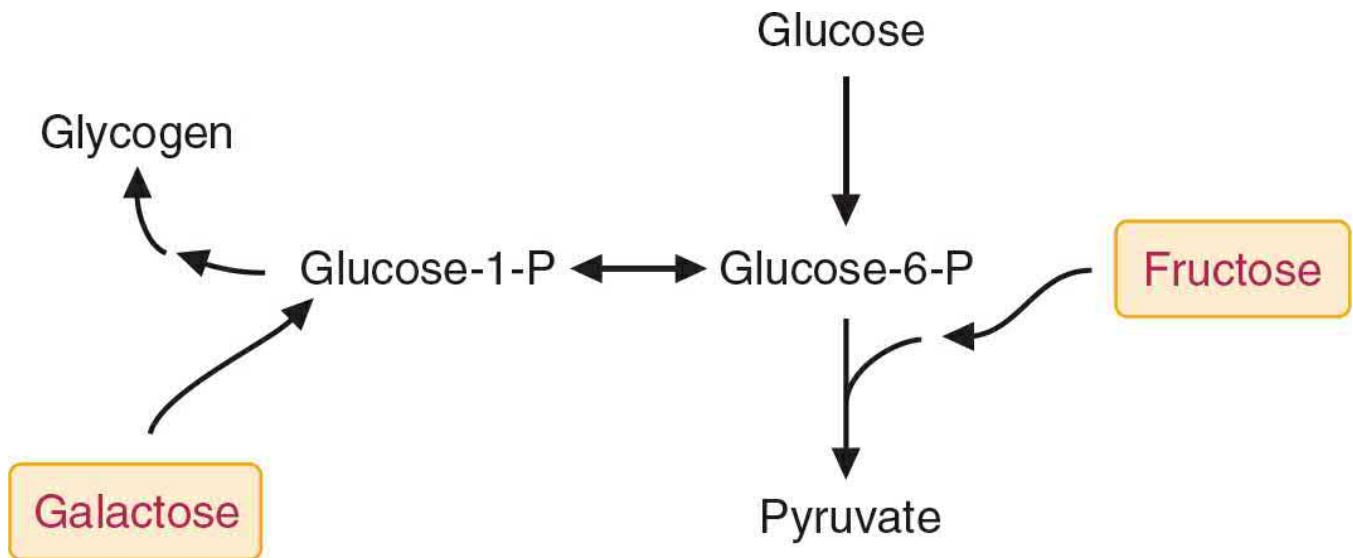

FIGURE IV.3 Overview of fructose and galactose metabolism. Fructose and galactose are converted to intermediates of glucose metabolism.

The major fate of glucose 6-phosphate is oxidation via the pathway of glycolysis (see Chapter 22), which provides a source of ATP (the major energy currency of the cell) for all cell types. Cells that lack mitochondria cannot oxidize other fuels. They produce ATP from anaerobic glycolysis (the conversion of glucose to lactic acid). Cells that contain mitochondria oxidize glucose to CO_2 and H_2O via glycolysis and the tricarboxylic acid (TCA) cycle (Fig. IV.4). Some tissues, such as the brain, depend on the oxidation of glucose to CO_2 and H_2O for energy because they have a limited capacity to use other fuels. The oxidation of fuels to generate ATP requires electron transfer through components of the inner mitochondrial membrane known as the electron transport chain (ETC).

FIGURE IV.4 Conversion of glucose to lactate or CO₂. ATP, adenosine triphosphate; Acetyl CoA, acetyl coenzyme A; ETC, electron transport chain; FAD(2H), reduced flavin adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide;

TCA, tricarboxylic acid.

Glucose produces the intermediates of glycolysis and the TCA cycle that are used for the synthesis of amino acids and both the glycerol and fatty acid moieties of triacylglycerols (Fig. IV.5).

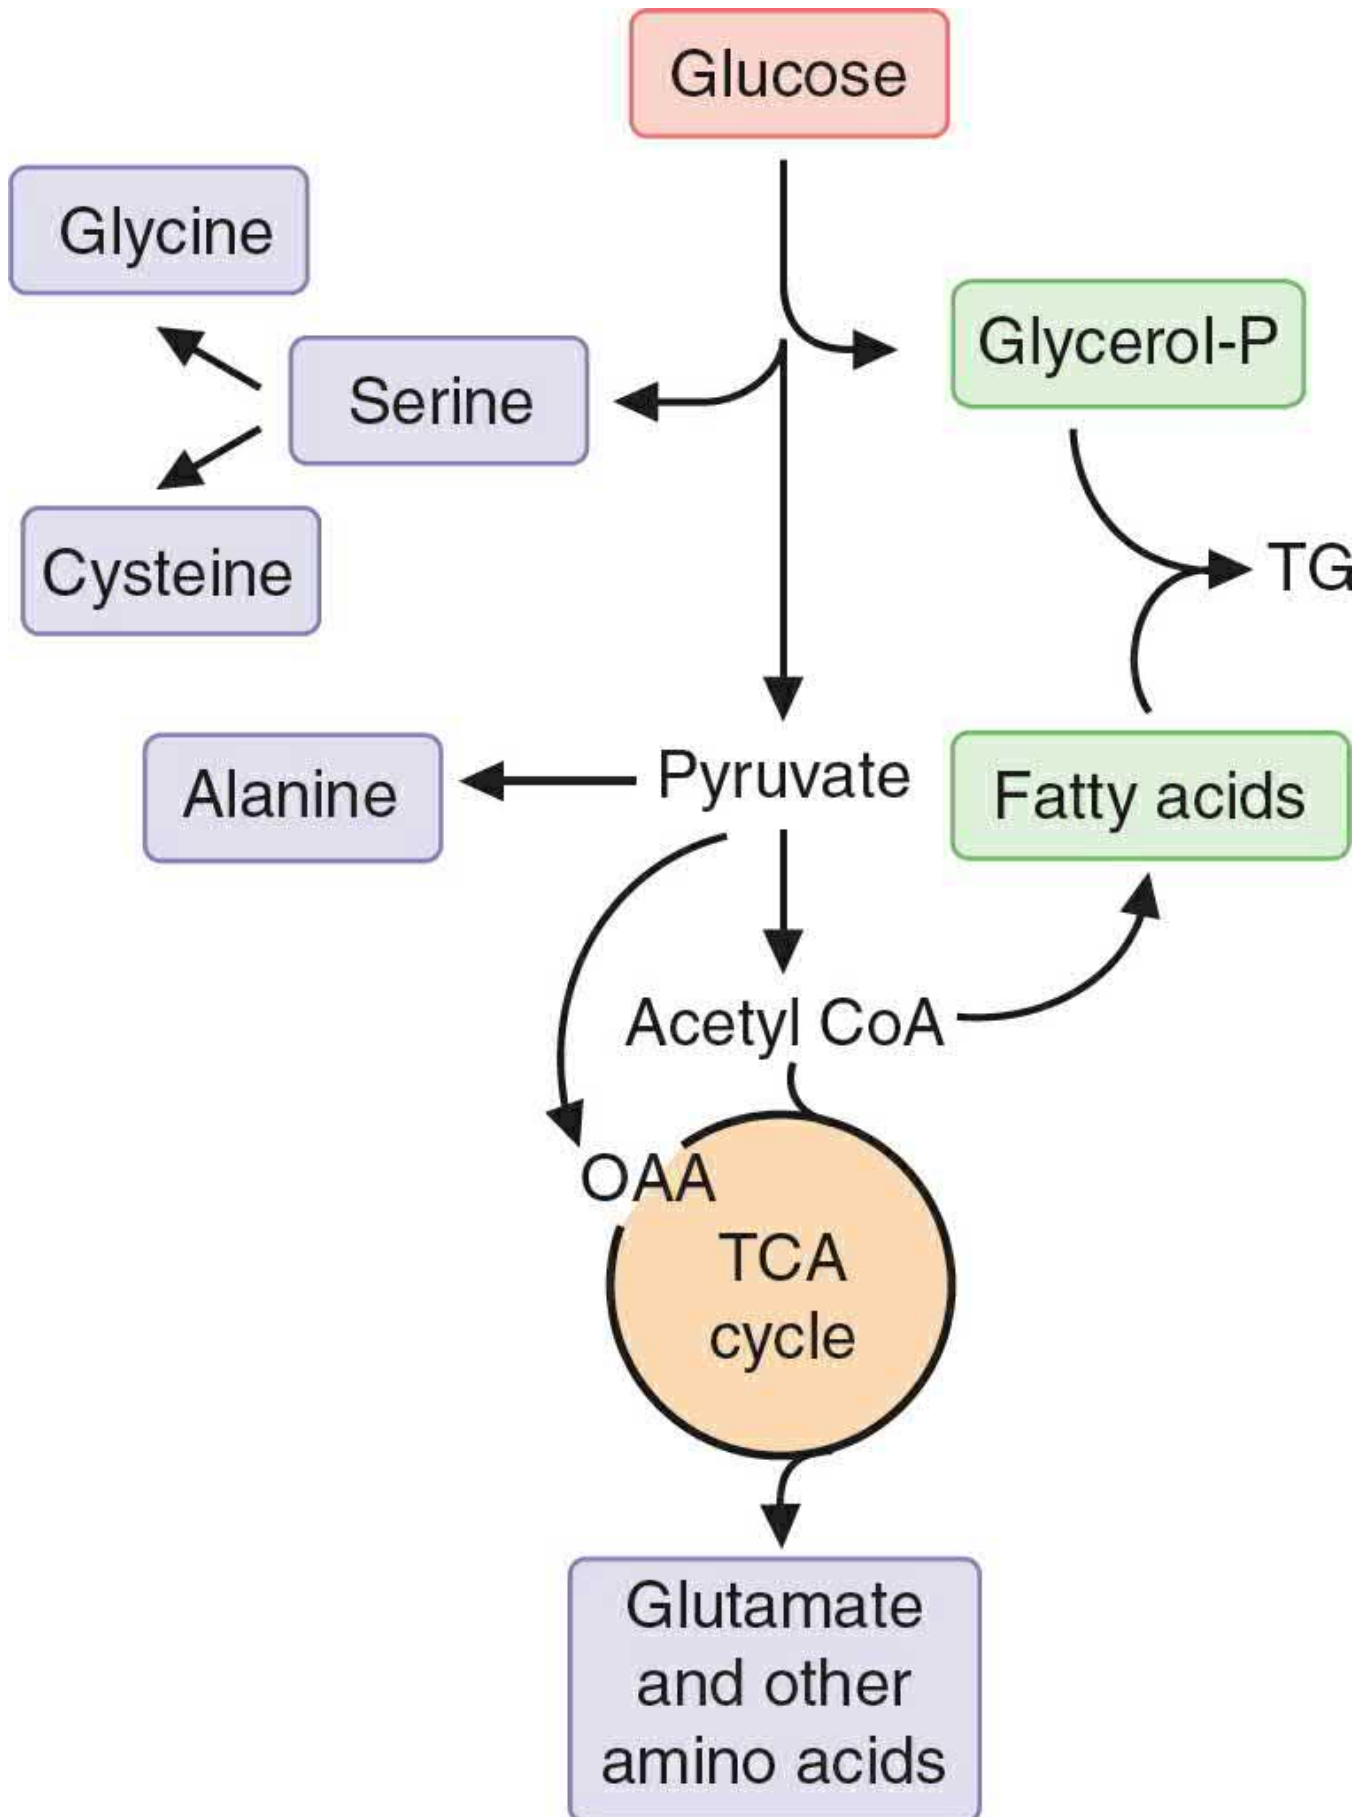

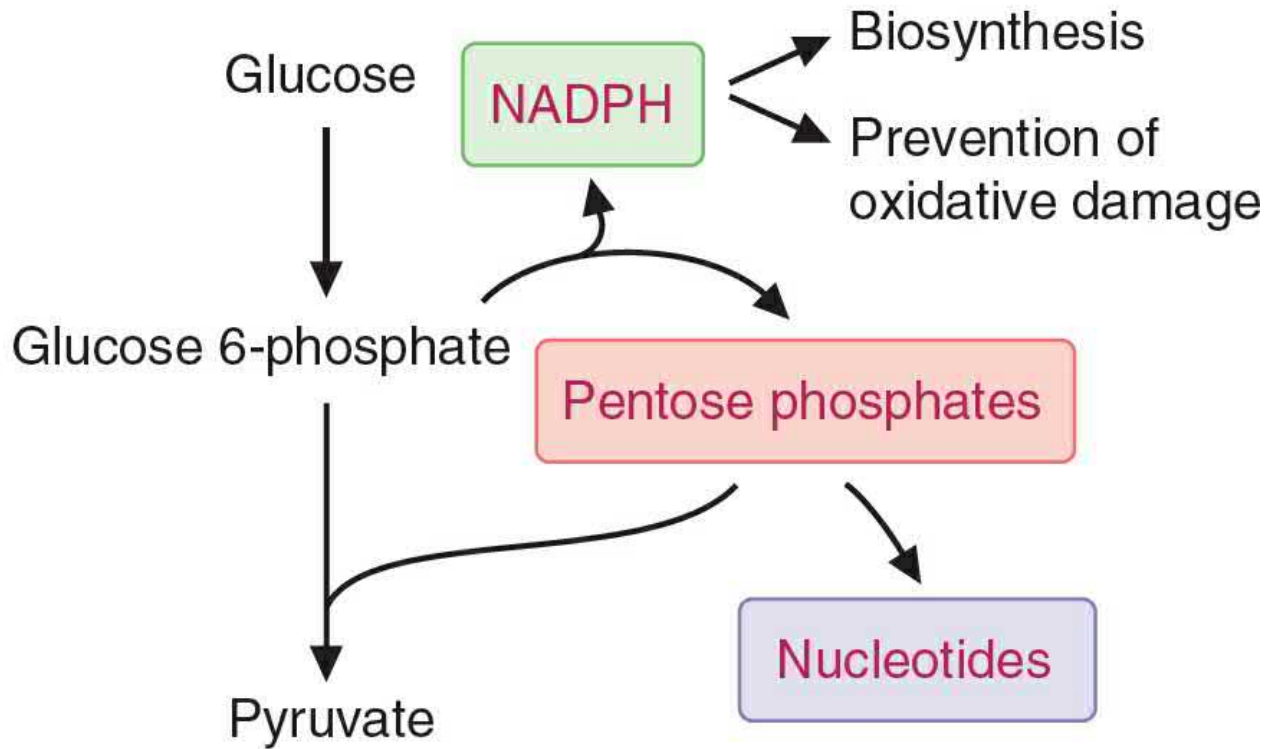

FIGURE IV.5 Conversion of glucose to amino acids and to the glycerol and FA moieties of TG. Acetyl CoA, acetyl coenzyme A; Glycerol-P, glycerol 3-phosphate; OAA, oxaloacetate; TCA, tricarboxylic acid; TG, triacylglycerols.

Another important fate of glucose 6-phosphate is oxidation via the pentose phosphate pathway, which generates nicotinamide adenine dinucleotide phosphate (NADPH). The reducing equivalents of NADPH are used for biosynthetic reactions and the prevention of oxidative damage to cells (see Chapter 27). In this pathway, glucose undergoes oxidation and decarboxylation to five-carbon sugars (pentoses), which may reenter the glycolytic pathway. They also may be used for nucleotide synthesis (Fig. IV.6). There are also nonoxidative reactions, which can convert six- and five-carbon sugars.

Oxidative Reactions

Nonoxidative Reactions

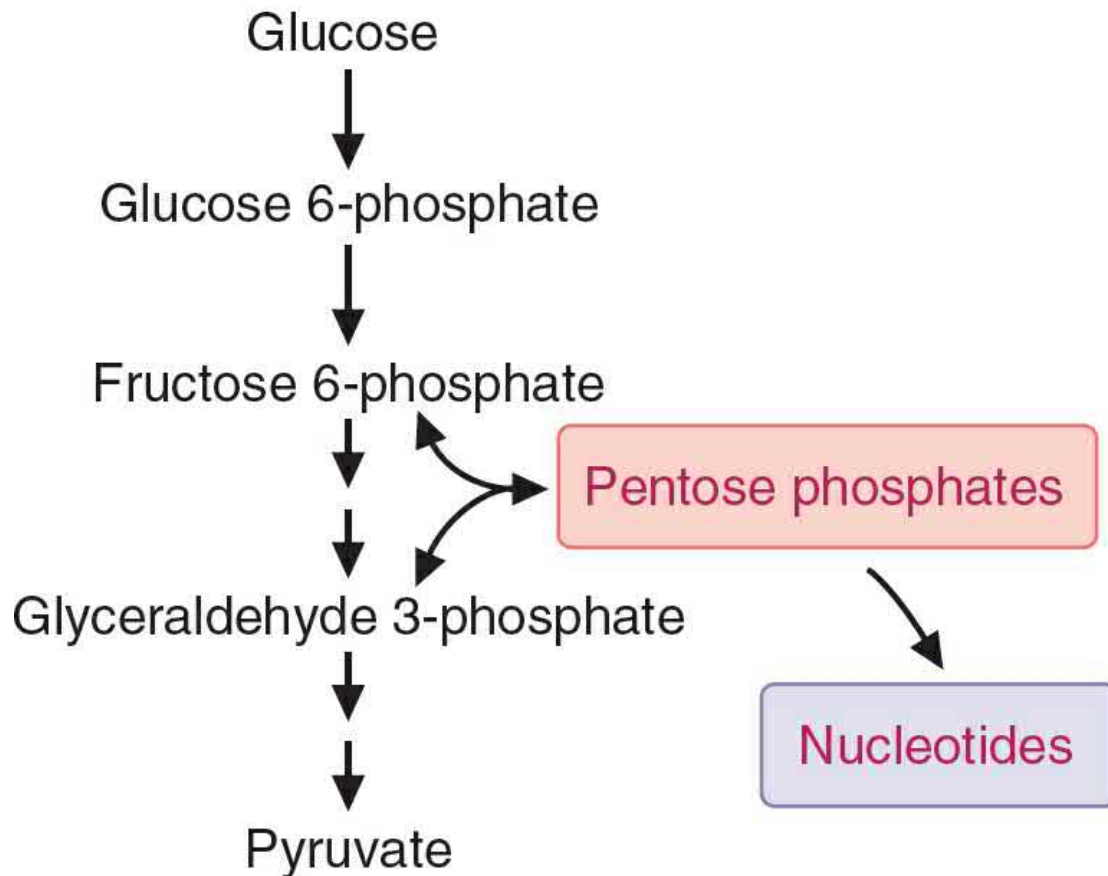

FIGURE IV.6 Overview of the pentose phosphate pathway. The oxidative reactions generate both NADPH and pentose phosphates. The nonoxidative reactions generate only pentose phosphates. NADPH, nicotinamide adenine dinucleotide phosphate.

Glucose 6-phosphate is also converted to uridine diphosphate (UDP)-glucose, which has many functions in the cell (Fig. IV.7). The major fate of UDP-glucose is the synthesis of glycogen, the storage polymer of glucose. Although most cells have glycogen to provide emergency supplies of glucose, the largest stores are in muscle and liver. Muscle glycogen is used to generate ATP during muscle contraction. Liver glycogen is used to maintain blood glucose during fasting and exercise or periods of enhanced need. UDP-glucose is also used for the formation of other sugars, and galactose and glucose are interconverted while attached to UDP. UDP-galactose is used for lactose synthesis in the mammary gland. In the liver, UDP-glucose is oxidized to UDP-glucuronate, which is used to convert bilirubin and other toxic compounds to glucuronides for excretion (see Fig. IV.7).

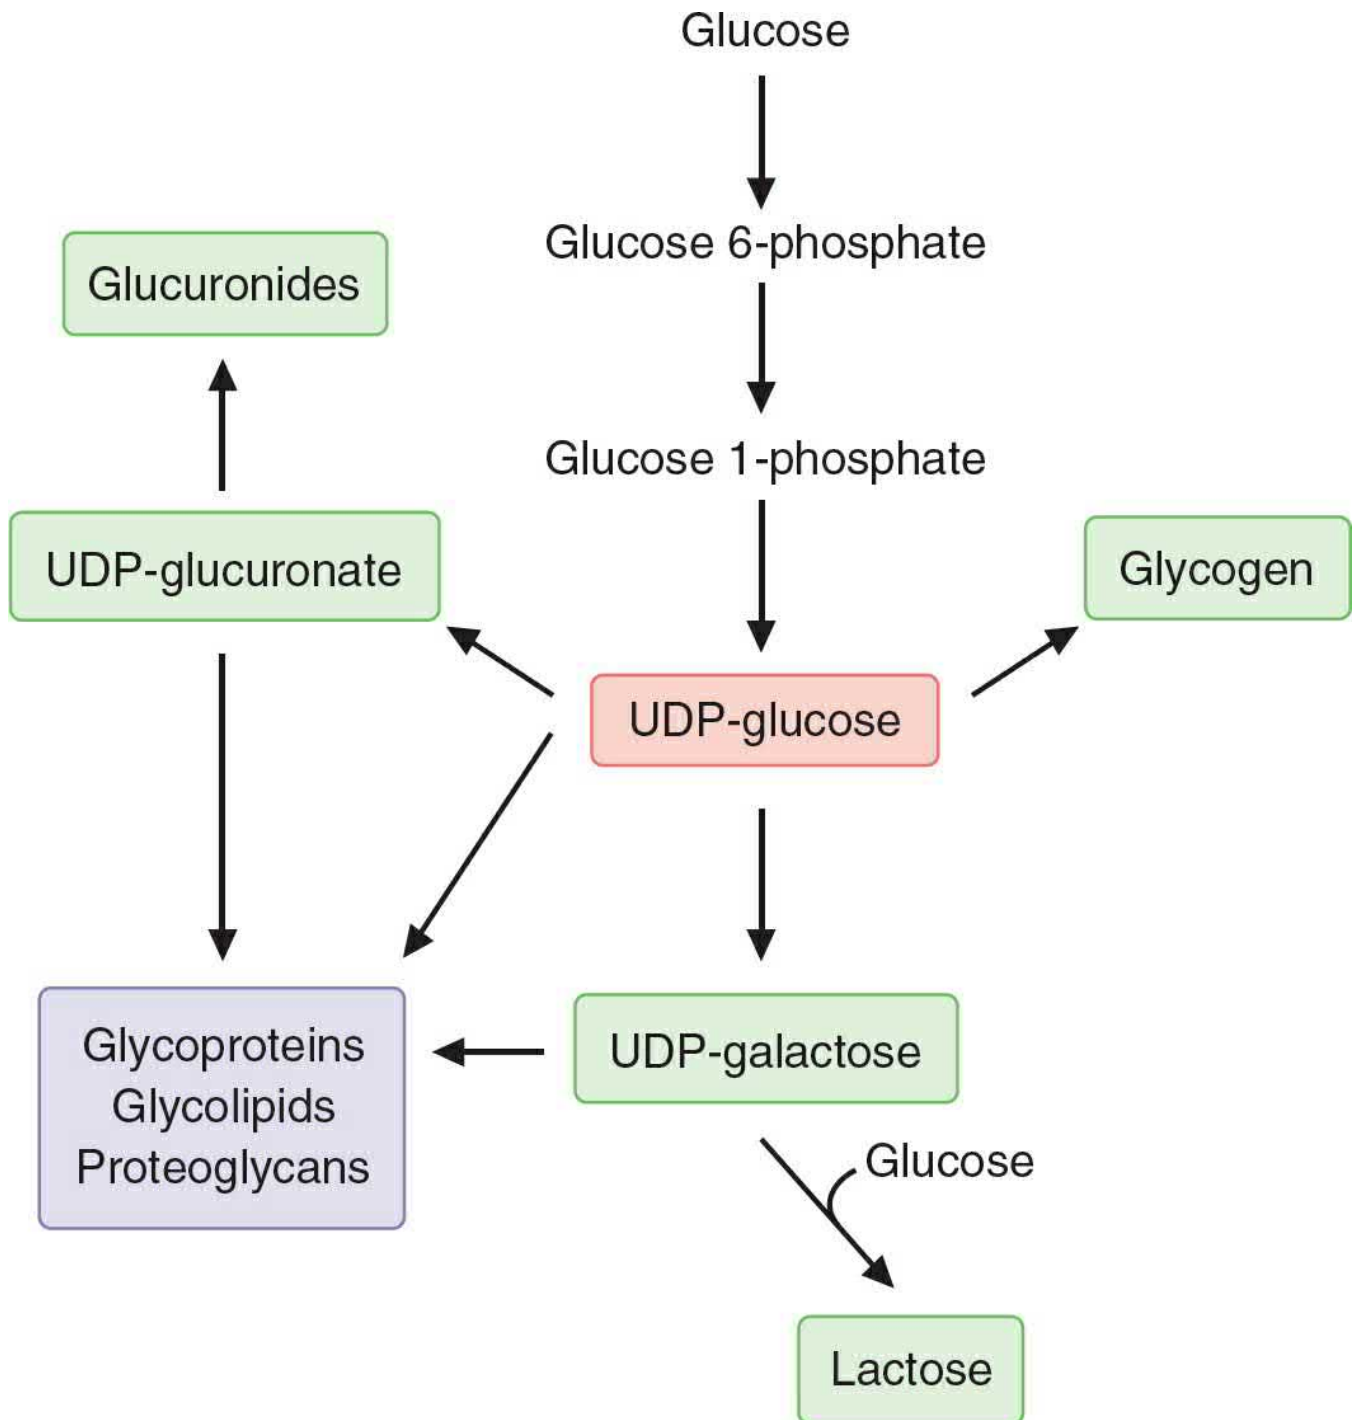

FIGURE IV.7 Products derived from UDP-glucose. UDP, uridine diphosphate.

Nucleotide sugars are also used for the synthesis of proteoglycans, glycoproteins, and glycolipids (see Fig. IV.7). Proteoglycans are major carbohydrate components of the extracellular matrix, cartilage, and extracellular fluids (such as the synovial fluid of joints), and they are discussed in more detail in Chapter 47. Most extracellular proteins are glycoproteins; that is, they contain covalently attached carbohydrates. For both cell membrane glycoproteins and glycolipids, the carbohydrate portion extends into the extracellular space.

All cells are continuously supplied with glucose under normal circumstances; the body maintains a relatively narrow range of glucose concentration in the blood (~70 to 100 mg/dL) in spite of the changes in dietary supply and tissue demand as we sleep and exercise. This process is called glucose homeostasis. Low blood glucose levels (hypoglycemia) are prevented by a release of glucose from the large glycogen stores in the liver (glycogenolysis); by synthesis of glucose from lactate, glycerol, and amino acids in the liver (gluconeogenesis) (Fig. IV.8); and to a limited extent by a release of fatty acids from adipose tissue stores (lipolysis) to provide an alternative fuel when glucose is in short supply. High blood glucose levels (hyperglycemia) are prevented both by the conversion of glucose to glycogen and by its conversion to triacylglycerols in the liver and adipose tissue. Thus, the pathways for glucose utilization as a fuel cannot be considered totally separate from pathways involving amino acid and fatty acid metabolism (Fig. IV.9).

FIGURE IV.8 Production of blood glucose from glycogen (by glycogenolysis) and from alanine, lactate, and glycerol (by gluconeogenesis). OAA, oxaloacetate; PEP, phosphoenolpyruvate; TCA, tricarboxylic acid.

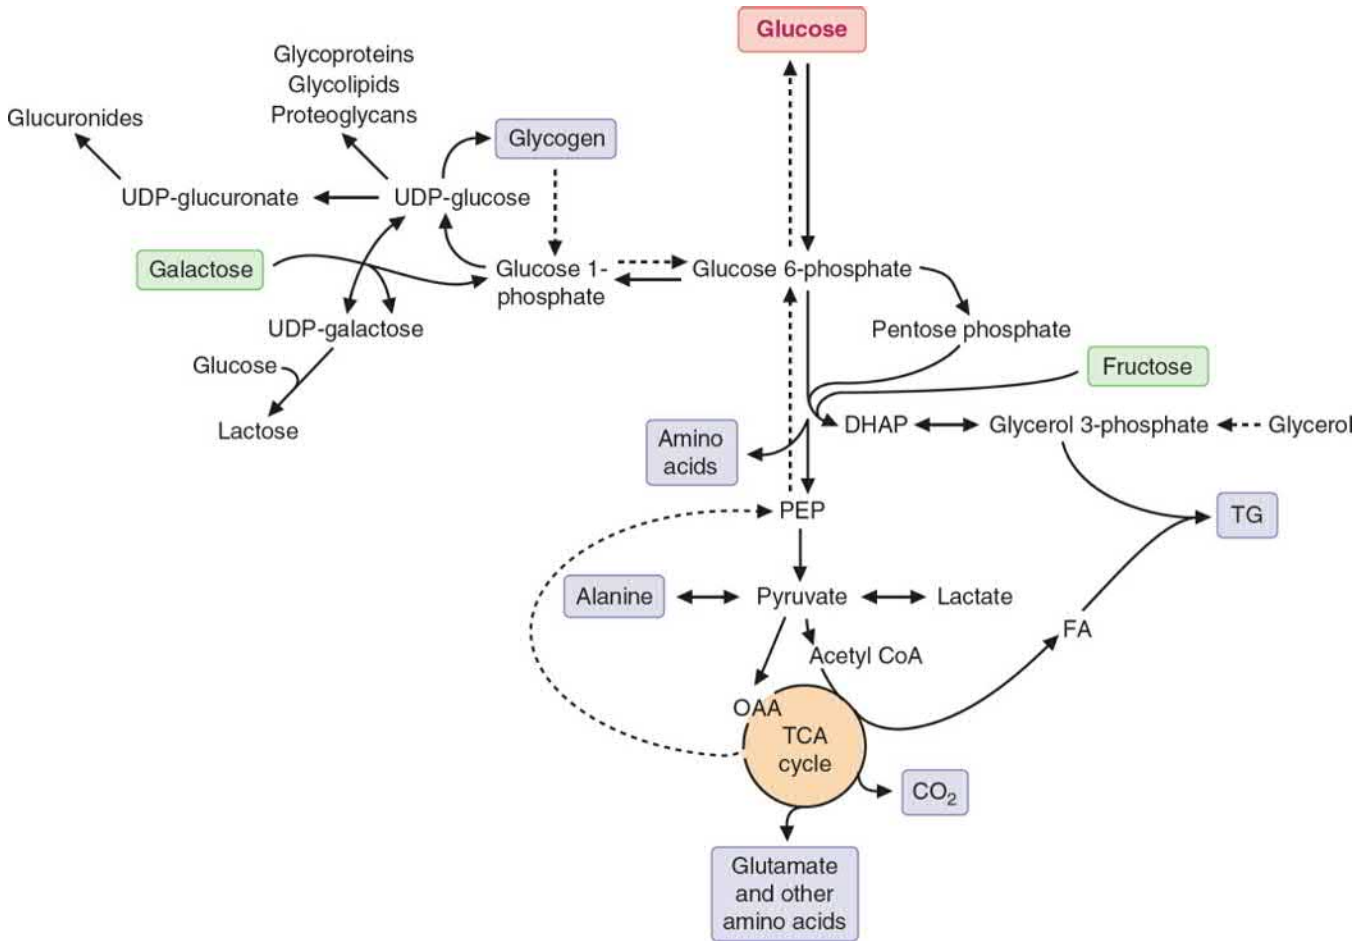

FIGURE IV.9 Overview of the major pathways of glucose metabolism. Pathways for production of blood glucose are shown by *dashed lines*. Acetyl CoA, acetyl coenzyme A; DHAP, dihydroxyacetone phosphate; FA, fatty acids; OAA, oxaloacetate; PEP, phosphoenolpyruvate; TCA, tricarboxylic acid; TG, triacylglycerols; UDP, uridine diphosphate.

Intertissue balance in the utilization and storage of glucose during fasting and feeding is accomplished principally by the actions of the hormones of metabolic homeostasis—insulin and glucagon (Fig. IV.10). However, cortisol, epinephrine, norepinephrine, and other hormones are also involved in intertissue adjustments of supply and demand in response to changes of physiologic state.

FIGURE IV.10 Pathways regulated by the release of glucagon (in response to a lowering of blood glucose levels) and insulin (released in response to an elevation of blood glucose levels). Tissue-specific differences occur in response to these

hormones, as detailed in the chapters of this section.

The oxidation of our food is an energy-generating process. The first two phases of energy transformation are part of cellular respiration, the overall process of using O_2 and energy derived from oxidizing fuels to generate ATP. We need to breathe principally because our cells require O_2 to generate adequate amounts of ATP from the oxidation of fuels to CO_2 . Cellular respiration uses >90% of the O_2 we inhale.

In phase 1 of respiration, energy is conserved from fuel oxidation by enzymes that transfer electrons from the fuels to the electron-accepting coenzymes nicotinamide adenine dinucleotide (NAD^+) and flavin adenine dinucleotide (FAD), which are reduced to NADH and FAD(2H), respectively (Fig. IV.11). The pathways for the oxidation of most fuels (glucose, fatty acids, ketone bodies, and many amino acids) converge in the generation of the activated 2-carbon acetyl group in acetyl coenzyme A (acetyl CoA). The complete oxidation of the acetyl group to CO_2 occurs in the TCA cycle, which collects the energy mostly as NADH and FAD(2H).

FIGURE IV.11 Cellular respiration. Δp , proton gradient; acetyl CoA, acetyl coenzyme A; ADP, adenosine diphosphate; ATP, adenosine triphosphate; FAD(2H), reduced flavin adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; P_i , inorganic phosphate; TCA, tricarboxylic acid.

In phase 2 of cellular respiration, the energy derived from fuel oxidation is converted to the high-energy phosphate bonds of ATP by the process of oxidative phosphorylation (see Fig. IV.11). Electrons are transferred from NADH and FAD(2H) to O_2 by the ETC, a series of electron-transfer proteins that are located in the inner mitochondrial membrane. Oxidation of NADH and FAD(2H) by O_2 generates an electrochemical potential across the inner mitochondrial membrane in the form of a transmembrane proton gradient (Δp). This electrochemical potential drives the synthesis of ATP from adenosine diphosphate (ADP) and inorganic phosphate (P_i) by a transmembrane enzyme called ATP synthase (or F_0F_1 ATPase).

In phase 3 of cellular respiration, the high-energy phosphate bonds of ATP are used for processes such as muscle contraction (mechanical work), maintaining low intracellular Na^+ concentrations (transport work), synthesis of larger molecules such as DNA in anabolic pathways (biosynthetic work), or detoxification (biochemical work). As a consequence of these processes, ATP is either directly or indirectly hydrolyzed to ADP and P_i , or to adenosine monophosphate (AMP) and pyrophosphate (PP_i).

Cellular respiration occurs in mitochondria (Fig. IV.12). The mitochondrial matrix, which is the compartment enclosed by the inner mitochondrial membrane, contains almost all of the enzymes for the TCA cycle and oxidation of fatty acids, ketone bodies, and most amino acids. The inner mitochondrial membrane contains the protein complexes of the ETC and ATP synthase, the enzyme complex that generates ATP from ADP and P_i . Some of the subunits of these complexes are encoded by mitochondrial DNA, which resides in the matrix. ATP is generated in the matrix, but most of the energy-using processes in the cell occur outside the mitochondrion. As a consequence, newly generated ATP must be continuously transported to the cytosol by protein transporters in the impermeable inner mitochondrial membrane and by diffusion through pores in the more permeable outer mitochondrial membrane.

FIGURE IV.12 Oxidative metabolism in mitochondria. The inner mitochondrial membrane forms infoldings, called cristae, which enclose the mitochondrial matrix. Most of the enzymes for the TCA cycle, the β -oxidation of fatty acids, and for mitochondrial DNA synthesis are found in the matrix. ATP synthase and the protein complexes of the electron transport chain are embedded in the inner mitochondrial membrane. The outer mitochondrial membrane is permeable to small ions, but the inner mitochondrial membrane is impermeable to almost all molecules. ATP, adenosine triphosphate; TCA, tricarboxylic acid.

The rates of fuel oxidation and ATP utilization are tightly coordinated through feedback regulation of the ETC and the pathways of fuel oxidation. Thus, if less energy is required for work, more fuel is stored as glycogen or fat in adipose tissue. The basal metabolic rate (BMR), caloric balance, and ΔG (the change in Gibbs free energy, which is the amount of energy available to do useful work) are quantitative ways of describing energy requirements and the energy that can be derived from fuel oxidation. The various types of enzyme regulation described in Chapter 9 are all used to regulate the rate of oxidation of different fuels to meet

energy requirements.

Fatty acids are a major fuel in the body. After eating, we store excess fatty acids and carbohydrates that are not oxidized as fat (triacylglycerols) in adipose tissue. Between meals, these fatty acids are released and circulate in the blood bound to albumin. In muscle, liver, and other tissues, fatty acids are oxidized to acetyl CoA in the pathway of β -oxidation. NADH and FAD(2H) generated from β -oxidation are reoxidized by O_2 in the ETC, thereby generating ATP (see Fig. IV.11). Small amounts of certain fatty acids are oxidized through other pathways that convert them to either oxidizable fuels or urinary excretion products (e.g., peroxisomal β -oxidation).

Not all acetyl CoA generated from β -oxidation enters the TCA cycle. In the liver, acetyl CoA generated from β -oxidation of fatty acids can also be converted to the ketone bodies acetoacetate and β -hydroxybutyrate. Ketone bodies are taken up by muscle and other tissues, which convert them back to acetyl CoA for oxidation in the TCA cycle. They become a major fuel for the brain during prolonged fasting. The discussion of fatty acid oxidation, and ketone body production, occurs in Section V of this text.

Amino acids derived from dietary or body proteins are also potential fuels that can be oxidized to acetyl CoA or converted to glucose and then oxidized (see Fig. IV.11). These oxidation pathways, like those of fatty acids, generate NADH or FAD(2H). Ammonia, which can be formed during amino acid oxidation, is toxic. It is therefore converted to urea in the liver and excreted in the urine. There are more than 20 different amino acids, each with a somewhat different pathway for oxidation of the carbon skeleton and conversion of its nitrogen to urea. Because of the complexity of amino acid metabolism, use of amino acids as fuels is considered separately in Section VI, Nitrogen Metabolism.

Glucose is a universal fuel used to generate ATP in every cell type in the body (Fig. IV.13). In glycolysis, 1 mol of glucose is converted to 2 mol of pyruvate and 2 mol of NADH by cytosolic enzymes. Small amounts of ATP are generated when high-energy pathway intermediates transfer phosphate to ADP in a process termed substrate-level phosphorylation. In aerobic glycolysis, the NADH produced from glycolysis is reoxidized by O_2 via the ETC and pyruvate enters the TCA cycle. In anaerobic glycolysis, the NADH is reoxidized by conversion of pyruvate to lactate, which enters the blood. Although anaerobic glycolysis has a low ATP yield, it is important for tissues with a low oxygen supply and few mitochondria (e.g., the kidney medulla) or tissues that are experiencing diminished blood flow (ischemia).

FIGURE IV.13 Glycolysis. In glycolysis, glucose is converted to pyruvate. If the pyruvate is reduced to lactate, the pathway does not require O_2 and is called anaerobic glycolysis (in *red*). If this pyruvate is converted instead to acetyl CoA and oxidized in the TCA cycle, glycolysis requires O_2 and is aerobic (in *black*). Acetyl CoA, acetyl coenzyme A; ATP, adenosine triphosphate; NADH, reduced nicotinamide adenine dinucleotide; TCA, tricarboxylic acid.

All cells continuously use ATP and require a constant supply of fuels to provide energy for the generation of ATP. Chapters 1 through 3 of this text outlined the basic patterns of fuel utilization in the human and provided information about dietary components.

The pathologic consequences of metabolic problems in fuel oxidation can be grouped into one of two categories: (1) lack of a required product or (2) excess of a substrate or pathway intermediate. The product of fuel oxidation is ATP, and an inadequate rate of ATP production occurs under a wide variety of medical conditions. Extreme conditions that interfere with ATP generation from oxidative phosphorylation, such as complete oxygen deprivation (anoxia) or cyanide poisoning, are fatal. A myocardial infarction is caused by a lack of adequate blood flow to regions of the heart (ischemia), thereby depriving cardiomyocytes of oxygen and fuel. Hyperthyroidism is associated with excessive heat generation from fuel oxidation, and in hypothyroidism, ATP generation can decrease to a fatal level. Conditions such as malnutrition, anorexia nervosa, or excessive alcohol consumption may decrease availability of thiamine, Fe^{2+} , and other vitamins and minerals required by the enzymes of fuel oxidation. Mutations in mitochondrial DNA or nuclear DNA result in deficient ATP generation from oxidative metabolism.

In contrast, problems arising from an excess of substrate or fuel are seen in diabetes mellitus, which may result in a potentially fatal ketoacidosis. Lactic acidosis occurs with a reduction in oxidative metabolism.

Definitions of Prefixes and Suffixes Used in Describing Clinical Conditions:

an-	without
-emia	blood

hyper-	excessive, above normal
hypo-	deficient, below normal
-osis	abnormal or diseased state
-uria	urine

Basic Concepts in the Regulation of Fuel Metabolism by Insulin, Glucagon, and Other Hormones

All cells use adenosine triphosphate (ATP) continuously and require a constant supply of fuels to provide energy for ATP generation. **Insulin** and **glucagon** are the two major hormones that regulate fuel mobilization and storage. Their function is to ensure that cells have a constant source of glucose, fatty acids, and amino acids for ATP generation and for cellular maintenance (Fig. 19.1).

FIGURE 19.1 Maintenance of fuel supplies to tissues. Glucagon release activates the pathways shown. ATP, adenosine triphosphate.

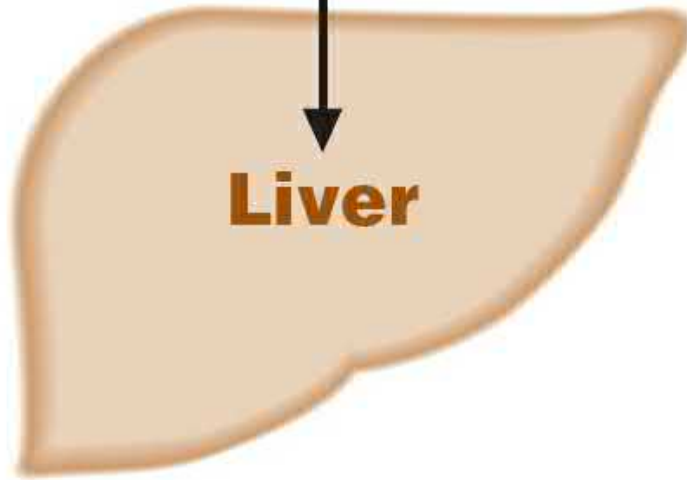

Because most tissues are partially or totally dependent on glucose for the generation of ATP and for the production of precursors of other pathways, insulin and glucagon **maintain blood glucose** levels near 70 to 100 mg/dL (90 mg/dL is the same as 5 mM), despite the fact that carbohydrate intake varies considerably over the course of a day. The maintenance of constant blood glucose levels (**glucose homeostasis**) requires these two hormones to regulate **carbohydrate, lipid, and amino acid metabolism** in accordance with the needs and capacities of individual tissues. Basically, the dietary intake of all fuels in excess of immediate need is stored, and the appropriate fuel is mobilized when demand occurs. For example, when dietary glucose is not available to cells in sufficient quantities, fatty acids are mobilized and used by skeletal muscle as a fuel (see Chapters 2 and 30). Under these circumstances, the liver can also convert fatty acids to ketone bodies that can be used by the brain. The fatty acids that are mobilized under these conditions spare glucose for use by the brain and other glucose-dependent tissues (such as red blood cells).

