As asthma involves inflammation and bronchoconstriction, treatment should be directed towards reducing inflammation and increasing bronchodilation. Treatment aims should include a lack of day and nighttime symptoms, no asthma exacerbations, no need for rescue medication, normal PEFs and no unwanted side effects from medication (BTS/SIGN, 2009; GINA, 2009). Anti-inflammatory drugs should be given to all but those with the mildest of symptoms. Other measures, such as avoidance of recognised trigger factors, may also contribute to the control of this disease. The lowest effective dose of drugs should be given to minimise short-term and long-term side effects. It should, however, always be remembered that asthma is a potentially life-threatening illness, is often undertreated and not all patients will achieve optimal control. Common therapeutic and practice problems encountered in the management of asthma are outlined in Box 25.1.

Chronic asthma

The pharmacological management of asthma depends upon the frequency and severity of a patient's symptoms. Infrequent attacks can be managed by treating each attack when it occurs, but with more frequent attacks, preventive therapy needs to be used.

Box 25.1 Management of common practice problems

- Reducing exposure to trigger risk factors may help to improve asthma control.
- Successful management of asthma requires a partnership between the patient and the health care provider.
- Aim to give patients the ability to control their asthma by supporting guided self-management.
- Individualised action plans improve health outcomes, particularly in moderate to severe disease.
- Increased use of reliever medication is a warning of deterioration of asthma control.
- Assessment of asthma control is essential when deciding to step up or step down treatment.
- At each treatment review, inhaler technique and adherence to treatment should be checked.
- The main treatments for exacerbations of asthma include repeated β_2-agonists, early use of corticosteroids and oxygen to raise S_aO_2 above 92%.
- Mild exacerbations (PEF reduction of <20%) can often be managed in community settings.
- After exacerbations, patients should be reviewed early to identify possible triggers and review the action plan.

S_aO_2, arterial oxygen concentration.

The preferred route of administration of the agents used in the management of asthma is by inhalation. This allows the drugs to be delivered directly to the airways in smaller doses and with fewer side effects than if systemic routes were used. Inhaled bronchodilators also have a faster onset of action than when administered systemically and give better protection from bronchoconstriction.

Treatment of chronic asthma should be managed in a step-wise progression. This section concentrates on management in adults, as outlined in Fig. 25.3, but corresponding management steps for children are available (BTS/SIGN, 2009). Therapy is moved up the steps according to the severity of the patient's asthma symptoms and response to current treatment. When a patient has been stable for at least 3 months (GINA, 2009), therapy should be stepped back down; for example, by halving the inhaled corticosteroid (ICS) dose. International guidelines aim for management to achieve and maintain clinical control, which is defined in Table 25.2. A model for patient review and adjustment of therapy, based on assessment of asthma control, has been suggested (Crompton et al., 2006) and is shown in Fig. 25.4. To help in patient education, the terms used to describe the effects of asthma medication are similar across all manufacturers and sources of education. 'Reliever' is used for agents that give immediate relief of symptoms. Agents that act to reduce inflammation or give long-term bronchodilation are referred to as 'controllers' or 'preventers'.

Reliever medication

Short-acting β-adrenoceptor agonist bronchodilators. β-Adrenoceptor agonists are the mainstay of asthma management. Salbutamol and terbutaline are selective β_2-agonists and have few β_1-mediated side effects such as cardiotoxicity. β_2-Receptors are, however, also present in myocardial tissue; cardiovascular stimulation resulting in tachycardia and palpitations is still the main dose-limiting toxicity with these agents when used in high dosage.

An inhaled β_2-agonist is the first-line agent in the management of asthma. This is used as required by the patient for the symptomatic relief of breathlessness and wheezing, for example, salbutamol 200 μcg when required. This may be the only treatment necessary for those with infrequent symptoms. There is no advantage to regular administration.

Additional bronchodilators. Additional bronchodilators may be required if the above therapy does not adequately control symptoms (Tables 25.3 and 25.4).

Inhaled anticholinergic agents. These block muscarinic (M1, M2, M3) receptors in bronchial smooth muscle but are generally of little additional value in asthma management. Ipratropium has a slower onset of action than β_2-agonists but a longer duration of action. Anticholinergics may be helpful in patients who also have a degree of obstructive airways disease.

Long acting β-adrenoreceptor agonist bronchodilators. When low-dose inhaled steroids fail to control asthma symptoms adequately at step 3, long-acting β_2-agonists should be added instead of increasing the steroid dose. Symptom relief after a trial period, for example, 4–6 weeks, must then be assessed to

STEP 5: CONTINUOUS OR FREQUENT USE OF ORAL STEROIDS

Use daily steroid tablet in lowest dose providing adequate control

Maintain high dose inhaled steroid at 2000 μcg/day*
Consider other treatments to minimize the use of steroid tablets
Refer patient for specialist care

STEP 4: PERSISTENT POOR CONTROL

Consider trials of:

• Increasing inhaled steroid up to 2000 μcg/day*

• Addition of a fourth drug e.g. leukotriene receptor antagonist, SR theophylline, β₂ agonist tablet

STEP 3: ADD-ON THERAPY

1. Add inhaled long acting β₂ agonist (LABA)
2. Assess control of asthma:
   • good response to LABA – continue LABA
   • benefit from LABA but control still inadequate – continue LABA and increase inhaled steroid dose to 800 μcg/day* (if not already on this dose)
   • no response to LABA – stop LABA and increase inhaled steroid to 800 μcg/day*. If control still inadequate, institute trial of other therapies, e.g. leukotriene receptor antagonist or SR theophylline

STEP 2: REGULAR PREVENTER THERAPY

Add inhaled steroid 200–800 μcg/day*

400 μcg is an appropriate starting dose for many patients

Start a dose of inhaled steroid appropriate to severity of disease

STEP 1: MILD INTERMITTENT ASTHMA

Inhaled short-acting β₂ agonist as required

* BDP or equivalent

Fig. 25.3 Summary of stepwise management in adults (reproduced by permission of the BMJ Publishing Group, from BTS/SIGN, 2009).

Table 25.2 Levels of asthma control (GINA, 2009)

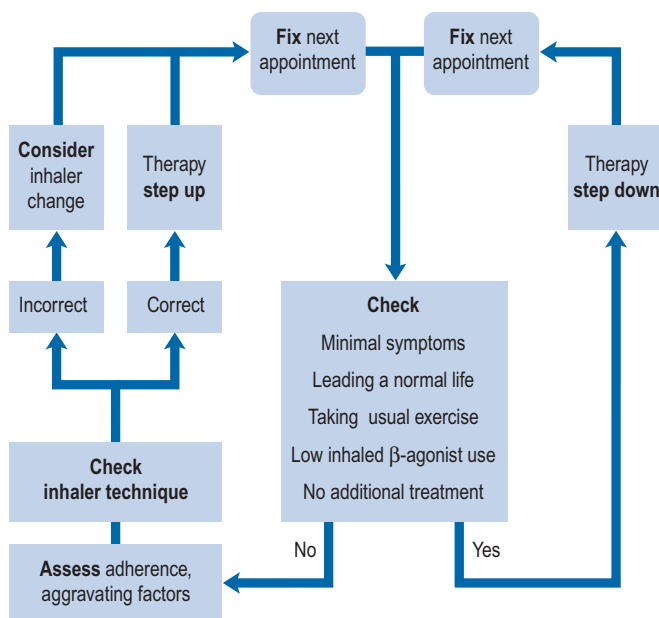
Characteristic	Controlled all of the following	Partly controlled any measure present in any week	Uncontrolled
Daytime symptoms	Twice or less/week	More than twice/week	Three or more features of partly controlled asthma present in any week
Limitation of activities	None	Any	
Nocturnal symptoms/awakening	None	Any	
Need for reliever/rescue treatment	Twice or less/week	More than twice/week	
Lung function (PEF or FEV₁)	Normal	<80% predicted or personal best (if known)	
Any exacerbation should prompt a review of maintenance treatment to ensure that it is adequate.			


Fig. 25.4 Adjusting therapy to achieve asthma control (from Crompton et al., 2006 reproduced by permission. Copyright Elsevier publishing).

see if the LABA has been effective and whether further treatment needs to be added to or existing treatment changed.

Meta-analysis of LABA trials has shown a potential increase in asthma deaths of 1 death in 1000 patient-years of use, but this increased risk is lessened when used alongside ICSs (Saltpeter et al., 2006). Taking this evidence into account, it is advised that LABAs should

- only be added if regular use of standard-dose ICS has failed to control asthma adequately
- not be initiated in patients with rapidly deteriorating asthma
- be introduced at a low dose and the effect properly monitored before considering dose increase
- be discontinued in the absence of benefit
- be reviewed as appropriate; stepping down therapy should be considered when good long-term asthma control has been achieved (MHRA, 2008).

Combination ICS/LABA inhalers are available which may improve adherence compared to separate inhalers; as adherence to ICS is generally poor, using combination inhalers may ensure that the LABA is not used alone for variable periods of time.

A formoterol and budesonide combination inhaler can be given both as maintenance therapy and for symptomatic relief. Current trial evidence shows that this dosing method is an alternative at step 3 for adults who are poorly controlled on SABA and ICS, have experienced one or more severe exacerbations in the previous 12 months, or as an alternative to increasing the ICS dose to above 2 mg/day at step 4 (NPC, 2008).

Oral bronchodilators. Oral bronchodilators can also be added, for example, theophylline at steps 3–4 or β_2-agonists at step 4 for additional symptom control. Slow-release forms should be used, usually twice daily, although these can be used in a single night-time dose if nocturnal symptoms are troublesome.

Theophylline should be started at a dose of 400–500 mg/day in adults and, if required, increased after 7 days to 800–1000 mg/day. In children, higher doses may be required but this will be determined by the age of the child (see Chapter 10).

Theophylline has a narrow therapeutic index and its hepatic metabolism varies greatly between individuals. Theophylline clearance is affected by a variety of factors, including disease states and concurrent drug therapy. The dose used should, therefore, take into account these factors, which are listed in Table 25.5. Plasma levels may be taken after 3–4 days at the higher dose, and it has been normal practice to adjust the dose to keep the plasma level within a therapeutic window of 10–20 mg/L, although improvements in respiratory function are seen at levels as low as 5 mg/L in some patients. As the bronchodilating effects of theophylline are proportional to the log of the plasma concentrations, there is proportionally less bronchodilation as the plasma level increases. The mild side effects such as nausea and vomiting are seen at concentrations as low as 13 mg/L but are more common over 20 mg/L. Significant cardiac symptoms, tachycardia and persistent vomiting are usually seen at concentrations of 40 mg/L while severe CNS effects, such as seizures, have been seen at 30 mg/L but are more common above 50 mg/L.

Table 25.3 Comparison of inhaled bronchodilators

Drug	Onset of action (min)	Peak action (min)	Duration of action (h)
Ipratropium	3–10	60–120	4–6
Formoterol	2–3		12
Salbutamol	5–15	60[a]	4–6
Salmeterol	10-14	150[a]	12[a]
Terbutaline	5–30	60–120	3–6
[a]Approximate or median value.			

Table 25.4 Daily dose range for selected bronchodilators

Drug and route	Age and total daily dosage range			
Aminophylline Intravenous injection	Adult; 5 mg/kg (single dose)	1 month–18 years; 5 mg/kg (single dose) up to 500 mg maximum		
Intravenous infusion Oral	16 years–adult; 500 mg/kg/h Child over 40 kg–adult; 225–450 mg m/r twice a day	9–16 years; 800 mg/kg/h	1 month–9 years; 1 mg/kg/h	
Formoterol Inhaled	6 years–adult; 12–24 μcg twice a day			
Ipratropium bromide Inhaled	12 years–adult; 20–40 μcg 3–4 times daily	6–12 years; 20–40 μcg 3 times daily	1 month–6 years; 20 μcg 3 times daily	
Nebulised for acute bronchospasm	Adult; 500 μcg repeated as necessary	6–12 years; 250–500 μcg repeated as necessary (max. 1 mg daily)	Under 5 years; 125–250 μcg repeated as necessary (max. 1 mg daily)	
Salbutamol Inhaled	5 years–adult; 200 μcg when required, up to 4 times a day	Child, 100 μcg when required, up to 4 times a day		
Nebulised for acute bronchospasm	Adult; 2.5–5 mg repeated as necessary	6–18 years; 2.5–5 mg repeated every 20–30 min if necessary	2–5 years; 2.5 mg repeated every 20–30 min if necessary	Under 2 years; 2.5 mg repeated every 20–30 min if necessary
Salmeterol Inhaled	12 years–adult; 50–100 μcg twice a day	4–12 years; 50 μcg twice a day	2–4 years; 25 μcg twice a day	
Terbutaline Inhaled	5 years–adult; 500 μcg when required, up to four times a day			
Nebulised for acute bronchospasm	Adult; 5–10 mg repeated as necessary	6–18 years; 5–10 mg repeated every 20–30 min if necessary	2–5 years; 5 mg repeated every 20–30 min if necessary	Under 2 years; 5 mg repeated every 20–30 min if necessary
Theophylline Oral	12 years–adult; 175–500 mg (m/r) twice a day	6–12 years; 175–250 mg (m/r) twice a day		

Differing brands of theophylline have differing bioavailabilities, so brands should not be interchanged.