Insulin and glucagon are important for the regulation of fuel storage and fuel mobilization (Fig. 19.2). Insulin, released from the β -cells of the pancreas in response to carbohydrate ingestion, promotes glucose utilization as a fuel and glucose storage as fat and glycogen. **Insulin, therefore, is a major anabolic hormone.** In addition to its storage function, insulin increases protein synthesis and cell growth. Blood insulin levels decrease as glucose is taken up by tissues and utilized. Glucagon, the major insulin **counterregulatory hormone**, is decreased in response to a carbohydrate meal and elevated during fasting. Its concentration in the blood increases as circulating levels of glucose fall, a response that promotes glucose production via **glycogenolysis** (glycogen degradation) and **gluconeogenesis** (glucose synthesis from amino acids and other noncarbohydrate precursors). Increased levels of circulating glucagon relative to insulin also stimulate the **mobilization of fatty acids** from adipose tissue. **Epinephrine** (the fight-or-flight hormone) and **cortisol** (a glucocorticoid released from the adrenal cortex in response to fasting and chronic stress) have effects on fuel metabolism that oppose those of insulin. Therefore, epinephrine and cortisol are considered to be insulin counterregulatory hormones.

Cortisol will stimulate both glycogen synthesis and gluconeogenesis. TG, triglyceride.

Insulin and glucagon are polypeptide hormones synthesized as **prohormones** in the pancreatic β - and α -cells, respectively. **Proinsulin** is cleaved into mature insulin and a connection peptide (**C-peptide**) in storage vesicles and precipitated with Zn^{2+} . Insulin secretion is regulated principally by changes in blood glucose levels. Glucagon is also synthesized as a prohormone and cleaved into mature glucagon within storage vesicles. Its release is regulated principally through changes in the level of glucose and insulin bathing the α -cells located in the pancreatic islets of Langerhans.

Glucagon exerts its effects on cells by binding to a receptor located on the plasma membrane of target cells for this hormone. The binding to these specific receptors by glucagon stimulates the synthesis of the intracellular second messenger, cyclic adenosine monophosphate (**cAMP**) (Fig. 19.3). cAMP activates **protein kinase A (PKA)**, which phosphorylates key regulatory enzymes, thereby activating some while inhibiting others. Insulin, on the other hand, promotes the dephosphorylation of these key enzymes, leading to their activation or deactivation, depending on the enzyme. Changes in cAMP levels also induce or repress the synthesis of a number of enzymes.

FIGURE 19.3 Cellular response to glucagon, which is released from the pancreas in response to a decrease in blood glucose levels. cAMP, cyclic adenosine monophosphate.

Insulin binds to a receptor on the cell surface of insulin-sensitive tissues and initiates a cascade of intracellular events that differs from those stimulated by glucagon. Insulin binding activates both autophosphorylation of the receptor and the phosphorylation of other enzymes by the receptor's **tyrosine kinase** domain (see Chapter 10, Section XII.B.1). The complete routes for **signal transduction** between this point and the final effects of insulin on the regulatory enzymes of fuel metabolism have not yet been fully established.

THE WAITING ROOM

Deborah S. returned to her physician for her monthly office visit. She has been seeing her physician for over a year because of obesity and elevated blood glucose levels. She still weighed 198 lb, despite trying to adhere to her diet. Her blood glucose level at the time of the visit, two hours after lunch, was 221 mg/dL (reference range, 70 to 140 mg/dL). She suffers from type 2 diabetes, an impaired response to insulin. Understanding the actions of insulin and glucagon is critical for understanding this disorder.

Connie C. is a 46-year-old woman who 6 months earlier began noting episodes of fatigue and confusion in the morning before eating and sometimes after jogging. These episodes were occasionally accompanied by blurred vision and an unusually urgent sense of hunger. The ingestion of food relieved all of her symptoms within 25 to 30 minutes. In the last month, these attacks have occurred more frequently throughout the day, and she has learned to diminish their occurrence by eating between meals. As a result, she has recently gained 8 lb.

A random (nonfasting) serum glucose level done at 4:30 P.M. during her first office visit was subnormal at 61 mg/dL. Her physician, suspecting she was having episodes of hypoglycemia, ordered a series of fasting serum glucose, insulin, and C-peptide levels. In addition, he asked **Connie C.** to keep a careful diary of all the symptoms that she experienced when her attacks were most severe.

I. Metabolic Homeostasis

Living cells require a constant source of fuels from which to derive ATP for the maintenance of normal cell function and growth. Therefore, a balance must be achieved among carbohydrate, fat, and protein intake, their rates of oxidation, and their rates of storage when they are present in excess of immediate need. Alternatively, when the demand for these substrates increases, the rate of mobilization from storage sites and the rate of their *de novo* synthesis also require balanced regulation. The control of the balance between substrate need and substrate availability is referred to as metabolic homeostasis (Fig. 19.4). The intertissue integration required for metabolic homeostasis is achieved in three principal ways:

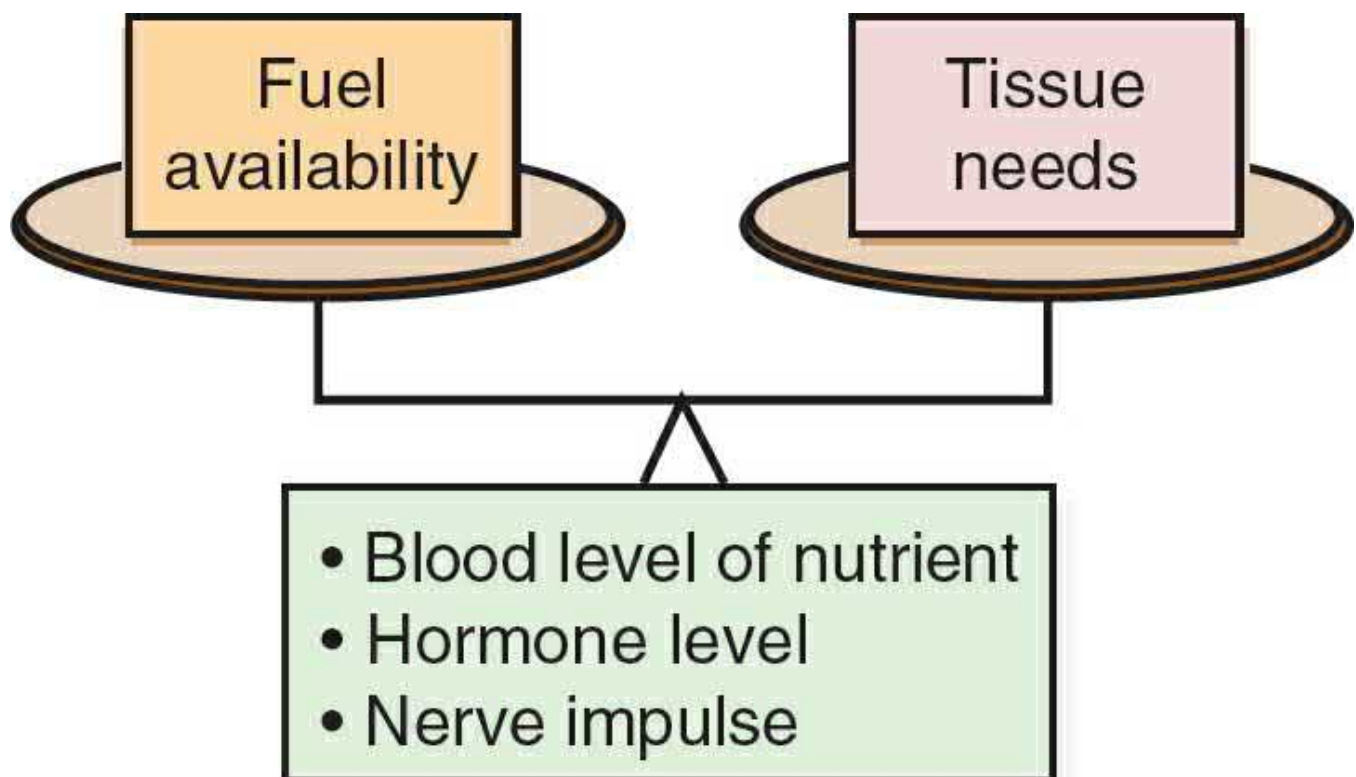

FIGURE 19.4 Metabolic homeostasis. The balance between fuel availability and the needs of tissues for different fuels is achieved by three types of messages: the level of the fuel or nutrients in the blood, the level of one of the hormones of metabolic homeostasis, or nerve impulses that affect tissue metabolism or the release of hormones.

- The concentration of nutrients or metabolites in the blood affects the rate at which they are used or stored in different tissues.
- Hormones carry messages to their individual tissues about the physiologic state of the body and the nutrient supply or demand.
- The central nervous system uses neural signals to control tissue metabolism, either directly or through the release of hormones.

Fatty acids provide an example of the influence that the level of a compound in the blood has on its own rate of metabolism. The concentration of fatty acids in the blood is the major factor determining whether skeletal muscles will use fatty acids or glucose as a fuel (see Chapter 30). In contrast, hormones are (by definition) intravascular carriers of messages between their sites of synthesis and their target tissues. Epinephrine, for example, is a flight-or-fight hormone that in times of stress signals an immediate need for increased fuel availability. Its level is regulated principally through the activation of the sympathetic nervous system.

Insulin and glucagon, however, are the two major hormones that regulate fuel storage and mobilization (see Fig. 19.2). Insulin is the major anabolic hormone of the body. It promotes the storage of fuels and the utilization of fuels for growth. Glucagon is the major hormone of fuel mobilization (Fig. 19.5). Other hormones, such as epinephrine, are released as a response of the central nervous system to hypoglycemia, exercise, or other types of physiologic stress. Epinephrine and other stress hormones also increase the availability of fuels (see Fig. 19.5). The major hormones of fuel homeostasis, insulin and glucagon, fluctuate continuously in response to our daily eating pattern.

FIGURE 19.5 Signals that regulate metabolic homeostasis. The major stress hormones are epinephrine and cortisol. ATP, adenosine triphosphate.

Glucose has a special role in metabolic homeostasis. Many tissues (e.g., the brain, red blood cells, kidney medulla, exercising skeletal muscle) are dependent on glycolysis for all or a part of their energy needs. As a consequence, these tissues require uninterrupted access to glucose to meet their rapid rate of ATP use. In the adult, a minimum of 190 g glucose is required per day: approximately 150 g for the brain and 40 g for other tissues. Significant decreases of blood glucose below 60 mg/dL limit glucose metabolism in the brain and may elicit hypoglycemic symptoms (as experienced by **Connie C.**), presumably because the overall process of glucose flux through the blood–brain barrier, into the interstitial fluid, and subsequently into the neuronal cells is slow at low blood glucose levels because of the K_m values of the glucose transporters required for this to occur (see Chapter 21).

The continuous efflux of fuels from their storage depots, during exercise, for example, is necessitated by the high amounts of fuel required to meet the need for ATP under these conditions. Disastrous results would occur if even a day's supply of glucose, amino acids, and fatty acids could not enter cells normally and were instead left circulating in the blood. Glucose and amino acids would be at such high concentrations in the circulation that the hyperosmolar effect would cause progressively severe neurological deficits and even coma. The concentration of glucose and amino acids would rise above the renal tubular threshold for these substances (the maximal concentration in the blood at which the kidney can completely resorb metabolites), and some of these compounds would be wasted as they spilled over into the urine. Nonenzymatic glycation of proteins would increase at higher blood glucose levels, altering the function of tissues in which these proteins reside.

Triacylglycerols, present primarily in chylomicrons and very-low-density lipoproteins (VLDL), would rise in the blood, increasing the likelihood of atherosclerotic vascular disease. These potential metabolic derangements emphasize the need to maintain a normal balance between fuel storage and fuel use.

Hyperglycemia may cause a constellation of symptoms such as polyuria and subsequent polydipsia (increased thirst). The inability to move glucose into cells necessitates the oxidation of lipids as an alternative fuel. As a result, adipose stores are used, and a patient with poorly controlled diabetes mellitus loses weight in spite of a good appetite. Extremely high levels of serum glucose can cause a hyperosmolar hyperglycemic state in patients with type 2 diabetes mellitus. Such patients usually have sufficient insulin responsiveness to block fatty acid release and ketone body formation, but they are unable to significantly stimulate glucose entry into peripheral tissues. The severely elevated levels of glucose in the blood compared with those inside the cell lead to an osmotic effect that causes water to leave the cells and enter the blood. Because of the osmotic diuretic effect of hyperglycemia, the kidney produces more urine, leading to dehydration, which, in turn, may lead to even higher levels of blood glucose. If dehydration becomes severe, further cerebral dysfunction occurs and the patient may become comatose. Chronic hyperglycemia also produces pathologic effects through the nonenzymatic glycation of a variety of proteins. Hemoglobin A (HbA), one of the proteins that becomes glycated, forms HbA_{1c} (see Chapter 7). **Deborah S.**'s high levels of HbA_{1c} (9.5% of the total HbA, compared with the reference range of 4.7% to 6.4%) indicate that her blood glucose has been significantly elevated over the last 12 to 14 weeks, the half-life of hemoglobin in the bloodstream.

All membrane and serum proteins exposed to high levels of glucose in the blood or interstitial fluid are candidates for nonenzymatic glycation. This process distorts protein structure and slows protein degradation, which leads to an accumulation of these products in various organs, thereby adversely affecting organ function. These events contribute to the long-term microvascular and macrovascular complications of diabetes mellitus, which include diabetic retinopathy, nephropathy, and neuropathy (microvascular), in addition to atherosclerosis of the coronary, cerebral and peripheral arteries (macrovascular).

II. Major Hormones of Metabolic Homeostasis

The hormones that contribute to metabolic homeostasis respond to changes in the circulating levels of fuels that, in part, are determined by the timing and composition of our diet. Insulin and glucagon are considered the major hormones of metabolic homeostasis because they continuously fluctuate in response to our daily eating pattern. They provide good examples of the basic concept of hormonal regulation. Certain features of the release and action of other insulin counterregulatory hormones, such as epinephrine, norepinephrine, and cortisol, will be described and compared with insulin and glucagon.

Insulin is the major anabolic hormone that promotes the storage of nutrients: glucose storage as glycogen in liver and muscle, conversion of glucose to triacylglycerols in liver and their storage in adipose tissue, and amino acid uptake and protein synthesis in skeletal muscle (Fig. 19.6). It also increases the synthesis of albumin and other proteins by the liver. Insulin promotes the use of glucose as a fuel by facilitating its transport into muscle and adipose tissue. At the same time, insulin acts to inhibit fuel mobilization.

FIGURE 19.6 Major sites of insulin action on fuel metabolism. VLDL, very-low-density lipoprotein; ⊕, stimulated by insulin; ⊖, inhibited by insulin.

Connie C.'s studies confirmed that her fasting serum glucose levels were below normal with an inappropriately high insulin level. She continued to experience the fatigue, confusion, and blurred vision she had described on her first office visit. These symptoms are referred to as the neuroglycopenic manifestations of severe hypoglycemia (neurologic symptoms resulting from an inadequate supply of glucose to the brain for the generation of ATP).

Connie C. also noted the symptoms that are part of the adrenergic response to hypoglycemic stress. Stimulation of the sympathetic nervous system (because of the low levels of glucose reaching the brain) results in the release of epinephrine, a stress hormone, from the adrenal medulla. Elevated epinephrine levels cause tachycardia (rapid heartbeat), palpitations, anxiety, tremulousness, pallor, and sweating.

In addition to the symptoms described by **Connie C.**, individuals may experience confusion, lightheadedness, headache, aberrant behavior, blurred vision, loss of consciousness, or seizures. When severe and prolonged, death may occur.

Glucagon acts to maintain fuel availability in the absence of dietary glucose by stimulating the release of glucose from liver glycogen (see Chapter 26), by stimulating gluconeogenesis from lactate, glycerol, and amino acids (see Chapter 28), and, in conjunction with decreased insulin, by mobilizing fatty acids from adipose

triacylglycerols to provide an alternate source of fuel (see Chapter 30 and Fig. 19.7). Its sites of action are principally the liver and adipose tissue; it has no influence on skeletal muscle metabolism because muscle cells lack glucagon receptors. The message carried by glucagon is that “glucose is gone”; that is, the current supply of glucose is inadequate to meet the immediate fuel requirements of the body.

FIGURE 19.7 Major sites of glucagon action in fuel metabolism. ⊕, pathways stimulated by glucagon; ⊖, pathways inhibited by glucagon.

The release of insulin from the β -cells of the pancreas is dictated primarily by the level of glucose in the blood bathing the β -cells in the islets of Langerhans. The highest levels of insulin occur approximately 30 to 45

minutes after a high-carbohydrate meal (Fig. 19.8). They return to basal levels as the blood glucose concentration falls, approximately 120 minutes after the meal. The release of glucagon from the α -cells of the pancreas, conversely, is controlled principally through a reduction of glucose and/or a rise in the concentration of insulin in the blood bathing the α -cells in the pancreas. Therefore, the lowest levels of glucagon occur after a high-carbohydrate meal. Because all of the effects of glucagon are opposed by insulin, the simultaneous stimulation of insulin release and suppression of glucagon secretion by a high-carbohydrate meal provides integrated control of carbohydrate, fat, and protein metabolism.

FIGURE 19.8 Blood glucose, insulin, and glucagon levels after a high-carbohydrate meal.

Insulin and glucagon are not the only regulators of fuel metabolism. The intertissue balance between the use and storage of glucose, fat, and protein is also accomplished by the circulating levels of metabolites in the blood, by neuronal signals, and by the other hormones of metabolic homeostasis (epinephrine, norepinephrine, cortisol, and others) (Table 19.1). These hormones oppose the actions of insulin by mobilizing fuels. Like glucagon, they are insulin counterregulatory hormones (Fig. 19.9). Of all these hormones, only insulin and glucagon are synthesized and released in direct response to changing levels of fuels in the blood. The release of cortisol, epinephrine, and norepinephrine is mediated by neuronal signals. Rising levels of the insulin counterregulatory hormones in the blood reflect, for the most part, a current increase in the demand for fuel.

TABLE 19.1 Physiologic Actions of Insulin and Insulin Counterregulatory Hormones

HORMONE	FUNCTION	MAJOR METABOLIC PATHWAYS AFFECTED
Insulin	<ul style="list-style-type: none">• Promotes fuel storage after a meal• Promotes growth	<ul style="list-style-type: none">• Stimulates glucose storage as glycogen (muscle and liver)• Stimulates fatty acid synthesis and storage after a high-carbohydrate meal• Stimulates amino acid uptake and protein synthesis
Glucagon	<ul style="list-style-type: none">• Mobilizes fuels• Maintains blood glucose levels during fasting	<ul style="list-style-type: none">• Activates gluconeogenesis and glycogenolysis (liver) during fasting• Activates fatty acid and glycerol release from adipose tissue
Epinephrine	<ul style="list-style-type: none">• Mobilizes fuels during acute stress	<ul style="list-style-type: none">• Stimulates glucose production from glycogen (muscle and liver)• Stimulates fatty acid and glycerol release from adipose tissue
Cortisol	<ul style="list-style-type: none">• Provides for changing requirements during stress	<ul style="list-style-type: none">• Stimulates amino acid mobilization from muscle protein to provide precursors for gluconeogenesis; inhibits glucose uptake and oxidation in muscle• Stimulates gluconeogenesis to produce glucose for liver glycogen synthesis• Stimulates fatty acid and glycerol release from adipose tissue• Inhibits insulin secretion by the β-cells of the pancreas and increases glucagon secretion by the α-cells of the pancreas

FIGURE 19.9 Major insulin counterregulatory hormones. The stress of a low blood glucose level mediates the release of the major insulin counterregulatory hormones through neuronal signals. Hypoglycemia is one of the stress signals that stimulate the release of cortisol, epinephrine, and norepinephrine. ACTH is released from the pituitary and stimulates the release of cortisol (a glucocorticoid) from the adrenal cortex. Neuronal signals stimulate the release of epinephrine from the adrenal medulla and norepinephrine from nerve endings. Neuronal signals also play a minor role in the release of glucagon. Although norepinephrine has counterregulatory actions, it is not a major counterregulatory hormone. ACTH, adrenocorticotropic hormone.

III. Synthesis and Release of Insulin and Glucagon

A. Endocrine Pancreas

Insulin and glucagon are synthesized in different cell types of the endocrine pancreas, which consists of microscopic clusters of small glands, the islets of Langerhans, scattered among the cells of the exocrine pancreas. The α -cells secrete glucagon and the β -cells secrete insulin into the hepatic portal vein via the pancreatic veins.

The message that insulin carries to tissues is that glucose is plentiful and can be used as an immediate fuel or can be converted to storage forms such as triacylglycerol in adipocytes or glycogen in liver and muscle.

Because insulin stimulates the uptake of glucose into tissues where it may be immediately oxidized or stored for later oxidation, this regulatory hormone lowers blood glucose levels. Therefore, one of the possible causes of **Connie C.**'s hypoglycemia is insulinoma, a tumor that produces excessive insulin.

Whenever an endocrine gland continues to release its hormone in spite of the presence of signals that normally would suppress its secretion, this persistent inappropriate release is said to be "autonomous." Secretory neoplasms of endocrine glands generally produce their hormonal product autonomously in a chronic fashion.

B. Synthesis and Secretion of Insulin

Insulin is a polypeptide hormone. The active form of insulin is composed of two polypeptide chains (the A-chain and the B-chain) linked by two interchain disulfide bonds. The A-chain has an additional intrachain disulfide bond (Fig. 19.10).

FIGURE 19.10 Cleavage of proinsulin to insulin. Proinsulin is converted to insulin by proteolytic cleavage, which removes the C-peptide and a few additional amino acid residues. Cleavage occurs at the *arrows*. (Republished with permission of McGraw Hill LLC from Murray RK, Granner DK, Mayes PA, et al. *Harper's Biochemistry*. 23rd ed. Appleton & Lange; 1993:560; permission conveyed through Copyright Clearance Center, Inc.)

Insulin, like many other polypeptide hormones, is synthesized as a prohormone that is converted in the rough endoplasmic reticulum (RER) to proinsulin. The "pre" sequence, a short hydrophobic signal sequence at the *N*-terminal end, is cleaved as it enters the lumen of the RER. Proinsulin folds into the proper conformation, and disulfide bonds are formed between the cysteine residues. It is then transported in microvesicles to the Golgi complex. It leaves the Golgi complex in storage vesicles, where a protease removes the biologically inactive "connecting peptide" (C-peptide) and a few small remnants, resulting in the formation of biologically active insulin (see Fig. 19.10). Zinc ions are also transported in these storage vesicles. Cleavage of the C-peptide decreases the solubility of the resulting insulin, which then coprecipitates with zinc. Exocytosis of the insulin storage vesicles from the cytosol of the β -cell into the blood is stimulated by rising levels of glucose in the blood bathing the β -cells.

Glucose enters the β -cell via specific glucose transporter proteins known as GLUT 2 (see Chapter 21). Glucose is phosphorylated through the action of glucokinase to form glucose 6-phosphate, which is metabolized through glycolysis, the tricarboxylic acid (TCA) cycle, and oxidative phosphorylation. These reactions result in an increase in ATP levels within the β -cell (circle 1 in Fig. 19.11). As the β -cell ATP/adenosine diphosphate (ADP) ratio increases, the activity of a membrane-bound, ATP-dependent K^+ channel (K^+_{ATP}) is inhibited (i.e., the channel is closed) (circle 2 in Fig. 19.11). The closing of this channel leads to membrane depolarization (as the membrane is normally hyperpolarized, see circle 3 in Fig. 19.11), which activates a voltage-gated Ca^{2+} channel that allows Ca^{2+} to enter the β -cell such that intracellular Ca^{2+} levels increase significantly (Fig. 19.11, circle 4). The increase in intracellular Ca^{2+} stimulates the fusion of insulin containing exocytotic vesicles with the plasma membrane, resulting in insulin secretion (Fig. 19.11, circle 5). Thus, an increase in glucose levels within the β -cells initiates insulin release.

FIGURE 19.11 Release of insulin by the β -cells. Details are given in the text. ATP, adenosine triphosphate; TCA, tricarboxylic acid; \oplus , stimulation; \ominus , inhibition; $\Delta\psi$, membrane potential.

Other intracellular metabolites, particularly nicotinamide adenine dinucleotide phosphate (NADPH), have been proposed to play important roles in insulin release in response to glucose. This will be discussed further in later chapters.

 **Dianne A.** has type 1 diabetes mellitus. This metabolic disorder is usually caused by antibody-mediated (autoimmune) destruction of the β -cells of the pancreas. Susceptibility to type 1 diabetes mellitus is, in part, conferred by a genetic defect in the human leukocyte antigen (HLA) region of β -cells that codes for the major histocompatibility complex II (MHC II). This protein presents an intracellular antigen to the cell surface for “self-recognition” by the cells involved in the immune response. Because of this defective protein, a cell-mediated immune response leads to varying degrees of β -cell destruction

and eventually to dependence on exogenous insulin administration to control the levels of glucose in the blood.

C. Stimulation and Inhibition of Insulin Release

The release of insulin occurs within minutes after the pancreas is exposed to a high glucose concentration. The threshold for insulin release is approximately 80 mg of glucose per dL. Above 80 mg/dL, the rate of insulin release is not an all-or-nothing response but is proportional to the glucose concentration up to approximately 300 mg/dL. As insulin is secreted, the synthesis of new insulin molecules is stimulated, so that secretion is maintained until blood glucose levels fall. Insulin is rapidly removed from the circulation and degraded by the liver (and, to a lesser extent, by kidney and skeletal muscle), so blood insulin levels decrease rapidly once the rate of secretion slows.

 Autonomous hypersecretion of insulin from a suspected pancreatic β -cell tumor (an insulinoma) can be demonstrated in several ways. The simplest test is to simultaneously draw blood for the measurement of both glucose and insulin (and C-peptide) at a time when the patient is spontaneously experiencing the characteristic adrenergic or neuroglycopenic symptoms of hypoglycemia. During such a test, **Connie C.'s** glucose levels fell to 45 mg/dL (normal, 80 to 100 mg/dL), and her ratio of insulin to glucose was far higher than normal. The elevated insulin levels markedly increased glucose uptake by the peripheral tissues, resulting in a dramatic lowering of blood glucose levels. In normal individuals, as blood glucose levels drop, insulin levels also drop. Insulin levels were determined by radioimmunoassay; see the Biochemical Comments in Chapter 41 for a description of this method.

 A rare form of diabetes known as maturity-onset diabetes of the young (MODY) results from mutations in either pancreatic glucokinase or specific nuclear transcription factors. MODY type 2 is caused by a glucokinase mutation that results in an enzyme with reduced activity because of either an elevated K_m for glucose or a reduced V_{max} for the reaction. Because insulin release depends on normal glucose metabolism within the β -cell that yields a critical ATP/ADP ratio in the β -cell, individuals with this glucokinase mutation cannot significantly metabolize glucose unless glucose levels are higher than normal. Thus, although these patients can release insulin, they do so at higher-than-normal glucose levels, and are, therefore, almost always in a mild hyperglycemic state. Interestingly, however, these patients are somewhat resistant to the long-term complications of chronic hyperglycemia. The mechanism for this seeming resistance is not well understood.

Neonatal diabetes is a very rare inherited disorder in which newborns develop diabetes within the first 6 months of life. The diabetes may be permanent, requiring lifelong insulin treatment, or transient. One of the most common mutations leading to permanent neonatal diabetes is in the *KCNJ11* gene, which encodes a subunit of the K^+_{ATP} channel in various tissues including the pancreas. This is an activating mutation, which keeps the K^+_{ATP} channel open and less susceptible to ATP inhibition. If the K^+_{ATP} channel cannot be closed, activation of the Ca^{2+} channel will not occur, and insulin secretion will be impaired.

Several factors other than the blood glucose concentration can modulate insulin release (Table 19.2). The pancreatic islets are innervated by the autonomic nervous system, including a branch of the vagus nerve. These neural signals help to coordinate insulin release with the secretory signals initiated by the ingestion of fuels. However, signals from the central nervous system are not required for insulin secretion. Certain amino acids also can stimulate insulin secretion, although the amount of insulin released during a high-protein meal is very much lower than that released by a high-carbohydrate meal. Gastric-inhibitory polypeptide (GIP) and glucagonlike peptide 1 (GLP-1), gut hormones released after the ingestion of food, also aid in the onset of insulin release. Epinephrine, secreted in response to fasting, stress, trauma, and vigorous exercise, decreases the release of insulin. Epinephrine release signals energy utilization, which indicates that less insulin needs to be secreted, as insulin stimulates energy storage.

D. Synthesis and Secretion of Glucagon

Glucagon, a polypeptide hormone, is synthesized in the α -cells of the pancreas by cleavage of the much larger preproglucagon, a 160-amino acid peptide. Like insulin, preproglucagon is produced on the RER and is converted to proglucagon as it enters the lumen of the endoplasmic reticulum. Proteolytic cleavage at various sites produces the mature 29-amino acid glucagon (molecular weight 3,500 daltons) and larger glucagon-containing fragments (named glucagonlike peptides 1 and 2). Glucagon is rapidly metabolized, primarily in the liver and kidneys. Its plasma half-life is only about 3 to 5 minutes.

Deborah S. is taking a sulfonylurea compound known as glipizide to treat her diabetes. The sulfonylureas act on the K^+ ATP channels on the surface of the pancreatic β -cells. The K^+ ATP channels contain pore-forming subunits (encoded by the *KCNJ11* gene) and regulatory subunits (the subunit to which sulfonylurea compounds bind, encoded by the *ABCC8* gene). The binding of the drug to the sulfonylurea receptor closes K^+ channels (as do elevated ATP levels), which, in turn, increases Ca^{2+} movement into the interior of the β -cell. This influx of calcium modulates the interaction of the insulin storage vesicles with the plasma membrane of the β -cell, resulting in the release of insulin into the circulation.

Patients have been described who have an activating mutation in the *ABCC8* gene (which would make it difficult to close the K^+ ATP channel), and this is another common mutation leading to neonatal diabetes. Activating mutations in the *KCNJ11* gene also have the same effect.

Glucagon secretion is regulated principally by circulating levels of glucose and insulin. Increasing levels of each inhibit glucagon release. Glucose probably has both a direct suppressive effect on secretion of glucagon from the α -cell and an indirect effect, the latter being mediated by its ability to stimulate the release of insulin. The direction of blood flow in the islets of the pancreas carries insulin from the β -cells in the center of the islets to the peripheral α -cells, where it suppresses glucagon secretion.

Conversely, certain hormones stimulate glucagon secretion. Among these are the catecholamines (including epinephrine) and cortisol (Table 19.3).

Many amino acids also stimulate glucagon release (Fig. 19.12). Thus, the high levels of glucagon that would be expected in the fasting state do not decrease after a high-protein meal. In fact, glucagon levels may increase, stimulating gluconeogenesis in the absence of dietary glucose. The relative amounts of insulin and glucagon in the blood after a mixed meal are dependent on the composition of the meal because glucose stimulates insulin release and amino acids stimulate glucagon release. However, amino acids also induce insulin secretion but not to the same extent that glucose does. Although this may seem paradoxical, it actually makes good sense. Insulin release stimulates amino acid uptake by tissues and enhances protein synthesis. However, because glucagon levels also increase in response to a protein meal, and the critical factor is the insulin-to-glucagon ratio, sufficient glucagon is released that gluconeogenesis is enhanced (at the expense of protein synthesis), and the amino acids that are taken up by the tissues serve as a substrate for gluconeogenesis. The synthesis of glycogen and triglycerides is also reduced when glucagon levels rise in the blood.

FIGURE 19.12 Release of insulin and glucagon in response to a high-protein meal. This figure shows the increase in the release of insulin and glucagon into the blood after an overnight fast followed by the ingestion of 100 g protein (equivalent to a slice of roast beef). Insulin levels do not increase nearly as much as they do after a high-carbohydrate meal (see Fig. 19.8).

The levels of glucagon, however, significantly increase above those present in the fasting state.

 Measurements of proinsulin and the connecting peptide between the α - and β -chains of insulin (C-peptide) in **Connie C.'s** blood during her hospital fast provided confirmation that she had an insulinoma. Insulin and C-peptide are secreted in approximately equal proportions from the β -cell, but C-peptide is not cleared from the blood as rapidly as insulin. Therefore, it provides a reasonably accurate estimate of the rate of insulin secretion. Plasma C-peptide measurements are also useful in helping to differentiate between endogenous and exogenous insulin because exogenous insulin lacks the C-peptide.

In fasting subjects, the average level of immunoreactive glucagon in the blood is 75 pg/mL and does not vary as much as insulin during the daily fasting–feeding cycle. However, only 30% to 40% of the measured immunoreactive glucagon is mature pancreatic glucagon. The rest is composed of larger immunoreactive fragments that are also produced in the pancreas or in the intestinal L-cells.

IV. Mechanisms of Hormone Action

For a hormone to affect the flux of substrates through a metabolic pathway, it must be able to change the rate at which that pathway proceeds by increasing or decreasing the rate of the slowest step(s). Either directly or indirectly, hormones affect the activity of specific enzymes or transport proteins that regulate the flux through a pathway. Thus, ultimately, the hormone must either cause the amount of the substrate for the enzyme to increase (if substrate supply is a rate-limiting factor), change the conformation at the active site by phosphorylating the enzyme, change the concentration of an allosteric effector of the enzyme, or change the amount of the protein by inducing or repressing its synthesis or by changing its turnover rate or location. Insulin, glucagon, and other hormones use all of these regulatory mechanisms to determine the rate of flux in metabolic pathways. The effects mediated by phosphorylation or changes in the kinetic properties of an enzyme occur rapidly, within minutes. In contrast, it may take hours for induction or repression of enzyme synthesis to change the amount of an enzyme in the cell.

The details of hormone action were described in Chapter 10 and are only summarized here.

 Patients with type 1 diabetes mellitus, such as **Dianne A.**, have almost undetectable levels of insulin in their blood. Patients with type 2 diabetes mellitus, such as **Deborah S.**, conversely, have normal or even elevated levels of insulin in their blood; however, the level of insulin in their blood is inappropriately low relative to their elevated blood glucose concentration. In type 2 diabetes mellitus, skeletal muscle, liver, and other tissues exhibit resistance to the actions of insulin. As a result, insulin has a smaller than normal effect on glucose and fat metabolism in such patients. Levels of insulin in the blood must be higher than normal to maintain normal blood glucose levels. In the early stages of type 2 diabetes mellitus, these compensatory adjustments in insulin release may keep the blood glucose levels near the normal range. Over time, as the β -cells' capacity to secrete high levels of insulin declines, blood glucose levels increase and exogenous insulin becomes necessary.

A. Signal Transduction by Hormones That Bind to Plasma Membrane Receptors

Hormones initiate their actions on target cells by binding to specific receptors or binding proteins. In the case of polypeptide hormones (such as insulin and glucagon) and catecholamines (epinephrine and norepinephrine), the action of the hormone is mediated through binding to a specific receptor on the plasma membrane (see Chapter 10, Section XII). The first message of the hormone is transmitted to intracellular enzymes by the activated receptor and an intracellular second messenger; the hormone does not need to enter the cell to exert its effects. (In contrast, steroid hormones such as cortisol and the thyroid hormone triiodothyronine [T_3] enter the cytosol and eventually move into the cell nucleus to exert their effects.)

The mechanism by which the message carried by the hormone ultimately affects the rate of the regulatory enzyme in the target cell is called **signal transduction**. The three basic types of signal transduction for hormones binding to receptors on the plasma membrane are (1) receptor coupling to adenylate cyclase, which produces cAMP; (2) receptor kinase activity; and (3) receptor coupling to hydrolysis of phosphatidylinositol bisphosphate (PIP_2). The hormones of metabolic homeostasis each use one of these mechanisms to carry out their physiologic effect. In addition, some hormones and neurotransmitters act through receptor coupling to gated ion channels (described in Chapter 10).

 The physiologic importance of insulin's usual action of mediating the suppressive effect of glucose on glucagon secretion is apparent in patients with types 1 and 2 diabetes mellitus. Despite the presence of hyperglycemia, glucagon levels in such patients initially remain elevated (near fasting levels), either because of the absence of insulin's suppressive

effect or because of the resistance of the α -cells to insulin's suppressive effect even in the face of adequate insulin levels in type 2 patients. Thus, these patients have inappropriately high glucagon levels, leading to the suggestion that diabetes mellitus is actually a "bi-hormonal" disorder.

During the "stress" of hypoglycemia, the autonomic nervous system stimulates the pancreas to secrete glucagon, which tends to restore the serum glucose level to normal. The increased activity of the adrenergic nervous system (through epinephrine) also alerts a patient, such as **Connie C.**, to the presence of increasingly severe hypoglycemia. Hopefully, this will induce the patient to ingest simple sugars or other carbohydrates, which, in turn, will also increase glucose levels in the blood. **Connie C.** gained 8 lb before resection of her pancreatic insulin-secreting adenoma through this mechanism.

1. Signal Transduction by Insulin

Insulin initiates its action by binding to a receptor on the plasma membrane of insulin's many target cells (see Fig. 10.19). The insulin receptor has two types of subunits: the α -subunits to which insulin binds and the β -subunits which span the membrane and protrude into the cytosol. The cytosolic portion of the β -subunit has tyrosine kinase activity. On binding of insulin, the tyrosine kinase phosphorylates tyrosine residues on the β -subunit (autophosphorylation) as well as on several other enzymes within the cytosol. A principal substrate for phosphorylation by the receptor, insulin-receptor substrate 1 (IRS-1), then recognizes and binds to various signal transduction proteins in regions referred to as SH2 domains. IRS-1 is involved in many of the physiologic responses to insulin through complex mechanisms that are the subject of intensive investigation. The basic tissue-specific cellular responses to insulin, however, can be grouped into five major categories: (1) insulin reverses glucagon-stimulated phosphorylation; (2) insulin works through a phosphorylation cascade that stimulates the phosphorylation of several enzymes; (3) insulin induces and represses the synthesis of specific enzymes; (4) insulin acts as a growth factor and has a general stimulatory effect on protein synthesis; and (5) insulin stimulates glucose and amino acid transport into cells (see Fig. IV.10 in the introduction to Section IV).

Several mechanisms have been proposed for the action of insulin in reversing glucagon-stimulated phosphorylation of the enzymes of carbohydrate metabolism. From the student's point of view, the ability of insulin to reverse glucagon-stimulated phosphorylation occurs as if it were lowering cAMP and stimulating phosphatases that could remove those phosphates added by PKA. In reality, the mechanism is more complex and still not fully understood.

2. Signal Transduction by Glucagon

The pathway for signal transduction by glucagon is one that is common to a number of hormones; the glucagon receptor is coupled to adenylate cyclase and cAMP production (see Fig. 10.21). Glucagon, through G-proteins, activates the membrane-bound adenylate cyclase, increasing the synthesis of the intracellular second messenger 3',5'-cyclic AMP (cAMP) (see Fig. 10.23). cAMP activates PKA (cAMP-dependent protein kinase), which changes the activity of enzymes by phosphorylating them at specific serine residues. Phosphorylation activates some enzymes and inhibits others.

The G-proteins, which couple the glucagon receptor to adenylate cyclase, are proteins in the plasma membrane that bind guanosine triphosphate (GTP) and have dissociable subunits that interact with both the receptor and adenylate cyclase. In the absence of glucagon, the stimulatory G_s -protein complex binds guanosine diphosphate (GDP) but cannot bind to the unoccupied receptor or adenylate cyclase (see Fig. 10.22). Once glucagon binds to the receptor, the receptor also binds the G_s -complex, which then releases GDP and binds GTP. The α -subunit then dissociates from the β - and γ -subunits and binds to adenylate cyclase, thereby activating it. As the GTP on the α -subunit is hydrolyzed to GDP, the subunit dissociates and recomplexes with the β - and γ -subunits. Only continued occupancy of the glucagon receptor can keep adenylate cyclase active.

Although glucagon works by activating adenylate cyclase, a few hormones inhibit adenylate cyclase. In this case, the inhibitory G-protein complex is called a G_i -complex. cAMP is the intracellular second messenger for a number of hormones that regulate fuel metabolism. The specificity of the physiologic response to each hormone results from the presence of specific receptors for that hormone in target tissues. For example, glucagon activates glucose production from glycogen in liver but not in skeletal muscle because glucagon receptors are present in liver but are absent in skeletal muscle. However, skeletal muscle has adenylate cyclase, cAMP, and PKA, which can be activated by epinephrine binding to the β_2 -receptors in the membranes of muscle cells. Liver cells also have epinephrine receptors.

cAMP is very rapidly degraded to AMP by a membrane-bound phosphodiesterase. The concentration of cAMP is thus very low in the cell, so changes in its concentration can occur rapidly in response to changes in the rate of synthesis. The amount of cAMP present at any time is a direct reflection of hormone binding and the

activity of adenylate cyclase. It is not affected by ATP, ADP, or AMP levels in the cell.

cAMP transmits the hormone signal to the cell by activating PKA (cAMP-dependent protein kinase). As cAMP binds to the regulatory subunits of PKA, these subunits dissociate from the catalytic subunits, which are thereby activated (see Chapter 9, Fig. 9.11). Activated PKA phosphorylates serine residues of key regulatory enzymes in the pathways of carbohydrate and fat metabolism. Some enzymes are activated and others are inhibited by this change in phosphorylation state. The message of the hormone is terminated by the action of semispecific protein phosphatases that remove phosphate groups from the enzymes. The activity of the protein phosphatases is also controlled through hormonal regulation.

Changes in the phosphorylation state of proteins that bind to cAMP response elements (CREs) in the promoter region of genes contribute to the regulation of gene transcription by a number of cAMP-coupled hormones (see Chapter 15). For instance, cAMP response element-binding protein (CREB) is directly phosphorylated by PKA, a step essential for the initiation of transcription. Phosphorylation at other sites on CREB, by a variety of kinases, also may play a role in regulating transcription.

The mechanism for signal transduction by glucagon illustrates some of the important principles of hormonal signaling mechanisms. The first principle is that specificity of action in tissues is conferred by the receptor on a target cell for glucagon. In general, the major actions of glucagon occur in liver, adipose tissue, and certain cells of the kidney that contain glucagon receptors. The second principle is that signal transduction involves amplification of the first message. Glucagon and other hormones are present in the blood in very low concentrations. However, these minute concentrations of hormone are adequate to initiate a cellular response because the binding of one molecule of glucagon to one receptor ultimately activates many PKA molecules, each of which phosphorylates hundreds of downstream enzymes. The third principle involves the integration of metabolic responses. For instance, the glucagon-stimulated phosphorylation of enzymes simultaneously activates glycogen degradation, inhibits glycogen synthesis, and inhibits glycolysis in the liver (see Fig. IV.10 in the introduction to Section IV). The fourth principle involves augmentation and antagonism of signals. An example of augmentation involves the actions of glucagon and epinephrine (which is released during exercise). Although these hormones bind to different receptors, each can increase cAMP and stimulate glycogen degradation. A fifth principle is that of rapid signal termination. In the case of glucagon, both the termination of the G_s-protein activation and the rapid degradation of cAMP contribute to signal termination.

Phosphodiesterase is inhibited by methylxanthines, a class of compounds that includes caffeine. Would the effect of a methylxanthine on fuel metabolism be similar to fasting or to a high-carbohydrate meal?