High-dose β₂-agonists. High-dose β₂-agonists are only considered if conventional doses do not achieve adequate symptom control. Nebulised drugs such as salbutamol 2.5–5 mg per dose are given.

Terbutaline has been given by continuous subcutaneous infusion in the maintenance treatment of difficult to treat asthma.

Preventer medication

Anti-inflammatory agents. Regular anti-inflammatory treatment should be used for patients who are not controlled on a SABA alone (BTS/SIGN, 2009). Corticosteroids are the most commonly used anti-inflammatory agents (Table 25.6), but others such as the cromones are available.

Inhaled corticosteroids. Corticosteroids suppress the chronic airway inflammation associated with asthma. At present, ICSs are the initial drugs of choice, with a starting dose for an adult of beclometasone or budesonide 400 μcg/day (or an equivalent) given in divided doses.

The threshold frequency of β₂-agonist use which prompts the start of ICSs has not been fully established but national guidance (BTS/SIGN, 2009) recommends considering ICS for patients with any of the following:

- Exacerbations of asthma in the past 2 years
- Using inhaled β₂-agonists three times a week or more
- Symptoms three times a week or more
- Waking one night a week with symptoms

Table 25.5 Factors affecting theophylline clearance

Decreased clearance	Increased clearance
Congestive cardiac failure	Cigarette smoking
Cor pulmonale	Children 1–12 years
Chronic obstructive pulmonary disease	High-protein, low-carbohydrate diet
Viral pneumonia	Barbecued meat
Acute pulmonary oedema	Carbamazepine
Cirrhosis	Phenobarbital
Premature and term babies	Phenytoin
Elderly	Sulfinpyrazone
Obesity	
High-carbohydrate, low-protein diet	
Cimetidine	
Erythromycin	
Oral contraceptives	
Ciprofloxacin	
Propranolol	

If symptoms persist, the ICS dose is increased stepwise accordingly. The ICS dose should be reduced, if possible, once symptoms and PEF rates have improved and stabilised. If a patient's asthma cannot be controlled by the above ICS dose and the inhaler technique and adherence are adequate, the dose can be increased to a maximum of 1.5–2 mg a day.

All ICSs have dose-related side effects. Adrenal suppression occurs at around doses of >1500 μcg/day of beclometasone in adults. In children, doses of 400 μcg/day of beclometasone or more are associated with growth failure and adrenal suppression; children treated at these doses should be under the care of a specialist paediatrician. Oropharyngeal side effects such as candidiasis are also more common at higher doses (Box 25.2). Measures to minimise this can be tried, such as using a large-volume spacer device and rinsing the mouth with water or brushing teeth after inhalation, but there is little evidence to confirm how effective these are.

Cromones. Inhaled sodium cromoglicate and nedocromil sodium are less effective than corticosteroids in asthma. Although rarely used, they may be possible alternatives if corticosteroids cannot be tolerated.

Leukotriene receptor antagonists. Two leukotriene receptor antagonists, montelukast and zafirlukast, are currently licensed in the UK. Leukotriene receptor antagonists are included in step 4 as add-on therapy for adult patients but are less effective than LABAs in controlling asthma when added to ICSs. If these agents are initiated, then a 4–6 week trial should be undertaken; if there is no improvement in control, the drug should be stopped. They seem to be of particular value in aspirin-induced asthma, possibly due to the role of leukotrienes in this form of asthma.

Anti-IgE monoclonal antibodies. The first of these, omalizumab, is used for the treatment of severe persistent IgE (30–1500 iu/mL)-mediated asthma as add-on therapy to existing optimised therapy in adults and individuals over 12 years of age who have severe unstable disease (NICE, 2007). Patient response should be measured and omalizumab discontinued after 16 weeks if no adequate response is seen.

Oral corticosteroids. Oral corticosteroids should only be used, at step 5, if symptom control cannot be achieved with maximum doses of inhaled bronchodilators and steroids. They should be given as a single morning dose to minimise adrenal suppression. Alternate-day dosing produces fewer side effects but is less effective in controlling asthma.

Short courses (of up to 3 weeks) of high-dose oral steroids, 40–50 mg daily, can be safely used during exacerbations of asthma.

Steroid-sparing agents. Immunosuppressive agents can be tried in an attempt to reduce a regular steroid dose. Methotrexate, ciclosporin and gold have been tried with varying

Table 25.6 Inhaled corticosteroids used for the prophylaxis of asthma

Drug and age range	Total daily dosage range (MDI)	
	Standard dose	High dose
Beclometasone diproprionate or budesonide[a]		
Adult	100–400 μcg twice a day	400–1000 μcg twice a day
12–18 years	100–400 μcg twice a day	400–1000 μcg twice a day
Under 12 years	100–200 μcg twice a day	200–400 μcg twice a day
Ciclesonide		
Adult	80 μcg once daily	160 μcg once daily
Fluticasone		
Adult	50–200 μcg twice a day	400–1000 μcg twice a day
12–18 years	50–200 μcg twice a day	200–500 μcg twice a day
4–12 years	50–100 μcg twice a day	100–200 μcg twice a day
Mometasone		
Adult	200–400 μcg once daily	400 μcg twice a day
12-18 years	200 μcg twice a day	Up to 400 μcg twice a day

[a]There are bioavailability differences between CFC-free steroid inhalers. Always check dosing for specific brands.

Box 25.2 Adverse reactions associated with drugs used in the management of asthma

β$_2$-Agonists
- *By inhalation*: adverse drug reactions are uncommon
- *Nebulisation, orally or parenterally*: fine tremor (usually the hands), nervous tension, headache, peripheral vasodilation, tachycardia. The adverse reactions often diminish as tolerance develops with continued administration
- *High doses*: hypokalaemia, aggravation of angina

Inhaled corticosteroids
- Hoarseness, oral or pharyngeal candidiasis
- Adrenal suppression may occur with high doses, for example, beclometasone diproprionate above 1500 μcg daily

Oral corticosteroids
- Prolonged use of these results in exaggeration of some of the normal physiological effects of steroids
- Mineralocorticoid effects include: hypertension, potassium loss, muscle weakness, and sodium and water retention. These effects are most notable with fludrocortisone, are significant with hydrocortisone, occur only slightly with prednisolone and methylprednisolone and are negligible with dexametasone and betametasone
- Glucocorticoid effects include: precipitation of diabetes, osteoporosis, development of a paranoic state, depression, euphoria, peptic ulceration, immunosuppression, Cushing's syndrome (moon face, striae and acne), growth suppression in children, worsening of infection, skin thinning, striae atrophicae, increased hair growth, perioral dermatitis and acne
- Adrenal suppression occurs with high doses and/or prolonged treatment. Steroid therapy must be gradually withdrawn in these patients to avoid precipitating an adrenal crisis of hypotension, weight loss, arthralgia and, sometimes, death

Ipratropium bromide
- Occasionally: dry mouth
- Precipitation of acute glaucoma with nebulised therapy, possibly worsened by co-administration of salbutamol. A mouthpiece should be used to minimise the exposure of the eyes to the nebulised drug
- Rarely: systemic anticholinergic effects such as urinary retention and constipation

Methotrexate
- Myelosuppression, mucositis and, rarely, pneumonitis

Nedocromil sodium
- Mild and transient nausea, coughing, transient bronchospasm, throat irritation, headache and a bitter taste

Sodium cromoglicate
- Coughing, transient bronchospasm and throat irritation due to inhalation of the powder

Theophylline
- Although about 5% of the population experience minor adverse effects (nausea, diarrhoea, nervousness and headache), increasing the plasma concentration results in more serious effects. The following is a guide to the plasma levels at which the adverse reactions usually occur:
  - Above 20 mg/L: persistent vomiting, insomnia, gastro-intestinal bleeding, cardiac arrhythmias
  - Above 35 mg/L: hyperglycaemia, hypotension, more serious cardiac arrhythmias, convulsions, permanent brain damage and death
- Individual patients may suffer these effects at plasma levels other than those quoted, for example, convulsions have occurred in patients at 25 mg/L

Leukotriene receptor antagonists
- Abdominal pain, headache, diarrhoea, dizziness, upper respiratory tract infections. Rarely: acute hepatitis (associated with zafirlukast), Churg–Strauss syndrome

---

success. All have potentially toxic side effects and need to be closely monitored.

Acute severe asthma

The management of acute asthma depends on the severity of the attack and its response to treatment, as well as an appreciation of the patient's past history and present treatment. If an acute attack becomes persistent and difficult to treat, it is known as acute severe asthma. The aims of treatment are to prevent any deterioration in the patient's condition and hasten recovery.

Prevention. The ideal way of treating an acute attack is to empower patients to recognise when their condition is deteriorating so they can initiate treatment to prevent the attack becoming severe. This can be achieved with an individualised self-management plan.

The dose of inhaled β$_2$-agonist should be increased, and a short course of oral steroids commenced, for example, prednisolone at a dose of 40–50 mg every morning for 1 week. The dose of ICS is often also increased, but there is limited evidence to support this.

If the condition deteriorates further, hospital admission may become necessary. This could be a self-referral from the patient, responding to criteria drawn up by the doctor, such as their PEF falling below 50% of their usual best. The education of patients and their relatives in the management of

acute attacks should always stress the prompt initiation of further treatment and early referral.

Immediate management. The immediate treatment of acute severe asthma should take place in the patient's home if a moderate attack. Admission to hospital is considered if PEF drops below 50% predicted or normal, or the patient cannot complete sentences in one breath or is too breathless to talk, or if life-threatening features are present. A suggested treatment protocol for management in hospital is outlined in Fig. 25.5.

Management of severe acute asthma in adults in Emergency Department

Measure peak expiratory flow and arterial saturations

Time

PEF > 50–75% best or predicted
Moderate asthma

SpO$_2$ ≥ 92%
PEF > 50–75% best or predicted

no features of acute severe asthma

PEF 33– 50% best or predicted
Acute severe asthma
Features of severe asthma
- PEF < 50% best or predicted
- Respiration ≥ 2.5/min
- SpO$_2$ ≥ 92%
- Pulse ≥ 110 breaths/min
- Cannot complete sentence in one breath

PEF < 33% best or predicted
Life threatening asthma
- SpO$_2$ < 92%
- Silent chest, cyanosis, poor respiratory effort
- Arrhythmia, hypotension
- Exhaustion, altered consciousness

5 mins

Give salbutamol (give 4 puffs initially and give a further 2 puffs, every 2 minuutes according to response up to a maximum of 10 puffs preferably via spacer

Give salbutamol 5 mg by oxygen driven nebuliser

Obtain senior/ICU help now if any life threatening features are present

IMMEDIATE MANAGEMENT
- Oxygen to maintain SpO$_2$ 94–98%
- Salbutamol 5 mg plus ipratropium 0.5 mg via oxygen-driven nebuliser
- Prednisolone 40–50 mg orally or IV hydrocortisone 100 mg

15–20 mins

Clinically stable AND PEF > 75%

Clinically stable AND PEF < 75%

No life threatening features AND PEF 50–75%

Life threatening features OR PEF < 50%

Repeat salbutamol 5 mg nebuliser Give prednisolone 40–50 mg orally

Measure arterial blood gases
Markers of severity:
- 'Normal' or raised PaCO$_2$ (PaCO$_2$ > 4.6 kPa; 35 mmHg)
- Severe hypoxia (PaO$_2$ < 8 kPa; 60 mmHg)
- Low pH (or high H$^+$)

60 mins

Patient recovering AND PEF > 75%

No signs of severe asthma AND PEF 50–75%

Signs of servere asthma OR PEF < 50%

Observe and monitor
- SpO$_2$
- heart rate
- respiratory rate

- Give/repeat salbutamol 5 mg with ipratropium 0.5 mg by oxygen-driven nebuliser after 15 minutes
- Consider continuous salbutamol nebuliser 5–10 mg/hr
- Consider IV magnesium sulphate 1.2–2 g over 20 minutes
- Correct fluid/electrolytes, especially K$^+$ disturbances
- Chest x-ray
- Repeat ABG

120 mins

Patient stable AND PEF > 50%

Signs of severe asthma OR PEF < 50%

ADMIT
Patient should be accompanied by a nurse or doctor at all times

Potential discharge

- In all patients who received nebulised β$_2$ agonists prior to presentation, consider an extended observation period prior to discharge
- If PEF < 50% on presentation, give prednisolone 40–50 mg/day for 5 days
- In all patients ensure treatment supply of inhaled steroid and β$_2$ agonist and check inhaler technique
- Arrange GP follow up for 2 days post-discharge
- Fax or e-mail disharge letter to GP
- Refer to asthma liaison nurse/chest clinic

Peak expiratory flow rate — normal values

Height
Men
190 cm (75 in)
183 cm (72 in)
175 cm (69 in)
167 cm (66 in)
160 cm (63 in)

Height
Women
183 cm (72 in)
175 cm (69 in)
167 cm (66 in)

152 cm (60 in)

Age (years)

Fig. 25.5 Management of acute severe asthma in adults in hospital reproduced by permission of the Scottish Intercollegiate Guidelines Network from BTS/SIGN, 2009.