Ann R., to stay thin, frequently fasts for prolonged periods, but she jogs every morning (see Chapter 2). The release of epinephrine and norepinephrine and the increase of glucagon and fall of insulin during her exercise provide coordinated and augmented signals that stimulate the release of fuels above the fasting levels. Fuel mobilization will occur, of course, only as long as she has fuel stored as triacylglycerols.

B. Signal Transduction by Cortisol and Other Hormones That Interact with Intracellular Receptors

Signal transduction by the glucocorticoid cortisol and other steroids that have glucocorticoid activity and by thyroid hormone involves hormone binding to intracellular (cytosolic) receptors or binding proteins, after which this hormone-binding protein complex, if not already in the nucleus, moves into the nucleus, where it interacts with chromatin. This interaction changes the rate of gene transcription in the target cells (see Chapter 15). The cellular responses to these hormones continue as long as the target cell is exposed to the specific hormones. Thus, disorders that cause a chronic excess in their secretion result in an equally persistent influence on fuel metabolism. For example, chronic stress such as that seen in prolonged sepsis may lead to varying degrees of glucose intolerance (hyperglycemia) if high levels of epinephrine and cortisol persist.

Inhibition of phosphodiesterase by methylxanthine would increase cAMP and have the same effects on fuel metabolism as would an increase of glucagon and epinephrine, as in the fasted state. Increased fuel mobilization would occur through glycogenolysis (the release of glucose from glycogen) and through lipolysis (the release of fatty acids from triacylglycerols).

The effects of cortisol on gene transcription are usually synergistic to those of certain other hormones. For instance, the rates of gene transcription for some of the enzymes in the pathway for glucose synthesis from amino acids (gluconeogenesis) are induced by glucagon as well as by cortisol.

C. Signal Transduction by Epinephrine and Norepinephrine

Epinephrine and norepinephrine are catecholamines (Fig. 19.13). They can act as neurotransmitters or as hormones. A neurotransmitter allows a neural signal to be transmitted across the junction or synapse between the nerve terminal of a proximal nerve axon and the cell body of a distal neuron. A hormone, conversely, is released into the blood and travels in the circulation to interact with specific receptors on the plasma membrane or cytosol of cells of the target organ. The general effect of these catecholamines is to prepare us for fight or flight. Under these acutely stressful circumstances, these “stress” hormones increase fuel mobilization, cardiac output, blood flow, and so on, which enables us to meet these stresses. The catecholamines bind to adrenergic receptors (the term **adrenergic** refers to nerve cells or fibers that are part of the involuntary or autonomic nervous system, a system that employs norepinephrine as a neurotransmitter).

FIGURE 19.13 Structure of epinephrine and norepinephrine. Epinephrine and norepinephrine are synthesized from tyrosine and act as both hormones and neurotransmitters. They are catecholamines, the term catechol referring to a ring structure containing two hydroxyl groups.

There are nine different types of adrenergic receptors: α_{1A} , α_{1B} , α_{1D} , α_{2A} , α_{2B} , α_{2C} , β_1 , β_2 , and β_3 . Only the three β - and α_1 -receptors are discussed here. The three β -receptors work through the adenylate cyclase–cAMP system, activating a G_s -protein, which activates adenylate cyclase, and eventually PKA. The β_1 -receptor is the major adrenergic receptor in the human heart and is primarily stimulated by norepinephrine. On activation, the

β_1 -receptor increases the rate of muscle contraction, in part because of PKA-mediated phosphorylation of phospholamban (see Chapter 45). The β_2 -receptor is present in liver, skeletal muscle, and other tissues and is involved in the mobilization of fuels (such as the release of glucose through glycogenolysis). It also mediates vascular, bronchial, and uterine smooth muscle contraction. Epinephrine is a much more potent agonist for this receptor than norepinephrine, whose major action is neurotransmission. The β_3 -receptor is found predominantly in adipose tissue and to a lesser extent in skeletal muscle. Activation of this receptor stimulates fatty acid oxidation and thermogenesis, and agonists for this receptor may prove to be beneficial weight loss agents. The α_1 -receptors, which are postsynaptic receptors, mediate vascular and smooth muscle contraction. They work through the PIP_2 system (see Chapter 10, Section XII.C.3) via activation of a G_q -protein and phospholipase C- β . This receptor also mediates glycogenolysis in liver.

Deborah S., a patient with type 2 diabetes mellitus, is experiencing insulin resistance. Her levels of circulating insulin are normal to high, although inappropriately low for her elevated level of blood glucose. However, her insulin target cells, such as muscle and fat, do not respond as those of a nondiabetic subject would to this level of insulin. For most patients with type 2 diabetes, the site of insulin resistance is subsequent to binding of insulin to its receptor; that is, the number of receptors and their affinity for insulin is near normal. However, the binding of insulin at these receptors does not elicit most of the normal intracellular effects of insulin discussed previously. Consequently, there is little stimulation of glucose metabolism and storage after a high-carbohydrate meal and little inhibition of hepatic gluconeogenesis.

CLINICAL COMMENTS

Deborah S. has type 2 diabetes mellitus whereas **Dianne A.** has type 1 diabetes mellitus. Although the pathogenesis differs for these major forms of diabetes mellitus, both cause varying degrees of hyperglycemia. In type 1 diabetes mellitus, antibodies directed at a variety of proteins within the β -cells gradually destroy the pancreatic β -cells. As insulin-secretory capacity by the β -cells gradually diminishes below a critical level, the symptoms of chronic hyperglycemia develop rapidly. In type 2 diabetes mellitus, these symptoms develop more subtly and gradually over the course of months or years. Eighty-five percent or more of type 2 patients are overweight and, like **Ivan A.**, have a high waist-hip ratio with regard to adipose tissue disposition. This abnormal distribution of fat in the visceral (peri-intestinal) adipocytes is associated with reduced sensitivity of fat cells, muscle cells, and liver cells to the actions of insulin outlined previously. This insulin resistance can be diminished through weight loss, specifically in the visceral depots. The development of type 2 diabetes mellitus, coupled with obesity and high blood pressure, can lead to the metabolic syndrome, a common clinical entity that is discussed in more detail in section V of the text.

Connie C. underwent an ultrasonographic (ultrasound) study of her upper abdomen, which showed a 2.6-cm mass in the midportion of her pancreas. With this finding, her physicians decided that further noninvasive studies would not be necessary before surgery and removal of the mass. At the time of surgery, a yellow-white 2.8-cm mass consisting primarily of insulin-rich β -cells was resected from her pancreas. No cytologic changes of malignancy were seen on microscopic examination of the surgical specimen, and no evidence of malignant behavior by the tumor (such as local metastases) was found. She had an uneventful postoperative recovery and no longer experienced the signs and symptoms of insulin-induced hypoglycemia.

BIOCHEMICAL COMMENTS

Actions of Insulin. One of the important cellular responses to insulin is the reversal of glucagon-stimulated phosphorylation of enzymes. Mechanisms proposed for this action include the inhibition of adenylate cyclase, a reduction of cAMP levels, the stimulation of phosphodiesterase, the release of a second messenger from a bound glycosylated phosphatidylinositol, and the phosphorylation of enzymes at a site that antagonizes PKA phosphorylation. Not all of these physiologic actions of insulin occur in each of the insulin-sensitive organs of the body.

Insulin is also able to antagonize the actions of glucagon at the level of specific induction or repression of key regulatory enzymes of carbohydrate metabolism. For instance, the rate of synthesis of messenger RNA (mRNA) for phosphoenolpyruvate carboxykinase, a key enzyme of the gluconeogenic pathway, is increased

severalfold by glucagon (via cAMP) and decreased by insulin. Thus, all of the effects of glucagon, even the induction of certain enzymes, can be reversed by insulin. This antagonism is exerted through an insulin-sensitive hormone response element (IRE) in the promoter region of the genes. Insulin causes repression of the synthesis of enzymes that are induced by glucagon.

The general stimulation of protein synthesis by insulin (its mitogenic or growth-promoting effect) appears to occur through a general increase in rates of mRNA translation for a broad spectrum of structural proteins. These actions result from a phosphorylation cascade initiated by autophosphorylation of the insulin receptor and ending in the phosphorylation of subunits of proteins that bind to and inhibit eukaryotic initiation factors (eIFs). When phosphorylated, the inhibitory proteins are released from the eIFs, allowing translation of mRNA to be stimulated. In this respect, the actions of insulin are similar to those of other hormones that act as growth factors and that also have receptors with tyrosine kinase activity.

In addition to signal transduction, activation of the insulin receptor mediates the internalization of receptor-bound insulin molecules, increasing their subsequent degradation. Although unoccupied receptors can be internalized and eventually recycled to the plasma membrane, the receptor can be irreversibly degraded after prolonged occupation by insulin. The result of this process, referred to as receptor downregulation, is an attenuation of the insulin signal. The physiologic importance of receptor internalization on insulin sensitivity is poorly understood but could lead eventually to chronic hyperglycemia.

KEY CONCEPTS

- ◆ Glucose homeostasis is directed toward the maintenance of constant blood glucose levels.
- ◆ Insulin and glucagon are the two major hormones that regulate the balance between fuel mobilization and storage. They maintain blood glucose levels near 70 to 100 mg/dL despite varying carbohydrate intake during the day.
- ◆ If dietary intake of all fuels is in excess of immediate need, it is stored as either glycogen or fat. Conversely, appropriately stored fuels are mobilized when demand requires.
- ◆ Insulin is released in response to carbohydrate ingestion and promotes glucose utilization as a fuel and glucose storage as fat and glycogen. Insulin secretion is regulated principally by blood glucose levels.
- ◆ Glucagon promotes glucose production via glycogenolysis (glycogen degradation) and gluconeogenesis (glucose synthesis from amino acids and other noncarbohydrate precursors).
- ◆ Glucagon release is regulated principally through suppression by rising levels of glucose and rising levels of insulin. Glucagon levels decrease in response to a carbohydrate meal and increase during fasting. Increased levels of glucagon relative to insulin stimulate the release of fatty acids from adipose tissue.
- ◆ Glucagon acts by binding to a receptor on the cell surface, which stimulates the synthesis of the intracellular second messenger, cAMP.
- ◆ cAMP activates PKA, which phosphorylates key regulatory enzymes, activating some and inhibiting others.
- ◆ Insulin acts via a receptor tyrosine kinase and leads to the dephosphorylation of the key enzymes phosphorylated in response to glucagon.
- ◆ Hormones that antagonize insulin action, known as insulin counterregulatory hormones, include glucagon, epinephrine, and cortisol.
- ◆ Diseases discussed in this chapter are summarized in Table 19.4.

TABLE 19.4 Diseases Discussed in Chapter 19

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Type 2 diabetes	Both	Emergence of insulin resistance, owing to a wide variety of causes; tissues do not respond to insulin as they normally would.
Insulinoma	Both	Periodic release of insulin from a tumor of the pancreatic β -cells, leading to hypoglycemic symptoms, which are accompanied by excessive appetite and weight gain.
Hyperglycemia	Both	Constantly elevated levels of glucose in the circulation owing to a wide variety of causes. Hyperglycemia leads to protein glycation and potential loss of protein function in a variety of tissues.

Type 1 diabetes	Both	No production of insulin by the pancreatic β -cells, caused by autoimmune destruction of the β -cells. Hyperglycemia and ketoacidosis may result from the lack of insulin.
Maturity-onset diabetes of the young	Genetic	Forms of diabetes caused by specific mutations, such as a mutation in pancreatic glucokinase, which alters the set point for insulin release from the β -cells.
Neonatal diabetes	Genetic	One cause of neonatal diabetes is a mutation in a subunit of the potassium channel in various tissues. Such a mutation in the pancreas leads to permanent opening of the potassium channel, keeping intracellular calcium levels low, and difficulty in releasing insulin from the β -cells.

REVIEW QUESTIONS—CHAPTER 19

- A patient with type 1 diabetes mellitus takes an insulin injection before eating dinner but then gets distracted and does not eat. Approximately 3 hours later, the patient becomes shaky, sweaty, and confused. These symptoms have occurred because of which one of the following?

 - Increased glucagon release from the pancreas
 - Decreased glucagon release from the pancreas
 - High blood glucose levels
 - Low blood glucose levels
 - Elevated ketone body levels
- Concerning our patient in question 19.1, if the patient had fallen asleep before recognizing the symptoms the patient could lose consciousness while sleeping. If that were to occur, and the paramedics called to help the patient, the administration of which one of the following would help to reverse this effect?

 - Insulin
 - Normal saline
 - Triglycerides
 - Epinephrine
 - Short-chain fatty acids
- Caffeine is a potent inhibitor of the enzyme cAMP phosphodiesterase. Which one of the following consequences would you expect to occur in the liver after drinking two cups of strong espresso coffee?

 - A prolonged response to insulin
 - A prolonged response to glucagon
 - An inhibition of protein kinase A
 - An enhancement of glycolytic activity
 - A reduced rate of glucose export to the circulation
- Assume that an increase in blood glucose concentration from 5 to 10 mM would result in insulin release by the pancreas. A mutation in pancreatic glucokinase can lead to maturity-onset diabetes of the young (MODY) because of which one of the following within the pancreatic β -cell?

 - A reduced ability to raise cAMP levels
 - A reduced ability to raise ATP levels
 - A reduced ability to stimulate gene transcription
 - A reduced ability to activate glycogen degradation
 - A reduced ability to raise intracellular lactate levels
- Which one of the following organs has the highest demand for glucose as a fuel?

 - Brain
 - Muscle (skeletal)
 - Heart
 - Liver
 - Pancreas
- Glucagon release does not alter muscle metabolism because of which one of the following?

 - Muscle cells lack adenylate cyclase.
 - Muscle cells lack protein kinase A.
 - Muscle cells lack G-proteins.

- D. Muscle cells lack GTP.
 - E. Muscle cells lack the glucagon receptor.
7. A male patient with fasting hypoglycemia experiences tremors, sweating, and a rapid heartbeat. These symptoms have been caused by the release of which one of the following hormones?
 - A. Insulin
 - B. Epinephrine
 - C. Cortisol
 - D. Glucagon
 - E. Testosterone
 8. A patient has tried many different “fad” diets to lose weight. Which one of the following meals would lead to the lowest level of circulating glucagon shortly after the meal?
 - A. High-fat meal
 - B. Low-protein meal
 - C. Low-fat meal
 - D. Low-carbohydrate meal
 - E. High-carbohydrate meal
 9. A 45-year-old patient was admitted to the hospital in a coma caused by severe hyperglycemia and was treated with insulin and fluids. He has been placed on long- and short-acting insulin injected daily to control his blood glucose levels. What test could be ordered at this point to determine if the patient has type 1 versus type 2 diabetes?
 - A. C-peptide level
 - B. Insulin level
 - C. Insulin antibodies
 - D. Proglucagon level
 - E. Glucagon level
 10. The patient in the previous question had very high blood glucose levels, and his urine also contained high blood glucose levels. The high blood glucose levels can lead to cerebral dysfunction owing to which one of the following?
 - A. Dehydration
 - B. Reduced lipid concentrations in the blood
 - C. Increased lipid concentrations in the blood
 - D. Hyperhydration
 - E. High ammonia levels
 - F. Low ammonia levels
 1. A major difference between the effects of cortisol and glucagon in the liver is which one of the following?
 - A. Activation of gluconeogenesis
 - B. Inhibition of glycolysis
 - C. Activation of glycogen degradation
 - D. Activation of fatty acid synthesis
 - E. Enhancement of glucose transport
 2. Persistent hyperglycemia, as may be observed in a patient with type 1 diabetes over many years, may lead to peripheral neuropathy later in life. The peripheral neuropathy is caused, in part, by which one of the following?
 - A. Increased fatty acid utilization by the neurons
 - B. Decreased fatty acid utilization by the neurons
 - C. Decreased glucose uptake by the neurons
 - D. Increased glycogen synthesis by the neurons
 - E. Nonenzymatic glycation of neuronal membrane proteins
 3. The advent of genetic engineering has allowed for the production of recombinant insulin containing amino acid substitutions, and, mixed with zinc, is used for insulin injections for patients who require insulin. Two types of recombinant insulin produced are “slow acting” and “fast acting.” “Fast-acting” insulin reaches the bloodstream more rapidly from the injection site than the “slow-acting” insulin, which will last for a longer time within the blood because it is released more slowly from the injection site. A property of the recombinant protein to create a fast-acting insulin could be which one of the following?
 - A. An increased affinity for zinc
 - B. A decreased affinity for zinc

- C. A decreased affinity for the insulin receptor
 - D. Insulin injected with the C-peptide attached
 - E. Insulin produced lacking the disulfide bonds found in native insulin
4. A tumor that overproduces which one of the following hormones would lead to symptoms similar to type 1 diabetes?
- A. Insulin
 - B. Epinephrine
 - C. Norepinephrine
 - D. Glucagon
 - E. Cortisol
5. Glucagon release from the pancreas is affected by a variety of factors. Which of the following best characterizes primary effectors of glucagon release? Choose the one best answer.

	Insulin	Amino Acids	Glucose	Epinephrine
A	Increases	Decreases	Increases	Increases
B	Increases	Increases	Decreases	Decreases
C	Increases	Decreases	Increases	Increases
D	Decreases	Increases	Decreases	Increases
E	Decreases	Decreases	Increases	Decreases
F	Decreases	Increases	Decreases	Decreases

ANSWERS TO REVIEW QUESTIONS

1. **The answer is D.** Once insulin is injected, glucose transport into the peripheral tissues will be enhanced. If the patient does not eat, the normal, fasting level of glucose will drop even further because of the injection of insulin, which increases the movement of glucose into muscle and fat cells. The patient becomes hypoglycemic, as a result of which epinephrine is released from the adrenal medulla. This, in turn, leads to the signs and symptoms associated with high levels of epinephrine in the blood. Answers A and B are incorrect because as glucose levels drop, glucagon will be released from the pancreas to raise blood glucose levels, which would alleviate the symptoms. Answer E is incorrect because ketone body production does not produce hypoglycemic symptoms, nor would they be significantly elevated only a few hours after the insulin shock the patient is experiencing.
2. **The answer is D.** When the patient took the insulin, the hormone stimulated glucose transport into the muscle and fat cells. This had the effect of lowering blood glucose levels, and, by not eating, the patient became severely hypoglycemic, to the point that the blood glucose levels were below the K_m for the glucose transporters for the nervous system. The administration of epinephrine will stimulate the liver to release glucose, via glycogenolysis and gluconeogenesis, and will raise blood glucose levels sufficiently to overcome insulin-induced hypoglycemia. The addition of insulin would only exacerbate the problem. Addition of triglycerides will not aid the nervous system, as the fatty acids cannot cross the blood–brain barrier. Normal saline will not add nutrients for the nervous system. Short-chain fatty acids also cannot enter the nervous system.
3. **The answer is B.** When glucagon binds to its receptor, the enzyme adenylate cyclase is eventually activated (through the action of G-proteins), which raises cAMP levels in the cell. The cAMP phosphodiesterase opposes this rise in cAMP and hydrolyzes cAMP to 5'-AMP. If the phosphodiesterase is inhibited by caffeine, cAMP levels would stay elevated for an extended period of time, enhancing the

glucagon response. The glucagon response in liver is to export glucose (thus, E is incorrect) and to inhibit glycolysis (thus, D is incorrect). cAMP activates protein kinase A, making answer C incorrect as well. The effect of insulin is to reduce cAMP levels (thus, A is incorrect).

4. **The answer is B.** Insulin release is dependent on an increase in the ATP/ADP ratio within the pancreatic β -cell. In MODY, the mutation in glucokinase results in a less active glucokinase at glucose concentrations that normally stimulate insulin release. Thus, higher concentrations of glucose are required to stimulate glycolysis and the TCA cycle to effectively raise the ratio of ATP to ADP. Answer A is incorrect because cAMP levels are not related to the mechanism of insulin release. Answer C is incorrect because initially transcription is not involved, as insulin release is owing to exocytosis of preformed insulin in secretory vesicles. Answer D is incorrect because the pancreas will not degrade glycogen under conditions of high blood glucose, and answer E is incorrect because lactate does not play a role in stimulating insulin release.
5. **The answer is A.** The brain requires glucose because fatty acids cannot readily cross the blood–brain barrier to enter neuronal cells. Thus, glucose production is maintained at an adequate level to allow the brain to continue to burn glucose for its energy needs. The other organs listed as possible answers can switch to the use of alternative fuel sources (lactate, fatty acids, amino acids) and are not as dependent on glucose for their energy requirements as is the brain.
6. **The answer is E.** Muscle does not express glucagon receptors, so they are refractory to actions of glucagon. Muscle does, however, contain GTP (made via the TCA cycle), G-proteins, PKA, and adenylate cyclase (epinephrine stimulation of muscle cells raises cAMP levels and activates protein kinase A).
7. **The answer is B.** Insulin does lower blood glucose and cause hypoglycemia, but this would produce symptoms of fatigue, confusion, and blurred vision. When hypoglycemia is present, the body releases glucagon, cortisol, epinephrine, and norepinephrine to raise blood glucose levels. Epinephrine causes tremors, sweating, and elevated pulse rate (fight-or-flight response). Testosterone is not involved.
8. **The answer is E.** Carbohydrates are more rapidly absorbed and have the greatest and most rapid influence on elevating blood glucose levels, which stimulates insulin production and reduces glucagon secretion from the pancreas. In addition, both elevated blood glucose and elevated insulin levels suppress glucagon release. Many amino acids stimulate glucagon release, and a low-protein diet would still lead to glucagon secretion from the pancreas to a greater extent than a high-carbohydrate diet. High- or low-fat diets will not stimulate insulin release, and because gluconeogenesis is required to synthesize glucose under such diets, glucagon secretion would still be occurring.
9. **The answer is A.** Type 1 diabetes mellitus is caused by a lack of insulin (and therefore neither proinsulin nor C-peptide is produced as well), whereas type 2 diabetes mellitus is cellular resistance to secreted insulin (therefore, endogenous insulin and C-peptide are still produced in patients with type 2 diabetes). Measurement of an absolute insulin level would not be helpful because the patient is injecting insulin each day. However, if the patient is still producing insulin, he would also produce the C-peptide and would be classified as a type 2 diabetic. If C-peptide levels are not detected, the patient is classified as having type 1 diabetes. Individuals with type 1 diabetes can have islet cell antibodies in their blood, but not insulin antibodies. The presence of antibodies against insulin in the blood would lead to a reduced response to insulin or a form of type 2 diabetes. The measurement of glucagon or proglucagon levels would not differentiate type 1 from type 2 diabetes because both glucagon and proglucagon would still be produced in individuals with diabetes. The levels of glucagon secreted in both types of diabetes are similar.
10. **The answer is A.** The elevated glucose in the blood leads to osmotic diuresis, as water leaves cells to enter the blood, and urine, to reduce the glucose concentration in those fluids. As the water leaves the tissues and enters the urine, blood volume also decreases, leading to even higher blood glucose concentrations. The loss of water leads to severe dehydration and reduced blood flow to the brain (owing to reduced blood volume), which will lead to cerebral dysfunction. The brain cannot use lipids as an energy source, so altering lipid concentrations in the blood will not affect cerebral function. The cerebral dysfunction is actually occurring under higher-than-normal blood glucose concentrations; it is the reduced blood volume that leads to the dysfunction. Carbohydrates do not contain a nitrogen group, so they do not produce ammonia. High levels of ammonia can cause cerebral dysfunction, but it does not come about owing to high blood glucose levels.
11. **The answer is C.** Cortisol, acting on liver, leads to enhanced gluconeogenesis and increased glycogen storage (to store glucose for the stresses to come). Glucagon also enhances gluconeogenesis but also activates glycogen degradation for the liver to export glucose. Both will lead to an inhibition of glycolysis

(because both activate gluconeogenesis). Neither hormone activates fatty acid synthesis (insulin will stimulate fatty acid synthesis), and neither hormone will increase glucose uptake into the liver.

12. **The answer is E.** Because of chronically elevated blood glucose levels, nonenzymatic glycation of membrane proteins can occur, as well as intracellular proteins (as exemplified by elevated levels of HbA1c in individuals with chronically high blood glucose levels). The glycation interferes with the function of the proteins, thereby reducing the ability of the neurons to transmit signals. Neurons do not utilize fatty acids as an energy source owing to inefficient transport of the fatty acid into the neuron (answers A and B are incorrect). Glucose uptake is regulated by the K_m of the glucose transporters and would not be decreased under conditions of chronic hyperglycemia. The neurons also only contain a small amount of glycogen, and glycogen synthesis does not increase as blood glucose concentration increases within the neuron.
13. **The answer is B.** Through decreasing the insulin's molecule affinity for zinc, the insulin will be able to leave the injection site in a shorter time period than insulin with a higher affinity for zinc. Because the complex with zinc is precipitated (usually as a hexamer), it takes time for insulin to leave the complex from the injection site to enter the bloodstream. If a modified insulin has a reduced affinity for zinc, it would be easier to leave the injection site to enter the bloodstream. If the recombinant insulin had a reduced affinity for the insulin receptor, it would require more insulin to be released to see a response, so the insulin would not be considered fast acting. Insulin, containing the C-peptide, has no biologic activity nor does an insulin molecule that lacks the disulfide bonds holding the A and B peptides together.
14. **The answer is D.** A glucagonoma, although rare, would lead to excessive glucagon release, skewing the insulin-to-glucagon ratio, therefore promoting glucose export from the liver, hyperglycemia, excessive thirst and hunger, polyuria, and unintentional weight loss, all symptoms of type 1 diabetes. Excessive insulin release would lead to hypoglycemia (the muscle and fat cells will be stimulated to take up insulin from the blood). Release of excessive epinephrine or norepinephrine would lead to tachycardia (rapid heartbeat), high blood pressure, anxiety, excessive sweating, and palpitations. They can cause hyperglycemia as a result of stimulating glucagon release, but patients with type 1 diabetes do not exhibit the other symptoms observed with elevated epinephrine or norepinephrine release. Excessive cortisol release will lead to weight gain and elevated blood pressure, but not weight loss.
15. **The answer is D.** Glucagon release is negatively impacted by both insulin and glucose (glucose has both a primary effect and a secondary effect of inducing insulin release), whereas amino acids and epinephrine stimulate glucagon release from the pancreas.

Cellular Bioenergetics: Adenosine Triphosphate and O₂

Bioenergetics refers to **cellular energy transformations**.

The Adenosine Triphosphate–Adenosine Diphosphate (ATP–ADP) Cycle. In cells, the **available free energy** of fuels is transformed into the physiologic responses that are necessary for life. The central role of the **high-energy phosphate bonds of ATP** in these processes is summarized in the **ATP–ADP cycle** (Fig. 20.1). To generate ATP through cellular respiration, fuels are degraded by oxidative reactions that transfer most of their **available free energy** to nicotinamide adenine dinucleotide (NAD⁺) and flavin adenine dinucleotide (FAD) to generate the reduced form of these coenzymes, **NADH** and **FAD(2H)**. When NADH and FAD(2H) are oxidized by O₂ in the electron transport chain (ETC), the energy is used to regenerate ATP in the process of **oxidative phosphorylation**. Energy available from cleavage of the high-energy phosphate bonds of ATP can be used directly for **mechanical work** (e.g., muscle contraction) or for **transport work** (e.g., an Na⁺ gradient generated by **Na⁺, K⁺-ATPase**). It can also be used for **biochemical work** (energy-requiring chemical reactions), such as **anabolic pathways** (biosynthesis of large molecules such as proteins) or detoxification reactions. **Phosphoryl transfer** reactions, **protein conformational changes**, and the formation of **activated intermediates** containing **high-energy bonds** (e.g., uridine diphosphate [UDP]-sugars) facilitate these energy transformations. Energy released from foods that is not used for work against the environment is transformed into **heat**.

FIGURE 20.1 The ATP–ADP cycle. ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, inorganic phosphate.

ATP Homeostasis. Fuel oxidation is regulated to maintain **ATP homeostasis** (“homeo,” same; “stasis,” state). Regardless of whether the level of cellular fuel utilization is high (with increased ATP consumption) or low (with decreased ATP consumption), the available ATP within the cell is maintained at a constant level by appropriate increases or decreases in the rate of fuel oxidation. Problems in ATP homeostasis and energy balance occur in obesity, hyperthyroidism, and myocardial infarction (MI).

Energy from Fuel Oxidation. Fuel oxidation is **exergonic**; it releases energy. The maximum quantity of energy released that is available for useful work (e.g., ATP synthesis) is called ΔG^0 , the **change in Gibbs free energy** at pH 7.0 under standard conditions. Fuel oxidation has a **negative** ΔG^0 ; that is, the products have a lower available free energy than the reactants and their formation is energetically favored. ATP synthesis from ADP and inorganic phosphate (P_i) is **endergonic**: It requires energy and has a positive ΔG^0 . To proceed in our cells, all pathways must have a negative ΔG^0 . How is this accomplished for anabolic pathways such as glycogen synthesis? These metabolic pathways incorporate reactions that expend high-energy bonds to compensate for the energy-requiring steps. Because the ΔG^0 values for a sequence of reactions **are additive**, the overall pathway becomes energetically favorable.

Fuels are oxidized principally by donating electrons to NAD^+ and FAD, which then donate electrons to O_2 in the ETC. The **caloric value** of a fuel is related to its ΔG^0 for transfer of electrons to O_2 , and its **reduction potential, E^0** (a measure of its willingness to donate, or accept, electrons). Because fatty acids are more reduced than carbohydrates, they have a higher caloric value. The high affinity of oxygen for electrons (a high positive reduction potential) drives fuel oxidation forward, with release of energy that can be used for ATP synthesis in oxidative phosphorylation. However, smaller amounts of ATP can be generated without the use of O_2 in **anaerobic glycolysis**.

Fuel oxidation can also generate **NADPH**, which usually donates electrons to biosynthetic pathways and detoxification reactions. For example, in some reactions catalyzed by **oxygenases**, NADPH is the electron donor and O_2 is the electron acceptor.

M To assess for thyroid function, one must understand how the hormones T_3 and T_4 are released from the thyroid (see Chapter 41). Both the hypothalamus and the pituitary gland monitor the level of free T_3 in the blood bathing them. When the concentration of free T_3 in the blood drops, the pituitary releases thyroid-stimulating hormone (TSH), which stimulates the thyroid to release T_3 and T_4 . The pituitary is under the control of the hypothalamus, which releases TSH-releasing hormone (TSHRH) under the appropriate conditions. Thus, if one notices low serum T_3 or T_4 levels, it may represent a thyroid or pituitary problem. Understanding the physiology enables the appropriate tests to be run to determine where the defect lies.

T_3 and T_4 are measured using sensitive techniques that involve antibody recognition (radioimmunoassay; see Chapter 41). TSH levels can be determined in a similar fashion, using a sandwich technique (which requires the use of two distinct antibodies that recognize TSH).

Through the appropriate interpretation of these tests, one can determine if thyroid or pituitary function is impaired, and design treatment accordingly.

THE WAITING ROOM

Otto S. is a 26-year-old medical student who has completed his first year of medical school. He is 5 ft 10 in tall and began medical school weighing 154 lb, within his ideal weight range (see Chapter 1). By the time he finished his last examination in his first year, he weighed 187 lb. He had calculated his basal metabolic rate (BMR) at approximately 1,680 kcal and his energy expenditure for physical exercise equal to 30% of his BMR. He planned on returning to his pre-medical school weight in 6 weeks over the summer by eating 576 kcal less each day and playing 7 hours of tennis every day. However, he did a summer internship instead of playing tennis. When he started his second year of medical school, he weighed 210 lb.

Stanley T. is a 26-year-old man who noted heat intolerance, with heavy sweating, heart palpitations, and tremulousness. Over the past 4 months, he has lost weight in spite of a good appetite. He is sleeping poorly and describes himself as feeling “jittery inside.”

On physical examination, his heart rate is rapid (116 beats/minute) and he appears restless and fidgety. His skin feels warm, and he is perspiring profusely. A fine hand tremor is observed as he extends his arms in front of his chest. His thyroid gland appears to be diffusely enlarged and, on palpation, is approximately three times normal size. Thyroid function tests confirm that his thyroid gland is secreting excessive amounts of the thyroid hormones T_4 (tetraiodothyronine) and T_3 (triiodothyronine), the major thyroid hormones present in the blood.

Cora N. is a 64-year-old female who had a myocardial infarction (MI; often referred to as a “heart attack”) 8 months ago. Although she has managed to lose 6 lb since the MI, she remains overweight and has not reduced the fat content of her diet adequately. The graded aerobic exercise program she started 5 weeks after her infarction is now followed irregularly, falling far short of the cardiac conditioning intensity prescribed by her cardiologist. She is readmitted to the hospital cardiac care unit (CCU) after experiencing a severe “viselike pressure” in the mid-chest area while cleaning ice from the windshield of her car. The electrocardiogram (ECG) shows evidence of a new anterior wall MI. In addition, signs and symptoms of left ventricular failure are present.

Cora N. suffered a heart attack 8 months ago and had a significant loss of functional heart muscle. She occasionally gets chest pain while walking. The pain she is experiencing is called angina pectoris and is a crushing pressure or constricting pain located in the center of the chest, and sometimes radiating to the neck or arms (see **Ann J.**, Chapters 6 and 7). The most common cause of angina is partial blockage of coronary arteries from atherosclerosis. The heart muscle cells beyond the block receive an inadequate blood flow and oxygen and they die when ATP production falls too low.

I. Energy Available to Do Work

The basic principle of the adenosine triphosphate–adenosine diphosphate (ATP–ADP) cycle is that fuel

oxidation generates ATP, and hydrolysis of ATP to ADP provides the energy to perform most of the work required in the cell. ATP has, therefore, been called the energy currency of the cells. To keep up with the demand, we must constantly replenish our ATP supply through the use of oxygen (O₂) for fuel oxidation.

The amount of energy from ATP cleavage available to do useful work is related to the difference in energy levels between the products and substrates of the reaction and is called the change in **Gibbs free energy**, ΔG (Δ , difference; G, Gibbs free energy). In cells, the ΔG for energy production from fuel oxidation must be greater than the ΔG of energy-requiring processes, such as protein synthesis and muscle contraction, for life to continue.

The heart is a specialist in the transformation of ATP chemical bond energy into mechanical work. Each single heartbeat uses approximately 2% of the ATP in the heart. If the heart were not able to regenerate ATP, all its ATP would be hydrolyzed in <1 minute. Because the amount of ATP required by the heart is so high, it must rely on the pathway of oxidative phosphorylation for generation of this ATP. In **Cora N.**'s heart, hypoxia (the lack of oxygen) is affecting her ability to generate ATP.

A. The High-Energy Phosphate Bonds of ATP

The amount of energy released or required by bond cleavage or formation is determined by the chemical properties of the substrates and products. The bonds between the phosphate groups in ATP are called phosphoanhydride bonds (Fig. 20.2). When these bonds are hydrolyzed, energy is released because the products of the reaction (ADP and phosphate) are more stable, with lower chemical potential energies, than the reactants (ATP and water [H₂O]). The instability of the phosphoanhydride bonds arises from their negatively charged oxygen atoms in the phosphate groups, which repel each other and strain the bonds between them. It takes energy to make the phosphate groups stay together. In contrast, there are fewer negative charges in ADP to repel each other. The phosphate group as a free anion is more stable than it is in ATP because of an increase in resonance structures (i.e., the electrons of the oxygen double bond are shared by all the oxygen atoms). As a consequence, ATP hydrolysis is energetically favorable and proceeds with release of energy as heat.

FIGURE 20.2 Hydrolysis of ATP to ADP and inorganic phosphate (P_i). Cleavage of the phosphoanhydride bonds between either the β - and γ -phosphates or between the α - and β -phosphates releases the same amount of energy, approximately 7.3 kcal/mol. However, hydrolysis of the phosphate–adenosine bond (a phosphoester bond) releases less energy (≈ 3.4 kcal/mol), and consequently, this bond is not considered a high-energy phosphate bond. During ATP hydrolysis, the change in disorder during the reaction is small and so ΔG values at physiologic temperature (37°C) are similar to those at standard temperature (25°C). ΔG is affected by pH, which alters the ionization state of the phosphate groups of ATP and by the intracellular concentration of Mg²⁺ ions, which bind to the β - and γ -phosphate groups of ATP. ADP, adenosine diphosphate; ATP, adenosine triphosphate.

In the cell, ATP is not hydrolyzed directly. Energy released as heat from ATP hydrolysis cannot be transferred efficiently into energy-requiring processes, such as biosynthetic reactions or maintenance of an ion gradient. Instead, cellular enzymes transfer the phosphate group to a metabolic intermediate or protein that is part of the energy-requiring process (a phosphoryl transfer reaction).

B. Change in Free Energy (ΔG) during a Reaction

How much energy can be obtained from ATP hydrolysis to do the work required in the cell? The maximum amount of useful energy that can be obtained from a reaction is called ΔG —the change in Gibbs free energy. The value of ΔG for a reaction can be influenced by the initial concentration of substrates and products, by temperature, pH, and pressure. The ΔG^0 for a reaction refers to the energy change for a reaction starting at 1 M substrate and product concentrations and proceeding to equilibrium (equilibrium, by definition, occurs when there is no change in substrate and product concentrations with time). ΔG° is the value for ΔG^0 under standard conditions (pH = 7.0, $[\text{H}_2\text{O}] = 55 \text{ M}$, and 25°C), as well as standard concentrations (Table 20.1).

TABLE 20.1 Thermodynamic Expressions, Laws, and Constants	
DEFINITIONS	
ΔG	Change in free energy, or Gibbs free energy
ΔG^0	Standard free-energy change, ΔG starting with 1 M concentrations of substrates and products
ΔG°	Standard free-energy change at 25°C , pH 7.0
ΔH	Change in enthalpy, or heat content
ΔS	Change in entropy, or increase in disorder
K'_{eq}	Equilibrium constant at 25°C , pH 7.0, incorporating $[\text{H}_2\text{O}] = 55.5 \text{ M}$ and $[\text{H}^+] = 10^{-7} \text{ M}$ in the constant
ΔE°	Change in reduction potential
P	Biochemical symbol for a high-energy phosphate bond, i.e., a bond that is hydrolyzed with the release of more than about 7 kcal/mol of heat
LAWS OF THERMODYNAMICS	
First law of thermodynamics, the conservation of energy: In any physical or chemical change, the total energy of a system, including its surroundings, remains constant.	
Second law of thermodynamics: The universe tends toward disorder. In all natural processes, the total entropy of a system always increases.	
Constants	
Units of ΔG and $\Delta H = \text{cal/mol}$ or J/mol : $1 \text{ cal} = 4.18 \text{ J}$	
T, absolute temperature: K, Kelvin = $273 + ^\circ\text{C}$ ($25^\circ\text{C} = 298^\circ\text{K}$)	
R, universal gas constant: $1.98 \text{ cal/mol}\cdot\text{K}$ or $8.31 \text{ J/mol}\cdot\text{K}$	
F, Faraday constant: $F = 23 \text{ kcal/mol}\cdot\text{Volt}$ or $96,500 \text{ J/V}\cdot\text{mol}$	
Units of E° , V	
FORMULAS	
$\Delta G = \Delta H - T\Delta S$	
$\Delta G^{\circ} = -RT \ln K_{\text{eq}}'$	
$\Delta G^{\circ} = -n F \Delta E^{\circ}$	
$\ln = 2.303 \log_{10}$	

ΔG° is equivalent to the chemical bond energy of the products minus that of the reactants, corrected for energy that has gone into entropy (an increase in amount of molecular disorder). This correction for change in entropy is very small for most reactions that occur in cells, and thus the ΔG° for hydrolysis of various chemical bonds reflects the amount of energy available from that bond.

The value -7.3 kcal/mol (-30.5 kJ/mol) that is generally used for the ΔG° of ATP hydrolysis is thus the amount of energy available from hydrolysis of ATP under standard conditions that can be spent on energy-requiring processes; it defines the “monetary value” of our “ATP currency.” Although the difference between cellular conditions (pH 7.3, 37°C) and standard conditions is very small, the difference between cellular concentrations of ATP, ADP, and inorganic phosphate (P_i) and the standard 1 M concentrations is huge and greatly affects the availability of energy in the cell.

C. Exothermic and Endothermic Reactions

The value of ΔG° tells you whether the reaction requires or releases energy, the amount of energy involved,

and the ratio of products to substrates at equilibrium. The negative value for the $\Delta G^{0'}$ of ATP hydrolysis indicates that, if you begin with equimolar (1 M) concentrations of substrates and products, the reaction proceeds in the forward direction with the release of energy. From initial concentrations of 1 M, the ATP concentration will decrease, and ADP and P_i will increase until equilibrium is reached.

For a reaction in which a substrate S is converted to a product P, the ratio of the product concentration to the substrate concentration **at equilibrium** is given by:

$$\Delta G^{0'} = -RT \ln[P]/[S] \quad \text{Equation 20.1}$$

Table 20.2 indicates a more general form of this equation; R is the gas constant (1.98 cal/mol-°K), and T is equal to the temperature in degrees Kelvin.

TABLE 20.2 A General Expression for ΔG	
To generalize the expression for ΔG , consider a reaction in which	
$aA + bB \rightleftharpoons cC + dD$	
The lowercase letters denote that a moles of A will combine with b moles of B to produce c moles of C and d moles of D.	
$\Delta G^{0'} = -RT \ln K_{eq} = -RT \ln \frac{[C]_{eq}^c [D]_{eq}^d}{[A]_{eq}^a [B]_{eq}^b}$	
and, when not in equilibrium,	
$\Delta G = \Delta G^{0'} + RT \ln \frac{[C]^c [D]^d}{[A]^a [B]^b}$	

Thus, the difference in available free energies of the substrate and product ($\Delta G^{0'}$) determines the concentration of each at equilibrium.

Reactions such as ATP hydrolysis are **exergonic** (release energy) or **exothermic** (release heat). Both exergonic and exothermic reactions have a negative $\Delta G^{0'}$ and release energy while proceeding in the forward direction to equilibrium. **Endergonic**, or **endothermic**, reactions have a positive $\Delta G^{0'}$ for the forward direction (the direction shown), and the backward direction is favored. For example, in the pathway of glycogen synthesis, phosphoglucomutase (PGM) converts glucose 6-phosphate (G6P) to glucose 1-phosphate (G1P). G1P has a higher phosphate bond energy than G6P because the phosphate is on the aldehyde carbon (Fig. 20.3). The $\Delta G^{0'}$ value for the forward direction (G6P \rightarrow G1P) is therefore positive. Beginning at equimolar concentrations of both compounds, there is a net conversion of G1P back to G6P and, at equilibrium, the concentration of G6P is higher than G1P. The exact ratio is determined by the $\Delta G^{0'}$ for the reaction.

Glucose 6-phosphate (G6P)

Glucose 1-phosphate (G1P)

For $G6P \rightarrow G1P$:

$$\Delta G^{0'} = +1.6 \text{ kcal/mol}$$

$$\Delta G^{0'} = -RT \ln \frac{[G1P]}{[G6P]}$$

FIGURE 20.3 The PGM reaction. The forward direction (formation of G1P) is involved in converting glucose to glycogen, and the reverse direction in converting glycogen to G6P. G1P, glucose 1-phosphate; G6P, glucose 6-phosphate; PGM, phosphoglucomutase.