Oxygen is administered to achieve an oxygen saturation of 92% or more. A β_2-agonist is administered by metered dose inhaler (MDI) with a spacer attachment (4 puffs, then 2 puffs every 2 min until 10 mg or symptom relief) as there is no demonstrable difference between this and using a nebuliser. With more severe symptoms, or during an admission to hospital, nebulisers are used because they permit a high dose (10–20 times the dose of a MDI) and they require no coordination on the part of the patient between inspiration and actuation, which is helpful in those distressed. Patients undergoing an acute attack often have an inspiratory rate that is too low to use an MDI effectively.

Corticosteroids are also given in the acute attack; oral prednisolone (40–50 mg daily, for 5 days). Intravenous hydrocortisone (100 mg) should only be required if the patient cannot take oral medication. This reduces and prevents the inflammation that causes oedema and hypersecretion of mucus and hence helps to relieve the resultant smooth muscle spasm. The clinical response to both oral and parenteral steroids has an onset at 1–2 h with a peak effect at 6–8 h. If life-threatening features are present, such as cyanosis, bradycardia, confusion, exhaustion or unconsciousness, higher dose bronchodilators are used: nebulised salbutamol 5 mg with ipratropium bromide 500 μcg, repeated after 15 min; with subsequent consideration to continuous nebulisation of salbutamol at 5–10 mg/h. The addition of an anticholinergic such as ipratropium often gives a response that is greater than that of the two agents used alone.

Intravenous aminophylline can be given with a bolus dose of 250 mg over 30 min, followed by a continuous infusion of 500 μcg/kg/h. The bolus should be omitted if the patient is known to take oral theophylline or aminophylline. The choice between intravenous aminophylline and β_2-agonist depends on concurrent therapy and side effect profiles. The dose of intravenous aminophylline used must also take into account recent theophylline therapy in addition to other factors (Table 25.7). Serious toxicity can occur with parenteral aminophylline and patients must be carefully monitored for nausea and vomiting, the most common early signs of toxicity.

Table 25.7 Intravenous aminophylline dosing in acute severe asthma

	Aminophylline dose	Patient characteristics
Loading dose	5 mg/kg over 20–30 min	Adults and children
	3 mg/kg over 10–15 min	Previous theophylline therapy (although some authorities do not use a loading dose in these patients)
Maintenance dose	500 μcg/kg/h	Non-smoking adults
	700 μcg/kg/h	Children under 12 or smokers
	200 μcg/kg/h	Cardiac failure, liver impairment, pneumonia

If the aminophylline infusion is continued for more than 24 h, the plasma theophylline concentration may be measured to guide any necessary alteration in infusion rate in order to maintain the level in the optimum range of 10–20 mg/L.

Intravenous magnesium sulphate, 1.2–2 g as a 20-min infusion, has been shown to help in some patients who have not had a good response to initial treatment. There is, however, no evidence to support repeated dosing regardless of therapeutic outcome.

Further deterioration in condition may require assisted mechanical ventilation on an intensive care unit. Regular monitoring of arterial blood gases and oxygen saturation is performed to help detect any deterioration in condition.

Antibiotics are only indicated where there is evidence of a bacterial infection.

Ongoing management. The subsequent management of acute severe asthma depends on the patient's clinical response. All patients should be monitored throughout their treatment with objective measures of their PEFs before and after bronchodilator treatment and with continual monitoring of their arterial blood gas concentrations to ensure adequate oxygen is being given.

As the patient responds to treatment, infusions can be stopped and other treatment changed or tailed off as described above. As improvement continues, an inhaled β_2-agonist is substituted for the nebulised form and the oral corticosteroids stopped or reduced to a maintenance dose if clinically necessary. Throughout the treatment programme, potential drug interactions should be anticipated and managed appropriately (Table 25.8).

All patients should have a follow-up after an acute attack with symptoms monitored, reasons for admission addressed and inhaler technique checked. A self-management plan should be drawn up and discussed with each patient.

Patient care

The correct use of drugs and the education of patients are the cornerstones of asthma management. There are three main steps in the education of the asthmatic patient.

1. The patient should have an understanding of the action of each of the medicines they use.
2. The appropriate choice of inhalation device(s) should be made and the patient educated to use them correctly.
3. An individualised action (self-management) plan should be developed for each patient.

All members of the health care team should provide education and support for the asthmatic patient at regular intervals. The need for each patient to understand their asthma and its management must be balanced against the dangers of overwhelming the patient with information, particularly when the asthma has been newly diagnosed. To try to overcome this, a 'ladder of asthma knowledge' has been proposed. Patients are counseled in a gradual manner, each session adding to the previous one in content and reinforcing existing knowledge (Box 25.3).

Table 25.8 Common clinically significant interactions with drugs used in the management of asthma

Drug	Interacting drug	Probable mechanism and clinical result
β_2-Agonists	Methyldopa	Acute hypotension possible with β_2-agonist infusions
Corticosteroids	Anticoagulants	High-dose steroids enhance anticoagulant effect of coumarins
	Antifungals	Metabolism of steroids possibly affected by antifungal agents
	Barbiturates	Accelerates steroid metabolism
	β_2-Agonists	Increased risk of hypokalaemia with high doses
	Carbamazepine	Reduced steroid effect due to increased metabolism
	Ciclosporin	Increases plasma concentration of prednisolone
	Methotrexate	Increased risk of haematological toxicity
	Phenytoin	Reduced steroid effect due to increased metabolism
	Rifampicin	Reduced steroid effect due to increased metabolism
Theophylline	Azithromycin	May increase theophylline plasma levels
	β_2-Agonists (high dose)	Increased risk of hypokalaemia
	Carbamazepine	Induction of theophylline metabolism resulting in decreased plasma levels
	Clarithromycin	Inhibition of theophylline metabolism resulting in increased plasma levels
	Cimetidine	Inhibition of theophylline metabolism resulting in increased plasma levels
	Ciprofloxacin	Increased plasma concentration. Possible risk of convulsions
	Diltiazem	Increased theophylline plasma levels
	Erythromycin (oral)	Inhibition of theophylline metabolism resulting in increased plasma levels
	Fluconazole	Possible increase in theophylline plasma level
	Dihydropyridine calcium antagonists	May increase theophylline plasma levels
	Fluvoxamine	Increased theophylline plasma levels, halve theophylline dose
	Isoniazid	May increase theophylline plasma levels
	Ketoconazole	Possible increase in theophylline plasma level
	Lithium carbonate	Reducing plasma lithium concentrations as theophylline enhances lithium renal clearance
	Norfloxacin	Increased plasma concentration. Possible risk of convulsions
	Phenytoin	Plasma concentrations of theophylline and phenytoin both reduced
	Primidone	Induction of theophylline metabolism resulting in decreased plasma levels
	Rifampicin	Induction of theophylline metabolism resulting in decreased plasma levels
	Ritonavir	Metabolism of theophylline increased
	Smoking (tobacco)	Induction of theophylline metabolism resulting in decreased plasma levels
	St John's wort	Reduced theophylline plasma levels
	Verapamil	Increased theophylline plasma levels