It is often said that a reaction with a negative $\Delta G^{0'}$ proceeds spontaneously in the forward direction, meaning that products accumulate at the expense of reactants. However, $\Delta G^{0'}$ is not an indicator of the velocity of the reaction or of the rate at which equilibrium can be reached. In the cell, the velocity of the reaction depends on the efficiency and amount of enzyme available to catalyze the reaction (see Chapter 9), so “spontaneously” in this context can be misleading.

 The reaction catalyzed by PGM is reversible and functions in the synthesis of glycogen from glucose as well as the degradation of glycogen back to glucose. If the $\Delta G^{0'}$ for conversion of G6P to G1P is +1.65 kcal/mol, what is the $\Delta G^{0'}$ of the reverse reaction?

The equations for calculating ΔG are based on the first law of thermodynamics (see Table 20.1). The change in heat that occurs during a reaction is ΔH , the change in enthalpy of the reaction. At constant temperature and pressure, ΔH is equivalent to the available free energy of the products minus that of the reactants. ΔG , the maximum amount of useful work available from a reaction, is equal to $\Delta H - T\Delta S$. $T\Delta S$ is a correction for the amount of energy that has gone into an increase in the entropy (disorder in arrangement of molecules) of the system. Thus, $\Delta G = \Delta H - T\Delta S$, where ΔH is the change in enthalpy, T is the temperature of the system in Kelvin, and ΔS is the change in entropy or increased disorder of the system. ΔS is often negligible in reactions such as ATP hydrolysis, in which the numbers of substrates (H_2O , ATP) and products (ADP, P_i) are equal and no gas is formed. Under these conditions, the values for ΔG at physiologic temperature (37°C) are similar to those at standard temperature (25°C).

 The $\Delta G^{0'}$ for the reverse reaction is -1.65 kcal. The change in free energy is the same for the forward and reverse directions but has opposite sign. Because negative $\Delta G^{0'}$ values indicate favorable reactions, this reaction under standard conditions favors the conversion of G1P to G6P.

II. Energy Transformations to Do Mechanical and Transport Work

For work in the cell to be done, a mechanism must be available for converting the chemical bond energy of ATP into another form, such as a Na^+ gradient across a membrane. These energy transformations usually involve intermediate steps in which ATP is bound to a protein, and cleavage of the bound ATP results in a conformational change of the protein.

A. Mechanical Work

In **mechanical work**, the high-energy phosphate bond of ATP is converted into movement by changing the conformation of a protein. For example, in contracting muscle fibers, the hydrolysis of ATP while it is bound to myosin ATPase changes the conformation of myosin so that it is in a “cocked” position, ready to associate with the sliding actin filament. Thus, exercising muscle fibers have almost a 100-fold higher rate of ATP utilization and caloric requirements than resting muscle fibers (see Fig. e-20.1 ). Motor proteins, such as kinesins that transport chemicals along fibers, provide another example of mechanical work in a cell.

B. Transport Work

In **transport work**, called **active transport**, the high-energy phosphate bond of ATP is used to transport compounds against a concentration gradient (see Chapter 10, Fig. 10.6). In plasma membrane ATPases (P-ATPases) and vesicular ATPases (V-ATPases), the chemical bond energy of ATP is used to reversibly phosphorylate the transport protein and change its conformation. For example, as the Na^+ , K^+ -ATPase binds and cleaves ATP, it becomes phosphorylated and changes its conformation to release three Na^+ ions to the outside of the cell, thereby building up a higher extracellular than intracellular concentration of Na^+ . Na^+ reenters the cell on co-transport proteins that drive the uptake of amino acids and many other compounds into the cell. Thus, Na^+ must be continuously transported back out. The expenditure of ATP for Na^+ transport occurs

even while we sleep and is estimated to account for 10% to 30% of our BMR.

A large number of other active transporters also convert ATP chemical bond energy into an ion gradient (membrane potential). Vesicular ATPases pump protons into lysosomes. Ca^{2+} -ATPases in the plasma membrane move Ca^{2+} out of the cell against a concentration gradient. Similar Ca^{2+} -ATPases pump Ca^{2+} into the lumen of the endoplasmic reticulum and the sarcoplasmic reticulum (in muscle). Thus, a considerable amount of energy is expended in maintaining a low cytoplasmic Ca^{2+} level.

Otto S. had difficulty following his proposed diet and exercise regimen and has been gaining weight. He has a positive caloric balance, because his daily energy expenditure is less than his daily energy intake (see Chapter 2). Although the energy expenditure for physical exercise is only approximately 30% of the BMR in a sedentary individual, it can be 100% or more of the BMR in a person who exercises strenuously for several hours or more. The large increase in ATP utilization for muscle contraction during exercise accounts for its contribution to the daily energy expenditure.

In the thermodynamic perspective of energy expenditure, when energy intake to the body exceeds energy expended, the difference is effectively stored as fat.

III. Biochemical Work

The high-energy phosphate bonds of ATP are also used for **biochemical work**. Biochemical work occurs in **anabolic pathways**, which are pathways that synthesize large molecules (e.g., DNA, glycogen, triacylglycerols, and proteins) from smaller compounds. Biochemical work also occurs when toxic compounds are converted to nontoxic compounds that can be excreted (e.g., the liver converts NH_4^+ ions to urea in the urea cycle). In general, formation of chemical bonds between two organic molecules (e.g., C–C bonds in fatty acid synthesis or C–N bonds in protein synthesis) requires energy and is therefore biochemical work. How do our cells get these necessary energy-requiring reactions to occur?

To answer this question, the next sections consider how energy is used to synthesize glycogen from glucose (Fig. 20.4). Glycogen is a storage polysaccharide consisting of glucosyl units linked together through glycosidic bonds. If an anabolic pathway, such as glycogen synthesis, were to have an overall positive $\Delta G^{0'}$, the cell would be full of glucose and intermediates of the pathway but very little glycogen would be formed. To avoid this, cells do biochemical work and spend enough of their ATP currency to give anabolic pathways an overall negative $\Delta G^{0'}$.

FIGURE 20.4 Energetics of glycogen synthesis. Compounds containing high-energy bonds are shown in red. (1) Glucose is transported into the cell. (2) Glucose phosphorylation uses the high-energy phosphate bond (~P) of ATP in a phosphoryl transfer step. (4) Conversion of G6P to G1P by phosphoglucumutase. (5) UDP-glucose pyrophosphorylase cleaves a ~P bond in UTP, releasing pyrophosphate and forming UDP-glucose, an activated intermediate. (6) The pyrophosphate is hydrolyzed, releasing additional energy. (7) The phosphoester bond of UDP-glucose is cleaved during the addition of a glucosyl unit to the end of a glycogen polysaccharide chain. The UDP acts as the leaving group in this reaction. G6P also can be metabolized via glycolysis (3) when energy is required. ADP, adenosine diphosphate; ATP, adenosine triphosphate.; G1P, glucose 1-phosphate; G6P, glucose 6-phosphate; UDP, uridine diphosphate; UTP, uridine triphosphate.

The ΔG° for the conversion of G6P to G1P is +1.65 kcal/mol. What is the ratio of [G1P] to [G6P] at equilibrium?

A. Adding ΔG° Values

Reactions in which chemical bonds are formed between two organic molecules are usually catalyzed by enzymes that transfer energy from cleavage of ATP in a phosphoryl transfer reaction or by enzymes that cleave a high-energy bond in an activated intermediate of the pathway. Because the ΔG° values in a reaction sequence are additive, the pathway acquires an overall negative ΔG° , and the reactions in the pathway will occur to move toward an equilibrium state in which the concentration of final products is greater than that of the initial reactants.

1. Phosphoryl Transfer Reactions

One of the characteristics of Gibbs free energy is that ΔG° values for consecutive steps or reactions in a sequence can be added together to obtain a single value for the overall process. Thus, the high-energy phosphate bonds of ATP can be used to drive a reaction forward that would otherwise be highly unfavorable energetically. Consider, for example, synthesis of G6P from glucose, the first step in glycolysis and glycogen synthesis (see Fig. 20.4, circle 2). If the reaction were to proceed by addition of inorganic phosphate to glucose, G6P synthesis would have a positive ΔG° value of 3.3 kcal/mol (Table 20.3). However, when this reaction is coupled to cleavage of the high-energy ATP bond through a phosphoryl transfer reaction, the ΔG° for G6P synthesis acquires a net negative value of -4.0 kcal/mol, which can be calculated from the sum of the two reactions. G6P cannot be transported back out of the cell, and, therefore, the net negative ΔG° for G6P synthesis helps the cell to trap glucose for its own metabolic needs.

TABLE 20.3 ΔG° for the Transfer of a Phosphate from ATP to Glucose

Glucose + P_i \rightarrow glucose 6-P + H_2O	$\Delta G^{\circ} = +3.3$ kcal/mol
ATP + H_2O \rightarrow ADP + P_i	$\Delta G^{\circ} = -7.3$ kcal/mol
Sum: glucose + ATP \rightarrow glucose 6-P + ADP	$\Delta G^{\circ} = -4.0$ kcal/mol

ADP, adenosine diphosphate; ATP, adenosine triphosphate.

The net value for synthesis of G6P from glucose and ATP would be the same whether the two reactions are catalyzed by the same enzyme, are catalyzed by two separate enzymes, or are not catalyzed by an enzyme at all, because the net value of G6P synthesis is dictated by the amount of energy in the chemical bonds being broken and formed.

2. Activated Intermediates in Glycogen Synthesis

To synthesize glycogen from glucose, energy is provided by the cleavage of three high-energy phosphate bonds in ATP, uridine triphosphate (UTP), and pyrophosphate (PP_i) (see Fig. 20.4, steps 2, 5, and 6). Energy transfer is facilitated by phosphoryl group transfer and by formation of an activated intermediate (uridine diphosphate [UDP]-glucose). Step 4, the conversion of G6P to G1P, has a positive ΔG° . This step is pulled and pushed in the desired direction by the accumulation of substrate and removal of product in reactions that have a negative ΔG° from cleavage of high-energy bonds. In step 5, the UTP high-energy phosphate bond is cleaved to form the activated sugar, UDP-glucose (Fig. 20.5). This reaction is further facilitated by cleavage of the high-energy bond in the pyrophosphate (step 6) that is released in step 5 (approximately -7.7 kcal). In step 7, cleavage of the bond between UDP and glucose in the activated intermediate provides the energy for attaching the glucose moiety to the end of the glycogen molecule (approximately -3.3 kcal). In general, the amount of ATP

phosphate bond energy used in an anabolic pathway, or detoxification pathway, must provide the pathway with an overall negative ΔG^0 , so that the concentration of products is favored over that of reactants.

Uridine diphosphate glucose (UDP-glucose)

FIGURE 20.5 UDP-glucose contains a high-energy pyrophosphate bond, shown in the *green box*. UDP, uridine diphosphate.

Stanley T. has increased blood levels of thyroid hormones, which accelerate basal metabolic processes that use ATP in our organs (e.g., Na^+ , K^+ -ATPase), thereby increasing the BMR. An increased BMR was used for a presumptive diagnosis of hyperthyroidism before development of the tests to measure T_3 and T_4 . Because **Stanley T.** did not fully compensate for his increased ATP requirements with an increased caloric intake, he was in negative caloric balance and lost weight.

A As shown in Table 20.2, $\Delta G^0 = -RT \ln K_{\text{eq}}$. For this reaction, $K_{\text{eq}} = [\text{G1P}]/[\text{G6P}]$. The constant R is 1.98×10^{-3} kcal/mol-K, and T is $(273 + 25)$ K, so $RT = -0.593$ kcal/mol. Substituting in the previous equation then gives $1.65 = -0.593 \ln[\text{G1P}]/[\text{G6P}]$. Thus, $\ln[\text{G1P}]/[\text{G6P}] = -2.78$, and $[\text{G1P}]/[\text{G6P}] = e^{-2.78}$, or 0.062. So the ratio of $[\text{G1P}]$ to $[\text{G6P}]$ at equilibrium is 0.062.

Approximately 70% of our resting daily energy requirement arises from work carried out by our largest organs: the heart, brain, kidneys, and liver. Using their rate of oxygen consumption and an assumption that for each mole of oxygen atom consumed, 2.5 mol of ATP are synthesized (see Chapter 24), it can be estimated that each of these organs is using and producing several times its own weight in ATP each day.

Estimated Daily Use of ATP (g ATP/g Tissue)	
Heart	16
Brain	6
Kidneys	24
Liver	6
Skeletal muscle (rest)	0.3

The heart, which rhythmically contracts, is using this ATP for mechanical work. In contrast, skeletal muscles in a resting individual use far less ATP per gram of tissue. The kidney has an ATP consumption per gram of tissue similar to that of the heart and uses this ATP largely for transport work to recover usable nutrients and to maintain pH and electrolyte balance. The brain, likewise, uses most of its ATP for transport work, maintaining the ion gradients necessary for conduction of nerve impulses. The liver, in contrast, has a high rate of ATP consumption and utilization to carry out metabolic work (biosynthesis and detoxification). **Otto S.** realizes that his resting daily energy requirement will remain constant, and for him to lose weight he will have to eat less, exercise more or both.

B. ΔG Depends on Substrate and Product Concentrations

$\Delta G^{0'}$ reflects the energy difference between reactants and products at specific concentrations (each at 1 M) and standard conditions (pH 7.0, 25°C). However, these are not the conditions prevailing in cells, in which variations from “standard conditions” are relevant to determining actual free-energy changes and hence the direction in which reactions are likely to occur. One aspect of free-energy changes contributing to the forward direction of anabolic pathways is the dependence of ΔG , the free-energy change of a reaction, on the initial substrate and product concentrations. Reactions in the cell with a positive $\Delta G^{0'}$ can proceed in the forward direction if the concentration of substrate is raised to high enough levels, or if the concentration of product is decreased to very low levels. Product concentrations can be very low if, for example, the product is rapidly used in a subsequent energetically favorable reaction, or if the product diffuses or is transported away.

1. The Difference between ΔG and $\Delta G^{0'}$

The driving force toward equilibrium starting at any concentration of substrate and product is expressed by ΔG , and not by $\Delta G^{0'}$, which is the free-energy change to reach equilibrium starting with 1 M concentrations of substrate and product. For a reaction in which the substrate S is converted to the product P,

$$\Delta G = \Delta G^{0'} + RT \ln[P]/[S] \quad \text{Equation 20.2}$$

(See Table 20.2 for the general form of this equation.)

The expression for ΔG has two terms: $\Delta G^{0'}$, the energy change to reach equilibrium starting at equal and 1 M concentrations of substrates and products; and the second term, the energy change to reach equal concentrations of substrate and product starting from any initial concentration. (When $[P] = [S]$ and $[P]/[S] = 1$, $\ln [P]/[S] = 0$, and $\Delta G = \Delta G^{0'}$.) The second term will be negative for all concentrations of substrate greater than product, and the greater the substrate concentration, the more negative this term will be. Thus, if the substrate concentration is suddenly raised high enough or the product concentration is decreased low enough, ΔG (the sum of the first and second terms) will also be negative, and conversion of substrate to product becomes thermodynamically favorable.

2. The Reversibility of the PGM Reaction in the Cell

The effect of substrate and product concentration on ΔG and the direction of a reaction in the cell can be illustrated with conversion of G6P to G1P—the reaction catalyzed by PGM in the pathway of glycogen synthesis (see Fig. 20.3). The reaction has a small positive $\Delta G^{0'}$ for G1P synthesis (+1.65 kcal/mol) and, at equilibrium, the ratio of $[G1P]/[G6P]$ is approximately 6/94 (which was determined using the equation $\Delta G^{0'} = -RT \ln K_{eq}$). However, if another reaction uses G1P such that this ratio suddenly becomes 3/94, there is now a driving force for converting more G6P to G1P and restoring the equilibrium ratio. Substitution in Equation 20.2 gives ΔG , the driving force to equilibrium, as $+1.65 + RT \ln[G1P]/[G6P] = 1.65 + (-2.06) = -0.41$ kcal/mol, which is a negative value. Thus, a decrease in the ratio of product to substrate has converted the synthesis of G1P from a thermodynamically unfavorable to a thermodynamically favorable reaction that will proceed in the forward direction until equilibrium is reached.

Given a $\Delta G^{0'}$ of +1.65 kcal/mol for the conversion of G6P to G1P and a $\Delta G^{0'}$ of -4.0 kcal/mol for the conversion of glucose + ATP to G6P + ADP, what is the value of $\Delta G^{0'}$ for the conversion of glucose to G1P?

C. Activated Intermediates with High-Energy Bonds

Many biochemical pathways form activated intermediates containing high-energy bonds to facilitate biochemical work. The term “high-energy bond” is a biologic term defined by the ΔG^0 for ATP hydrolysis; any bond that can be hydrolyzed with the release of approximately as much, or more, energy than ATP is called a high-energy bond. The high-energy bond in activated intermediates, such as UDP-glucose in glycogen synthesis, facilitate energy transfer.

Cells use guanosine triphosphate (GTP) and cytidine triphosphate (CTP), as well as UTP and ATP, to form activated intermediates. Different anabolic pathways generally use different nucleotides as their direct source of high-energy phosphate bonds: UTP is used for combining sugars, CTP in lipid synthesis, and GTP in protein synthesis.

The high-energy phosphate bonds of UTP, GTP, and CTP are energetically equivalent to ATP and are synthesized from ATP by nucleoside diphosphokinases and nucleoside monophosphokinases. For example, UTP is formed from UDP by a nucleoside diphosphokinase in the reaction:

ADP is converted back to ATP by the process of oxidative phosphorylation, using energy supplied by fuel oxidation.

Energy-requiring reactions often generate the nucleoside diphosphate ADP. Adenylate kinase, an important enzyme in cellular energy balance, is a nucleoside monophosphate kinase that transfers a phosphate from one ADP to another ADP to form ATP and adenosine monophosphate (AMP):

This enzyme can thus regenerate ATP under conditions in which ATP utilization is required.

In addition to the nucleoside triphosphates, other compounds containing high-energy bonds are formed to facilitate energy transfer in anabolic and catabolic pathways (e.g., 1,3-bis-phosphoglycerate in glycolysis and acetyl coenzyme A in the tricarboxylic acid cycle) (Fig. 20.6). Creatine phosphate contains a high-energy phosphate bond that allows it to serve as an energy reservoir for ATP synthesis and transport in muscle cells, neurons, and spermatozoa. A common feature of these molecules is that all of these high-energy bonds are “unstable,” and their hydrolysis yields substantial free energy because the products are much more stable as a result of electron resonance within their structures.

1,3-Bisphosphoglycerate

Phosphoenolpyruvate

Creatine phosphate

Acetyl CoA

FIGURE 20.6 Some compounds with high-energy bonds, 1,3-bisphosphoglycerate and phosphoenolpyruvate, are intermediates of glycolysis. Creatine phosphate is a high-energy phosphate reservoir and shuttle in brain, muscle, and spermatozoa. Acetyl CoA is a precursor of the TCA cycle. The high-energy bonds are shown in *red*. TCA, tricarboxylic acid.

IV. Thermogenesis

According to the first law of thermodynamics, energy cannot be destroyed. Thus, energy from oxidation of a fuel (its caloric content) must be equal to the amount of heat released, the work performed against the environment, and the increase in order of molecules in our bodies. Some of the energy from fuel oxidation is converted into heat as the fuel is oxidized and some heat is generated as ATP is used to do work. If we become less efficient in converting energy from fuel oxidation into ATP, or if we use an additional amount of ATP for muscular contraction, we will oxidize an additional amount of fuel to maintain ATP homeostasis (constant cellular ATP levels). With the oxidation of additional fuel, we release additional heat. Thus, heat production is a natural consequence of “burning fuel.”

The term **thermogenesis** refers to energy expended for the purpose of generating heat in addition to that expended for ATP production. To maintain the body at 37°C despite changes in environmental temperature, it is necessary to regulate fuel oxidation and its efficiency (as well as heat dissipation). In shivering thermogenesis, we respond to sudden cold with asynchronous muscle contractions (shivers) that increase ATP utilization and therefore fuel oxidation and the release of energy as heat. In nonshivering thermogenesis (adaptive thermogenesis), the efficiency of converting energy from fuel oxidation into ATP is decreased. More fuel needs to be oxidized to maintain constant ATP levels, and thus more heat is generated.

Stanley T. has increased thyroid hormone levels that increase his rate of ATP utilization and fuel oxidation. An excess of thyroid hormones also may affect the efficiency of ATP production, resulting in fewer ATP produced for a given level of O₂ consumption. The increased rate of ATP utilization and diminished efficiency stimulate oxidative metabolism, resulting in a much greater rate of heat production. The hyperthyroid patient, therefore, complains of constantly feeling hot (heat intolerance) and sweaty. (Perspiration allows dissipation of excess heat through evaporation from the skin surface.)

V. Energy from Fuel Oxidation

Fuel oxidation provides energy for bodily processes principally through generation of the reduced coenzymes nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide [FAD(2H)]. They are used principally to generate ATP in oxidative phosphorylation. However, fuel oxidation also generates NADPH, which is most often used directly in energy-requiring processes. Carbohydrates also may be used to generate ATP through a nonoxidative pathway, called anaerobic glycolysis.

A. Energy Transfer from Fuels through Oxidative Phosphorylation

Fuel oxidation is our major source of ATP and our major means of transferring energy from the chemical bonds of the fuels to cellular energy-requiring processes. The amount of energy available from a fuel is equivalent to the amount of heat that is generated when a fuel is burned. To conserve this energy for the generation of ATP, the process of cellular respiration transforms the energy from the chemical bonds of fuels into the reduction state of electron-accepting coenzymes, NAD⁺ and FAD (Fig. 20.7, circle 1). As these compounds transfer electrons to O₂ in the electron transport chain (ETC), most of this energy is transformed into an electrochemical gradient across the inner mitochondrial membrane (Fig. 20.7, circle 2). Much of the energy in the electrochemical gradient is used to regenerate ATP from ADP in oxidative phosphorylation (phosphorylation that requires O₂).

FIGURE 20.7 Overview of energy transformations in oxidative phosphorylation. The electrochemical potential gradient across the mitochondrial membrane (Δp) is represented by two components, the $\Delta p\text{H}$, the proton gradient, and $\Delta\psi$, the membrane potential. The role of the electrochemical potential in oxidative phosphorylation is discussed in more depth in Chapter 24. Acetyl CoA, acetyl coenzyme A; ADP, adenosine diphosphate; ATP, adenosine triphosphate; FAD(2H), reduced flavin adenine dinucleotide; NADH, reduced nicotinamide adenine dinucleotide; Pi, inorganic phosphate.

$\Delta G^{0'}$ for the overall reaction is the sum of the individual reactions, or -2.35 kcal. The individual reactions are as follows:

$$\Delta G^{0'} = -4.0 \text{ kcal/mol}$$

$$\Delta G^{0'} = +1.65 \text{ kcal/mol}$$

Therefore,

$$\Delta G^{0'} = -2.35 \text{ kcal/mol}$$

Thus, the cleavage of ATP has made the synthesis of G1P from glucose energetically favorable.

1. Oxidation–Reduction Reactions

Oxidation–reduction reactions always involve a pair of chemicals: an electron donor, which is oxidized in the reactions; and an electron acceptor, which is reduced in the reaction. In fuel metabolism, the fuel donates electrons and is oxidized, and NAD^+ and FAD accept electrons and are reduced.

To remember this, think of the acronym LEO GER: **L**oss of **E**lectrons = **O**xidation; **G**ain of **E**lectrons = **R**eduction. Compounds are oxidized in the body in essentially three ways: (1) the transfer of electrons from the compound as a hydrogen atom or a hydride ion, (2) the direct addition of oxygen from O_2 , and (3) the direct

donation of electrons (e.g., $\text{Fe}^{2+} \rightarrow \text{Fe}^{3+}$) (see Chapter 5). Fuel oxidation involves the transfer of electrons as a hydrogen atom or a hydride ion, and thus reduced compounds have more hydrogen relative to oxygen than the oxidized compounds. Consequently, aldehydes are more reduced than acids, and alcohols are more reduced than aldehydes.

When is NAD^+ , rather than FAD, used in a particular oxidation–reduction reaction? It depends on the chemical properties of the electron donor and the enzyme catalyzing the reaction. In oxidation reactions, NAD^+ accepts two electrons as a hydride ion to form NADH, and a proton (H^+) is released into the medium (Fig. 20.8). It is generally used for metabolic reactions involving oxidation of alcohols and aldehydes. In contrast, FAD accepts two electrons as hydrogen atoms, which are donated singly from separate atoms (e.g., formation of a double bond or a disulfide) (Fig. 20.9).

FIGURE 20.8 Reduction of NAD⁺ and NADP⁺. These structurally related coenzymes are reduced by accepting two electrons as H⁻, the hydride ion.

FIGURE 20.9 Reduction of FAD. FAD accepts two electrons as two hydrogen atoms and is reduced. The reduced coenzyme is denoted in this text as FAD(2H) because it often accepts a total of two electrons one at a time, never going to the fully reduced form, FADH₂. FMN consists of riboflavin with one phosphate group attached. FAD, flavin adenine dinucleotide; FAD(2H), reduced flavin adenine dinucleotide; FMN, flavin mononucleotide.

As the reduced coenzymes donate these electrons to O₂ through the ETC, they are reoxidized. The energy derived from reoxidation of NADH and FAD(2H) is available for the generation of ATP by oxidative phosphorylation. In our analogy of ATP as currency, the reduced coenzymes are our paychecks for oxidizing fuels. Because our cells spend ATP so fast, we must immediately convert our paychecks into ATP cash.

Q **Otto S.** decided to lose weight by decreasing his intake of fat and alcohol (ethanol) and increasing his intake of carbohydrates. Compare the structure of ethanol with that of glucose and fatty acids (below). On the basis of their oxidation states, which compound provides the most energy (calories) per gram?

Glucose

Ethanol

A fatty acid

2. Reduction Potential

Each oxidation–reduction reaction makes or takes a fixed amount of energy, (ΔG^0), which is directly proportional to the ΔE^0 (the difference in reduction potentials of the oxidation–reduction pair). The **reduction potential** of a compound, E^0 , is a measure in volts of the energy change when that compound accepts electrons (becomes reduced); $-\Delta E^0$ is the energy change when the compound donates electrons (becomes oxidized). E^0 can be considered an expression of the willingness of the compound to accept electrons. Some examples of reduction potentials are shown in Table 20.4. Oxygen, which is the best electron acceptor, has the largest positive reduction potential (i.e., is the most willing to accept electrons and be reduced). As a consequence, the transfer of electrons from all compounds to O_2 is energetically favorable and occurs with energy release.

TABLE 20.4 Reduction Potentials of Some Oxidation–Reduction Half-Reactions

REDUCTION HALF-REACTIONS	E^0 AT pH 7.0
$\frac{1}{2}\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}$	0.816
Cytochrome a– $\text{Fe}^{3+} + 1\text{e}^- \rightarrow$ cytochrome a– Fe^{2+}	0.290
$\text{CoQ} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{CoQ-H}_2$	0.060
Fumarate + $2\text{H}^+ + 2\text{e}^- \rightarrow$ succinate	0.030
Oxalacetate + $2\text{H}^+ + 2\text{e}^- \rightarrow$ malate	–0.102
Acetaldehyde + $2\text{H}^+ + 2\text{e}^- \rightarrow$ ethanol	–0.163
Pyruvate + $2\text{H}^+ + 2\text{e}^- \rightarrow$ lactate	–0.200
Riboflavin + $2\text{H}^+ + 2\text{e}^- \rightarrow$ riboflavin- H_2	–0.200
$\text{FAD} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{FAD(2H)}$	–0.220 ^a

$\text{NAD}^+ + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{NADH} + \text{H}^+$	-0.320
$\text{Acetate} + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{acetaldehyde}$	-0.468

^aThis is the value for free FAD; when FAD is bound to a protein, its value can be altered in either direction. FAD, flavin adenine dinucleotide.

The more negative the reduction potential of a compound, the greater is the energy available for ATP generation when that compound passes its electrons to oxygen. The $\Delta G^{0'}$ for transfer of electrons from NADH to O_2 is greater than the transfer from FAD(2H) to O_2 (see the reduction potential values for NADH and FAD(2H) in Table 20.4). Thus, the energy available for ATP synthesis from NADH is approximately -53 kcal, and from the FAD-containing flavoproteins in the electron transfer chain approximately -41 kcal.

To calculate the free-energy change of an oxidation-reduction reaction, the reduction potential of the electron donor (NADH) is added to that of the acceptor (O_2). The $\Delta E^{0'}$ for the net reaction is calculated from the sum of the half-reactions. For NADH donation of electrons, it is +0.320 V, opposite of that shown in Table 20.4 (remember, Table 20.4 shows the $E^{0'}$ for accepting electrons), and for O_2 acceptance it is +0.816 V. The number of electrons being transferred is 2 (so, $n = 2$). The direct relationship between the energy changes in oxidation-reduction reactions and $\Delta G^{0'}$ is expressed by the Nernst equation:

 In palmitate and other fatty acids, most carbons are more reduced than those in glucose or ethanol (more of the carbons have electrons in C-H bonds). Therefore, fatty acids have the greatest caloric content per gram, 9 kcal. In glucose, the carbons have already formed bonds with oxygen, and fewer electrons in C-H bonds are available to generate energy. Thus, the complete oxidation of glucose provides roughly 4 kcal/g. In ethanol, one carbon is a methyl group with C-H bonds and one has an -OH group. Therefore, the oxidation state is intermediate between those of glucose and fatty acids, and ethanol thus has a caloric value of 7 kcal/g.

$$\Delta G^{0'} = -nF \Delta E^{0'} \quad \text{Equation 20.3}$$

where n is the number of electrons transferred and F is Faraday constant (23 kcal/mol-V). Thus, a value of approximately -53 kcal/mol is obtained for the energy available for ATP synthesis by transferring two electrons from NADH to oxygen. The $\Delta E^{0'}$ for FAD(2H) to donate electrons to O_2 is 1.016 V, compared to a $\Delta E^{0'}$ of 1.136 V for electron transfer from NADH to O_2 .

3. Caloric Values of Fuels

The caloric value of a food is related directly to its oxidation state, which is a measure of $\Delta G^{0'}$ for transfer of electrons from that fuel to O_2 . The electrons donated by the fuel are from its C-H and C-C bonds. Fatty acids such as palmitate [$\text{CH}_3(\text{CH}_2)_{14}\text{COOH}$] have a caloric value of roughly 9 kcal/g. Glucose is already partially oxidized and has a caloric value of only about 4 kcal/g. The carbons, on average, contain fewer C-H bonds from which to donate electrons.

The caloric value of a food is applicable in humans only if our cells have enzymes that can oxidize that fuel by transferring electrons from the fuel to NAD^+ , NADP^+ , or FAD. When we burn wood in a fireplace, electrons are transferred from cellulose and other carbohydrates to O_2 , releasing energy as heat. However, wood has no caloric content for humans; we cannot digest it and convert cellulose to a form that can be oxidized by our enzymes. Cholesterol, although it is a lipid, also has no caloric value for us because we cannot oxidize the carbons in its complex ring structure in reactions that generate NADH, FAD(2H), or NADPH.

B. NADPH in Oxidation-Reduction Reactions

NADP^+ is similar to NAD^+ and has the same reduction potential. However, NADP^+ has an extra phosphate group on the ribose, which affects its enzyme binding (see Fig. 20.8). Consequently, most enzymes use either NAD^+ or NADP^+ , but seldom both. In certain reactions, fuels are oxidized by transfer of electrons to NADP^+ to form NADPH. For example, G6P dehydrogenase, in the pentose phosphate pathway, transfers electrons from G6P to NADP^+ instead of NAD^+ . NADPH usually donates electrons to biosynthetic reactions such as fatty acid synthesis, and to detoxification reactions that use oxygen directly. Consequently, the energy in its reduction potential is usually used in energy-requiring reactions without first being converted to ATP currency.

C. Anaerobic Glycolysis

Not all ATP is generated by fuel oxidation. In **anaerobic glycolysis**, glucose is degraded in reactions that form high-energy phosphorylated intermediates of the pathway (Fig. 20.10). These activated high-energy intermediates provide the energy for the generation of ATP from ADP without involving electron transfer to O_2 . Therefore, this pathway is called anaerobic glycolysis, and ATP is generated from substrate-level phosphorylation rather than from oxidative phosphorylation (see Chapter 24). Anaerobic glycolysis is a critical source of ATP for cells that have a decreased O_2 supply, either because they are physiologically designed that way (e.g., cells in the kidney medulla, rapidly working muscle, red blood cells) or because their supply of O_2 has been pathologically decreased (e.g., coronary artery disease).

FIGURE 20.10 Anaerobic glycolysis. Phosphate is transferred from high-energy intermediates of the pathway to ADP. Because NADH from the pathway is reoxidized by reduction of pyruvate to lactate, no oxygen is required. ADP, adenosine diphosphate; ATP, adenosine triphosphate; NADH, nicotinamide adenine dinucleotide; P_i , inorganic phosphate.

VI. Oxygenases and Oxidases Not Involved in ATP Generation

Approximately 90% to 95% of the oxygen we consume is used by the terminal oxidase in the ETC for ATP generation via oxidative phosphorylation. The remainder of the O_2 is used directly by oxygenases and other oxidases, enzymes that oxidize a compound in the body by transferring electrons directly to O_2 (Fig. 20.11). The large positive reduction potential of O_2 makes all of these reactions extremely favorable thermodynamically, but the electronic structure of O_2 slows the speed of electron transfer. These enzymes, therefore, contain a metal ion that facilitates reduction of O_2 .

Oxidases

Mono-oxygenases

Dioxygenases

FIGURE 20.11 Oxidases and oxygenases. The fate of O_2 is shown in red. S represents an organic substrate.

A. Oxidases

Oxidases transfer electrons from the substrate to O_2 , which is reduced to water (H_2O) or to hydrogen peroxide (H_2O_2). The terminal protein complex in the ETC, called cytochrome oxidase, is an oxidase because it accepts electrons donated to the chain by NADH and FAD(2H) and uses these to reduce O_2 to water. Most of the other oxidases in the cell form hydrogen peroxide (H_2O_2) instead of H_2O and are called peroxidases. Peroxidases are generally confined to peroxisomes to protect DNA and other cellular components from toxic free radicals (compounds containing single electrons in an outer orbital) generated by hydrogen peroxide.

B. Oxygenases

Oxygenases, in contrast to oxidases, incorporate one or both of the atoms of oxygen into the organic substrate (see Fig. 20.11). Monooxygenases, enzymes that incorporate one atom of oxygen into the substrate and the other into H₂O, are often named hydroxylases (e.g., phenylalanine hydroxylase, which adds a hydroxyl group to phenylalanine to form tyrosine) or mixed-function oxidases. Monooxygenases require an electron-donor substrate, such as NADPH, a coenzyme such as FAD, which can transfer single electrons, and a metal or similar compound that can form a reactive oxygen complex. They are usually found in the endoplasmic reticulum and occasionally in mitochondria. Dioxygenases, enzymes that incorporate both atoms of oxygen into the substrate, are used in the pathways for converting arachidonate into prostaglandins, thromboxanes, and leukotrienes.

VII. Energy Balance

Our total energy expenditure is equivalent to our oxygen consumption (Fig. 20.12). The **resting metabolic rate** (energy expenditure of a person at rest, at 25°C, after an overnight fast) accounts for approximately 60% to 70% of our total energy expenditure and O₂ consumption, and physical exercise accounts for the remainder. Of the resting metabolic rate, approximately 90% to 95% of O₂ consumption is used by the mitochondrial ETC, and only 5% to 10% is required for nonmitochondrial oxidases and oxygenases and is not related to ATP synthesis. Approximately 20% to 30% of the energy from this mitochondrial O₂ consumption is lost by proton leak back across the mitochondrial membrane, which dissipates the electrochemical gradient without ATP synthesis. The remainder of our O₂ consumption is used for ATPases that maintain ion gradients and for biosynthetic pathways.

FIGURE 20.12 Estimated contribution of processes to energy utilization in standard state. (Reproduced with permission from Rolfe DF, Brown GC. Cellular energy utilization and molecular origin of standard metabolic rate in mammals. *Physiol Rev.* 1997;77(3):731–758. © 1997, the American Physiological Society.)

ATP homeostasis refers to the ability of our cells to maintain constant levels of ATP despite fluctuations in the rate of utilization. Thus, increased utilization of ATP for exercise or biosynthetic reactions increases the rate of fuel oxidation. The major mechanism employed is feedback regulation; all of the pathways of fuel oxidation that lead to generation of ATP are feedback-regulated by ATP levels, or by compounds related to the concentration of ATP. In general, the less ATP is used, the less fuel will be oxidized to generate ATP.

According to the first law of thermodynamics, the energy (in calories) in our consumed fuel can never be lost. Consumed fuel is either oxidized to meet the energy demands of the BMR plus exercise or it is stored as fat. Thus, an intake of calories in excess of those expended results in weight gain. The simple statement, “If you eat too much and don’t exercise, you will gain weight,” is really a summary of the bioenergetics of the ATP–ADP cycle.

CLINICAL COMMENTS

Otto S. visited his physician, who noted the increased weight. The physician recommended several diet modifications to **Otto S.** that would decrease the caloric content of his diet and pointed out the importance of exercise for weight reduction. He reminded **Otto S.** that the American Heart Association recommends that

adults get at least 150 minutes per week of moderate-intensity aerobic activity or 75 minutes per week of vigorous aerobic activity or a combination of both. He also reminded **Otto S.** that he would want to be a role model for his patients. **Otto S.** decided to begin an exercise regimen that included at least 30 minutes of running and tennis at least 5 days a week.

Stanley T. exhibited the classical signs and symptoms of hyperthyroidism (increased secretion of the thyroid hormones, T_3 and T_4 ; see Fig. 10.15 for the structure of T_3), including a goiter (enlarged thyroid gland). T_3 is the more active form of the hormone. T_4 is synthesized and secreted in approximately 10 times greater amounts than T_3 . Liver and other cells contain an enzyme (a deiodinase) that removes one of the iodines from T_4 , converting it to T_3 . Thyroid function tests confirmed this diagnosis.

Thyroid hormones (principally T_3) modulate cellular energy production and utilization through their ability to increase gene transcription (see Fig. 15.13) of many proteins involved in intermediary metabolism, including enzymes in the tricarboxylic acid (TCA) cycle and oxidative phosphorylation. They increase the rate of ATP utilization by the Na^+ , K^+ -ATPase, and other enzymes. They also affect the efficiency of energy transformations, so that either more fuel must be oxidized to maintain a given level of ATP or more ATP must be expended to achieve the desired physiologic response. The loss of weight experienced by **Stanley T.**, in spite of a very good appetite, reflects his increased caloric requirements and less efficient utilization of fuels. The result is enhanced oxidation of adipose tissue stores as well as a catabolic effect on muscle and other protein-containing tissues. Through mechanisms that are not well-understood, increased levels of thyroid hormone in the blood also increase the activity or “tone” of the sympathetic (adrenergic) nervous system. An activated sympathetic nervous system leads to a more rapid and forceful heartbeat (tachycardia and palpitations), increased nervousness (anxiety and insomnia), tremulousness (a sense of shakiness or jitteriness), and other symptoms.

Systolic heart failure occurs when the weakened pumping action of the left ventricular heart muscle, often from ischemia, leads to a reduced blood flow from the heart to the rest of the body. This leads to an increase in blood volume in the vessels that bring oxygenated blood from the lungs to the left side of the heart. The pressure inside these pulmonary vessels eventually reaches a critical level, above which water from the blood moves down a “pressure gradient” from the capillary lumen into alveolar air spaces of the lung (transudation). The patient experiences shortness of breath as the fluid in the air spaces interferes with oxygen exchange from the inspired air into arterial blood, causing hypoxia. The hypoxia then stimulates the respiratory center in the central nervous system, leading to a more rapid respiratory rate in an effort to increase the oxygen content of the blood. As the patient inhales deeply, the physician hears gurgling/crackling sounds (known as inspiratory rales or crackles) with a stethoscope placed over the posterior lung bases. These sounds represent the bubbling of inspired air as it enters the fluid-filled pulmonary alveolar air spaces.

Cora N. was in left ventricular heart failure (LVF) when she presented to the hospital with her second heart attack in 8 months. The diagnosis of LVF was suspected, in part, by her rapid heart rate (104 beats/minute) and respiratory rate. On examining her lungs, her physician heard respiratory rales (or crackles), caused by inspired air bubbling in fluid that had filled her lung air spaces secondary to LVF. This condition is referred to as systolic heart failure.

Cora N.'s rapid heart rate (tachycardia) resulted from a reduced capacity of her ischemic, failing left ventricular muscle to eject a normal amount of blood into the arteries leading away from the heart with each contraction. The resultant drop in intra-arterial pressure signaled a reflex response in the central nervous system that, in turn, caused an increase in heart rate in an attempt to bring the total amount of blood leaving the left ventricle each minute (the cardiac output) back toward a more appropriate level to maintain systemic blood pressure.

Initial treatment of **Cora N.**'s systolic heart failure will include efforts to reduce the workload of the heart by decreasing blood volume (preload) with diuretics and decreasing her blood pressure (afterload), and the administration of oxygen by nasal cannula to increase the oxygen levels in her blood.

BIOCHEMICAL COMMENTS

Active Transport and Cell Death. Most of us cannot remember when we first learned that we would die if we stopped breathing. But exactly how cells die from a lack of oxygen is an intriguing question. Hypoxia leads to both physical and transcriptional changes. Pathologists generally describe two histologically distinct types of

cell death: necrosis and apoptosis (programmed cell death). Cell death from a lack of O_2 , such as occurs during a MI, can be very rapid, and is considered necrosis. The lack of ATP for the active transport of Na^+ and Ca^{2+} triggers some of the death cascades that lead to necrosis (Fig. 20.13).

FIGURE 20.13 Hypoxia, Ca^{2+} , Na^+ , and cell death. Without an adequate O_2 supply, decreased ATP synthesis from oxidative phosphorylation results in an increase of cytoplasmic Na^+ and Ca^{2+} ions. Increased ion levels can trigger death cascades that involve increased permeability of the plasma membrane, loss of ion gradients, decreased cytosolic pH, mitochondrial Ca^{2+} overload, and a change in mitochondrial permeability called the mitochondrial permeability transition. The *solid lines* show the first sequence of events; the *dashed lines* show how these events feedback to accelerate the mitochondrial deterioration, making recovery of oxidative phosphorylation impossible. ATP, adenosine triphosphate.

The influx of Na^+ and loss of the Na^+ gradient across the plasma membrane is an early event accompanying ATP depletion during interruption of the O_2 supply. One consequence of the increased intracellular Na^+ concentration is that other transport processes driven by the Na^+ gradient are impaired. For example, the Na^+/H^+ exchanger, which normally pumps out H^+ generated from metabolism in exchange for extracellular Na^+ , can no

longer function, and intracellular pH may drop. The increased intracellular H^+ may impair ATP generation from anaerobic glycolysis. As a consequence of increased intracellular ion concentrations, water enters the cells and hydropic swelling occurs. Swelling is accompanied by the release of creatine kinase MB subunits, troponin I, and troponin C into the blood. Some of these enzymes are measured in the blood to help diagnose a MI (see Chapters 6 and 7). Swelling is an early event and is considered a reversible stage of cell injury.

Normally, intracellular Ca^{2+} concentration is carefully regulated to fluctuate at low levels (intracellular Ca^{2+} concentration is $<10^{-7}$ M, compared to approximately 10^{-3} M in extracellular fluid). Fluctuations of Ca^{2+} concentration at these low levels regulate myofibrillar contraction, energy metabolism, and other cellular processes. However, when the Ca^{2+} concentration is increased above this normal range, it triggers cell death (necrosis). High Ca^{2+} concentrations activate a phospholipase that increases membrane permeability, resulting in further loss of ion gradients across the cell membrane. They also trigger opening of the mitochondrial permeability transition pore, which results in loss of mitochondrial function and further impairs oxidative phosphorylation.

Intracellular Ca^{2+} levels may increase as a result of cell swelling, the lack of ATP for ATP-dependent Ca^{2+} pumps, or the loss of the Na^+ gradient. Normally, Ca^{2+} -ATPases located in the plasma membrane pump Ca^{2+} out of the cell. Ca^{2+} -ATPases in the endoplasmic reticulum and in the sarcoplasmic reticulum of heart and other muscles sequester Ca^{2+} within the membranes, where it is bound by a low-affinity binding protein. Ca^{2+} is released from the sarcoplasmic reticulum in response to a nerve impulse, which signals contraction, and the increase of Ca^{2+} stimulates both muscle contraction and the oxidation of fuels. Within the heart, another Ca^{2+} transporter protein, the Na^+/Ca^{2+} exchange transporter, coordinates the efflux of Ca^{2+} in exchange for Na^+ , so that Ca^{2+} is extruded with each contraction.

Hypoxia also induces the transcription of genes in an attempt to compensate for the hypoxic conditions. A family of transcription factors, known as hypoxia-inducible factors (HIFs), are activated under hypoxic conditions. These factors bind to hypoxia-responsive elements (promoter-proximal elements) in the regulatory region of target genes. More than 70 target genes are regulated by HIFs, including the gene for erythropoietin, which stimulates increased red blood cell production. Induction of these genes allows cells to adapt to and survive for some time under these hypoxic conditions.

KEY CONCEPTS

- ◆ Bioenergetics refers to cellular energy transformations.
- ◆ The high-energy phosphate bonds of ATP are a cell's primary source of energy.
- ◆ ATP is generated through cellular respiration, the oxidation of fuels to carbon dioxide and water.
- ◆ ATP can also be generated, at reduced levels, via anaerobic glycolysis (in the absence of O_2).
- ◆ The electrons captured from fuel oxidation generate NADH and FAD(2H), which are used to regenerate ATP via the process of oxidative phosphorylation.
- ◆ The energy available from ATP hydrolysis can be used for:
 - ◆ Mechanical work (muscle contraction)
 - ◆ Transport work (establishment of ion gradients across membranes)
 - ◆ Biochemical work (energy-requiring chemical reactions, including detoxification reactions)
- ◆ Energy released from fuel oxidation that is not used for work is transformed into and released as heat.
- ◆ The many pathways of fuel oxidation are coordinately regulated to maintain ATP homeostasis.
- ◆ $\Delta G^{0'}$ is the change in Gibbs free energy at pH 7.0 under standard conditions between the substrates and products of a reaction.
- ◆ Fuel oxidation has a negative $\Delta G^{0'}$; the products formed have less chemical energy than the reactants (an exergonic reaction pathway).
- ◆ ATP synthesis has a positive $\Delta G^{0'}$ and is endergonic; the reaction requires energy.
- ◆ Metabolic pathways have an overall negative $\Delta G^{0'}$, which is obtained by summing all of the $\Delta G^{0'}$ values for each reaction in the pathway.
- ◆ Oxidation–reduction reactions can be related to changes in free energy, the use of $E^{0'}$, the chemical's affinity for electrons. Compounds with higher $E^{0'}$ values have greater affinity for electrons than those with lower $E^{0'}$ values.
- ◆ Diseases discussed in this chapter are summarized in Table 20.5.

TABLE 20.5 Diseases Presented in This Chapter

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Obesity	Both	Understanding daily caloric needs can enable one to gain or lose weight through alterations in exercise and eating habits.
Hyperthyroidism	Both	Thyroid hormone is important in regulating energy metabolism; excessive T3 and T4 release enhances metabolism, leading to weight loss and a greater rate of heat production.
Heart attack (MI)	Both	The heart requires a constant level of energy, derived primarily from lactate, glucose, and fatty acids. This is necessary so that the rate of contraction can remain constant or increase during appropriate periods. Interference of oxygen flow to certain areas of the heart will reduce energy generation, leading to a MI.

MI, myocardial infarction.

REVIEW QUESTIONS—CHAPTER 20

- ATP is the cells major chemical form of energy, and often is converted to ADP during reactions, thereby releasing energy to allow the reaction to proceed in the forward direction. The highest-energy phosphate bond in ATP is located between which of the following groups?
 - Adenosine and phosphate
 - Ribose and phosphate
 - Ribose and adenine
 - Two hydroxyl groups in the ribose ring
 - Two phosphate groups
- All cells require energy to survive, and the laws of thermodynamics need to be followed within biologic systems. Which one of the following bioenergetic terms or phrases is defined correctly?
 - The first law of thermodynamics states that the universe tends toward a state of increased order.
 - The second law of thermodynamics states that the total energy of a system remains constant.
 - The change in enthalpy of a reaction is a measure of the total amount of heat that can be released from changes in the chemical bonds.
 - ΔG^{0r} of a reaction is the standard free-energy change measured at 37°C and a pH of 7.4.
 - A high-energy bond is a bond that releases >3 kcal/mol of heat when it is hydrolyzed.
- In order for a cell to carry out its biologic functions, the intracellular reactions need to be directed to follow a certain pathway. Which one statement below best describes the direction a chemical reaction will follow?
 - A reaction with positive free energy will proceed in the forward direction if the substrate concentration is raised high enough.
 - Under standard conditions, a reaction will proceed in the forward direction if the free energy ΔG^{0r} is positive.
 - The direction of a reaction is independent of the initial substrate and product concentrations because the direction is determined by the change in free energy.
 - The concentration of all of the substrates must be higher than that of all of the products for the reaction to proceed in the forward direction.
 - The enzyme for the reaction must be working at >50% of its maximum efficiency for the reaction to proceed in the forward direction.
- Mr. P., has just suffered a heart attack. As a consequence, his heart will display which one of the following changes?
 - Increased intracellular O_2 concentration
 - Increased intracellular ATP concentration
 - Increased intracellular H^+ concentration
 - Decreased intracellular Ca^{2+} concentration
 - Decreased intracellular Na^+ concentration
- Many biologic reactions are oxidation–reduction reactions that utilize a biologic electron carrier. Which one of the following statements correctly describes reduction of one of these electron carriers, NAD^+ or FAD ?
 - NAD^+ is reduced to $NADH$ and H^+ .
 - FAD is reduced to $FADH_2$ and $2H^+$.
 - NAD^+ is reduced to $NADH$ and $2H^+$.
 - FAD is reduced to $FADH$ and H^+ .
 - NAD^+ is reduced to $NADH_2$ and $2H^+$.

- A. NAD^+ accepts two electrons as hydrogen atoms to form $\text{NAD}(2\text{H})$.
 - B. NAD^+ accepts two electrons that are each donated from a separate atom of the substrate.
 - C. NAD^+ accepts two electrons as a hydride ion to form NADH .
 - D. FAD releases a proton as it accepts two electrons.
 - E. FAD must accept two electrons at a time.
6. Active transport is necessary to move compounds into or out of the cell or mitochondria. Transport work can occur when ATP donates its phosphate group to a transport protein, thereby altering the conformation of that protein. Which one of the following mechanisms allows this conformational change to occur?
- A. A gain of ionic interactions, which alter tertiary and/or quaternary structure of the protein
 - B. Loss of ionic interactions, thereby altering the proteins tertiary and/or quaternary structure
 - C. Loss of hydrogen bonds in the primary structure of the protein
 - D. Gain of hydrophobic interactions, leading to an alteration in the proteins tertiary and/or quaternary structure
 - E. Loss of hydrophobic interactions, leading to an alteration in the proteins tertiary and/or quaternary structure
7. The ΔG° values are determined under standard biochemical conditions, and reflect the energy either required, or released, as a particular reaction proceeds. Given the ΔG° values below, determine the overall ΔG° for the following reaction:

Creatine + ATP yields creatine-phosphate + ADP

The half-reactions are as follows:

$\text{ATP} + \text{H}_2\text{O}$ yields $\text{ADP} + \text{inorganic phosphate}$ $\Delta G^\circ = -7.3 \text{ kcal/mol}$

$\text{Creatine-phosphate} + \text{H}_2\text{O}$ yields $\text{creatine} + \text{inorganic phosphate}$ $\Delta G^\circ = -10.3 \text{ kcal/mol}$

- A. -3.0 kcal/mol
 - B. -10.3 kcal/mol
 - C. -17.6 kcal/mol
 - D. $+3.0 \text{ kcal/mol}$
 - E. $+10.3 \text{ kcal/mol}$
 - F. $+17.6 \text{ kcal/mol}$
8. When athletes expend vast amounts of energy, they are sometimes seen on the sidelines using supplemental oxygen. More than 90% of the oxygen we breathe is used for the generation of which one of the following?
- A. ATP
 - B. ADP
 - C. NAD^+
 - D. FAD
 - E. Acetyl-CoA
9. ATP is the cells major energy-carrying molecule, and in order for a cell to survive, the cell must be able to regenerate ATP when ATP levels drop. Which one of the following statements accurately describes an aspect of ATP metabolism?
- A. ATP is more stable than ADP.
 - B. ATP has more positively charged phosphate groups than ADP.
 - C. Phosphate groups repel each other, which in ATP leads to strained bond formation.
 - D. Heat from ATP hydrolysis is used to drive energy-requiring processes.
 - E. ATP is hydrolyzed directly in the cell.
10. All physiologic processes in living cells require energy transformation. Which one of the following would be considered biochemical work utilizing the high-energy phosphate bonds of ATP?
- A. Contracting muscle fibers
 - B. Developing a Na^+ gradient across a membrane
 - C. Transporting compounds against a concentration gradient
 - D. Converting toxic compounds to nontoxic compounds in the liver
 - E. Undergoing catabolic pathways
1. Consider the reaction $\text{A} \rightarrow \text{B}$. The ΔG° for this reaction is $+1.8 \text{ kcal/mol}$. If the concentration of B is, at

equilibrium, 1.0 mM, what would be the concentration of A at equilibrium, at 25°C?

- A. 20 mM
- B. 2.0 mM
- C. 0.20 mM
- D. 0.02 mM
- E. 0.002 mM

2. Consider the following series of reactions, along with their standard free energy change:

What would be the standard free energy change for the conversion of D → A?

- A. +0.67 kcal/mol
- B. -1.18 kcal/mol
- C. -3.54 kcal/mol
- D. -4.21 kcal/mol
- E. -5.99 kcal/mol

3. Consider the following reaction:

The enzyme that catalyzes this reaction is best classified as which of the following?

- A. Dehydratase
- B. Dioxygenase
- C. Oxidase
- D. Oxygenase
- E. Peroxidase

4. Given the standard oxidation–reduction potentials for the following two reactions:

The free-energy change for the following reaction would be which one of the following?

- A. -53.0 kcal/mol
- B. -47.7 kcal/mol
- C. -4.77 kcal/mol
- D. +4.77 kcal/mol
- E. +47.7 kcal/mol

5. Consider the structure of the following three fatty acids:

1. $CH_3-(CH_2)_{14}-COO^-$
2. $CH_3-(CH_2)_7-CH=CH-(CH_2)_5-COO^-$
3. $CH_3-(CH_2)_2-CH=CH-(CH_2)_4-CH=CH-(CH_2)_4-COO^-$

What is the order of energy yield (from most energy to least energy) when the above three fatty acids are oxidized completely to carbon dioxide and water?

- A. iii > ii > i
- B. i > ii > iii
- C. ii > i > iii

- D. ii > iii > i
E. i > iii > ii

ANSWERS TO REVIEW QUESTIONS

- The answer is E.** Both of the high-energy phosphate bonds in ATP are located between phosphate groups (both the α - and β -phosphates, and the β - and γ -phosphates). The phosphate bond between the α -phosphate and ribose (or adenosine) is not a high-energy bond (thus, A and B are incorrect); and there is no phosphate between the ribose and adenine, or two hydroxyl groups in the ribose ring; therefore, answers C and D are incorrect.
- The answer is C.** The change in enthalpy, ΔH , is the total amount of heat that can be released in a reaction. The first law of thermodynamics states that the total energy of a system remains constant, and the second law of thermodynamics states the universe tends toward a state of disorder (thus, A and B are incorrect). Answer D is incorrect because $\Delta G^{0'}$ is the standard free-energy change measured at 25°C and a pH of 7. Answer E is incorrect because a high-energy bond releases more than about 7 kcal/mol of heat when it is hydrolyzed. The definition of a high-energy bond is based on the hydrolysis of one of the high-energy bonds of ATP.
- The answer is A.** The concentration of the substrates and products influence the direction of a reaction. Answer B is incorrect because reactions with a positive free energy, at 1 M concentrations of substrate and product, will proceed in the reverse direction. Answer C is incorrect because substrate and product concentrations do influence the free energy of a reaction. Answer D is incorrect because the free energy must be considered (in addition to the substrate and product concentrations) to determine the direction of a reaction. Answer E is false; an enzyme's efficiency does not influence the direction of a reaction.
- The answer is C.** A heart attack results in decreased pumping of blood, and thus a decreased oxygen supply to the heart (thus, A is incorrect). The lack of oxygen leads to a lack of ATP (thus, B is incorrect) owing to an inability to perform oxidative phosphorylation. The lack of ATP impairs the working of Na^+ , K^+ -ATPase, which pumps sodium out of the cell in exchange for potassium. Therefore, intracellular levels of sodium will increase as Na^+ enters the cell through other transport mechanisms (thus, E is incorrect). The high intracellular sodium concentration then blocks the functioning of the Na^+/H^+ antiporter (which sends protons out of the cell in exchange for sodium). Because intracellular sodium is high, the driving force for this reaction is lost, which leads to increased intracellular H^+ , or a lower intracellular pH (thus, C is correct). The intracellular pH also decreases because of glycolysis in the absence of oxygen, which produces lactic acid. The loss of the sodium gradient, coupled with the lack of ATP, leads to increased calcium in the cell (thus, D is incorrect) owing to an inability to pump calcium out.
- The answer is C.** NAD^+ accepts two electrons as hydride ions to form NADH (thus, A and B are incorrect). Answers D and E are incorrect because FAD can accept two single electrons from separate atoms, together with protons, or can accept a pair of electrons.
- The answer is A.** When a protein is phosphorylated the most likely sites of phosphorylation are the hydroxyl groups of serine, threonine, or tyrosine. Prior to phosphorylation those hydroxyl groups on the amino acid side chains can only participate in hydrogen bonds. When phosphorylated, the oxygen of the hydroxyl group is now covalently linked to the phosphate, which has two negative charges. This allows this group to form ionic bonds, which were not available prior to phosphorylation. The formation of ionic bonds then alters the tertiary and/or the quaternary structure of the protein. The addition of phosphate groups reduces the hydrophobicity of this region of the protein, and the primary structure of the protein is the linear sequence of amino acids and does not involve hydrogen bond formation.
- The answer is D.** $\Delta G^{0'}$ values are additive for a series of reactions. In order to generate the overall reaction required, creatine + ATP yields ADP + creatine-phosphate, the second reaction listed in the question needs to be reversed. Upon reversing a reaction, the sign of the standard free energy is reversed, in this case becoming +10.3 for the reaction creatine + inorganic phosphate yields creatine-phosphate + water. Upon summing the first reaction, and the reversed second reaction, the overall reaction is obtained, and the $\Delta G^{0'} = 10.3 - 7.3$, or +3.0 kcal/mol.
- The answer is A.** More than 90% of the oxygen we breathe is used for cellular respiration, the overall process of transferring the electrons obtained from oxidizing fuels to oxygen in order to generate ATP. When ATP energy is needed, a high-energy phosphate bond of ATP is cleaved, forming ADP. NAD^+ and

FAD are electron-accepting coenzymes that accept electrons from fuels as they are oxidized, and the electron carriers are reduced to NADH and FAD(2H). NADH and FAD(2H) donate their electrons to the electron transfer chain in order to generate ATP via oxidative phosphorylation. Generation of acetyl CoA is only phase 1 of cellular respiration and does not by itself generate ATP. In phase 2, oxidation of acetyl CoA in the TCA cycle collects energy as NADH and FAD(2H) in order to generate ATP.

9. **The answer is C.** The instability of the phosphoanhydride bonds arises from their negatively charged phosphate groups that repel each other and strain their bonds. ATP has more negatively charged phosphate groups (4) than ADP (3), reflective of ATP containing two high-energy bonds, and ADP one high-energy bond. In the cell, ATP is not hydrolyzed directly; rather it is hydrolyzed in specific reactions that require energy to be pushed toward product formation. ATP is also used to form phosphate intermediates that are then substrates for other reactions in a metabolic pathway. The heat released from ATP hydrolysis is used for thermogenesis, but cannot be used to drive other energy-requiring processes.
10. **The answer is D.** Biochemical work occurs in anabolic pathways (synthesizing large molecules) or when toxic compounds are converted to nontoxic compounds that can be excreted. Muscle fiber contraction is mechanical work and generating a sodium gradient, or transporting compounds against a concentration gradient are considered transport work. Catabolic pathways lead to the generation of ATP.
11. **The answer is A.** The basic equation to use to answer this question is Equation 20.2; $\Delta G^\circ = \Delta G^{o'} + RT \ln ([B]/[A])$. At equilibrium $\Delta G^\circ = 0$, so $\Delta G^{o'} = -RT \ln ([B]/[A])$. $\Delta G^{o'}$ is given as + 1.8 kcal/mol, and [B] is given as 1 mM. $R = 1.98 \times 10^{-3}$ kcal/mol-°K, and $T = 298^\circ\text{K}$ (25°C). One can then solve for [A], which is equal to 21.3 mM. Because the reaction is unfavorable (the value for $\Delta G^{o'}$ is positive), the [A] should be greater than the [B].
12. **The answer is B.** To answer this question, the reactions have to run “backward,” such that $D \rightarrow C$, then $C \rightarrow B$, and $B \rightarrow A$. The standard free-energy changes for these reactions are -2.45, +0.73, and +0.44 kcal/mol, respectively (the signs are changed because of the reactions going in reverse). Summing up the free-energy changes for the three reactions yields -1.18 kcal/mol.
13. **The answer is D.** The reaction depicted is a hydroxylation reaction in which one atom of oxygen is found in the product (as part of the hydroxyl group) and the other atom of oxygen is found in water. These reactions require a reduction of oxygen, and the electrons are coming from both the substrate and NADPH in order to let the reaction to proceed. While oxygen is reduced, both the substrate and NADPH are oxidized. Oxygenases catalyze this type of reaction. A dehydratase catalyzes the removal of water from two adjacent carbon atoms, a dioxygenase results in both atoms of molecular oxygen being incorporated into the product (instead of just one), and an oxidase transfers electrons directly to oxygen to produce water or hydrogen peroxide. Oxidase catalyzed reactions do not result in one atom of oxygen being found in the product of the reaction. Peroxidases either utilize or generate hydrogen peroxide and are usually located in the peroxisome. The reaction in the question is not generating or utilizing a peroxide.
14. **The answer is B.** The Nernst equation is required to answer this question, which is $\Delta G^\circ = -nF\Delta E^\circ$, where n is the number of electrons transferred (in this case two), F is Faraday’s constant (23 kcal/mol-volt), and ΔE° is the redox potential of the overall reaction. In this case, the two equations to be summed are as follows:

Adding the two equations yields a ΔE° of +1.036 volts. Using these values in the Nernst equation, one gets $\Delta G^\circ = -(2)(23)(1.036)$ kcal/mol, or -47.7 kcal/mol.

15. **The answer is B.** An examination of the three structures shown indicates that structure (i) is the most reduced (there are no double bonds in the structure), whereas structure (ii) has one double bond, and structure (iii) has two double bonds. Structure (i) would provide more electrons as the molecule is oxidized than structure (ii), which would provide more electrons than structure (iii). The order is therefore $i > ii > iii$.

Digestion, Absorption, and Transport of Carbohydrates

Carbohydrates are the largest source of dietary calories for most of the world's population. The major carbohydrates in the U.S. diet are starch, lactose, and sucrose. The **starches amylose** and **amylopectin** are polysaccharides composed of hundreds to millions of glucosyl units linked together through α -1,4- and α -1,6-glycosidic bonds (Fig. 21.1). **Lactose** is a disaccharide composed of glucose and galactose, linked together through a β -1,4-glycosidic bond. **Sucrose** is a disaccharide composed of glucose and fructose, linked through an α -1,2-glycosidic bond. The digestive processes convert all of these dietary carbohydrates to their constituent monosaccharides by **hydrolyzing glycosidic bonds** between the sugars.

FIGURE 21.1 The structures of common dietary carbohydrates. For disaccharides and higher, the sugars are linked through glycosidic bonds between the anomeric carbon of one sugar and a hydroxyl group on another sugar. The glycosidic bond may be either α or β , depending on its position above or below the plane of the sugar containing the anomeric carbon. (See Chapter 5, Section II.A, to review terms used in the description of sugars.) The starch amylose is a polysaccharide of glucose residues linked with α -1,4-glycosidic bonds. Amylopectin is amylose with the addition of α -1,6-glycosidic branch points. Dietary sugars may be monosaccharides (single sugar residues), disaccharides (two sugar residues), oligosaccharides (several sugar residues), or polysaccharides (hundreds of sugar residues). For clarity, the hydrogen atoms are not shown in the figure.

The digestion of starch begins in the mouth (Fig. 21.2). The **salivary** gland releases α -**amylase**,

which converts starch to smaller polysaccharides called α -**dextrins**. Salivary α -amylase is inactivated by the acidity of the stomach (hydrochloric acid [HCl]). **Pancreatic α -amylase** and bicarbonate are secreted by the exocrine pancreas into the lumen of the small intestine, where bicarbonate neutralizes the gastric secretions. Pancreatic α -amylase continues the digestion of α -dextrins, converting them to disaccharides (**maltose**), trisaccharides (**maltotriose**), and oligosaccharides called **limit dextrins**. Limit dextrins usually contain four to nine glucosyl residues and an **isomaltose** branch (two glucosyl residues attached through an α -1,6-glycosidic bond).

FIGURE 21.2 Overview of carbohydrate digestion. **Digestion** of the carbohydrates occurs first, followed by **absorption** of monosaccharides. Subsequent metabolic reactions occur after the sugars are absorbed.

The digestion of the disaccharides lactose and sucrose, as well as further digestion of maltose, maltotriose, and limit dextrins, occurs through **disaccharidases** attached to the membrane surface of the **brush border (microvilli)** of intestinal epithelial cells. **Glucoamylase** hydrolyzes the α -1,4-bonds of dextrins. The **sucrase-isomaltase complex** hydrolyzes sucrose, most of maltose, and almost all of the isomaltose formed by glucoamylase from limit dextrins. **Lactase-glycosylceramidase** (β -glycosidase) hydrolyzes the β -glycosidic bonds in **lactose** and **glycolipids**. A fourth disaccharidase complex, **trehalase**, hydrolyzes the bond (an α -1,1-glycosidic bond) between two glucosyl units in the sugar trehalose. The monosaccharides produced by these hydrolases (glucose, fructose, and galactose) are then transported into the intestinal epithelial cells.

Dietary fiber, composed principally of polysaccharides, cannot be digested by human enzymes in the intestinal tract. In the colon, dietary fiber and other nondigested carbohydrates may be converted to gases (H_2 , CO_2 , and methane) and short-chain fatty acids (principally acetic acid, propionic acid, and butyric acid) by bacteria in the colon.

Glucose, galactose, and fructose formed by the digestive enzymes are transported into the absorptive epithelial cells of the small intestine by protein-mediated **Na^+ -dependent active transport** and **facilitative diffusion**. Monosaccharides are transported from these cells into the blood and circulate to the liver and peripheral tissues, where they are taken up by facilitative transporters. Facilitative transport of glucose across epithelial cells and other cell membranes is mediated by a family of **tissue-specific glucose transport proteins (GLUT I to GLUT V)**. The type of transporter found in each cell reflects the role of glucose metabolism in that cell.

THE WAITING ROOM

Denise V. is a 20-year-old exchange student from Nigeria who has noted gastrointestinal bloating, abdominal cramps, and intermittent diarrhea ever since arriving in the United States 6 months ago. A careful history shows that these symptoms occur most commonly about 45 minutes to 1 hour after eating breakfast but may occur after other meals as well. Dairy products, which were not a part of **Denise V.**'s diet in Nigeria, were identified as the probable offending agent because her gastrointestinal symptoms disappeared when milk and milk products were eliminated from her diet.

Deborah S.'s fasting and postprandial blood glucose levels are frequently above the normal range in spite of good compliance with insulin therapy. Her physician has referred her to a dietician skilled in training diabetic patients in the successful application of an appropriate American Diabetes Association diet. As part of the program, **Deborah S.** is asked to incorporate foods containing fiber into her diet, such as whole grains (e.g., wheat, oats, corn), legumes (e.g., peas, beans, lentils), tubers (e.g., potatoes, peanuts), and fruits.

Nina M. is a 13-month-old baby girl, the second child born to unrelated parents. Her mother had a healthy, full-term pregnancy, and **Nina M.**'s birth weight was normal. She did not respond well to breastfeeding and was changed entirely to a formula based on cows' milk at 6 weeks. Between 9 and 18 weeks of age, she was admitted to the hospital twice with a history of screaming after feeding but was discharged after observation without a specific diagnosis. Elimination of cows' milk from her diet did not relieve her symptoms; **Nina M.**'s mother reported that when **Nina M.** turned 1 year old she introduced some fruit juice into her diet the screaming bouts were worse, particularly after drinking juice. She also noticed that **Nina M.** frequently had gas and a distended abdomen. She was still thriving (weight > 97th percentile), with no abnormal findings on physical examination. A stool sample was taken.

The dietary sugar in fruit juice and other sweets is sucrose, a disaccharide composed of glucose and fructose joined through

their anomeric carbons. **Nina M.**'s symptoms of pain and abdominal distension are caused by an inability to digest sucrose or absorb fructose, which are converted to gas by colonic bacteria. The possibility of carbohydrate malabsorption was considered, and a hydrogen breath test was recommended.

I. Dietary Carbohydrates

Carbohydrates are the largest source of calories in the average American diet and usually constitute 40% to 45% of our caloric intake. The plant starches **amylopectin** and **amylose**, which are present in grains, tubers, and vegetables, constitute approximately 50% to 60% of the carbohydrate calories consumed. These starches are polysaccharides, containing 10,000 to 1 million glucosyl units. In amylose, the glucosyl residues form a straight chain linked via α -1,4-glycosidic bonds; in amylopectin, the α -1,4-chains contain branches connected via α -1,6-glycosidic bonds (see Fig. 21.1). The other major sugar found in fruits and vegetables is **sucrose**, a disaccharide of glucose and fructose (see Fig. 21.1). Sucrose and small amounts of the monosaccharides **glucose** and **fructose** are the major natural sweeteners found in fruit, honey, and vegetables. **Dietary fiber**, the part of the diet that cannot be digested by human enzymes of the intestinal tract, is also composed principally of plant polysaccharides and a polymer called lignin.

Most foods derived from animals, such as meat or fish, contain very little carbohydrate except for small amounts of glycogen (which has a structure similar to amylopectin) and glycolipids. The major dietary carbohydrate of animal origin is lactose, a disaccharide composed of glucose and galactose that is found exclusively in milk and milk products (see Fig. 21.1). Sweeteners, in the form of sucrose and high-fructose corn syrup (starch, partially hydrolyzed and isomerized to fructose), also appear in the diet as additives to processed foods. On average, a person in the United States consumes 65 lb of added sucrose and 40 lb of high-fructose corn syrup solids per year.

Starch blockers were marketed many years ago as a means of losing weight without having to exercise or reduce your daily caloric intake. Starch blockers were based on a protein found in beans, which blocked the action of amylase. Thus, as the advertisements proclaimed, one could eat a large amount of starch during a meal, and as long as you took the starch blocker, the starch would pass through the digestive track without being metabolized. Unfortunately, this was too good to be true, and starch blockers were never shown to be effective in aiding weight loss. This was probably because of a combination of factors, such as inactivation of the inhibitor by the low pH in the stomach and an excess of amylase activity as compared with the amount of starch blocker ingested. Recently, this issue has been revisited, as a starch blocker from wheat has been developed that may work as advertised, although much more research is required to determine whether this amylase inhibitor will be safe and effective in humans. Additionally, newer (and improved) preparations of the bean extract are also being readvertised.

Although all cells require glucose for metabolic functions, neither glucose nor other sugars are specifically required in the diet. Glucose can be synthesized from many amino acids found in dietary protein. Fructose, galactose, xylulose, and all the other sugars required for metabolic processes in the human can be synthesized from glucose.

II. Digestion of Dietary Carbohydrates

In the digestive tract, dietary polysaccharides and disaccharides are converted to monosaccharides by **glycosidases**, enzymes that hydrolyze the glycosidic bonds between the sugars. All of these enzymes exhibit some specificity for the sugar, the glycosidic bond (α or β), and the number of saccharide units in the chain. The monosaccharides formed by glycosidases are transported across the intestinal mucosal cells into the interstitial fluid and subsequently enter the bloodstream. Undigested carbohydrates enter the colon, where bacteria may ferment them.

Amylase activity in the gut is abundant and is not normally rate-limiting for the process of digestion. Alcohol-induced pancreatitis or surgical removal of part of the pancreas can decrease pancreatic secretion. Pancreatic exocrine secretion into the intestine also can be decreased because of cystic fibrosis (as in **Susan F.**, see Chapter 16), in which mucus blocks the pancreatic duct, which eventually degenerates. However, pancreatic exocrine secretion can be decreased to 10% of normal and still not affect the rate of starch digestion, because amylases are secreted in the saliva and pancreatic fluid in excessive amounts. In contrast, protein and fat digestion are more strongly affected in cystic fibrosis.

A. Salivary and Pancreatic α -Amylase

The digestion of starch (amylopectin and amylose) begins in the mouth, where chewing mixes the food with

saliva. The salivary glands secrete approximately 1 L of liquid per day into the mouth, containing **salivary α -amylase** and other components. α -Amylase is an **endoglycosidase**, which means that it hydrolyzes internal α -1,4-bonds between glucosyl residues at random intervals in the polysaccharide chains (Fig. 21.3). The shortened polysaccharide chains that are formed are called α -dextrins. Salivary α -amylase is largely inactivated by the acidity of the stomach contents, which contain HCl secreted by the parietal cells.

FIGURE 21.3 Action of salivary and pancreatic α -amylases.

The acidic gastric juice enters the duodenum, the upper part of the small intestine, where digestion continues. Secretions from the exocrine pancreas (~1.5 L/day) flow down the pancreatic duct and also enter the duodenum. These secretions contain bicarbonate (HCO_3^-), which neutralizes the acidic pH of stomach contents, and digestive enzymes, including pancreatic α -amylase.

Pancreatic α -amylase continues to hydrolyze the starches and glycogen, forming the disaccharide maltose, the trisaccharide maltotriose, and oligosaccharides. These oligosaccharides, called limit dextrans, are usually four to nine glucosyl units long and contain one or more α -1,6-branches. The two glucosyl residues that contain the α -1,6-glycosidic bond eventually become the disaccharide isomaltose.

α -Amylase has no activity toward sugar-containing polymers other than glucose linked by α -1,4-bonds. α -Amylase displays no activity toward the α -1,6-bond at branch points and has little activity for the α -1,4-bond at the nonreducing end of a chain.

 Acarbose is a U.S. Food and Drug Administration (FDA)-approved drug that blocks the activities of pancreatic α -amylase and brush-border α -glucosidases (with a specificity for glucose). The drug is produced from a microorganism and is a unique tetrasaccharide. Acarbose can be used in patients with type 2 diabetes. It reduces the rate at which ingested carbohydrate reaches the bloodstream after a meal, but flatulence and diarrhea (because of colonic bacterial metabolism of

the nondigested sugars) are side effects of taking this drug and it is not used very often.

B. Disaccharidases of the Intestinal Brush-Border Membrane

The dietary disaccharides lactose and sucrose, as well as the products of starch digestion, are converted to monosaccharides by glycosidases attached to the membrane in the brush border of absorptive cells. The different glycosidase activities are found in four glycoproteins: glucoamylase, the sucrase–isomaltase complex, the smaller glycoprotein trehalase, and lactase–glucosylceramidase (Table 21.1). These glycosidases are collectively called the small intestinal disaccharidases, although glucoamylase is really an oligosaccharidase.

COMPLEX	CATALYTIC SITES	PRINCIPAL ACTIVITIES
β-Glucoamylase	α-Glucosidase	Split α-1,4-glycosidic bonds between glucosyl units, beginning sequentially with the residue at the tail end (nonreducing end) of the chain. This is an exoglycosidase. Substrates include amylose, amylopectin, glycogen, and maltose.
	β-Glucosidase	Same as above, but with slightly different specificities and affinities for the substrates
Sucrase–isomaltase	Sucrase–maltase	Splits sucrose, maltose, and maltotriose
	Isomaltase–maltase	Splits α-1,6-bonds in several limit dextrans, as well as the α-1,4-bonds in maltose and maltotriose
β-Glycosidase	Glucosyl–ceramidase	Splits β-glycosidic bonds between glucose or galactose and hydrophobic residues, such as the glycolipids glucosylceramide and galactosylceramide. Also known as phlorizin hydrolase for its activity on an artificial substrate
	Lactase	Splits the β-1,4-bond between glucose and galactose. To a lesser extent also splits the β-1,4-bond between some cellulose disaccharides
Trehalase	Trehalase	Splits bond in trehalose, which is two glucosyl units linked α-1,1 through their anomeric carbons

 Can the glycosidic bonds of the structure shown below be hydrolyzed by α-amylose?

1. Glucoamylase

Glucoamylase and the sucrase–isomaltase complex have similar structures and exhibit a great deal of sequence homogeneity. A membrane-spanning domain near the *N*-terminus attaches the protein to the luminal membrane. The long polypeptide chain forms two globular domains, each with a catalytic site. In glucoamylase, the two catalytic sites have similar activities, with only small differences in substrate specificity. The protein is heavily glycosylated, with oligosaccharides that protect it from digestive proteases.

No. This polysaccharide is cellulose, which contains β -1,4-glycosidic bonds. Pancreatic and salivary α -amylase cleave α -1,4-bonds between glucosyl units.

Glucosylase is an **exoglycosidase** that is specific for the α -1,4-bonds between glucosyl residues (Fig. 21.4A). It begins at the nonreducing end of a polysaccharide or limit dextrin, and it sequentially hydrolyzes the bonds to release glucose monosaccharides. It will digest a limit dextrin down to isomaltose, the glucosyl disaccharide with an α -1,6-branch, that is subsequently hydrolyzed principally by the isomaltase activity in the sucrase–isomaltase complex.

FIGURE 21.4 **A.** Glucoamylase activity. Glucoamylase is an α -1,4-exoglycosidase that initiates cleavage at the nonreducing end of the sugar. Thus, for maltotriose, the bond labeled 1 is hydrolyzed first, which then allows the bond at position 2 to be the next one hydrolyzed. **B.** Isomaltase activity. *Arrows* indicate the α -1,6-bonds that are cleaved. **C.** Trehalose. This disaccharide contains two glucose moieties linked by an unusual bond that joins their anomeric carbons. It is cleaved by trehalase.

2. Sucrase–Isomaltase Complex

The structure of the sucrase–isomaltase complex is similar to that of glucoamylase, and these two proteins have a high degree of sequence homology. However, after the single polypeptide chain of sucrase–isomaltase is inserted through the membrane and the protein protrudes into the intestinal lumen, an intestinal protease clips it into two separate subunits that remain attached to each other, forming a functional heterodimer. Each subunit has a catalytic site that differs in substrate specificity from the other through noncovalent interactions. The sucrase–maltase site accounts for approximately 100% of the intestine’s ability to hydrolyze sucrose in addition to maltase activity; the isomaltase–maltase site accounts for almost all of the intestine’s ability to hydrolyze α -1,6-bonds (see Fig. 21.4B), in addition to maltase activity. Together, these sites account for approximately 80% of the maltase activity of the small intestine. The remainder of the maltase activity is found in the glucoamylase complex.

Individuals with genetic deficiencies of the sucrase–isomaltase complex show symptoms of sucrose intolerance but are able to digest normal amounts of starch in a meal without problems. The maltase activity in the glucoamylase complex, and residual activity in the sucrase–isomaltase complex (which is normally present in excess of need), is apparently sufficient to digest normal amounts of dietary starch.

3. Trehalase

Trehalase is only half as long as the other disaccharidases and has only one catalytic site. It hydrolyzes the glycosidic bond in trehalose, a disaccharide composed of two glucosyl units linked by an α -bond between their anomeric carbons (see Fig. 21.4C). Trehalose, which is found in insects, algae, mushrooms, and other fungi, is not currently a major dietary component in the United States. However, unwitting consumption of trehalose can cause nausea, vomiting, and other symptoms of severe gastrointestinal distress if consumed by an individual deficient in the enzyme. Trehalase deficiency was discovered when a woman became very sick after eating mushrooms and was initially thought to have α -amanitin poisoning.

4. α -Glycosidase Complex (Lactase-Glucosylceramidase)

The β -glycosidase complex is another large glycoprotein found in the brush border that has two catalytic sites extending in the lumen of the intestine. However, its primary structure is very different from that of the other

enzymes, and it is attached to the membrane through its carboxyl end by a phosphatidylglycan anchor (see Fig. 10.5). The lactase catalytic site hydrolyzes the β -bond connecting glucose and galactose in lactose (a β -galactosidase activity; Fig. 21.5). The major activity of the other catalytic site in humans is the β -bond between glucose or galactose and ceramide in glycolipids (this catalytic site is sometimes called **phlorizin hydrolase**, named for its ability to hydrolyze an artificial substrate).

FIGURE 21.5 Lactase activity. Lactase is a β -galactosidase. It cleaves the β -galactoside lactose, the major sugar in milk, forming galactose and glucose.

Which of the bonds in the structure shown below are hydrolyzed by the sucrose–isomaltase complex? Which by glucoamylase?

5. Location within the Intestine

The production of maltose, maltotriose, and limit dextrins by pancreatic α -amylase occurs in the duodenum, the most proximal portion of the small intestine. Sucrase–isomaltase activity is highest in the jejunum, where the enzymes can hydrolyze sucrose and the products of starch digestion. β -Glycosidase activity is also highest in the jejunum. Glucoamylase activity increases progressively along the length of the small intestine, and its activity is highest in the ileum. Thus, it presents a final opportunity for digestion of starch oligomers that have escaped amylase and disaccharidase activities at the more proximal regions of the intestine.

M **Nina M.** was given a hydrogen breath test, a test measuring the amount of hydrogen gas released after consuming a test dose of sugar. In this test, the patient breathes into a portable meter or a collecting bag attached to a nonportable device. The larger, nonportable devices measure the hydrogen in the breath via gas chromatography. The portable devices measure the hydrogen gas produced using hydrogen-specific electrodes and measuring a current that is created when hydrogen comes into contact with the electrode. The association of **Nina M.**'s symptoms with her ingestion of fruit juices suggests that she might have a problem resulting from low sucrase activity or an inability to absorb fructose. Her ability to thrive and her adequate weight gain suggest that any deficiencies of the sucrase–isomaltase complex must be partial and do not result in a functionally important reduction in maltase activity (maltase activity is also present in the glucoamylase complex). Her urine tested negative for sugar, suggesting the problem is in digestion or absorption, because only sugars that are absorbed and enter the blood can be found in urine. The basis of the hydrogen breath test is that if a sugar is not absorbed, it is metabolized in the intestinal lumen by bacteria that produce various gases, including hydrogen. The test can be accompanied by measurements of the amount of sugar that appear in the blood or feces, and acidity of the feces.

C. Metabolism of Sugars by Colonic Bacteria

Not all of the starch ingested as part of foods is normally digested in the small intestine (Fig. 21.6). Starches that are high in amylose, or are less well-hydrated (e.g., starch in dried beans), are resistant to digestion and enter the colon. Dietary fiber and undigested sugars also enter the colon. Here, colonic bacteria rapidly metabolize the saccharides, forming gases, short-chain fatty acids, and lactate. The major short-chain fatty acids formed are acetic acid (two carbons), propionic acid (three carbons), and butyric acid (four carbons). The short-chain fatty acids are absorbed by the colonic mucosal cells and can provide a substantial source of energy for these cells. The major gases formed are hydrogen gas (H_2), carbon dioxide (CO_2), and methane (CH_4). These gases are released through the colon, resulting in flatulence, or through the breath. Incomplete products of digestion in the intestines increase the retention of water in the colon, resulting in diarrhea.

FIGURE 21.6 Some indigestible carbohydrates. These compounds are components of dietary fiber.

D. Lactose Intolerance

Lactose intolerance refers to a condition of pain, nausea, and flatulence after the ingestion of foods containing lactose, most notably dairy products. Although lactose intolerance is often caused by low levels of lactase, it also can be caused by intestinal injury (defined in the following text).

1. Nonpersistent and Persistent Lactase

Lactase activity increases in the human from about 6 to 8 weeks of gestation, and it rises during the late gestational period (21 to 32 weeks) through full term. It remains high for about 1 month after birth and then begins to decline. For most of the world's population, lactase activity decreases to adult levels at approximately 5 to 7 years of age. Adult levels are <10% of those present in infants. These populations have **adult hypolactasia** (formerly called adult lactase deficiency) and exhibit the lactase nonpersistence phenotype. In people who are derived mainly from Western Northern Europeans, and milk-dependent Nomadic tribes of Saharan Africa, the levels of lactase remain at, or only slightly below, infant levels throughout adulthood (lactase persistence phenotype). Thus, adult hypolactasia is the normal condition for most of the world's population (Table 21.2).

TABLE 21.2 Prevalence of Late-Onset Lactase Deficiency

GROUP	PREVALENCE (%)
<i>U.S. Population</i>	
Asians	100
American Indians (Oklahoma)	95
Black Americans	81
Mexican Americans	56
White Americans	24
<i>Other Populations</i>	
Ibo, Yoruba (Nigeria)	89
Italians	71
Aborigines (Australia)	67
Greeks	53
Danes	3
Dutch	0

Data from Biller HA, Grand RS. Lactose intolerance. *Annu Rev Med.* 1990;41:141–148.

In contrast, **congenital lactase deficiency** is a severe autosomal-recessive inherited disease in which lactase activity is significantly reduced, or totally absent. The disorder presents as soon as the newborn is fed breast milk or lactose-containing formula, resulting in watery diarrhea, weight loss, and dehydration. Treatment consists of removal of lactose from the diet, which allows for normal growth and development to occur.

Bonds (1) and (3) would first be hydrolyzed by glucoamylase. Bond (2) requires isomaltase. Bonds (4) and (5) can then be hydrolyzed by the sucrase–isomaltase complex, or by the glucoamylase complex, all of which can convert maltotriose and maltose to glucose.

2. Intestinal Injury

Intestinal diseases that injure the absorptive cells of the intestinal villi diminish lactase activity along the intestine, producing a condition known as secondary lactase deficiency. Kwashiorkor (protein malnutrition), colitis, gastroenteritis, tropical and nontropical sprue, and excessive alcohol consumption fall into this category. These diseases also affect other disaccharidases, but sucrase, maltase, isomaltase, and glucoamylase activities are usually present at such excessive levels that there are no pathologic effects. Lactase is usually the first activity lost and the last to recover.