Box 25.3 Ladder of asthma knowledge for patients

Step 1: Patient/carer understands what relief medication does, side effects which may occur, aims of treatment, what is happening to them and their chest. Education material is made available
Step 2: Patient/carer accepts and agrees about use of medication, importance of preventers and recognition of symptoms
Step 3: Patient/carer knows how to monitor PEF and symptoms, when to increase dose of inhaled steroids and contact their medical practice
Step 4: Patient/carer confident to manage own medication, increasing and decreasing dose using PEF or symptom monitoring, start oral steroids and attend their medical practice

Knowledge

Increasing the patients' knowledge about their asthma therapy is a necessary component of asthma management. However, education alone has not been shown to have a beneficial effect on morbidity. Education programmes must, therefore, also look at modifying their behaviour and attitude to asthma. Counselling should lead to increased patient confidence in the ability to self-manage asthma, thereby decrease hospital admission rates and emergency visits by primary care doctors, increase adherence and improve quality of life.

Specific counselling on drug therapy should concentrate on three areas: drugs used to relieve symptoms, drugs used to prevent asthma attacks, and drugs which are given only as reserve treatment for severe attacks.

Inhalation device

The choice of a suitable inhalation device is vital in asthma management. The incorrect use of inhalers will lead to sub-optimal treatment. A review of inhaler technique studies has concluded that up to 50% of patients in Europe are unable to use their inhaler correctly (Crompton et al., 2006). There is no demonstrable difference in efficacy between the various devices available. Other factors, therefore, need to be considered when choosing the appropriate device, including the patient's age, severity of disease, manual dexterity, co-ordination and personal preference. The range of different devices available for the drugs commonly used in asthma is shown in Table 25.9.

Table 25.9 Inhalation devices and spacer devices available

Drug	Type of inhaler device						
	Metered dose	Breath-actuated spacer for MDI	Single-dose spacer for MDI	Multiple-dose dry powder inhaler	Nebuliser dry powder inhaler	Large-volume	Small-volume
Salbutamol	✓	✓	✓	✓	✓	✓	✓
Ipratropium	✓		✓		✓		✓
Terbutaline				✓	✓		
Salmeterol	✓			✓			✓
Formoterol			✓				
Tiotropium[a]	✓[b]		✓				
Beclometasone	✓	✓	✓	✓			✓
Budesonide	✓			✓	✓	✓	✓
Ciclesonide	✓						✓
Fluticasone	✓			✓	✓	✓	✓
Mometasone				✓			
Cromoglicate	✓	✓	✓		✓		✓
Nedocromil	✓						✓

[a]Only licensed for use in COPD.
[b]Delivers a soft aerosol 'mist'.

Metered dose aerosol inhalers

The pressurised MDI is the most widely prescribed inhalation device in the UK (Fig. 25.6). It usually contains a solution or suspension of active drug, with a typical particle size of 2–5 µm, in a liquefied propellant. Operation of the device releases a metered dose of the drug with a droplet size of 35–45 µm. The increased droplet size is due to the propellant, which evaporates when expelled from the inhaler. Inhalers have now been switched from chlorofluorocarbon (CFC) propellants to newer, non-CFC, hydrofluoroalkanes.

MDIs have the advantage of being multidose, small and widely available for most drugs used in asthma management. Their main disadvantage is that correct use requires a good technique. A particular problem for many patients is co-ordinating the beginning of inspiration with the actuation of the inhaler. Even when this is done correctly, MDIs only deliver about 10% of drug to the airways, with 80% deposited in the oropharynx. Corticosteroids administered by MDIs can cause dysphonia and oral candidiasis. The candidiasis can be minimised either by advising patients to gargle with water after using the inhaler and to expel the water from the mouth afterwards, or by using a spacer device. Newer devices are utilising other mechanisms to produce an aerosol such as a soft mist inhaler (SMI) which may give benefits in lung deposition and ease of use.

Fig. 25.6 Pressurised metered dose inhaler.

Table 25.10 Inhaler device choice for children

Age group	Drug group	First choice device	Second choice device
0–2 years	All	MDI + spacer + facemask	Nebuliser
3–4 years	All	MDI + spacer	Nebuliser or dry powder
5–15 years	Bronchodilators	MDI or dry	Powder or breath-actuated MDI
5–15 years	Corticosteroids	MDI + spacer	Dry powder or breath-actuated MDI

Younger children, in particular, find MDIs difficult to use and the addition of a spacer device can make this easier, allowing inhalation over several ambient breaths.

The correct technique for using MDIs is as follows:

1. MDIs have a mouthpiece dust cap which has to be removed before use (patients may fail to remove this). The cap must be replaced after use to prevent subsequent inhalation of foreign bodies.
2. The MDI must be vigorously shaken. This distributes the drug particles uniformly throughout the propellant (newer CFC-free inhalers may be solutions and not require shaking – see manufacturer's literature). The MDI must be held upright.
3. The patient should breathe out gently, but not fully.
4. The tongue should be placed on the floor of the mouth and the inhaler placed between the lips, which are then closed round the mouthpiece.
5. The patient should now start to breathe in slowly and deeply through the mouth.
6. The canister is pressed to release the dose while the patient continues to breathe in. This synchronisation of inspiration and actuation, so that there is a supporting stream of air to carry the drug to the lungs, is probably the most common point of failure in those with bad inhalation technique. Patients who are very short of breath, for example, during a severe asthma attack, find this particularly difficult.
7. The breath is held for at least 10 s. This allows the drug particles reaching the periphery of the lung to settle under gravity. Using this technique, about 15% of a dose may reach the lungs. Exhalation should be through the nose.
8. If a second dose is required, 30–60 s should elapse before repeating the inhalation procedure to allow the dosing chamber to re-fill.

Studies indicate that personal tuition improves inhaler technique, particularly if regularly repeated. Other methods of instruction include videos (see http://medguides.medicines.org.uk/demonstrations.aspx), package inserts and information leaflets or booklets provided by organisations such as Asthma UK and the pharmaceutical industry. Regular patient review, at least annually, is recommended. This can be used as an opportunity to check technique, along with assessment of the ability to generate the appropriate inspiratory flow for the device (Broeders et al., 2009).

Metered dose inhaler with a spacer extension

Extension devices allow greater evaporation of the propellant, so reducing particle size and velocity. This also reduces oropharyngeal deposition and potentially increases lung deposition. Oral candidiasis and dysphonia (impaired voice) from ICSs may also be reduced by using these devices. Spacers are useful for people who have poor co-ordination between inspiration and actuation and several types of spacer are available. In younger children, these offer advantages over MDIs alone with respect to adherence. Recommendations (see Table 25.10) have been published regarding device choice (NICE, 2000, 2002).

Large-volume (750 mL) spacers are available such as the Volumatic® (Fig. 25.7); these are manufacturer specific and have not been assessed or licensed for use with devices of other companies. These spacers have one-way valves that allow several inhalations of one dose from the spacer's chamber. No co-ordination is required between actuation of the MDI and inhalation. A large-volume spacer can be used instead of a nebuliser to deliver high doses of a β_2-agonist in acute severe asthma attacks. Disadvantages of these spacers include their large size, which renders them less portable, and their proven efficacy only with inhalers from the same manufacturer. Spacers should be washed regularly in warm, soapy water and left to drip dry without rinsing. Cloths should not be used for drying a spacer as this affects the antistatic coating of plastic spacers. All spacers should be replaced every 6–12 months. Facemasks are available for young children.

Small- and medium-volume spacer devices are available, either as an integral part of the design of some MDIs or as
Fig. 25.7 Large-volume spacer (Volumatic®).

a separate device (Fig. 25.8). These spacers have also been used to compensate for poor inhaler technique in adults and reduce the oropharyngeal deposition of steroids. These are more convenient to carry around than the larger spacers. The published evidence of additional benefit from these devices in either increasing efficacy or decreasing adverse effects is more limited than with large volume spacers.

Breath-actuated metered dose inhalers

These MDIs are actuated automatically by inspiratory flow rates of about 22–36 L/min. A breath-actuated MDI is illustrated in Fig. 25.9. These eliminate the need for the correct co-ordination of inspiration and actuation but require priming before each actuation.
Fig. 25.8   Medium-volume spacer (Aerochamber Plus®).

Dry powder inhalers

Several types of dry powder inhalers (DPIs) are available. These are propellant free and are designed to be easier to use than conventional MDIs. They are useful for those who have difficulty co-ordinating an MDI and can be used by children as young as 4 years old. Table 25.10 sets out the recommendations for device choice in children.

DPIs are available as either single-dose or multiple-dose devices (Fig. 25.10). Single-dose devices pierce or break a gelatin capsule to release the contents and must be regularly cleaned to avoid powder clogging the device. Multiple-dose devices are preferred by many patients since they avoid having to reload for each dose. Care must be taken to hold these devices in the correct orientation to avoid the powder falling out of the device before inhalation. Patients commenced on DPIs are sometimes concerned at the absence of any taste or spray plume which they have become accustomed to when using an MDI; reassurance that this is perfectly normal and that correct use of the DPI (including a check that the device is not empty) will ensure that the required dose is delivered should overcome this problem.

Nebulisers

A nebuliser produces an aerosol by blowing air or oxygen through a solution to produce droplets of 5 µm or less in size. Nebulisers require little co-ordination from the patient as any drug is inhaled through a facemask or mouthpiece using normal tidal breathing. Only about 13%

Fig. 25.9   Breath-actuated metered dose inhaler (Easi-breathe®).

Fig. 25.10   Multiple-dose dry powder inhaler (Turbohaler®).

of the dose used is deposited in the lungs, but because the doses used are higher than those used in other aerosol devices, patients will generally receive a higher dose than from an MDI. However, in mild and moderate exacerbations of asthma, no benefit has been shown over using 4–6 puffs of a MDI.

Nebulisers are useful in patients who are unable to use conventional inhalers, for example, children under 2 years old, patients with severe attacks of asthma unable to produce sufficient inspiratory effort and those lacking the co-ordination to use other inhalers. Nebulised bronchodilators can be used in acute severe asthma attacks, often avoiding the need for intravenous drugs.

Most of the short-acting β_2-agonists, as well as ipratropium bromide, fluticasone, budesonide and sodium cromoglicate, are available for nebulisation.

The safe and correct use of nebulisers requires careful counselling, especially if they are to be used in the home. The following points are critical for the correct use of a nebuliser.

1. Nebulisers should only be driven by compressed air or by oxygen at flow rates of at least 5–6 L/min to ensure that droplets of the correct size are produced.
2. To maximise nebulised drug, a minimum volume of 3–4 mL should be nebulised. This volume is required to reduce the amount of drug that is unavoidably left in the 'dead-space' (typically about 1 mL) at the end of nebulisation. This 'dead space' is less with newer nebulisers and no further dilution of commercial nebuliser solutions is used. Sodium chloride 0.9% must be used if solutions are diluted.
3. Most nebuliser chambers are disposable but will last 3–4 months when used by a patient at home. The chamber must be emptied after use, and each day, the chamber should be rinsed in hot water and dried by blowing air through the device. Several centres advocate that once a week the chamber

should be sterilised using 0.02% hypochlorite to prevent bacterial contamination; the chamber is then thoroughly rinsed to remove all traces of hypochlorite and then dried.
4. The nebuliser should be serviced at least once a year.

There are disadvantages with the use of nebulisers. Of particular concern is the overreliance on the nebuliser by some patients which results in a delay in seeking medical advice. The high doses of bronchodilators used can also increase the incidence of side effects, and these vary depending on the drug nebulised.

Self-management programmes

Every individual with asthma should be considered for a self-management education programme. These programmes will contain structured education along with an individualised action plan. They aim to give the individual more confidence by involving them in the management of their own asthma. The individual should then be able to deal with any fluctuation in their condition and know when to seek medical advice. Personalised action plans have been shown to improve health outcomes in individuals with asthma (Gibson et al., 2002).

Key elements of an action plan include being able to monitor symptoms, measure peak flow, understand their medicine and how it should be used, and knowing how to deal with fluctuations in severity of asthma according to written guidance. Symptom diaries, management guidance cards and peak flow reading diary cards are available from organisations such as Asthma UK and pharmaceutical companies who manufacture asthma products.