Lactose intolerance can either be the result of a primary deficiency of lactase production in the small bowel (as is the case for **Denise V.**) or it can be secondary to an injury to the intestinal mucosa, where lactase is normally produced. The lactose that is not absorbed is converted by colonic bacteria to lactic acid, methane gas (CH₄), and H₂ gas (see figure). The osmotic effect of the lactose and lactic acid in the bowel lumen is responsible for the diarrhea that is often seen as part of this syndrome. Similar symptoms can result from sensitivity to milk proteins (milk intolerance) or from the malabsorption of other dietary sugars.

In adults suspected of having a lactase deficiency, the diagnosis is usually made inferentially when avoidance of all dairy products results in relief of symptoms and a rechallenge with these foods reproduces the characteristic syndrome. If the results of these measures are equivocal, however, the malabsorption of lactose can be determined more specifically by measuring the H₂ content of the patient's breath after a test dose of lactose has been consumed.

Denise V.'s symptoms did not appear if she took available over-the-counter tablets containing lactase when she ate dairy products.

III. Dietary Fiber

Dietary fiber is the portion of the diet resistant to digestion by human digestive enzymes. It consists principally of plant materials that are polysaccharide derivatives and lignin (see Fig. 21.6). The components of fiber are often divided into the categories of soluble and insoluble fiber, according to their ability to dissolve in water. Insoluble fiber consists of three major categories: cellulose, hemicellulose, and lignins. Soluble fiber categories include pectins, mucilages, and gums (Table 21.3). Although human enzymes cannot digest fiber, the bacterial flora in the normal human gut may metabolize the more soluble dietary fibers to gases and short-chain fatty acids, much as they do undigested starch and sugars. Some of these fatty acids may be absorbed and used by the colonic epithelial cells of the gut, and some may travel to the liver through the hepatic portal vein. We may obtain as much as 10% of our total calories from compounds produced by bacterial digestion of substances in our digestive tract.

TABLE 21.3 Types of Fiber in the Diet

CLASSICAL NOMENCLATURE	CLASSES OF COMPOUNDS	DIETARY SOURCES
<i>Insoluble Fiber</i>		
Cellulose	Polysaccharide composed of glucosyl residues linked β -1,4	Whole wheat flour, unprocessed bran, vegetables
Hemicelluloses	Polymers of arabinoxylans or galactomannans	Bran cereals, whole grains
Lignin	Noncarbohydrate, polymeric derivatives of phenylpropane	Fruits and edible seeds, mature vegetables
<i>Water-Soluble Fiber (or Dispersible)</i>		
Pectic substances	Galacturonans, arabinogalactans, β -glucans, arabinoxylans	Apples, strawberries, carrots, citrus
Gums	Galactomannans, arabinogalactans	Oats, legumes, guar, barley
Mucilages	Wide range of branched and substituted galactans	Flax seed, psyllium, mustard seed

The 2015 Dietary Guideline Advisory Committee issued guidelines for fiber ingestion—anywhere from 22 to 34 g/day in adults, depending on the age and sex of the individual. No distinction was made between soluble and insoluble fibers. Adult males between the ages of 19 and 30 years require 34 g of fiber per day. Males between 31 and 50 years of age require 30.8 g of fiber per day. Males older than 51 years of age are recommended to consume 28 g of fiber per day. Adult women between 19 and 30 years of age require 28 g/day. Women between the ages of 31 and 50 years of age are recommended to consume 25.2 g of fiber per day. Women older than 51 years of age are recommended to consume 22 g of fiber per day. These numbers are increased during pregnancy and lactation. One beneficial effect of fiber is seen in diverticular disease in which sacs or pouches may develop in the colon because of a weakening of the muscle and submucosal structures. Fiber is thought to “soften” the stool, thereby reducing pressure on the colonic wall and enhancing expulsion of feces.

Certain types of soluble fiber have been associated with disease prevention. For example, pectins may lower blood cholesterol levels by binding bile acids. β -Glucan (obtained from oats) has also been shown, in some studies, to reduce cholesterol levels through a reduction in bile acid resorption in the intestine (see Chapter 32). Pectins also may have a beneficial effect in the diet of individuals with diabetes mellitus by slowing the rate of absorption of simple sugars and preventing high blood glucose levels after meals. However, each of the beneficial effects that have been related to “fiber” is relatively specific for the type of fiber and the physical form of the food that contains the fiber. This factor, along with many others, has made it difficult to obtain conclusive results from studies of the effects of fiber on human health.

Beans, peas, soybeans, and other leguminous plants contain oligosaccharides with linked galactose residues that cannot be hydrolyzed for absorption, including sucrose with one, two, or three galactose residues attached (see Fig. 21.6). What is the fate of these polysaccharides in the intestine?

IV. Absorption of Sugars

Once the carbohydrates have been split into monosaccharides, the sugars are transported across the intestinal epithelial cells and into the blood for distribution to all tissues. Not all complex carbohydrates are digested at the same rate within the intestine, and some carbohydrate sources lead to a near-immediate rise in blood glucose levels after ingestion, whereas others slowly raise blood glucose levels over an extended period after ingestion. The **glycemic index** of a food is an indication of how rapidly blood glucose levels rise after consumption. Glucose and maltose have the highest glycemic indices (defined as 100). Table 21.4 indicates the glycemic index for a variety of food types. Although there is no need to memorize this table, note that cornflakes and potatoes have high glycemic indices, whereas yogurt and skim milk have particularly low-glycemic indices.

BREADS		LEGUMES	
Whole wheat	74	Soya beans	16
Specialty grain bread	53	Lentils	32
Pasta		Chickpeas	28
Spaghetti, white, boiled	49	Kidney beans (dried)	24
Cereal grains		Peanuts	15
Barley	28	Fruit	
White rice (boiled)	73	Banana	51
Brown rice (boiled)	68	Apple	36
Sweet corn	52	Apple juice	41
Breakfast cereals		Orange	43
Wheat flake biscuits	69	Watermelon	76
Cornflakes	81	Sugars	
Muesli	57	Maltose	105
Snacks		Fructose	15
Popcorn	65	Glucose	100
Chocolate	40	Honey	61
Root vegetables		Sucrose	65
Potatoes (instant, mash)	87	Dairy products	
Potato (new, white, boiled)	78	Ice cream	51
Potato, French fries	63	Whole milk	39
Sweet potato, boiled	63	Skim milk	37
		Yogurt, fruit	41

Values obtained from Atkinson FS, Foster-Powell K, Brand-Miller JC. International tables of glycemic index and glycemic load values. *Diabetes Care*. 2008;31:2281–2283.

The glycemic response to ingested foods depends not only on the glycemic index of the foods but also on the fiber and fat content of the food, as well as its method of preparation. Highly glycemic carbohydrates can be consumed before and after exercise, as their metabolism results in a rapid entry of glucose into the blood, where it is then immediately available for use by muscle cells. Low-glycemic carbohydrates enter the circulation slowly and can be used to best advantage if consumed before exercise, such that as exercise progresses, glucose is slowly being absorbed from the intestine into the circulation, where it can be used to maintain blood glucose levels during the exercise period.

 These sugars are not digested well by the human intestine but form good sources of energy for the bacteria of the gut. These bacteria convert the sugars to H₂, lactic acid, and short-chain fatty acids. The amount of gas released after a meal containing beans is especially notorious.

A. Absorption by the Intestinal Epithelium

Glucose is transported through the absorptive cells of the intestine by facilitated diffusion and by Na⁺-

dependent facilitated transport. (See Chapter 10 for a description of transport mechanisms.) The glucose molecule is extremely polar and cannot diffuse through the hydrophobic phospholipid bilayer of the cell membrane. Each hydroxyl group of the glucose molecule forms at least two hydrogen bonds with water molecules, and random movement would require energy to dislodge the polar hydroxyl groups from their hydrogen bonds and to disrupt the van der Waals forces between the hydrocarbon tails of the fatty acids in the membrane phospholipid. Glucose, therefore, enters the absorptive cells by binding to transport proteins, membrane-spanning proteins that bind the glucose molecule on one side of the membrane and release it on the opposite side. Two types of glucose transport proteins are present in the intestinal absorptive cells: the Na^+ -dependent glucose transporters and the facilitative glucose transporters (Fig. 21.7).

FIGURE 21.7 Na^+ -dependent and facilitative transporters in the intestinal epithelial cells. Both glucose and fructose are transported by the facilitated glucose transporters on the luminal and serosal sides of the absorptive cells. Glucose and galactose are transported by the Na^+ -glucose cotransporters on the luminal (mucosal) side of the absorptive cells. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P_i , inorganic phosphate.

 The dietitian explained to **Deborah S.** the reasons for a person with diabetes to follow a carbohydrate-controlled diet using meal-planning tools such as carbohydrate counting (www.diabetes.org, click on Healthy Living, and then Recipes and Nutrition). It is important for **Deborah S.** to add a variety of fibers, particularly soluble fiber, to her diet. The gel-forming, water-retaining pectins and gums found in foods such as oatmeal, nuts, beans, lentils, and apples delay gastric emptying and retard the rate of absorption of disaccharides and monosaccharides, thus reducing the rate at which blood glucose levels rise. Although research has shown that the total amount of carbohydrate is most influential on blood glucose levels, the quality of carbohydrate, the glycemic index of foods, may also need to be considered for optimal maintenance of blood glucose levels in persons with diabetes. Consumption of a low-glycemic-index diet results in a lower rise in blood glucose levels after eating, which can be more easily controlled by exogenous insulin. For example, **Deborah S.** is advised to eat pasta and barley (glycemic indices of 49 and 28, respectively) instead of potatoes (glycemic index of 63 to 87, depending on the method of preparation) and to incorporate breakfast cereals composed of wheat bran, barley, and oats into her morning routine. Because the total amount and the type of carbohydrate influence blood glucose levels, **Deborah S.** is advised to consume lower glycemic index foods in appropriate portions.

1. Na^+ -Dependent Transporters

Na⁺-dependent glucose transporters, which are located on the luminal side of the absorptive cells, enable these cells to concentrate glucose from the intestinal lumen. A low intracellular Na⁺ concentration is maintained by a Na⁺,K⁺-ATPase on the serosal (blood) side of the cell that uses the energy from adenosine triphosphate (ATP) cleavage to pump Na⁺ out of the cell into the blood. Thus, the transport of glucose from a low concentration in the lumen to a high concentration in the cell is promoted by the cotransport of Na⁺ from a high concentration in the lumen to a low concentration in the cell (secondary active transport). Similar transporters are found in the epithelial cells of the kidney, which are thus able to transport glucose against its concentration gradient.

2. Facilitative Glucose Transporters

Facilitative glucose transporters, which do not bind Na⁺, are located on the serosal side of the cells. Glucose moves via the facilitative transporters from the high concentration inside the cell to the lower concentration in the blood without the expenditure of energy. In addition to the Na⁺-dependent glucose transporters, facilitative transporters for glucose also exist on the luminal side of the absorptive cells. The best-characterized facilitative glucose transporters found in the plasma membranes of cells (referred to as GLUT 1 to GLUT 5) are described in Table 21.5. One common structural theme to these proteins is that they all contain 12 membrane-spanning domains. Note that the sodium-linked transporter on the luminal side of the intestinal epithelial cell is not a member of the GLUT family.

TRANSPORTER	TISSUE DISTRIBUTION	COMMENTS
GLUT 1	Human erythrocyte Blood–brain barrier Blood–retinal barrier Blood–placental barrier Blood–testis barrier	Expressed in cell types with barrier functions; a high-affinity glucose transport system
GLUT 2	Liver Kidney Pancreatic β-cell Serosal surface of intestinal mucosa cells	A high-capacity, low-affinity transporter May be used as the glucose sensor in the pancreas
GLUT 3	Brain (neurons)	Major transporter in the central nervous system; a high-affinity system
GLUT 4	Adipose tissue Skeletal muscle Heart muscle	Insulin-sensitive transporter; in the presence of insulin, the number of GLUT 4 transporters increases on the cell surface; a high-affinity system
GLUT 5	Intestinal epithelium Spermatozoa	This is actually a fructose transporter.

Genetic techniques have identified additional GLUT transporters (GLUT 6 to GLUT 12), but the roles of these transporters have not yet been fully described.

The epithelial cells of the kidney, which reabsorb glucose from the lumen of the renal tubule back into the blood, have Na⁺-dependent glucose transporters similar to those of intestinal epithelial cells. They are thus also able to transport glucose against its concentration gradient. Other types of cells use mainly facilitative glucose transporters that carry glucose down its concentration gradient.

3. Galactose and Fructose Absorption through Glucose Transporters

Galactose is absorbed through the same mechanisms as glucose. It enters the absorptive cells on the luminal side via the Na⁺-dependent glucose transporters and facilitative glucose transporters and is transported through the serosal side on the facilitative glucose transporters.

Fructose both enters and leaves absorptive epithelial cells by facilitated diffusion, apparently via transport proteins that are part of the GLUT family. The transporter on the luminal side has been identified as GLUT 5. Although this transporter can transport glucose, it has a much higher activity with fructose (see Fig. 21.7).

Other fructose transport proteins also may be present. For reasons as yet unknown, fructose is absorbed at a much more rapid rate when it is ingested as sucrose than when it is ingested as a monosaccharide.

B. Transport of Monosaccharides into Tissues

The properties of the GLUT transport proteins differ among tissues, reflecting the function of glucose metabolism in each tissue. In most cell types, the rate of glucose transport across the cell membrane is not rate-limiting for glucose metabolism. This is because the isoform of transporter present in these cell types has a relatively low K_m for glucose (i.e., a low concentration of glucose will result in half the maximal rate of glucose transport) or is present in relatively high concentration in the cell membrane so that the intracellular glucose concentration reflects that in the blood. Because the enzyme that initially metabolizes glucose in these (named hexokinase, see Chapter 22) cells has an even lower K_m for glucose (0.05 to 0.10 mM), variations in blood glucose levels do not affect the intracellular rate of glucose metabolism. However, in several tissues, the rate of transport becomes rate-limiting when the serum level of glucose is low or when low levels of insulin signal the absence of dietary glucose.

The erythrocyte (red blood cell) is an example of a tissue in which glucose transport is not rate-limiting. Although the glucose transporter (GLUT 1) has a K_m of 1 to 7 mM, it is present in extremely high concentrations, constituting approximately 5% of all membrane proteins. Consequently, as the blood glucose levels fall from a postprandial level of 140 mg/dL (7.5 mM) to the normal fasting level of 80 mg/dL (4.5 mM), or even the hypoglycemic level of 40 mg/dL (2.2 mM), the supply of glucose is still adequate for the rates at which glucose-dependent metabolic pathways operate.

In the liver, the K_m for the glucose transporter (GLUT 2) is relatively high compared with that of other tissues, probably 15 mM or above. This is in keeping with the liver's role as the organ that maintains blood glucose levels. Thus, the liver will convert glucose into other energy storage molecules only when blood glucose levels are high, such as the time immediately after ingesting a meal. In muscle and adipose tissue, the transport of glucose is greatly stimulated by insulin. The mechanism involves the recruitment of glucose transporters (specifically, GLUT 4) from intracellular vesicles into the plasma membrane (Fig. 21.8). In adipose tissue, the stimulation of glucose transport across the plasma membrane by insulin increases its availability for the synthesis of fatty acids and glycerol from the glycolytic pathway. In skeletal muscle, the stimulation of glucose transport by insulin increases its availability for energy generation (glycolysis) and glycogen synthesis.

FIGURE 21.8 Stimulation by insulin of glucose transport into muscle and adipose cells. Binding of insulin to its cell membrane receptor causes vesicles containing glucose transport proteins to move from inside the cell to the cell membrane.

V. Glucose Transport through the Blood–Brain Barrier and into Neurons

A hypoglycemic response is elicited by a decrease of blood glucose concentration to some point between 18 and 54 mg/dL (1 and 3 mM). The hypoglycemic response is a result of a decreased supply of glucose to the brain and starts with light-headedness and dizziness and may progress to coma. The slow rate of transport of glucose through the blood–brain barrier (from the blood into the cerebrospinal fluid) at low levels of glucose is thought to be responsible for this neuroglycopenic response. Glucose transport from the cerebrospinal fluid across the plasma membranes of neurons is rapid and is not rate-limiting for ATP generation from glycolysis.

In the brain, the endothelial cells of the capillaries have extremely tight junctions, and glucose must pass from the blood into the extracellular cerebrospinal fluid by GLUT 1 transporters in the endothelial cell membranes (Fig. 21.9) and then through the basement membrane. Measurements of the overall process of glucose transport from the blood into the brain (mediated by GLUT 3 on neural cells) show a $K_{m,app}$ of 7 to 11 mM and a maximal velocity not much greater than the rate of glucose utilization by the brain. Thus, decreases of blood glucose below the fasting level of 80 to 90 mg/dL (~5 mM) are likely to significantly affect the rate of glucose metabolism in the brain because of reduced glucose transport into the brain.

FIGURE 21.9 Glucose transport through the capillary endothelium in neural and nonneural tissues. Characteristics of transport in each type of tissue are listed by numbers that refer to the *numbers* in the drawing. G, glucose.

CLINICAL COMMENTS

Denise V. One out of five Americans experiences some form of gastrointestinal discomfort from 30 minutes to 12 hours after ingesting lactose-rich foods. Most become symptomatic when they consume >25 g lactose at one time (e.g., 1 pint of milk or its equivalent). **Denise V.**'s symptoms were caused by her “new” diet in this country, which included a glass of milk in addition to the milk she used on her cereal with breakfast each morning.

Management of lactose intolerance includes a reduction or avoidance of lactose-containing foods, depending on the severity of the deficiency of intestinal lactase. Hard cheeses (cheddar, Swiss, Jarlsberg) are low in lactose and may be tolerated by patients with only moderate lactase deficiency. Yogurt with “live and active cultures” printed on the package contains bacteria that release free lactases when the bacteria are lysed by gastric acid and proteolytic enzymes. The free lactases then digest the lactose. Commercially available milk products that have been hydrolyzed with a lactase enzyme provide a 70% reduction in total lactose content, which may be adequate to prevent digestive symptoms in mildly affected patients. Tablets and capsules containing lactase are also available and should be taken one-half hour before meals.

Many adults who have a lactase deficiency develop the ability to ingest small amounts of lactose in dairy products without experiencing symptoms. This adaptation probably involves an increase in the population of colonic bacteria that can cleave lactose and not a recovery or induction of human lactase synthesis. For many individuals, dairy products are the major dietary source of calcium, and their complete elimination from the diet can lead to osteoporosis. Therefore, other dietary sources such as beans, almonds, tofu, turnip greens, kale, and calcium-fortified juices/beverages or calcium supplements should be recommended. Lactose, however, is used as a “filler” or carrying agent in >1,000 prescription and over-the-counter drugs in this country. People with lactose intolerance often unwittingly ingest lactose with their medications.

Deborah S. Patients with poorly controlled diabetes such as **Deborah S.** frequently have elevations in serum glucose levels (hyperglycemia). This is often attributable to a lack of circulating, active insulin, which normally stimulates glucose uptake (through the recruitment of GLUT 4 transporters from the endoplasmic reticulum to the plasma membrane) by the peripheral tissues (heart, muscle, and adipose tissue). Without uptake by these tissues, glucose tends to accumulate within the bloodstream, leading to hyperglycemia.

Nina M. The large amount of H₂ produced on fructose ingestion suggested that **Nina M.**'s problem was one of a deficiency in fructose transport into the absorptive cells of the intestinal villi. If fructose were being absorbed properly, the fructose would not have traveled to the colonic bacteria, which metabolized the fructose to generate the hydrogen gas. If there were concern for deficiencies of the sucrase–isomaltase complex, a jejunal biopsy could be done; it would allow one to measure lactase, sucrase, maltase, and trehalase activities. Genetic testing for the presence of a mutation in one of these proteins is also becoming available. Although **Nina M.** had no sugar in her urine, malabsorption of disaccharides can result in their appearance in the urine if damage to the intestinal mucosal cells allows their passage into the interstitial fluid. When she was placed on a diet free of fruit juices and other foods containing fructose, she did well and could tolerate small amounts of pure sucrose.

More than 50% of the adult population is estimated to be unable to absorb fructose in high doses (50 g), and >10% cannot completely absorb 25 g fructose. These individuals, like those with other disorders of fructose metabolism, must avoid fruits and other foods that contain high concentrations of fructose.

BIOCHEMICAL COMMENTS

Cholera. Cholera is an acute watery diarrheal disorder caused by the water-borne, gram-negative bacterium *Vibrio cholerae*. It is a disease of antiquity; descriptions of epidemics of the disease date to before 500 BC. During epidemics, the infection is spread by large numbers of *Vibrio* that enter water sources from the voluminous liquid stools and contaminate the environment, particularly in areas of extreme poverty, where plumbing and modern waste-disposal systems are primitive or nonexistent. **Dennis V.** experienced cholera after eating contaminated shellfish (see Chapter 10).

After being ingested, the *V. cholerae* organisms attach to the brush border of the intestinal epithelium and secrete an exotoxin that binds irreversibly to a specific chemical receptor (G_{M1} ganglioside) on the cell surface.

This exotoxin catalyzes an adenosine diphosphate (ADP)-ribosylation reaction that increases adenylate cyclase activity and thus cyclic adenosine monophosphate (cAMP) levels in the enterocyte. As a result, the normal absorption of sodium, anions, and water from the gut lumen into the intestinal cell is markedly diminished. The exotoxin also stimulates the crypt cells to secrete chloride because of phosphorylation and activation of the cystic fibrosis transmembrane conductance regulator (CFTR), accompanied by cations and water, from the bloodstream into the lumen of the gut. The resulting loss of solute-rich diarrheal fluid may, in severe cases, exceed 1 L/hour, leading to rapid dehydration and even death.

The therapeutic approach to cholera takes advantage of the fact that the Na^+ -dependent transporters for glucose and amino acids are not affected by the cholera exotoxin. As a result, coadministration of glucose and Na^+ by mouth results in the uptake of glucose and Na^+ , accompanied by chloride and water, thereby partially correcting the ion deficits and fluid loss. Amino acids and small peptides are also absorbed by Na^+ -dependent cotransport involving transport proteins distinct from the Na^+ -dependent glucose transporters. Therefore, addition of protein to the glucose–sodium replacement solution enhances its effectiveness and markedly decreases the severity of the diarrhea. Adjunctive antibiotic therapy also shortens the diarrheal phase of cholera but does not decrease the need for the oral replacement therapy outlined earlier.

KEY CONCEPTS

- ◆ The major carbohydrates in the American diet are starch, lactose, and sucrose.
- ◆ Starch is a polysaccharide composed of many glucose units linked together through α -1,4- and α -1,6-glycosidic bonds.
- ◆ Lactose is a disaccharide composed of glucose and galactose.
- ◆ Sucrose is a disaccharide composed of glucose and fructose.
- ◆ Digestion converts all dietary carbohydrates to their respective monosaccharides.
- ◆ Amylase digests starch; it is found in the saliva and pancreas, which releases it into the lumen of the small intestine.
- ◆ Intestinal epithelial cells contain disaccharidases, which cleave lactose, sucrose, and digestion products of starch into monosaccharides.
- ◆ Dietary fiber is composed of polysaccharides that cannot be digested by human enzymes.
- ◆ Monosaccharides are transported into the absorptive intestinal epithelial cells via active transport systems.
- ◆ Monosaccharides released into the blood via the intestinal epithelial cells are recovered by tissues that utilize facilitative transporters.
- ◆ Diseases discussed in this chapter are summarized in Table 21.6.

TABLE 21.6 Diseases Discussed in This Chapter

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Lactose intolerance	Both	Reduced levels of lactase on the intestinal epithelial cell surface lead to reduced lactose digestion in the intestinal lumen, providing substrate for flora in the large intestine. Metabolism of the lactose by these bacteria leads to the generation of organic acids and gases.
Type 2 diabetes	Both	Healthy diets with controlled intake of carbohydrates will be beneficial in managing blood glucose levels.
Fructose malabsorption	Genetic	Inability to absorb fructose in the small intestine, leading to colonic bacteria metabolism of fructose and the generation of organic acids and gases
Cholera	Environmental	Increased cAMP levels in the intestinal epithelial cells lead to significant ion (chloride, sodium, and potassium) and water extrusion from the affected cells, leading to severe diarrhea.

cAMP, cyclic adenosine monophosphate.

REVIEW QUESTIONS—CHAPTER 21

1. The facilitative transporter that is most responsible for transporting fructose from the blood into cells is which one of the following?
 - A. GLUT 1
 - B. GLUT 2
 - C. GLUT 3
 - D. GLUT 4
 - E. GLUT 5
2. A patient with alcohol abuse disorder developed pancreatitis that affected his exocrine pancreatic function. He exhibited discomfort after eating a high-carbohydrate meal. The patient most likely had a reduced ability to digest which one of the following?
 - A. Starch
 - B. Lactose
 - C. Fiber
 - D. Sucrose
 - E. Maltose
3. A type 1 diabetic neglects to take his insulin injections while on a weekend vacation. Cells found within which tissue will be most greatly affected by this mistake?
 - A. Brain
 - B. Liver
 - C. Muscle
 - D. Red blood cells
 - E. Pancreas
4. After digestion of a piece of cake that contains flour, milk, and sucrose as its primary ingredients, the major carbohydrate products that enter the blood are which of the following?
 - A. Glucose
 - B. Fructose and galactose
 - C. Galactose and glucose
 - D. Fructose and glucose
 - E. Glucose, galactose, and fructose
5. A patient has a genetic defect that causes intestinal epithelial cells to produce disaccharidases of much lower activity than normal. Compared with a normal person, after eating a bowl of milk and oatmeal sweetened with table sugar, this patient will exhibit higher levels of which of the following?
 - A. Maltose, sucrose, and lactose in the stool
 - B. Starch in the stool
 - C. Galactose and fructose in the blood
 - D. Glycogen in the muscles
 - E. Insulin in the blood
6. The majority of calories in the U.S. diet are derived from carbohydrates, which can contain a variety of glycosidic bonds. Which one of the following carbohydrates contains glucosyl units linked through α -1,6-glycosidic bonds?
 - A. Amylose
 - B. Amylopectin
 - C. Lactose
 - D. Sucrose
 - E. Maltose
7. A patient has increased her dietary fiber intake in an effort to decrease constipation. She has recently noticed abdominal cramping and bloating as well as increased flatulence. Which one of the following best explains why this is happening?
 - A. Human enzymes in the small intestine break down the fiber and produce H_2 , CO_2 , and methane as byproducts.
 - B. Bacteria in the small intestine can convert fiber to H_2 , CO_2 , and methane.
 - C. Viruses in the unwashed vegetables convert fiber to H_2 , CO_2 , and methane.
 - D. Bacteria in the colon can convert fiber to H_2 , CO_2 , and methane.
 - E. Human enzymes in the colon can convert fiber to H_2 , CO_2 , and methane.
8. A patient with newly diagnosed diabetes avoided table sugar because he knew he had "sugar diabetes," but

continued to consume fruits, fruit drinks, milk, honey, and vegetables, resulting in poor diabetic control. The diet the patient was following contained carbohydrates primarily in which form? Choose the one best answer.

- A. Sucrose
 - B. Glucose
 - C. Fructose
 - D. Lactose
 - E. Xylulose
9. A 10-year-old patient had 3 days of severe diarrhea after developing a viral gastroenteritis. Now, whenever she drinks milk, she experiences nausea, abdominal pain, and flatulence. She never had this happen before after drinking milk. Which one of the following would be the best advice for this patient?
- A. She should never consume milk products again.
 - B. Her children will have lactose deficiency at birth.
 - C. Her ability to drink milk should return in a few days.
 - D. She has developed viral gastroenteritis again and should receive antibiotics.
 - E. The cause of the symptoms is a defect in the colon.
10. A runner wanted to “carb load” just before a race and wanted to pick something to eat that had a high glycemic index. Which one of the following foods should the runner pick?
- A. Ice cream
 - B. Malted milk balls
 - C. Oatmeal cookies
 - D. Spaghetti
 - E. Potato chips

Questions 11 and 12 refer to the following case: A newborn child of phenotypically normal parents experienced a number of seizures by the age of 3 months. The child often displays nystagmus (involuntary eye movements), and despite a diagnosis of epilepsy, and treatment for such, the child begins to develop microcephaly and developmental delay. Analysis of blood glucose levels was normal, but the glucose levels in the cerebrospinal fluid were significantly below normal. Genetic analysis indicated a mutation in one specific gene.

1. Based on the case history the child most likely has an inactivating mutation in which one of the following genes?
- A. GLUT 1
 - B. GLUT 2
 - C. GLUT 3
 - D. GLUT 4
 - E. GLUT 5
2. A potential treatment option for the child would be which one of the following?
- A. Insulin injections
 - B. Glucagon injections
 - C. A low-fat, high-carbohydrate diet
 - D. A high-fat, low-carbohydrate diet
 - E. A high-protein, high-carbohydrate diet
3. Individuals with a suspected carbohydrate absorption problem can take a hydrogen breath test to confirm the diagnosis. An increase in the hydrogen gas content of the breath during such a test is dependent on which of the following? Choose the one best answer.

	Carbohydrates in the Colon	Carbohydrates in the Small Intestine	Bacteria in the Colon	Exocrine Pancreas Function
A	Yes	No	Yes	No
B	Yes	Yes	No	No
C	Yes	No	Yes	Yes
D	No	Yes	No	Yes
E	No	No	Yes	No
F	No	Yes	No	Yes

4. An individual with type 1 diabetes mistakenly takes two doses of premeal insulin, but becomes distracted and forgets to eat dinner. The individual then faints about 2 hours later. Measurement of blood glucose levels when the paramedics arrive indicated a value of 41 mg/dL. The hypoglycemia is induced, in part, by an increased activity of which of the following, as compared to before the insulin injections?
- GLUT 1
 - GLUT 2
 - GLUT 3
 - GLUT 4
 - GLUT 5
5. One hundred grams of fresh pineapple fruit contains 11.9 g of total sugars. This includes, in part, 2.9 g of free glucose, 2.1 g of free fructose, and 3.1 g of sucrose. The total fructose level per 100 g of pineapple fruit is best estimated as which one of the following?
- 1.6 g
 - 2.1 g
 - 2.9 g
 - 3.7 g
 - 5.2 g

ANSWERS TO REVIEW QUESTIONS

- The answer is E.** The GLUT 5 transporter has a much higher affinity for fructose than for glucose and is the facilitator of choice for fructose uptake by cells. The other GLUT transporters do not transport fructose to any significant extent.
- The answer is A.** The pancreas produces α -amylase, which digests starch in the intestinal lumen. If pancreatic α -amylase cannot enter the lumen because of pancreatitis, the starch will not be digested to a significant extent. (The salivary α -amylase begins the process, but only for the time during which the food is in the mouth, as the acidic conditions of the stomach destroy the salivary activity.) The discomfort arises from the bacteria in the intestine digesting the starch and producing acids and gases. Lactose, sucrose, and maltose are all disaccharides that would be cleaved by the intestinal disaccharidases located on the brush border of the intestinal epithelial cells (thus, B, D, and E are incorrect). These activities might be slightly reduced, as the pancreas would also have difficulty excreting bicarbonate to the intestine, and the low pH of the stomach contents might reduce the activity of these enzymes. However, these enzymes are present in excess and will eventually digest the disaccharides. Fiber cannot be digested by human enzymes, so answer C is incorrect.

3. **The answer is C.** Insulin is required to stimulate glucose transport into muscle and fat cells, but not into brain, liver, pancreas, or red blood cells. Thus, muscle would be feeling the effects of glucose deprivation and would be unable to replenish its own glycogen supplies as a result of its inability to extract blood glucose, even though blood glucose levels would be high.
4. **The answer is E.** Flour contains starch, which will lead to glucose production in the intestine. Milk contains lactose, a disaccharide of glucose and galactose, which will be split by lactase in the small intestine. Sucrose is a disaccharide of glucose and fructose, which is split by sucrase in the small intestine. Thus, glucose, galactose, and fructose will all be available in the lumen of the small intestine for transport through the intestinal epithelial cells and into the circulation.
5. **The answer is A.** Salivary and pancreatic α -amylase will partially digest starch to glucose, but maltose and disaccharides will pass through the intestine and exit with the stool, as a result of the limited activity of the brush border enzymes. Because the amylase enzymes are working, there will only be normal levels of starch in the stool (thus, B is incorrect). Not all available glucose is entering the blood, so less insulin will be released by the pancreas (thus, E is incorrect), which will lead to less glucose uptake by the muscles and less glycogen production (thus, D is incorrect). Because neither lactose nor sucrose can be digested to a large extent in the intestinal lumen under these conditions, it would be difficult to have elevated levels of galactose or fructose in the blood (thus, C is incorrect).
6. **The answer is B.** The starch amylopectin is a branched polysaccharide of glucosyl units linked through α -1, 4-glycosidic bonds with α -1,6-glycosidic bonds as branch points. The straight chained starch amylose and the disaccharide maltose are both linked through α -1, 4-glycosidic bonds. The disaccharide sucrose contains an α -1, 2-glycosidic bond between glucose and fructose, whereas lactose contains a β -1, 4-glycosidic bond between galactose and glucose.
7. **The answer is D.** Human enzymes cannot digest dietary fiber. However, bacteria in the colon can convert fiber to short-chain fatty acids, H_2 , CO_2 , and methane. These gases give the symptoms of bloating, cramping, and excess gas (flatulence). Viruses do not metabolize fiber.
8. **The answer is A.** Sucrose and small amounts of glucose and fructose are the major natural sweeteners in fruit, honey, and vegetables. Lactose is the sugar found in milk and milk-derived products. Xylulose is a component of the pentose phosphate pathway, and its levels in fruits and vegetables are low.
9. **The answer is C.** With viral gastroenteritis, the cells lining the brush borders of the small intestine can be sloughed off into the lumen of the intestine, resulting in temporary lactose intolerance because of the lack of lactase activity. Once these cells regenerate, the symptoms should disappear. She does not have congenital lactase deficiency, so her children will not inherit a defect in lactose metabolism. Antibiotics have no effect on viral illnesses and should not be given for viral gastroenteritis.
10. **The answer is B.** Maltose (glucose α -1,4-glucose) has the highest glycemic index and would most rapidly raise blood sugar levels after ingestion. Malted grains and malted milk are high in maltose. All the other foods listed exhibit a glycemic index that is only about half the glycemic index of maltose, and the glucose derived from that food would require more time to reach the blood than the glucose derived from maltose.
11. **The answer is A.** The child has a GLUT 1 deficiency such that glucose cannot be transported from the blood through the endothelial cells lining the blood–brain barrier into the cerebrospinal fluid for the neurons to take up with their GLUT 3 transporters. If the mutation were in the GLUT 3 transporters, the glucose level in the cerebrospinal fluid would be normal, or elevated, but not depressed as it is in this patient. The lack of glucose for the nervous system is what leads to the seizures and other symptoms exhibited by the child. GLUT 2 and GLUT 4 transporters are expressed neither by the cells of the nervous system nor by the endothelial cells in the blood–brain barrier, so a loss of their activity would not affect glucose uptake into the nervous system. GLUT 5 is a fructose transporter, and the nervous system does not use fructose as a fuel.
12. **The answer is D.** Because the child cannot transport glucose effectively into the nervous system, an alternative energy source for the nervous system is ketone bodies, so a high-fat, low-carbohydrate diet (a ketogenic diet) would be best for the child. Insulin injections would reduce circulating blood glucose levels, whereas glucagon injections would increase circulating blood glucose levels, but given the GLUT 1 transporter mutation, increasing blood glucose levels would not significantly increase glucose transport into the cerebrospinal fluid. A high-carbohydrate diet would antagonize ketone body formation because of the release of insulin resulting from the elevated glucose in the diet. Although ketogenic diets have been effective at reducing seizure frequency, they have not been effective at reducing the other effects of GLUT 1 mutations.

13. **The answer is A.** A hydrogen breath test is dependent on colonic bacterial metabolism of nondigested sugars entering the colon from the small intestine. Under normal conditions, carbohydrates are digested into monosaccharides in the small intestine and then absorbed (transported) by the intestinal epithelial cells, from which they are transported into the blood for distribution throughout the body. If a particular carbohydrate cannot be absorbed in the small intestine, it will make its way to the colon, where the bacteria metabolize it to hydrogen gas, methane, and short-chain organic acids. The hydrogen produced is exhaled, which is then measured in a hydrogen breath test. The exocrine pancreas function does not impact colonic bacterial metabolism of carbohydrates; the exocrine pancreas functions are important for carbohydrate digestion and absorption in the small intestine.
14. **The answer is D.** In muscle and fat cells, the injection of insulin stimulates the translocation of GLUT 4 transporters from intracellular vesicles to the plasma membrane. Once in the plasma membrane, the rate of glucose transport from the blood into the muscle and fat cells is significantly increased, and in the absence of dietary glucose, hypoglycemia rapidly occurs. The response to insulin is specific for the GLUT 4 transporters; insulin signal transduction does not lead to increases in other GLUT transporters being translocated to the plasma membrane.
15. **The answer is D.** Sucrose is a dimer of glucose and fructose (1:1 ratio), and as glucose and fructose are isomers of each other, they both have the same molecular weight of 180 g per mole. Thus, the 3.1 g of sucrose in the fruit are equal amounts of glucose and fructose, or 1.55 g each. There are 2.1 g of free fructose in the fruit, for a total of $2.1 + 1.55$ g of fructose in 100 g of pineapple, or 3.7 total grams of fructose.

Generation of Adenosine Triphosphate from Glucose, Fructose, and Galactose: Glycolysis

Glucose is the universal fuel for human cells. Every cell type in the human is able to generate adenosine triphosphate (ATP) from glycolysis, the pathway in which glucose is oxidized and cleaved to form pyruvate. The importance of glycolysis in our fuel economy is related to the availability of glucose in the blood, as well as the ability of glycolysis to generate ATP in both the presence and absence of O₂. Glucose is the major sugar in our diet and the sugar that circulates in the blood to ensure that all cells have a continuous fuel supply. The brain uses glucose almost exclusively as a fuel.

Glycolysis begins with the phosphorylation of glucose-to-glucose 6-phosphate (**glucose 6-P**) by **hexokinase (HK)**. In subsequent steps of the pathway, one glucose 6-P molecule is oxidized to two **pyruvate** molecules with the generation of two molecules of **reduced nicotinamide adenine nucleotide (NADH)** (Fig. 22.1). A net generation of two molecules of ATP occurs through direct transfer of **high-energy phosphate** from intermediates of the pathway to adenosine diphosphate (ADP) (**substrate-level phosphorylation**).

FIGURE 22.1 Overview of glycolysis and the TCA cycle. Acetyl CoA, acetyl coenzyme A; ADP, adenosine diphosphate; ATP, adenosine triphosphate; Fructose 6-P, fructose 6-phosphate; Fructose-1,6-bis P, fructose 1,6-bisphosphate; Glucose 6-P, glucose 6-phosphate; NADH, reduced nicotinamide adenine dinucleotide; Pi, inorganic phosphate; TCA, tricarboxylic acid.

Glycolysis occurs in the **cytosol** and generates cytosolic NADH. Because NADH cannot cross the inner mitochondrial membrane, its reducing equivalents are transferred to the electron transport chain by either the **malate–aspartate shuttle** or the **glycerol 3-phosphate shuttle** (see Fig. 22.1). Pyruvate is then oxidized completely to CO_2 by pyruvate dehydrogenase and the tricarboxylic acid (TCA) cycle (see Chapter 23). Complete **aerobic oxidation** of glucose to CO_2 can generate approximately **30 to 32 mol of ATP per mole of glucose**.

When cells have a limited supply of oxygen (e.g., the kidney medulla), or few or no mitochondria (e.g., the red cell), or greatly increased demands for ATP (e.g., skeletal muscle during high-intensity exercise), they rely on **anaerobic glycolysis** for generation of ATP. In anaerobic glycolysis, **lactate dehydrogenase** oxidizes the NADH generated from glycolysis by reducing pyruvate to **lactate** (Fig. 22.2). Because O_2 is not required to reoxidize the NADH, the pathway is referred to as anaerobic. The energy yield from anaerobic glycolysis (2 mol ATP per mole of glucose) is much lower than the yield from aerobic oxidation. The lactate (lactic acid) is released into the blood. Under pathological conditions that cause **hypoxia**, tissues may generate enough lactic acid to cause **lactic acidemia**.

FIGURE 22.2 Anaerobic glycolysis (shown in red). The conversion of glucose to lactate generates 2 ATP from substrate-level phosphorylation. Because there is no net generation of reduced nicotinamide adenine dinucleotide (NADH), there is no need for O_2 , and thus the pathway is anaerobic. Acetyl CoA, acetyl coenzyme A; ATP, adenosine triphosphate; TCA, tricarboxylic acid.

In each cell, glycolysis is regulated to ensure that **ATP homeostasis** is maintained, without using more glucose than necessary. In most cell types, **HK**, the first enzyme of glycolysis, is inhibited by glucose 6-phosphate (see Fig. 22.1). Thus, glucose is not taken up and phosphorylated by a cell unless glucose 6-P enters a metabolic pathway, such as glycolysis or glycogen synthesis. The control of glucose 6-P entry into glycolysis occurs at phosphofructokinase-1 (**PFK-1**), the rate-limiting enzyme of the pathway. PFK-1 is **allosterically inhibited** by **ATP** and **allosterically activated** by adenosine monophosphate (**AMP**). AMP increases in the cytosol as ATP is hydrolyzed by energy-requiring reactions.

Glycolysis has functions in addition to ATP production. For example, in liver and adipose tissue, this pathway generates pyruvate as a precursor for **fatty acid biosynthesis**. Glycolysis also provides precursors for the synthesis of compounds such as amino acids and five-carbon sugar phosphates.

While glucose is at the center of carbohydrate metabolism and is the major dietary sugar, other sugars in the diet are converted to intermediates of glucose metabolism, and their fates parallel that of glucose.

Fructose, the second most common sugar in the adult diet, is ingested principally as the monosaccharide or as part of **sucrose** (Fig. 22.3). It is metabolized principally in the liver (and to a lesser extent in the small intestine and kidney) by phosphorylation at the 1-position to form **fructose 1-phosphate** (fructose 1-P), followed by conversion to intermediates of the glycolytic pathway. The major products of its metabolism in liver are, therefore, the same as for glucose (including lactate, blood glucose, and glycogen). **Essential fructosuria (fructokinase deficiency)** and **hereditary fructose intolerance** (a deficiency of the fructose 1-P cleavage by **aldolase B**) are inherited disorders of fructose metabolism.

Intermediates of glycolysis

FIGURE 22.3 Fructose. The sugar fructose is found in the diet as the free sugar in foods such as honey or as a component of the disaccharide sucrose in fruits and sweets. It also can be synthesized from glucose via the polyol pathway. In the lens of the eye, the polyol pathway contributes to the formation of cataracts. Fructose is metabolized by conversion to intermediates of glycolysis.

Fructose synthesis from glucose in the **polyol pathway** occurs in seminal vesicles and other tissues. **Aldose reductase** converts glucose to the sugar alcohol sorbitol (a polyol), which is then oxidized to fructose. In the lens of the eye, elevated levels of **sorbitol** in diabetes mellitus may contribute to the formation of **cataracts**.

Galactose is ingested principally as **lactose**, which is converted to galactose and glucose in the intestine. **Galactose** is converted to glucose principally in the liver. It is phosphorylated to galactose 1-phosphate (galactose 1-P) by **galactokinase** and activated to a uridine diphosphate (UDP)-sugar by **galactose 1-phosphate uridylyltransferase**. The metabolic pathway subsequently generates glucose 1-phosphate (glucose 1-P). **Classical galactosemia**, a deficiency of galactose 1-phosphate uridylyltransferase, results in the accumulation of galactose 1-phosphate in the liver and the inhibition of hepatic glycogen metabolism and other pathways that require UDP-sugars. Cataracts can occur from the accumulation of galactose in the blood, which is converted to **galactitol** (the sugar alcohol of galactose) in the lens of the eye.

THE WAITING ROOM

Linda F. is a 68-year-old woman who is admitted to the hospital emergency room with very low blood pressure (80/40 mm Hg) caused by an acute hemorrhage from a previously diagnosed ulcer of the stomach. Her bleeding stomach ulcer has reduced her effective blood volume severely enough to compromise her ability to perfuse (deliver blood to) her tissues. She is also known to have chronic obstructive pulmonary disease (COPD) as a result of 42 years of smoking two packs of cigarettes per day. Her respiratory rate is rapid and labored, her skin is cold and clammy, and her lips are slightly blue (cyanotic). She appears anxious and moderately confused.

The hematocrit (the percentage of the volume of blood occupied by packed red blood cells) and hemoglobin content (grams of hemoglobin in 100 mL of blood) are measured to determine whether the oxygen-carrying capacity of the blood is adequate. Both values can be decreased by conditions that interfere with erythropoiesis (the synthesis of red blood cells in bone marrow), such as iron deficiency. They also can be decreased during chronic bleeding as interstitial fluid replaces the lost blood volume and dilutes out the red blood cells, but not during immediate acute hemorrhage. The $p\text{CO}_2$ and $p\text{O}_2$ are the partial pressures of CO_2 and O_2 in the blood. The $p\text{O}_2$ and oxygen saturation determine whether adequate oxygen is available for tissues. Measurement of the $p\text{CO}_2$ and bicarbonate can distinguish between a metabolic and a respiratory acidosis (see Chapter 4).

As appropriate emergency measures are taken to stabilize her and elevate her blood pressure, blood is sent for immediate blood typing and crossmatching, so that blood transfusions can be started. A battery of laboratory tests is ordered, including venous hemoglobin, hematocrit, and an arterial blood gas, which includes an arterial pH, partial pressures of oxygen ($p\text{O}_2$) and carbon dioxide ($p\text{CO}_2$), bicarbonate, and oxygen saturation. Results show that the hemorrhaging and COPD have resulted in hypoxemia, with decreased oxygen delivery to her tissues, and both a respiratory and metabolic acidosis.

Otto S., a 26-year-old medical student, had gained weight during his first sedentary year in medical school. During his second year, he began watching his diet, jogging for an hour four times each week, and playing tennis twice a week. He has decided to compete in a 5-km race. To prepare for the race, he begins training with wind sprints, bouts of alternately running and walking.

Ivan A. is a 56-year-old morbidly obese accountant (see Chapters 1 through 3). He decided to see his dentist because he felt excruciating pain in his teeth when he ate ice cream. He really likes sweets and keeps hard candy in his pocket. The dentist noted from **Ivan A.**'s history that he had numerous cavities as a child in his

baby teeth. At this visit, the dentist found cavities in two of **Ivan A.**'s teeth.

Candice S. is an 18-year-old girl who presented to her physician for a precollege physical examination. While taking her medical history, the doctor learned that she carefully avoided eating all fruits and any foods that contained table sugar. She related that from a very early age, she had learned that these foods caused severe weakness and symptoms suggestive of low blood sugar such as tremulousness and sweating. Her medical history also indicated that her mother had told her that once she started drinking and eating more than breast milk, she became an irritable baby who often cried incessantly, especially after meals, and vomited frequently. At these times, her abdomen had become distended, and she became drowsy and apathetic. Her mother had intuitively eliminated certain foods from **Candice S.**'s diet, after which the severity and frequency of these symptoms diminished.

Erin G. is the third child in her family, with a normal pregnancy and vaginal delivery at home like her older siblings. Her mother was unable to get to the initial pediatrician visit because she was busy with all her young children but noticed that **Erin G.** began vomiting 3 days after birth, usually within 30 minutes after breastfeeding and finally brought her to the pediatrician at 3 weeks when she noticed her eyes were yellow. She also reported her abdomen became distended at these times, and she became irritable and cried frequently. The doctor agreed that **Erin G.** was slightly jaundiced. He also noted an enlargement of her liver and questioned the possibility of early cataract formation in the lenses of **Erin G.**'s eyes. He ordered liver and kidney function tests and did two separate dipstick urine tests in his office, one designed to measure only glucose in the urine and the other capable of detecting any of the reducing sugars.

I. Glycolysis

Glycolysis is one of the principal pathways for generating ATP in cells and is present in all cell types. The central role of glycolysis in fuel metabolism is related to its ability to generate ATP with, and without, oxygen. The oxidation of glucose to pyruvate generates ATP from **substrate-level phosphorylation** (the transfer of phosphate from high-energy intermediates of the pathway to ADP) and NADH. Subsequently, the pyruvate may be oxidized to CO₂ in the TCA cycle and ATP generated from electron transfer to oxygen in **oxidative phosphorylation** (see Chapter 23). However, if the pyruvate and NADH from glycolysis are converted to lactate (**anaerobic glycolysis**), ATP can be generated in the absence of oxygen, via substrate-level phosphorylation.

Glucose is readily available from our diet, internal glycogen stores, and the blood. Carbohydrate provides 50% or more of the calories in most diets, and glucose is the major carbohydrate. Other dietary sugars, such as fructose and galactose, are oxidized by conversion to intermediates of glycolysis. Glucose is stored in cells as glycogen, which can provide an internal source of fuel for glycolysis in emergency situations (e.g., decreased supply of fuels and oxygen during ischemia, due to a reduced blood flow). Insulin and other hormones maintain blood glucose at a constant level (glucose homeostasis), thereby ensuring that glucose is always available to cells that depend on glycolysis for generation of ATP.

After a high-carbohydrate meal, glucose is the major fuel for almost all tissues. Exceptions include intestinal mucosal cells, which transport glucose from the gut into the blood, and cells in the proximal convoluted tubule of the kidney, which return glucose from the renal filtrate to the blood. During fasting, the brain continues to oxidize glucose because it has a limited capacity for the oxidation of fatty acids or other fuels. Cells also continue to use glucose for the portion of their ATP generation that must be met by anaerobic glycolysis, due to either a limited oxygen supply or a limited capacity for oxidative phosphorylation (e.g., the red blood cell).

In addition to serving as an anaerobic and aerobic source of ATP, glycolysis is an anabolic pathway that provides biosynthetic precursors. For example, in liver and adipose tissue, this pathway generates pyruvate as a precursor for fatty acid biosynthesis. Glycolysis also provides precursors for the synthesis of compounds such as amino acids and of nucleotides. The integration of glycolysis with other anabolic pathways is discussed in Chapter 34.

A. The Reactions of Glycolysis

The glycolytic pathway, which cleaves 1 mol of glucose to 2 mol of the three-carbon compound pyruvate, consists of a preparative phase and an ATP-generating phase. In the initial **preparative phase** of glycolysis,

glucose is phosphorylated twice by ATP to form fructose 1,6-bisphosphate (Fig. 22.4). The ATP expenditure in the beginning of the preparative phase is sometimes called “priming the pump,” because this initial utilization of 2 mol of ATP per mole of glucose results in the production of 4 mol of ATP per mole of glucose in the ATP-generating phase.

FIGURE 22.4 Phases of the glycolytic pathway. ATP, adenosine triphosphate; Fructose-1,6-bis P, fructose 1,6-bisphosphate; NADH, reduced nicotinamide adenine dinucleotide.

In the **ATP-generating phase**, fructose 1,6-bisphosphate is split into two triose phosphates. Glyceraldehyde 3-phosphate (a triose phosphate) is oxidized by NAD^+ and phosphorylated using inorganic phosphate. The high-energy phosphate bond generated in this step is transferred to ADP to form ATP. The remaining phosphate is also rearranged to form another high-energy phosphate bond that is transferred to ADP. Because 2 mol of triose phosphate were formed, the yield from the ATP-generating phase is 4 ATP and 2 NADH. The result is a net yield of 2 mol of ATP, 2 mol of NADH, and 2 mol of pyruvate per mole of glucose.

1. Conversion of Glucose-to-Glucose 6-Phosphate

Glucose metabolism begins with the transfer of a phosphate from ATP to glucose to form glucose 6-P (Fig. 22.5). Phosphorylation of glucose commits it to metabolism within the cell because glucose 6-P cannot be transported back across the plasma membrane. The phosphorylation reaction is irreversible under physiological conditions because the reaction has a high negative $\Delta G^{0'}$. Phosphorylation does not, however, commit glucose to glycolysis.

Glucose

Glucose 6-P

FIGURE 22.5 Glucose 6-P metabolism. ADP, adenosine diphosphate; ATP, adenosine triphosphate; glucose 6-P, glucose 6-phosphate.

Glucose 6-P is a branch point in carbohydrate metabolism. It is a precursor for almost every pathway that uses glucose, including glycolysis, the pentose phosphate pathway (see Chapter 27), and glycogen synthesis (see Chapter 26). From the opposite point of view, it also can be generated from other pathways of carbohydrate metabolism, such as glycogenolysis (breakdown of glycogen), the pentose phosphate pathway, and gluconeogenesis (the synthesis of glucose from noncarbohydrate sources).

Hexokinases, the enzymes that catalyze the phosphorylation of glucose, are a family of tissue-specific isoenzymes that differ in their kinetic properties. The isoenzyme found in liver and β -cells of the pancreas has a much higher K_m than other HKs and is called **glucokinase**. In many cells, some of the HK is bound to porins in the outer mitochondrial membrane (voltage-dependent anion channels; see Chapter 24), which gives these enzymes first access to newly synthesized ATP, as it exits the mitochondria.

2. Conversion of Glucose 6-P to the Triose Phosphates

In the remainder of the preparative phase of glycolysis, glucose 6-P is isomerized to fructose 6-phosphate (fructose-6-P), again phosphorylated, and subsequently cleaved into two three-carbon fragments (Fig. 22.6). The isomerization, which positions a keto group next to carbon 3, is essential for the subsequent cleavage of the bond between carbons 3 and 4.

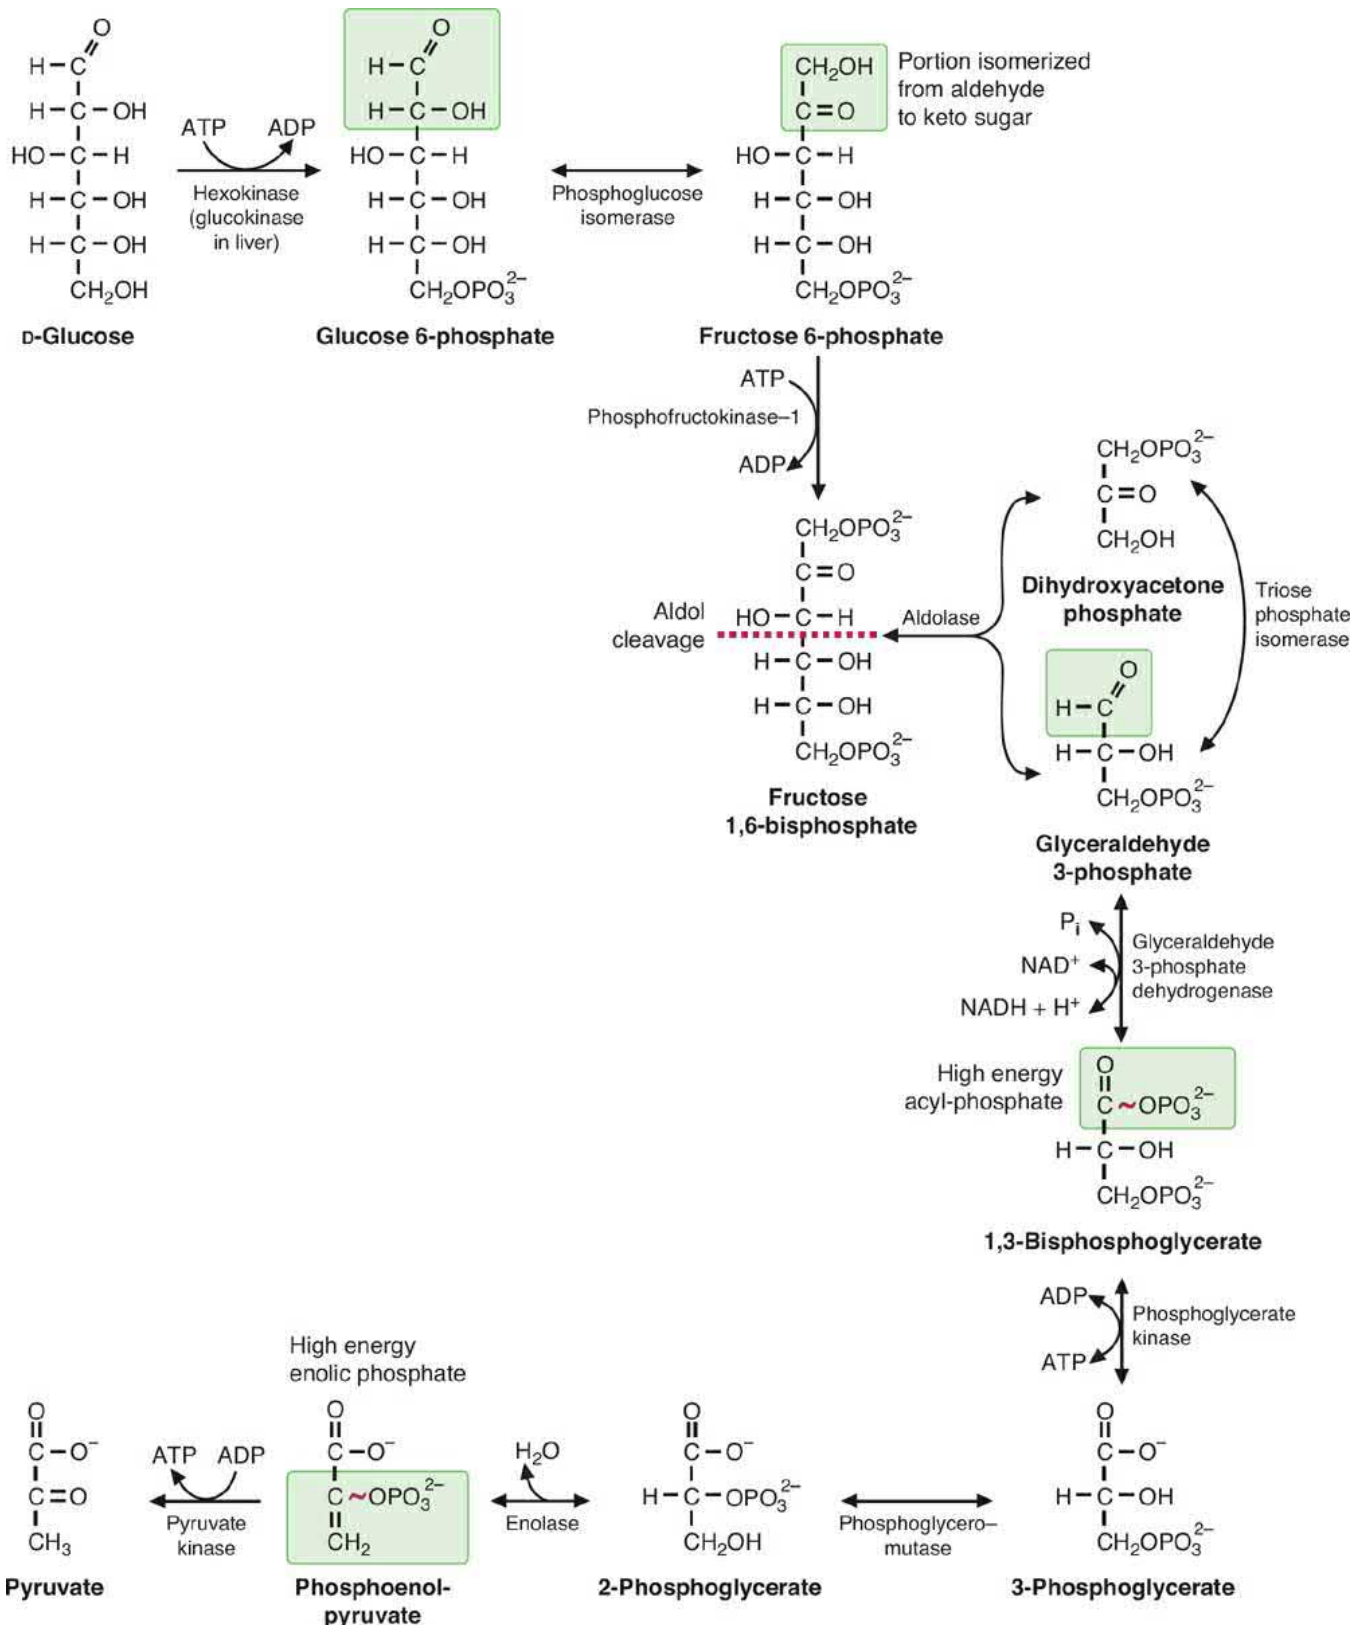

FIGURE 22.6 Reactions of glycolysis. High-energy phosphates are indicated by the *red squiggles*. ADP, adenosine diphosphate; ATP, adenosine triphosphate; NAD⁺, nicotinamide adenine dinucleotide; P_i, inorganic phosphate.

The next step of glycolysis, phosphorylation of fructose-6-P to fructose 1,6-bis-phosphate (fructose 1,6-bis-P) by phosphofruktokinase-1 (PFK-1), is generally considered the first committed step of the pathway. This phosphorylation requires ATP and is thermodynamically and kinetically irreversible. Therefore, PFK-1 irrevocably commits glucose to the glycolytic pathway. PFK-1 is a regulated enzyme in cells, and its regulation controls the entry of glucose into glycolysis. Like HK, it exists as tissue-specific isoenzymes whose regulatory

properties match variations in the role of glycolysis in different tissues.

Fructose 1,6-bis-P is cleaved into two phosphorylated three-carbon compounds (triose phosphates) by aldolase (see Fig. 22.6). Dihydroxyacetone phosphate (DHAP) and glyceraldehyde 3-phosphate (G3P) are the products. DHAP is isomerized to G3P by triose phosphate isomerase. Aldolase is named for the mechanism of the forward reaction, which is an aldol cleavage, and the mechanism of the reverse reaction, which is an aldol condensation. The enzyme exists as tissue-specific isoenzymes, which all catalyze the cleavage of fructose 1,6-bis-P but differ in their specificities for fructose 1-P. The enzyme uses a lysine residue at the active site to form a covalent bond with the substrate during the course of the reaction. Inability to form this covalent linkage inactivates the enzyme.

Thus, at this point in glycolysis, for every mole of glucose that enters the pathway, 2 mol of glyceraldehyde 3-P are produced and continue through the pathway at the expense of two high-energy bonds.

3. Oxidation and Substrate-Level Phosphorylation

In the next part of the glycolytic pathway, glyceraldehyde 3-P is oxidized and phosphorylated so that subsequent intermediates of glycolysis can donate phosphate to ADP to generate ATP. The first reaction in this sequence, catalyzed by glyceraldehyde 3-P dehydrogenase, is really the key to the pathway (see Fig. 22.6). This enzyme oxidizes the aldehyde group of glyceraldehyde 3-P to an enzyme-bound carboxyl group and transfers the electrons to NAD^+ to form NADH. The oxidation step is dependent on a cysteine residue at the active site of the enzyme, which forms a high-energy thioester bond during the course of the reaction. The high-energy intermediate immediately accepts an inorganic phosphate to form the high-energy acyl phosphate bond in 1,3-bisphosphoglycerate, releasing the product from the cysteine residue on the enzyme. This high-energy phosphate bond is the start of **substrate-level phosphorylation** (the formation of a high-energy phosphate bond where none previously existed, without the utilization of oxygen).

In the next reaction, catalyzed by phosphoglycerate kinase, the phosphate in this high-energy bond is transferred to ADP to form ATP. The energy of the acyl phosphate bond is high enough (~ 10 kcal/mol) so that transfer to ADP is an energetically favorable process. 3-Phosphoglycerate is also a product of this reaction.

To transfer the remaining low-energy phosphoester on 3-phosphoglycerate to ADP, it must be converted into a high-energy bond. This conversion is accomplished by moving the phosphate to the second carbon (forming 2-phosphoglycerate) and then removing water to form phosphoenolpyruvate (PEP). The enolphosphate bond is a high-energy bond (its hydrolysis releases ~ 14 kcal/mol of energy), so the transfer of phosphate to ADP by pyruvate kinase is energetically favorable (see Fig. 22.6) and not reversible. This final reaction converts PEP to pyruvate.

4. Summary of the Glycolytic Pathway

The overall net reaction in the glycolytic pathway is

The pathway occurs with an overall negative ΔG^0 of approximately -22 kcal/mol. Therefore, it cannot be reversed without the expenditure of energy.

When individuals with inactivating mutations in aldolase B ingest fructose, the extremely high levels of fructose 1-phosphate that accumulate in the liver and kidney cause several adverse effects. Hypoglycemia results from inhibition of glycogenolysis and gluconeogenesis. Glycogen phosphorylase (and possibly phosphoglucomutase and other enzymes of glycogen metabolism) are inhibited by the accumulated fructose 1-phosphate. Aldolase B is required for glucose synthesis from glyceraldehyde 3-phosphate and dihydroxyacetone phosphate, and its low activity in aldolase B-deficient individuals is further decreased by the accumulated fructose 1-phosphate. The inhibition of gluconeogenesis results in lactic acidosis. The accumulation of fructose 1-phosphate also substantially depletes the intracellular phosphate pools. The fructokinase reaction uses ATP at a rapid rate such that the mitochondria regenerate ATP rapidly, which leads to a drop in free phosphate levels. The low levels of phosphate release inhibition of AMP deaminase, which converts AMP to inosine monophosphate (IMP). The nitrogenous base of IMP (hypoxanthine) is degraded to uric acid. The lack of phosphate and depletion of adenine nucleotides lead to a loss of ATP, further contributing to the inhibition of biosynthetic pathways, including gluconeogenesis.

B. Fructose

Fructose is found in the diet as a component of sucrose in fruit, as a free sugar in honey, and in high-fructose corn syrup (see Fig. 22.3). Fructose enters epithelial cells and other types of cells by facilitated diffusion on the

GLUT V transporter. It is metabolized to intermediates of glycolysis. Problems with fructose absorption and metabolism are relatively more common than with other sugars.

1. Fructose Metabolism

Fructose is metabolized by conversion to glyceraldehyde-3-P and dihydroxyacetone phosphate, which are intermediates of glycolysis (Fig. 22.7). The steps parallel those of glycolysis. The first step in the metabolism of fructose, as with glucose, is phosphorylation. Fructokinase, the major kinase involved, phosphorylates fructose at the 1-position. Fructokinase has a high V_{max} and rapidly phosphorylates fructose as it enters the cell. The fructose 1-phosphate formed is not an intermediate of glycolysis but rather is cleaved by aldolase B to dihydroxyacetone phosphate (an intermediate of glycolysis) and glyceraldehyde. Glyceraldehyde is then phosphorylated to glyceraldehyde-3-phosphate by triose kinase. Dihydroxyacetone phosphate and glyceraldehyde 3-phosphate are intermediates of the glycolytic pathway and can proceed through it to pyruvate, the TCA cycle, and fatty acid synthesis. Alternatively, these intermediates can also be converted to glucose by gluconeogenesis. In other words, the fate of fructose parallels that of glucose.

FIGURE 22.7 Fructose metabolism. The pathway for the conversion of fructose to dihydroxyacetone-P and glyceraldehyde-3-P is shown in red. These two compounds are intermediates of glycolysis and are converted in the liver principally to glucose, glycogen, or fatty acids. In the liver, aldolase B cleaves both fructose-1-P in the pathway for fructose metabolism, and fructose-1,6-BP in the pathway for glycolysis. ADP, adenosine diphosphate; ATP, adenosine triphosphate; dihydroxyacetone-P, dihydroxyacetone phosphate; Fructose-6-P, fructose 6-phosphate; fructose-1,6-BP, fructose 1,6-bisphosphate; Glucose-1-P, glucose 1-phosphate; Glucose-6-P, glucose 6-phosphate; glyceraldehyde-3-P, glyceraldehyde 3-phosphate; TCA, tricarboxylic acid.

The metabolism of fructose occurs principally in the liver and to a lesser extent in the small intestinal

mucosa and proximal epithelium of the renal tubule because these tissues have both fructokinase and aldolase B. Aldolase exists as several isoforms: aldolases A, B, C, and fetal aldolase. Although all of these aldolase isoforms can cleave fructose 1,6-bisphosphate, the intermediate of glycolysis, only aldolase B can also cleave fructose 1-phosphate. Aldolase A, present in muscle and most other tissues, and aldolase C, present in brain, have almost no ability to cleave fructose 1-phosphate. Fetal aldolase, present in the liver before birth, is similar to aldolase C.

Essential fructosuria is a rare and benign genetic disorder caused by a deficiency of the enzyme fructokinase. Why is this disease benign, when a deficiency of aldolase B (hereditary fructose intolerance) can be fatal?

Aldolase B is the rate-limiting enzyme of fructose metabolism, although it is not a rate-limiting enzyme of glycolysis. It has a much lower affinity for fructose 1-phosphate than fructose 1,6-bisphosphate and is very slow at physiologic levels of fructose 1-phosphate. As a consequence, after ingesting a high dose of fructose, normal individuals accumulate fructose 1-phosphate in the liver while it is slowly converted to glycolytic intermediates. Individuals with hereditary fructose intolerance (a deficiency of aldolase B) accumulate much higher amounts of fructose 1-phosphate in their livers.

Other tissues also have the capacity to metabolize fructose but do so much more slowly. The HK isoforms present in muscle, adipose tissue, and other tissues can convert fructose-to-fructose 6-phosphate but react much more efficiently with glucose. As a result, fructose phosphorylation is very slow in the presence of physiologic levels of intracellular glucose and glucose 6-phosphate.

The accumulation of sorbitol in muscle and nerve tissues may contribute to the peripheral neuropathy characteristic of patients with poorly controlled diabetes mellitus. This is one of the many reasons it is so important for **Dianne A.** (who has type 1 diabetes mellitus) and **Deborah S.** (who has type 2 diabetes mellitus) to achieve good glycemic control.

2. Synthesis of Fructose in the Polyol Pathway

Fructose can be synthesized from glucose in the **polyol pathway**. The polyol pathway is named for the first step of the pathway, in which sugars are reduced to the sugar alcohol by the enzyme aldose reductase (Fig. 22.8). Glucose is reduced to the sugar alcohol sorbitol, and sorbitol is then oxidized to fructose. This pathway is present in seminal vesicles, which synthesize fructose for the seminal fluid. Spermatozoa use fructose as a major fuel source while in the seminal fluid and then switch to glucose once in the female reproductive tract. Utilization of fructose is thought to prevent acrosomal breakdown of the plasma membrane (and consequent activation), while the spermatozoa are still in the seminal fluid.

D-glucose

**Sorbitol
(polyol)**

D-fructose

FIGURE 22.8 The polyol pathway converts glucose to fructose. NAD^+ , nicotinamide adenine dinucleotide.

The polyol pathway is present in many tissues, but its function in all tissues is not understood. Aldose reductase is relatively nonspecific, and its major function may be the metabolism of an aldehyde sugar other than glucose. The activity of this enzyme can lead to major problems in the lens of the eye where it is responsible for the production of sorbitol from glucose and galactitol from galactose. When the concentration of glucose or galactose is elevated in the blood, their respective sugar alcohols are synthesized in the lens more rapidly than they are removed, resulting in increased osmotic pressure within the lens.

The accumulation of sugars and sugar alcohols in the lens of patients with hyperglycemia (e.g., diabetes mellitus) results in the formation of cataracts. Glucose levels are elevated and increase the synthesis of sorbitol and fructose. As a consequence, a high osmotic pressure is created in the lens. The high glucose and fructose levels also result in nonenzymatic glycation of lens proteins. The result of the increased osmotic pressure and the glycation of the lens protein is an opaque cloudiness of the lens known as a cataract. **Erin G.** seemed to have an early cataract, probably caused by the accumulation of galactose and its sugar alcohol galactitol.

C. Galactose Metabolism; Conversion to Glucose 1-Phosphate

Dietary galactose is metabolized principally by phosphorylation to galactose 1-phosphate and then conversion to UDP-galactose and glucose 1-phosphate (Fig. 22.9). The phosphorylation of galactose, again an important first step in the pathway, is carried out by a specific kinase, galactokinase. The formation of UDP-galactose is accomplished by the attack of the phosphate oxygen on galactose 1-phosphate on the α -phosphate of UDP-glucose, releasing glucose 1-phosphate while forming UDP-galactose. The enzyme that catalyzes this reaction is galactose 1-phosphate uridylyltransferase. The UDP-galactose is then converted to UDP-glucose by the reversible UDP-glucose epimerase (the configuration of the hydroxyl group on carbon 4 is reversed in this reaction). The net result of this sequence of reactions is that galactose is converted to glucose 1-phosphate, at the expense of one high-energy bond of ATP. The sum of these reactions is indicated in the following equations:

FIGURE 22.9 Metabolism of galactose. Galactose is phosphorylated to galactose 1-P by galactokinase. Galactose 1-P reacts with UDP-glucose to release glucose 1-P. Galactose thus can be converted to blood glucose, enter glycolysis, or enter any of the metabolic routes of glucose. In classical galactosemia, a deficiency of galactose 1-P uridylyltransferase (shown in *green*) results in the accumulation of galactose 1-P in tissues and the appearance of galactose in the blood and urine. In nonclassical galactosemia, a deficiency of galactokinase (shown in *red*) results in the accumulation of galactose. ADP, adenosine diphosphate; ATP, adenosine triphosphate; galactose 1-P, galactose 1-phosphate; glucose 1-P, glucose 1-phosphate; UDP, uridine diphosphate.

In essential fructosuria, fructose cannot be converted to fructose 1-phosphate. This condition is benign because no toxic metabolites of fructose accumulate in the liver, and the patient remains nearly asymptomatic. Some of the ingested fructose is slowly phosphorylated by HK in nonhepatic tissues and metabolized by glycolysis, and some appear in the urine. There is no renal threshold for fructose; the appearance of fructose in the urine (fructosuria) does not require a high-fructose concentration in the blood.

Hereditary fructose intolerance, conversely, results in the accumulation of fructose 1-phosphate and fructose. By inhibiting glycogenolysis and gluconeogenesis, the high levels of fructose 1-phosphate caused the hypoglycemia that **Candice S.** experienced as an infant when she became apathetic and drowsy, and as an adult when she experienced sweating and tremulousness.

The enzymes for galactose conversion to glucose 1-phosphate are present in many tissues, including the adult erythrocyte, fibroblasts, and fetal tissues. The liver has high activity of these enzymes and can convert dietary galactose to blood glucose and glycogen. The fate of dietary galactose, like that of fructose, therefore, parallels that of glucose. The ability to metabolize galactose is even greater in infants than in adults. Newborn infants ingest up to 1 g galactose per kilogram per feeding (as lactose). Yet the rate of metabolism is so high that the blood level in the systemic circulation is <3 mg/dL, and none of the galactose is lost in the urine.

One of the most serious problems of classical galactosemia is irreversible intellectual disability. Realizing this problem, **Erin G.**'s physician wanted to begin immediate dietary therapy. A test that measures galactose 1-phosphate uridylyltransferase activity in erythrocytes was ordered. This test is an enzymatic assay that mixes the unknown sample (in this case, a lysate from red blood cells, which contain the enzyme) with galactose 1-phosphate, UDP-glucose, and NADP⁺ in the presence of excess phosphoglucomutase and glucose 6-phosphate dehydrogenase. As the uridylyltransferase converts galactose 1-phosphate to UDP-galactose and glucose 1-phosphate, the glucose 1-phosphate is rapidly converted to glucose 6-phosphate by phosphoglucomutase. The glucose 6-phosphate is then converted to 6-phosphogluconate and NADPH by glucose 6-phosphate dehydrogenase. The resulting increase in absorbance at 340 nm allows a determination of the initial uridylyltransferase activity. The enzyme activity in **Erin G.**'s red blood cells was virtually absent, confirming the diagnosis of classical galactosemia.

Erin G.'s urine was negative for glucose when measured with the glucose oxidase strip but was positive for the presence of a reducing sugar. The reducing sugar was identified as galactose. Her liver function tests showed an increase in serum bilirubin and in several liver enzymes. Albumin was present in her urine. These findings and the clinical history increased her physician's suspicion that **Erin G.** had classical galactosemia. Classical galactosemia is caused by a deficiency of galactose 1-phosphate uridylyltransferase. In this disease, galactose 1-phosphate accumulates in tissues, and galactose is elevated in the blood and urine. This condition differs from the rarer deficiency of galactokinase (nonclassical galactosemia), in which galactosemia and galactosuria occur but galactose 1-phosphate is not formed. Both enzyme defects result in cataracts from galactitol formation by aldose reductase in the polyol pathway. Aldose reductase has a relatively high K_m for galactose, approximately 12 to 20 mM, so galactitol is formed only in galactosemic patients who have eaten galactose. Galactitol is not further metabolized and diffuses out of the lens very slowly. Thus, hypergalactosemia is even more likely to cause cataracts than hyperglycemia. **Erin G.**, although she is only 3 weeks old, appeared to have early cataracts forming in the lens of her eyes.

D. Oxidative Fates of Pyruvate and NADH

The NADH produced from glycolysis must be continuously reoxidized back to NAD⁺ to provide an electron acceptor for the glyceraldehyde 3-P dehydrogenase reaction and prevent product inhibition. Without oxidation of this NADH, glycolysis cannot continue. There are two alternate routes for oxidation of cytosolic NADH (Fig. 22.10). One route is aerobic, involving shuttles that transfer reducing equivalents across the mitochondrial membrane (see Chapter 23 for details of the shuttle systems) and ultimately to the electron transport chain and oxygen (see Fig. 22.10A). The other route is anaerobic (without the use of oxygen). In anaerobic glycolysis, NADH is reoxidized in the cytosol by lactate dehydrogenase, which reduces pyruvate to lactate (see Fig. 22.10B).

A. Aerobic glycolysis

B. Anaerobic glycolysis

FIGURE 22.10 Alternate fates of pyruvate. **A.** The pyruvate produced by glycolysis enters mitochondria and is oxidized to CO₂ and H₂O. The reducing equivalents in NADH enter mitochondria via a shuttle system. **B.** Pyruvate is reduced to lactate in the cytosol, thereby using the reducing equivalents in NADH. Acetyl CoA, acetyl coenzyme A; ADP, adenosine diphosphate; ATP, adenosine triphosphate; FAD(2H), reduced flavin adenine dinucleotide; Glycerol 3-P, glycerol 3-phosphate; NADH, nicotinamide adenine dinucleotide; P_i, inorganic phosphate; TCA, tricarboxylic acid.

The fate of pyruvate depends on the route used for NADH oxidation. If NADH is reoxidized in a shuttle system, pyruvate can be used for other pathways, one of which is oxidation to acetyl CoA and entry into the TCA cycle for complete oxidation. Alternatively, in anaerobic glycolysis, pyruvate is reduced to lactate and diverted away from other potential pathways. Thus, the use of the shuttle systems allows for more ATP to be generated than by anaerobic glycolysis, by both oxidizing the cytoplasmically derived NADH in the electron transport chain and by allowing pyruvate to be oxidized completely to CO₂.

The reason that shuttles are required for the oxidation of cytosolic NADH by the electron transport chain is that the inner mitochondrial membrane is impermeable to NADH, and no transport protein exists that can translocate NADH directly across this membrane.

E. Anaerobic Glycolysis

When the oxidative capacity of a cell is limited (e.g., such as in the red blood cell, which has no mitochondria), the pyruvate and NADH produced from glycolysis cannot be oxidized aerobically. The NADH is, therefore, oxidized to NAD⁺ in the cytosol by the reduction of pyruvate to lactate. This reaction is catalyzed by lactate dehydrogenase (LDH) (Fig. 22.11). The net reaction for anaerobic glycolysis is

Glycolysis

FIGURE 22.11 Lactate dehydrogenase reaction. Pyruvate, which may be produced by glycolysis, is reduced to lactate. The reaction, which occurs in the cytosol, requires nicotinamide adenine dinucleotide (NADH) and is catalyzed by lactate dehydrogenase. This reaction is readily reversible. NADH, nicotinamide adenine dinucleotide.

The confusion experienced by **Linda F.** in the emergency room is caused by an inadequate delivery of oxygen to the brain. Neurons have very high ATP requirements, and most of this ATP is provided by aerobic oxidation of glucose to pyruvate in glycolysis and by pyruvate oxidation to CO_2 in the TCA cycle. The brain has little or no capacity to oxidize fatty acids, so its glucose consumption is high (~125 to 150 g/day in the adult). Its oxygen demands are also high. If cerebral oxygen supply were completely interrupted, the brain would last only 10 seconds. The only reason that consciousness lasts longer during anoxia or asphyxia is that there is still some oxygen in the lungs and in circulating blood. A decrease of blood flow to approximately one-half of the normal rate results in a loss of consciousness.

1. Acid Production in Anaerobic Glycolysis

Anaerobic glycolysis results in acid production in the form of H^+ . Glycolysis forms pyruvic acid, which is reduced to **lactic acid**. At an intracellular pH of 7.35, lactic acid dissociates to form the carboxylate anion, **lactate**, and H^+ (the pK_a for lactic acid is 3.85). Lactate and the H^+ are both transported out of the cell into interstitial fluid by a transporter on the plasma membrane and eventually diffuse into the blood. If the amount of lactate generated exceeds the buffering capacity of the blood, the pH drops below the normal range, resulting in lactic acidosis (see Chapter 4).

2. Tissues Dependent on Anaerobic Glycolysis

Many tissues, including red and white blood cells, the kidney medulla, the tissues of the eye, and skeletal muscles, rely on anaerobic glycolysis for at least a portion of their ATP requirements (Table 22.1). Tissues (or cells) that are heavily dependent on anaerobic glycolysis usually have a low ATP demand, high levels of glycolytic enzymes, and few capillaries, such that oxygen must diffuse over a greater distance to reach target cells. The lack of mitochondria, or the increased rate of glycolysis, is often related to some aspect of cell

function. For example, the mature red blood cell has no mitochondria because oxidative metabolism might interfere with its function in transporting oxygen bound to hemoglobin. Some of the lactic acid generated by anaerobic glycolysis in skin is secreted in sweat, where it acts as an antibacterial agent. Many large tumors use anaerobic glycolysis for ATP production and lack capillaries in their core.

TABLE 22.1 Major Tissue Sites of Lactate Production in a Resting Man (an Average 70-kg Man Consumes about 300 g of Carbohydrate per Day)

DAILY LACTATE PRODUCTION (g/day)	
Total lactate production	115
Red blood cells	29
Skin	20
Brain	17
Skeletal muscle	16
Renal medulla	15
Intestinal mucosa	8
Other tissues	10

In tissues with some mitochondria, both aerobic and anaerobic glycolysis occur simultaneously. The relative proportion of the two pathways depends on the mitochondrial oxidative capacity of the tissue and its oxygen supply and may vary among cell types within the same tissue because of cell distance from the capillaries. When a cell's energy demand exceeds the capacity of the rate of the electron transport chain and oxidative phosphorylation to produce ATP, glycolysis is activated, and the increased NADH/NAD⁺ ratio will direct excess pyruvate into lactate. Because under these conditions pyruvate dehydrogenase, the TCA cycle, and the electron transport chain are operating as fast as they can, anaerobic glycolysis is meeting the need for additional ATP.

3. Fate of Lactate

Lactate released from cells undergoing anaerobic glycolysis is taken up by other tissues (primarily the liver, heart, and skeletal muscle) and oxidized back to pyruvate. In the liver, the pyruvate is used to synthesize glucose (gluconeogenesis), which is returned to the blood. The cycling of lactate and glucose between peripheral tissues and liver is called the **Cori cycle** (Fig. 22.12).

FIGURE 22.12 The Cori cycle. Glucose, produced in the liver by gluconeogenesis, is converted by glycolysis in muscle, red blood cells (RBC), and many other cells, to lactate. Lactate returns to the liver and is reconverted to glucose by gluconeogenesis. ATP, adenosine triphosphate.

The dental caries in **Ivan A.**'s mouth were caused principally by the low pH generated from lactic acid production by oral bacteria. Below a pH of 5.5, decalcification of tooth enamel and dentine occurs. Lactobacilli and *Streptococcus mutans* are major contributors to this process because almost all of their energy is derived from the conversion of glucose or fructose to lactic acid, and they are able to grow well at the low pH generated by this process. **Ivan A.**'s dentist explained that bacteria in his dental plaque could convert all the sugar in his candy into acid in <20 minutes. The acid is buffered by bicarbonate and other buffers in saliva, but saliva production decreases in the evening. Thus, the acid could dissolve the hydroxyapatite in his tooth enamel during the night.

In many other tissues, lactate is oxidized to pyruvate, which is then oxidized to CO₂ in the TCA cycle. Although the equilibrium of the lactate dehydrogenase reaction favors lactate production, flux occurs in the opposite direction if NADH is being rapidly oxidized in the electron transport chain (or is being used for gluconeogenesis):

The heart, with its huge mitochondrial content and oxidative capacity, is able to use lactate released from other tissues as a fuel. During exercise such as bicycle riding, lactate released into the blood from skeletal muscles in the leg might be used by resting skeletal muscles in the arm. In the brain, glial cells and astrocytes produce lactate, which is used by neurons or released into the blood.

In response to the hypoxemia caused by **Linda F.**'s COPD, she has increased hypoxia-inducible factor-1 (HIF-1) in her tissues. HIF-1 is a gene transcription factor found in tissues throughout the body (including brain, heart, kidney, lung, liver, pancreas, skeletal muscle, and white blood cells) that plays a homeostatic role in coordinating tissue responses to hypoxia. Each tissue will respond with a subset of the following changes. HIF-1 increases transcription of the genes for many of the glycolytic enzymes, including PFK-1, enolase, phosphoglycerate kinase, and lactate dehydrogenase. HIF-1 also increases synthesis of a number of proteins that enhance oxygen delivery to tissues, including erythropoietin, which increases the generation of red blood cells in bone marrow; vascular endothelial growth factor, which regulates angiogenesis (formation of blood vessels); and inducible nitric oxide synthase, which synthesizes nitric oxide, a vasodilator. As a consequence, **Linda F.** was able to maintain hematocrit and hemoglobin levels that were on the high side of the normal range, and her tissues had an increased capacity for anaerobic glycolysis.

Lactate dehydrogenase (LDH) is a tetramer composed of A subunits (also called M subunits, for skeletal muscle form) and B subunits (also called H subunits, for heart). Different tissues produce different amounts of the two subunits, which then combine randomly to form five different tetramers (M₄, M₃H₁, M₂H₂, M₁H₃, and H₄). These isoenzymes differ only slightly in their properties, but the kinetic properties of the M₄ form facilitate conversion of pyruvate to lactate in skeletal muscle, whereas the H₄ form facilitates conversion of lactate to pyruvate in the heart for energy generation.

The tissues of the eye are also partially dependent on anaerobic glycolysis.

The eye contains cells that transmit or focus light, and these cells, therefore, cannot be filled with opaque structures such as mitochondria or densely packed capillary beds. The corneal epithelium generates most of its ATP aerobically from its few mitochondria but still metabolizes some glucose anaerobically. Oxygen is supplied by diffusion from the air. The lens of the eye is composed of fibers that must remain birefringent to transmit and focus light, so mitochondria are nearly absent. The small amount of ATP required (principally for ion balance) can readily be generated from anaerobic glycolysis even though the energy yield is low. The lens is able to pick up glucose and release lactate into the vitreous body and aqueous humor. It does not need oxygen and has no need for capillaries.

II. Other Functions of Glycolysis

Glycolysis, in addition to providing ATP, generates precursors for biosynthetic pathways (Fig. 22.13). Intermediates of the pathway can be converted to ribose 5-phosphate, the sugar incorporated into nucleotides such as ATP. Other sugars, such as UDP-glucose, mannose, and sialic acid, are also formed from intermediates of glycolysis. Serine is synthesized from 3-phosphoglycerate and alanine from pyruvate. The backbone of triacylglycerols, glycerol 3-phosphate, is derived from dihydroxyacetone phosphate in the glycolytic pathway.

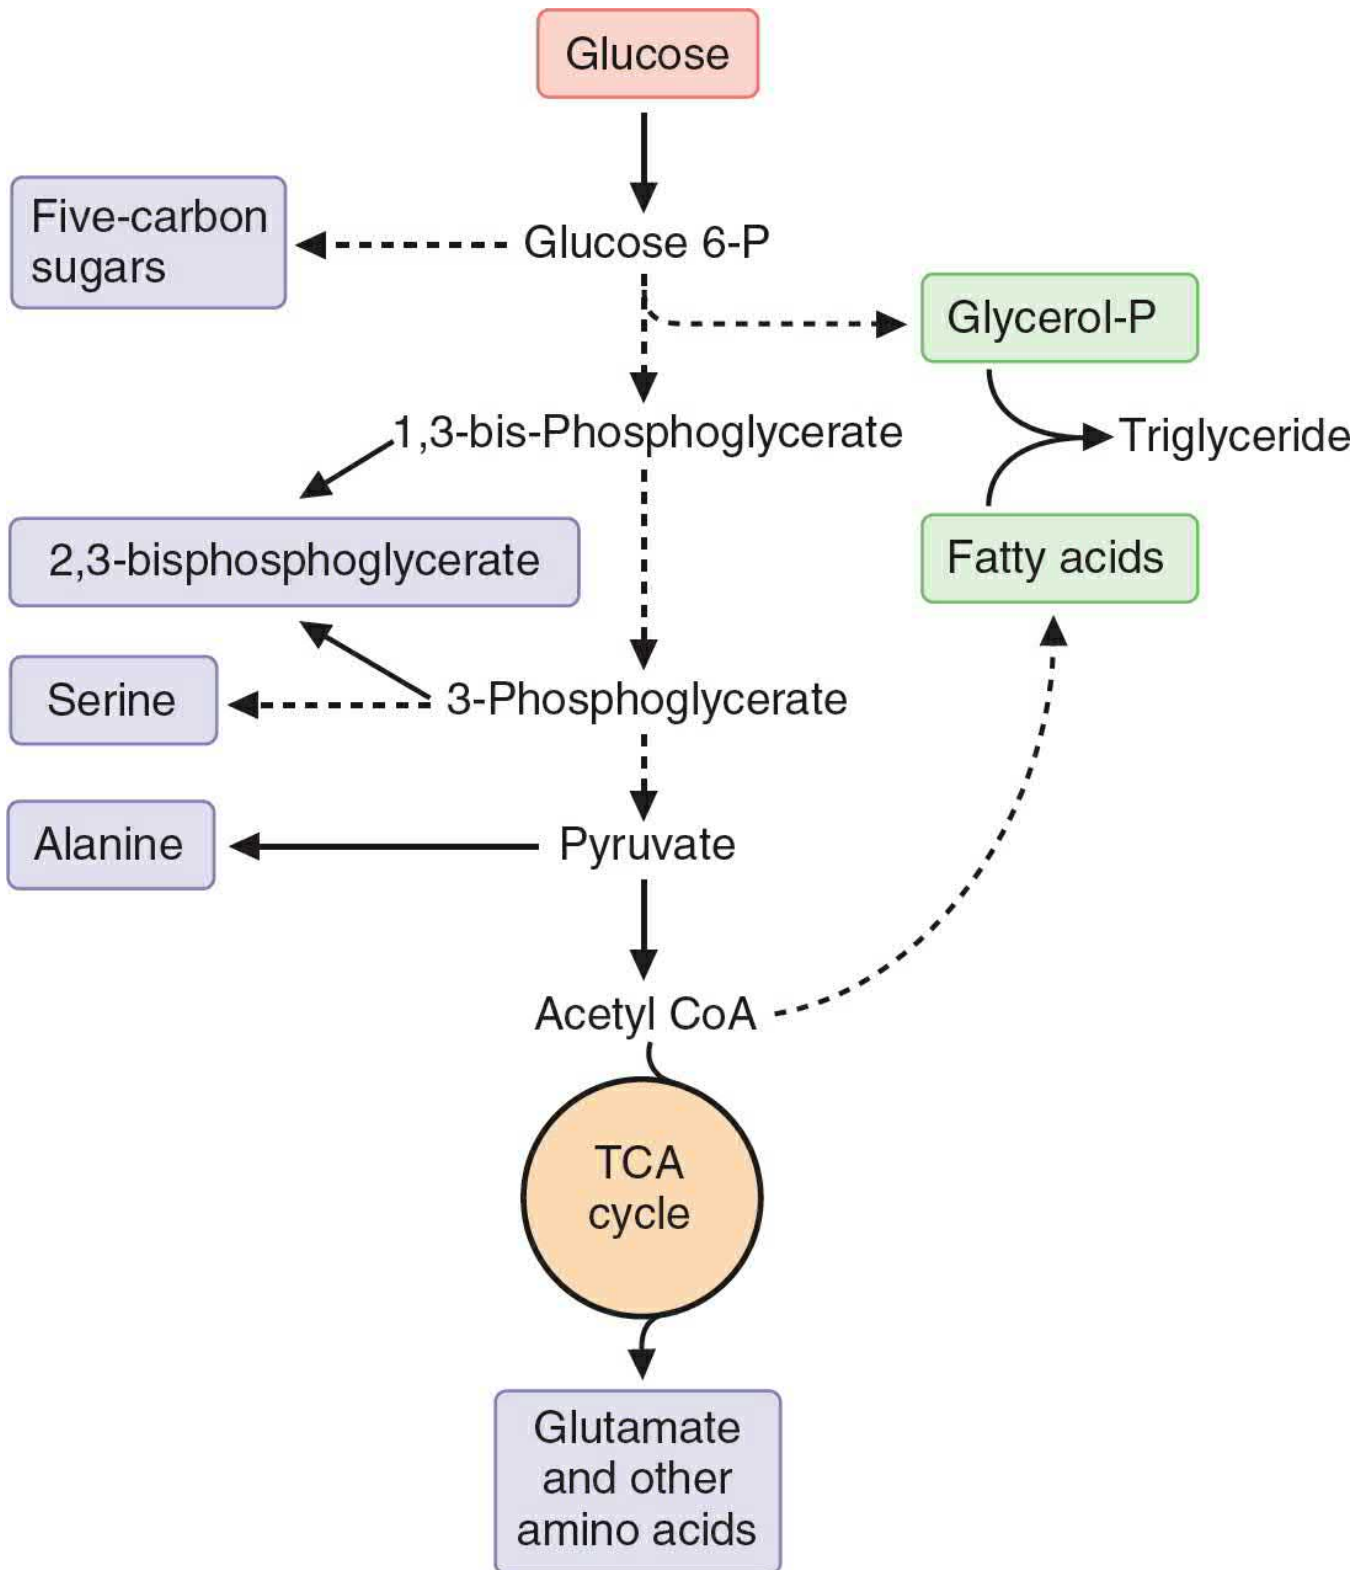

FIGURE 22.13 Biosynthetic functions of glycolysis. Compounds formed from intermediates of glycolysis are shown in the boxes. These pathways are discussed in later chapters. *Dotted lines* indicate that more than one step is required for the conversion shown in the figure. Acetyl CoA, acetyl coenzyme A; Glucose-6-P, glucose 6-phosphate; Glycerol-P, glycerol phosphate; RBC, red blood cells; TCA, tricarboxylic acid.

The liver is the major site of biosynthetic reactions in the body. In addition to those pathways mentioned previously, the liver synthesizes fatty acids from the pyruvate generated by glycolysis. It also synthesizes glucose from lactate, glycerol 3-phosphate, and amino acids in the gluconeogenic pathway, which is basically a reversal of glycolysis. Consequently, in liver, many of the glycolytic enzymes exist as isoenzymes with properties suited for these functions.

The bisphosphoglycerate shunt is a “side reaction” of the glycolytic pathway in which 1,3-bisphosphoglycerate is converted to 2,3-bisphosphoglycerate (2,3-BPG). Red blood cells form 2,3-BPG to serve as an allosteric inhibitor of oxygen binding to heme (see Chapter 42). 2,3-BPG re-enters the glycolytic pathway via dephosphorylation to 3-phosphoglycerate. 2,3-BPG also functions as a coenzyme in the conversion of 3-phosphoglycerate to 2-phosphoglycerate by the glycolytic enzyme phosphoglyceromutase. Because 2,3-BPG is not depleted by its role in this catalytic process, most cells need only very small amounts.

III. Regulation of Glycolysis by the Need for ATP

The principles of pathway regulation are summarized in Table 22.2. In pathways that are subject to feedback regulation, the first step of the pathway must be regulated so that precursors flow into alternative pathways if product is not needed. Another generalization concerning the regulation of metabolic pathways is that it occurs at the enzyme that catalyzes the rate-limiting (slowest) step in a pathway (see Table 22.2).

TABLE 22.2 Generalizations on the Regulation of Metabolic Pathways

1. Regulation matches function. The type of regulation used depends on the function of the pathway. Tissue-specific isozymes may allow the features of regulatory enzymes to match somewhat different functions of the pathway in different tissues.
2. Regulation of metabolic pathways occurs at rate-limiting steps, the slowest steps, in the pathway. These are reactions in which a small change of rate will affect the flux through the whole pathway.
3. Regulation usually occurs at the first committed step of a pathway or at metabolic branch points. In human cells, most pathways are interconnected with other pathways and have regulatory enzymes for every branch point.
4. Regulatory enzymes often catalyze physiologically irreversible reactions. These are also the steps that differ in biosynthetic and degradative pathways.
5. Many pathways have feedback regulation; that is, the end product of the pathway controls the rate of its own synthesis. Feedback regulation may involve inhibition of an early step in the pathway (feedback inhibition) or regulation of gene transcription.
6. Human cells use compartmentation to control access of substrate and activators or inhibitors to different enzymes.
7. Hormonal regulation integrates responses in pathways requiring more than one tissue. Hormones generally regulate fuel metabolism by:
 - a. Changing the phosphorylation state of enzymes
 - b. Changing the amount of enzyme present by changing its rate of synthesis (often induction or repression of mRNA synthesis) or degradation
 - c. Changing the concentration of an activator or inhibitor

One of the major functions of glycolysis is the generation of ATP, so the pathway is regulated to maintain ATP homeostasis in all cells. Phosphofructokinase-1 (PFK-1) and pyruvate dehydrogenase (PDH, see Chapter 23), which links glycolysis and the TCA cycle, are both major regulatory sites that respond to feedback indicators of the rate of ATP utilization (Fig. 22.14). The supply of glucose 6-P for glycolysis is tissue-dependent and can be regulated at the steps of glucose transport into cells, glycogenolysis (the degradation of glycogen to form glucose), or the rate of glucose phosphorylation by HK isoenzymes. Other regulatory mechanisms integrate the ATP-generating role of glycolysis with its anabolic roles.

FIGURE 22.14 Major sites of regulation in the glycolytic pathway. Hexokinase and phosphofructokinase-1 are the major regulatory enzymes in skeletal muscle. The activity of pyruvate dehydrogenase in the mitochondrion determines whether pyruvate is converted to lactate or to acetyl CoA. The regulation shown for pyruvate kinase occurs only for the liver (L) isoenzyme. acetyl CoA, acetyl coenzyme A; ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate; Fructose-6-P, fructose 6-phosphate; Fructose-1,6-bis P and F-1,6-bisP, fructose 1,6-bisphosphate; F-2,6-bisP, fructose 2,6-bisphosphate; Glucose-6-P, glucose 6-phosphate; Glyceraldehyde-3-P, glyceraldehyde 3-phosphate; NADH, reduced nicotinamide adenine dinucleotide; PEP, phosphoenolpyruvate; TCA, tricarboxylic acid.

All of the regulatory enzymes of glycolysis exist as tissue-specific isoenzymes, which alter the regulation of the pathway to match variations in conditions and needs in different tissues. For example, in the liver, an isoenzyme of pyruvate kinase introduces an additional regulatory site in glycolysis that contributes to the inhibition of glycolysis when the reverse pathway, gluconeogenesis, is activated.

A. Relationships among ATP, ADP, and AMP Concentrations

The AMP levels within the cytosol provide a better indicator of the rate of ATP utilization than the ATP concentration itself (Fig. 22.15). The concentration of AMP in the cytosol is determined by the equilibrium position of the adenylate kinase reaction, which catalyzes the following reaction:

FIGURE 22.15 Changes in adenosine triphosphate (ATP), adenosine diphosphate (ADP), and adenosine monophosphate (AMP) concentrations in skeletal muscle during exercise. The concentration of ATP decreases by only ~20% during exercise, and the concentration of ADP rises. The concentration of AMP, produced by the adenylate kinase reaction, increases manyfold and serves as a sensitive indicator of decreasing ATP levels. ADP, adenosine diphosphate; AMP, adenosine monophosphate; ATP, adenosine triphosphate.

The equilibrium is such that hydrolysis of ATP to ADP in energy-requiring reactions increases both the ADP and AMP contents of the cytosol. However, ATP is present in much higher quantities than AMP or ADP, so a small decrease of ATP concentration in the cytosol causes a much larger percentage increase in the small AMP pool. In skeletal muscles, for instance, ATP levels are approximately 5 mM and decrease by no more than

20% during strenuous exercise (see Fig. 22.15). At the same time, ADP levels may increase by 50%, and AMP levels, which are in the micromolar range, may increase by 300%. AMP activates a number of metabolic pathways, including glycolysis, glycogenolysis, and fatty acid oxidation (particularly in muscle tissues) to ensure that ATP homeostasis is maintained.

B. Regulation of Hexokinases

Hexokinases exist as tissue-specific isoenzymes whose regulatory properties reflect the role of glycolysis in different tissues. In most tissues, HK is a low- K_m enzyme with a high affinity for glucose (see Chapter 9). It is inhibited by physiological concentrations of its product, glucose 6-P (see Fig. 22.14). If glucose 6-P does not enter glycolysis or another pathway, it accumulates and decreases the activity of HK. In the liver, the isoenzyme glucokinase is a high- K_m enzyme that is not readily inhibited by glucose 6-P. Thus, glycolysis can continue in the liver even when energy levels are high, so that anabolic pathways, such as the synthesis of the major energy-storage compounds, glycogen, and fatty acids, can occur. Hepatic glucokinase, however, does bind to the glucokinase regulatory protein (GKRP) when glucose levels in the hepatocyte are low. When GKRP binds to glucokinase the complex translocates to the nucleus, removing glucokinase (and its enzymatic activity) from the cytoplasm. As glucose levels eventually rise in the hepatocyte the complex re-enters the cytoplasm, and the glucokinase is released from the GKRP such that glucokinase can phosphorylate glucose and initiate the glycolytic pathway.

C. Regulation of PFK-1

Phosphofructokinase-1 (PFK-1) is the rate-limiting enzyme of glycolysis and controls the rate of glucose 6-P entry into glycolysis in most tissues. PFK-1 is an allosteric enzyme that has a total of six binding sites: two are for substrates (Mg-ATP and fructose 6-P) and four are allosteric regulatory sites (see Fig. 22.14). The allosteric regulatory sites occupy a physically different domain on the enzyme than the catalytic site. When an allosteric effector binds, it changes the conformation at the active site and may activate or inhibit the enzyme (see also Chapter 9). The allosteric sites for PFK-1 include an inhibitory site for MgATP, an inhibitory site for citrate and other anions, an allosteric activation site for AMP, and an allosteric activation site for fructose 2,6-bisphosphate (fructose 2,6-bis-P) and other bisphosphates. Several different tissue-specific isoforms of PFK-1 are affected in different ways by the concentration of these substrates and allosteric effectors, but all contain these four allosteric sites.

Three different types of PFK-1 isoenzyme subunits exist: M (muscle), L (liver), and C (common). The three subunits show variable expression in different tissues, with some tissues having more than one type. For example, mature human muscle expresses only the M subunit, the liver expresses principally the L subunit, and erythrocytes express both the M and the L subunits. The C subunit is present in highest levels in platelets, placenta, kidney, and fibroblasts but is relatively common to most tissues. Both the M and L subunits are sensitive to AMP and ATP regulation, but the C subunits are much less so. Active PFK-1 is a tetramer, composed of four subunits. Within muscle, the M₄ form predominates; but within tissues that express multiple isoenzymes of PFK-1, heterotetramers can form that have full activity.

1. Allosteric Regulation of PFK-1 by AMP and ATP

ATP binds to two different sites on the enzyme, the substrate-binding site, and an allosteric-inhibitory site. Under physiological conditions in the cell, the ATP concentration is usually high enough to saturate the substrate-binding site and inhibit the enzyme by binding to the ATP allosteric site. This effect of ATP is opposed by AMP, which binds to a separate allosteric-activator site (Fig. 22.16). For most of the PFK-1 isoenzymes, the binding of AMP increases the affinity of the enzyme for fructose 6-P (e.g., it shifts the kinetic curve to the left). Thus, increases in AMP concentration can greatly increase the rate of the enzyme (see Fig. 22.16), particularly when fructose 6-P concentrations are low.

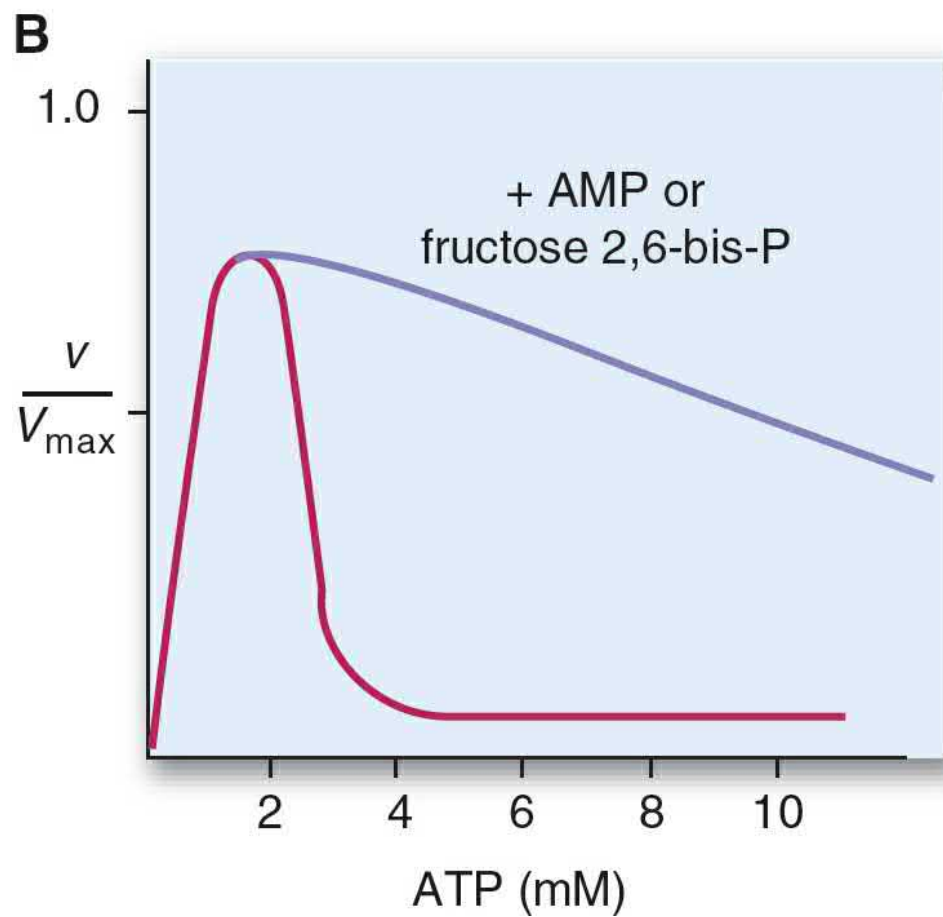

FIGURE 22.16 Regulation of PFK-1 by AMP, ATP, and fructose 2,6-bis-P. **A.** AMP and fructose 2,6-bis-phosphate activate PFK-1. **B.** ATP, as a substrate, increases the rate of the reaction at low concentrations but allosterically inhibits the enzyme at high concentrations. AMP, adenosine monophosphate; ATP, adenosine triphosphate; Fructose-6-P, fructose 6-phosphate; fructose 2,6-bis-P, fructose 2,6-bisphosphate; PFK-1, phosphofructokinase-1.

Otto S. has started high-intensity exercise that will increase the production of lactate in his exercising skeletal muscles. In skeletal muscles, the amount of aerobic versus anaerobic glycolysis that occurs varies with intensity of the exercise, with duration of the exercise, with the type of skeletal muscle fiber involved, and with the level of training. Human skeletal muscles are usually combinations of type I fibers (called fast glycolytic fibers, or white muscle fibers) and type IIb fibers (called slow oxidative fibers, or red muscle fibers). The designation “fast” or “slow” refers to their rate of shortening, which is determined by the isoenzyme of myosin ATPase present. Compared with glycolytic fibers, oxidative fibers have a higher content of mitochondria and myoglobin, which gives them a red color. The gastrocnemius, a muscle in the leg used for running, has a high content of type IIb fibers. However, these fibers will still produce lactate during sprints when the ATP demand exceeds their oxidative capacity.

2. Regulation of PFK-1 by Fructose 2,6-Bisphosphate

Fructose-2,6-bisP is also an allosteric activator of PFK-1 that opposes ATP inhibition. Its effect on the rate of activity of PFK-1 is qualitatively similar to that of AMP, but it has a separate binding site. Fructose 2,6-bisP is *not* an intermediate of glycolysis but is synthesized by an enzyme that phosphorylates fructose-6-P at the 2-position. The enzyme is, therefore, named phosphofructokinase-2 (PFK-2); it is a bifunctional enzyme with two separate domains, a kinase domain and a phosphatase domain. At the kinase domain, fructose 6-P is phosphorylated to fructose 2,6-bis-P; and at the phosphatase domain, fructose 2,6-bis-P is hydrolyzed back to fructose 6-P. PFK-2 is regulated through changes in the ratio of activity of the two domains. For example, in skeletal muscles, high concentrations of fructose 6-P activate the kinase and inhibit the phosphatase, thereby increasing the concentration of fructose 2,6-bis-P and activating glycolysis.

PFK-2 also can be regulated through phosphorylation by serine–threonine protein kinases. The liver isoenzyme contains a phosphorylation site near the amino-terminal that decreases the activity of the kinase and increases the phosphatase activity. This site is phosphorylated by the cAMP-dependent protein kinase (protein kinase A) and is responsible for decreased levels of liver fructose 2,6-bis-P during fasting conditions (as modulated by circulating glucagon levels, which is discussed in detail in Chapters 19 and 28). The cardiac isoenzyme contains a phosphorylation site near the carboxy terminal that can be phosphorylated in response to adrenergic activators of contraction (such as norepinephrine) and by increased AMP levels. Phosphorylation at this site increases the kinase activity and increases fructose 2, 6-bis-P levels, thereby contributing to the activation of glycolysis.

Under ischemic conditions, AMP levels within the heart increase rapidly because of the lack of ATP production via oxidative phosphorylation. The increase in AMP levels activates the AMP-activated protein kinase, which phosphorylates the heart isoenzyme of PFK-2 to activate its kinase activity. This results in increased levels of fructose 2,6-bis-P, which activates PFK-1 along with AMP so that the rate of glycolysis can increase to compensate for the lack of ATP production via aerobic means.

3. Allosteric Inhibition of PFK-1 at the Citrate Site

The function of the citrate-anion allosteric site is to integrate glycolysis with other pathways. For example, the inhibition of PFK-1 by citrate (an intermediate of the Krebs TCA cycle, see Chapter 23) may play a role in decreasing glycolytic flux in the heart during the oxidation of fatty acids.

A number of methods can be used to determine lactate levels in blood. Two of the most common utilize enzymatic methods. The first is the conversion of lactate to pyruvate (which also converts NAD^+ to NADH) in the presence of lactate dehydrogenase. Because NADH has considerable light absorption at 340 nm (and NAD^+ does not), one can follow the increase in absorbance at this wavelength as the reaction proceeds and determine the levels of lactate that were initially present in the sample. To ensure that all of the lactate is measured, hydrazine is added to the reaction; the hydrazine reacts with the pyruvate to remove the product of the lactate dehydrogenase reaction, which forces the reaction to go to completion. The second enzymatic procedure that is commonly used employs lactate oxidase, which converts lactate, in the presence of oxygen, to pyruvate and hydrogen peroxide. In this case, a second enzymatic reaction measures the amount of hydrogen peroxide produced (which removes the product of the lactate oxidase reaction, ensuring completion of the reaction). This second reaction utilizes peroxidase and a chromagen, which is converted to a colored product as the hydrogen peroxide is removed. The amount of colored product produced allows lactate levels to be determined accurately. Both procedures have been automated for use in the clinical laboratory.

D. Regulation of Pyruvate Kinase

Pyruvate kinase exists as tissue-specific isoenzymes, designated as R (red blood cells), L (liver), and M1/M2 (muscle and other tissues). The M1 form present in brain, heart, and muscle contains no allosteric sites, and pyruvate kinase does not contribute to the regulation of glycolysis in these tissues (these tissues also do not undergo significant gluconeogenesis). However, the liver isoenzyme can be inhibited through phosphorylation by the cAMP-dependent protein kinase and by several allosteric effectors that contribute to the inhibition of glycolysis during fasting conditions. These allosteric effectors include activation by fructose 1,6-bis-P, which ties the rate of pyruvate kinase to that of PFK-1, and inhibition by ATP, which signifies high energy levels.

IV. Lactic Acidemia

Lactate production is a normal part of metabolism. In the absence of disease, elevated lactate levels in the blood are associated with anaerobic glycolysis during exercise. In lactic acidosis, lactic acid accumulates in blood to levels that significantly affect the pH (lactate levels >5 mM and a decrease of blood pH below 7.2). A further discussion of lactic acidemia occurs in Chapter 24, after learning about oxidative phosphorylation.

CLINICAL COMMENTS

Linda F. was admitted to the hospital with severe hypotension caused by an acute hemorrhage. Her plasma lactic acid level was elevated, and her arterial pH was low. The underlying mechanism for **Linda F.**'s derangement in acid-base balance is a severe reduction in the amount of oxygen delivered to her tissues for cellular respiration (hypoxemia). Several concurrent processes contributed to this lack of oxygen. The first was her severely reduced blood pressure caused by a brisk hemorrhage from a bleeding gastric ulcer. The blood loss led to hypoperfusion and, therefore, reduced delivery of oxygen to her tissues. This led to increased lactate production from anaerobic glycolysis and an elevation of serum lactate to almost 10 times the normal levels. The marked reduction in the number of red blood cells in her circulation caused by blood loss further compromised oxygen delivery. Her pre-existing chronic obstructive pulmonary disease (COPD) added to her hypoxemia by decreasing her ventilation and, therefore, the transfer of oxygen to her blood (low pO_2). In addition, her COPD led to the retention of carbon dioxide (high pCO_2), which caused a respiratory acidosis because the retained CO_2 interacted with water to form carbonic acid (H_2CO_3), which dissociates to H^+ and bicarbonate. The reduction in her arterial pH to 7.18 (reference range = 7.35 to 7.45), therefore, resulted from both a mild respiratory acidosis (elevated pCO_2) and a more profound metabolic acidosis (elevated serum lactate levels).

During **Cora N.**'s myocardial infarction (see Chapter 20), the ischemic area in her heart had a limited supply of oxygen and blood-borne fuels. The absence of oxygen for oxidative phosphorylation would decrease the levels of ATP and increase those of AMP, an activator of PFK-1 and the AMP-dependent protein kinase, resulting in a compensatory increase of anaerobic glycolysis and lactate production. However, obstruction of a vessel leading to her heart would decrease lactate removal, resulting in a decrease of intracellular pH. Under these conditions, at very low pH levels, glycolysis is inhibited and unable to compensate for the lack of oxidative phosphorylation.

Otto S. In skeletal muscles, lactate production occurs when the need for ATP exceeds the capacity of the mitochondria for oxidative phosphorylation. Thus, increased lactate production accompanies an increased rate of the TCA cycle. The extent to which skeletal muscles use aerobic versus anaerobic glycolysis to supply ATP varies with the intensity of exercise. During low-intensity exercise, the rate of ATP use is lower, and fibers can generate this ATP from oxidative phosphorylation, with the complete oxidation of glucose to CO_2 . However, when **Otto S.** sprints, a high-intensity exercise, the ATP demand exceeds the rate at which the electron transport chain and the TCA cycle can generate ATP from oxidative phosphorylation. The increased AMP level signals the need for additional ATP and stimulates PFK-1. The $NADH/NAD^+$ ratio directs the increase in pyruvate production toward lactate. The fall in pH causes muscle fatigue and pain. As **Otto S.** trains, the amounts of mitochondria and myoglobin in his skeletal muscle fibers increase, and these fibers rely less on anaerobic glycolysis.

Ivan A. had two sites of dental caries: one on a smooth surface and one in a fissure. The decreased pH resulting

from lactic acid production by lactobacilli, which grow anaerobically within the fissure, is a major cause of fissure caries. *Streptococcus mutans* plays a major role in smooth-surface caries because it secretes dextran, an insoluble polysaccharide, which forms the base for plaque. *S. mutans* contains dextran-sucrase, a glucosyltransferase that transfers glucosyl units from dietary sucrose (the glucose-fructose disaccharide in sugar and sweets) to form the $\alpha(1 \rightarrow 6)$ and $\alpha(1 \rightarrow 3)$ linkages between the glucosyl units in dextran. Dextran-sucrase is specific for sucrose and does not catalyze the polymerization of free glucose, or glucose from other disaccharides or polysaccharides. Thus, sucrose is responsible for the cariogenic potential of candy. The sticky water-insoluble dextran mediates the attachment of *S. mutans* and other bacteria to the tooth surface. This also keeps the acids produced from these bacteria close to the enamel surface. Fructose from sucrose is converted to intermediates of glycolysis and is rapidly metabolized to lactic acid. Other bacteria present in the plaque produce different acids from anaerobic metabolism, such as acetic acid and formic acid. The decrease in pH that results initiates demineralization of the hydroxyapatite of the tooth enamel. **Ivan A.**'s caries in his baby teeth could have been caused by sucking on bottles containing fruit juice. The sugar in fruit juice is also sucrose, and babies who fall asleep with a bottle of fruit juice or milk (milk can also decrease the pH) in their mouth may develop caries. Rapid decay of these baby teeth can harm the development of their permanent teeth.

Candice S. Hereditary fructose intolerance (HFI) is caused by a low level of fructose 1-phosphate aldolase activity in aldolase B. Aldolase B is an isozyme of fructose 1,6-bisphosphate aldolase that is also capable of cleaving fructose 1-phosphate. In persons of European descent, the most common defect is a single missense mutation in exon 5 (G \rightarrow C), resulting in an amino acid substitution (Ala \rightarrow Pro). As a result of this substitution, a catalytically impaired aldolase B is synthesized in abundance. The exact prevalence of HFI in the United States is not established but is approximately 1 per 15,000 to 25,000 population. The disease is transmitted by an autosomal recessive inheritance pattern.

When affected patients such as **Candice S.** ingest fructose, fructose is converted to fructose 1-phosphate. Because of the deficiency of aldolase B, fructose 1-phosphate cannot be further metabolized to dihydroxyacetone phosphate and glyceraldehyde and accumulates in those tissues that have fructokinase (liver, kidney, and small intestine). Fructose is detected in the urine with the reducing sugar test (see the methods comment in Chapter 5). A DNA screening test (based on the generation of a new restriction site by the mutation) now provides a safe method to confirm a diagnosis of HFI.

In infants and small children, the major symptoms include poor feeding, vomiting, intestinal discomfort, and failure to thrive. The greater the ingestion of dietary fructose, the more severe is the clinical reaction. The result of prolonged ingestion of fructose is ultrastructural changes in the liver and kidney that result in hepatic and renal failure. Hereditary fructose intolerance is usually a disease of infancy because adults with fructose intolerance who have survived avoid the ingestion of fruits, table sugar, and other sweets.

Before the metabolic toxicity of fructose was appreciated, substitution of fructose for glucose in intravenous solutions, and of fructose for sucrose in enteral tube feeding or diabetic diets, was frequently recommended. (Enteral tube feeding refers to tubes placed into the gut; parenteral tube feeding refers to tubes placed into a vein, feeding intravenously.) Administration of intravenous fructose to patients with diabetes mellitus or other forms of insulin resistance avoided the hyperglycemia found with intravenous glucose, possibly because fructose metabolism in the liver bypasses the insulin-regulated step at phosphofructokinase-1. However, because of the unregulated flow of fructose through glycolysis, intravenous fructose feeding frequently resulted in lactic acidosis (see Fig. 22.7). In addition, the fructokinase reaction is very rapid, and tissues became depleted of ATP and phosphate when large quantities of fructose were metabolized over a short period. This led to cell death. Fructose is less toxic in the diet or in enteral feeding because of the relatively slow rate of fructose absorption.

Erin G. has galactosemia, which is caused by a deficiency of galactose 1-phosphate uridylyltransferase; it is one of the most common genetic diseases. Galactosemia is an autosomal recessive disorder of galactose metabolism that occurs in about 1 in 60,000 newborns. All of the states in the United States screen newborns for this disease because failure to begin immediate treatment results in intellectual disability. Failure to thrive is the most common initial clinical symptom. Vomiting or diarrhea occurs in most patients, usually starting within a few days of beginning milk ingestion. Signs of abnormal liver function, including jaundice or hepatomegaly, are present almost as frequently after the first week of life. The jaundice of intrinsic liver disease may be accentuated by the severe hemolysis in some patients. Cataracts have been observed within a few days of birth.

Management of patients requires eliminating galactose from the diet. Failure to eliminate this sugar results in progressive liver failure and death. In infants, artificial milk made from casein or soybean hydrolysate is used.

BIOCHEMICAL COMMENTS

The Mechanism of Glyceraldehyde 3-phosphate dehydrogenase. How is the first high-energy bond created in the glycolytic pathway? This is the work of the glyceraldehyde 3-phosphate dehydrogenase reaction, which converts glyceraldehyde 3-P to 1,3-bisphosphoglycerate. This reaction can be considered to be two separate half-reactions, the first being the oxidation of glyceraldehyde 3-P to 3-phosphoglycerate, and the second being the addition of inorganic phosphate to 3-phosphoglycerate to produce 1,3-bisphosphoglycerate. The ΔG° for the first reaction is approximately -12 kcal/mol; for the second reaction, it is approximately $+12$ kcal/mol. Thus, although the first half-reaction is extremely favorable, the second half-reaction is unfavorable and does not proceed under cellular conditions. So how does the enzyme help this reaction to proceed? This is accomplished through the enzyme forming a covalent bond with the substrate, using an essential cysteine residue at the active site to form a high-energy thioester linkage during the course of the reaction (Fig. 22.17). Thus, the energy that would be released as heat in the oxidation of glyceraldehyde 3-P to 3-phosphoglycerate is conserved in the thioester linkage that is formed (such that the ΔG° of the formation of the thioester intermediate from glyceraldehyde 3-P is close to zero). Then, the replacement of the sulfur with inorganic phosphate to form the final product, 1,3-bis-phosphoglycerate, is relatively straightforward, as the ΔG° for that conversion is also close to zero, and the acylphosphate bond retains the energy from the oxidation of the aldehyde. This is one example of how covalent catalysis by an enzyme can result in the conservation of energy between different bond types.

FIGURE 22.17 Mechanism of the glyceraldehyde 3-phosphate (glyceraldehyde-3-P) dehydrogenase reaction. (1) The enzyme forms a covalent linkage with the substrate, using a Cys group at the active site. The enzyme also contains bound NAD⁺ close to the active site. (2) The substrate is oxidized, forming a high-energy thioester linkage (in red) and NADH. (3) NADH has a

low affinity for the enzyme and is replaced by a new molecule of NAD^+ . (4) Inorganic phosphate (P_i) attacks the thioester linkage, releasing the product 1,3-bisphosphoglycerate and regenerating the active enzyme in a form ready to initiate another reaction. Cys, cysteine; NAD^+ , nicotinamide adenine dinucleotide.

KEY CONCEPTS

- ◆ Glycolysis is the pathway in which glucose is oxidized and cleaved to form pyruvate.
- ◆ The enzymes of glycolysis are in the cytosol.
- ◆ Glucose is the major sugar in our diet; all cells can utilize glucose for energy.
- ◆ Glycolysis generates two molecules of ATP through substrate-level phosphorylation and two molecules of NADH.
- ◆ The cytosolic NADH generated via glycolysis transfers its reducing equivalents to mitochondrial NAD^+ via shuttle systems across the inner mitochondrial membrane.
- ◆ The pyruvate generated during glycolysis can enter the mitochondria and be oxidized completely to CO_2 by pyruvate dehydrogenase and the TCA cycle.
- ◆ Anaerobic glycolysis generates energy in cells with a limited supply of oxygen or few mitochondria.
- ◆ Under anaerobic conditions, pyruvate is reduced to lactate by NADH, thereby regenerating the NAD^+ required for glycolysis to continue.
- ◆ Glycolysis is regulated to ensure that ATP homeostasis is maintained.
- ◆ The key regulated enzymes of glycolysis are HK, phosphofructokinase-1, and pyruvate kinase.
- ◆ Fructose is ingested principally as the monosaccharide or as part of sucrose. Fructose metabolism generates fructose 1-phosphate, which is then converted to intermediates of the glycolytic pathway.
- ◆ Galactose is ingested principally as lactose, which is converted to glucose and galactose in the intestine. Galactose metabolism generates, first, galactose 1-phosphate, which is converted to UDP-galactose. The end product is glucose 1-phosphate, which is isomerized to glucose 6-phosphate, which then enters glycolysis.
- ◆ The energy yield through glycolysis for both fructose and galactose is the same as for glucose metabolism.
- ◆ Diseases discussed in this chapter are summarized in Table 22.3.

TABLE 22.3 Diseases Discussed in Chapter 22

DISEASE OR DISORDER	ENVIRONMENTAL OR GENETIC	COMMENTS
Chronic obstructive pulmonary disease	Both	Can lead to inefficient energy production in the nervous system due to reduced oxygen delivery to the tissue
Obesity	Both	Lactate production via anaerobic glycolysis in the muscle occurs during vigorous exercise.
Dental caries	Environmental	Effects of carbohydrate metabolism on oral flora and acid production
Lactic acidemia	Both	Elevated lactic acid due to mutations in a variety of enzymes involved in carbohydrate and energy metabolism.
Hereditary fructose intolerance	Genetic	Lack of aldolase B, leading to an accumulation of fructose 1-phosphate after fructose ingestion. The increased levels of fructose 1-phosphate interfere with glycogen metabolism and can lead to hypoglycemia.
Galactosemia	Genetic	Mutations in either galactokinase or galactose 1-phosphate uridylyltransferase, leading to elevated galactose and/or galactose 1-phosphate levels. This can lead to cataract formation (high galactose) and intellectual disability (elevated galactose 1-phosphate levels) if not treated early in life.

REVIEW QUESTIONS—CHAPTER 22

1. Glucose is the body's universal fuel, which can be utilized by virtually all tissues. A major role of glycolysis is which one of the following?

- A. To synthesize glucose
 - B. To generate energy
 - C. To produce FAD(2H)
 - D. To synthesize glycogen
 - E. To use ATP to generate heat
2. Glycolysis generates energy such that cells have a source of energy to survive. Starting with glyceraldehyde 3-phosphate and synthesizing one molecule of pyruvate, the net yield of ATP and NADH would be which one of the following?
- A. 1 ATP, 1 NADH
 - B. 1 ATP, 2 NADH
 - C. 1 ATP, 4 NADH
 - D. 2 ATP, 1 NADH
 - E. 2 ATP, 2 NADH
 - F. 2 ATP, 4 NADH
 - G. 3 ATP, 1 NADH
 - H. 3 ATP, 2 NADH
 - I. 3 ATP, 4 NADH
3. Glycogen is the body's storage form of glucose. When glycogen is degraded, glucose 1-phosphate is formed. Glucose 1-phosphate can then be isomerized to glucose 6-phosphate. Starting with glucose 1-phosphate and ending with two molecules of pyruvate, what is the net yield of glycolysis in terms of ATP and NADH formed?
- A. 1 ATP, 1 NADH
 - B. 1 ATP, 2 NADH
 - C. 1 ATP, 3 NADH
 - D. 2 ATP, 1 NADH
 - E. 2 ATP, 2 NADH
 - F. 2 ATP, 3 NADH
 - G. 3 ATP, 1 NADH
 - H. 3 ATP, 2 NADH
 - I. 3 ATP, 3 NADH
4. Every human cell has the capacity to utilize glycolysis for energy production. Which one of the following statements correctly describes an aspect of glycolysis?
- A. ATP is formed by oxidative phosphorylation
 - B. Two molecules of ATP are used in the beginning of the pathway
 - C. Pyruvate kinase is the rate-limiting enzyme
 - D. One molecule of pyruvate and three molecules of CO₂ are formed from the oxidation of one glucose molecule
 - E. The reactions take place in the matrix of the mitochondria
5. Fructose is the second most common sugar in the human adult diet and its metabolism parallels glycolysis. Which one of the following substances is found in both the fructose metabolic pathway and the glycolytic pathway?
- A. Glucose 1-Phosphate
 - B. Fructose 1-Phosphate
 - C. Fructose 6-Phosphate
 - D. Fructose 1,6-Bisphosphate
 - E. Glyceraldehyde 3-Phosphate
6. A 4-week-old baby is being seen by the pediatrician due to frequent vomiting after meals and tenderness in the abdomen. Upon examination, the physician noted an enlarged liver and a hint of cataract formation in both of the child's eyes. A urine dipstick test for a reducing sugar gave a positive result. Blood glucose levels were slightly below normal. The compound which reacted with the urine dipstick test was most likely which one of the following?
- A. Glucose
 - B. Fructose
 - C. Lactose
 - D. Maltose
 - E. Galactose

7. Considering the child discussed in the previous question, measurement of which single intracellular metabolite would allow a determination of the enzyme deficiency?
 - A. Glucose 6-phosphate
 - B. Fructose 6-phosphate
 - C. Galactose 1-phosphate
 - D. Fructose 1-phosphate
 - E. UDP-glucose