An action plan can also include details of when to increase the dose of an inhaled steroid, when to take a short course of oral corticosteroids and when to self-refer to a general medical practitioner or local hospital (Table 25.11).

Table 25.11 Example of a personalised action plan setting out the action required in response to a given peak flow reading and/or symptoms

Peak flow	Example of symptoms	Action
>80% of personal best value	Intermittent or few symptoms	When required, β_2-agonist for symptom relief, continue regular inhaler corticosteroid, consider reducing the dosage every 3 months if stable
61–80% of best	Waking at night Symptoms of a cold	Double dose of inhaled corticosteroid if taking <400 μcg day BDP Start oral corticosteroid if taking >400 μcg/day BDP
40–60% of best	Increasing breathlessness or using a β_2-agonist every 2–3 h	Start oral corticosteroid course. Contact a doctor
<40% of best	Severe attack Poor response to β_2-agonist	Call emergency doctor or ambulance urgently

BDP, equivalent dose of beclometasone dipropionate.

Case studies

Case 25.1

Mr GT is 54 years old and has been diagnosed with asthma for 4 years. He is 180 cm tall and weighs 95 kg. He has recently been admitted to hospital with an acute exacerbation of his asthma, precipitated by a lower respiratory tract infection. During his admission, his steroid medication was altered from Qvar Easi-breathe® 100 μcg twice daily to Symbicort 400/12 Turbohaler® 1 puff twice daily. He also takes Salbutamol Easi-breathe® inhaler 200 μcg when required.

Questions

1. By how much has his ICSs dose been increased?
2. Should Mr GT be reviewed after discharge?
3. Would Mr GT benefit from self-management information and a personalised action plan?
4. Four months after his discharge, Mr GT has had no further exacerbations and his daily best PEF reading is around 520 L/min; he has no limitations of activity because of his asthma and uses his salbutamol inhaler between two and three times a week. How can Mr GT's level of asthma control be determined?
5. You determine that Mr GT's asthma is now controlled. Could his therapy now be stepped down? If so, how should this be done?

Answers

1. Qvar® is a hydrofluoroalkane CFC-free inhaler with microfine particles of a mass median diameter of 1.1 μm. Clinical studies show that adult patients require approximately half the dose of Qvar® to achieve the same degree of asthma control as with CFC-containing beclometasone inhalers. Care must always be taken when switching between ICS brands (see http://www.mhra.gov.uk/). Tables exist to help with determining equivalent doses (BTS/SIGN, 2009). Qvar® 200 μcg daily is equivalent to 400 μcg of other beclometasone/budesonide preparations, so Mr GT's ICS dose has been doubled.
2. He should be reviewed within 1 month of hospital discharge. This has been associated with a reduced risk of further acute episodes.
3. He would benefit from self-management information and a personalised action plan. The evidence of improved health outcomes for asthmatic patients is particularly good for those with moderate to severe disease and those who have had recent exacerbations.
   A personalised action plan should contain:

   • Advice about recognising loss of asthma control, as assessed by symptoms and PEF readings
   • The action to take if asthma deteriorates, including when and how to seek emergency help and when to commence a course of emergency oral steroids, which should be prescribed in advance.

4. Asthma control is usually assessed on the basis of clinical history, symptoms, inhaler usage and technique. An acute exacerbation is often indicative of poor control over a period of time.
   The level of asthma control for Mr GT can be determined by utilising tools such as the levels of asthma control in the GINA guidelines (GINA, 2009; Table 25.2) and the commonly used Royal College of Physicians, '3 questions':

• Have you had difficulty sleeping because of your asthma symptoms (including cough)?
• Have you had your usual asthma symptoms during the day (cough, wheeze, chest tightness or breathlessness)?
• Has your asthma interfered with your usual activities (e.g. housework, work/school, etc.)?

Management issues should also be discussed:
• Any issues of importance to the patient
• Inhaler technique must be checked, any deficiencies corrected, and if necessary a different device tried
• Adherence to prescribed medication should be assessed
• Mr GT has to be willing to try a step-down in his therapy. His ICS dose can be reduced slowly; a reduction of between 25% and 50% is usually tried every 3 months. A reduction to Symbicort® 200/6 1 puff twice daily could be attempted at this stage. The potential for worsening symptoms and the increased risk of exacerbation should be explained when step-down is attempted, particularly as the LABA dose is also being reduced. Opportunity should be taken to also promote general lifestyle advice:

  – Mr GT's body mass index is 29.3 and he is classed as overweight. He should be advised that a healthy diet and regular exercise will help with weight reduction and improve asthma control
  – Offer stop smoking advice if relevant
  – Advise him to avoid exposure to tobacco smoke
  – Provide allergen avoidance advice

Mr GT should be asked to keep twice daily PEF readings and a symptom diary. He will need to be reviewed again in 3 months unless symptoms deteriorate before then. Mr GT should be advised to consider increasing his medication again if his asthma deteriorates; his action plan can be adjusted accordingly.

Case 25.2

Mrs LJ is 32 years old and was recently diagnosed on hospital admission with breathlessness following exposure to cold air. You are conducting a follow-up review after her hospital admission.

Questions

1. What advice should you cover in your consultation with Mrs LJ? Mrs LJ tells you that she has a cat and wonders if this could be affecting her asthma.
2. What information can you give Mrs LJ on allergen avoidance?

Answers

1. Effective management of asthma requires a partnership between the patient and the health care professionals involved in providing the care. The aim is to enable and empower the patient to gain the confidence, skills and knowledge to take a major role in the management of their asthma (GINA, 2009). Open-ended questions such as 'If we could make one thing better about your asthma what would it be?' may help to elicit a patient-centred agenda (BTS/SIGN, 2009). Topics that should be covered in this and subsequent consultations include:

• Nature of the disease
• Nature of the treatment
• Identification of areas where the patient most wants treatment to have effect
• How to use the treatment, particularly inhaler technique. Websites with video instruction, such as http://www.medicines.org.uk/Guides/Pages/how-to-use-your-inhaler-videos can be used to reinforce verbal instruction and demonstration.

- Develop self-monitoring/self-assessment skills
- Negotiate a personalised action plan in light of identified patient goals
- Recognise and manage acute exacerbations
- Appropriate allergen or trigger avoidance, for example, smoking, pollen, exercise, air pollution and stress
- Ensure Mrs LJ has received a current influenza vaccination

Practical information and treatment plans should be reinforced with written instruction; this can also be from patient support groups such as Asthma UK http://www.asthma.org.uk/. Every subsequent consultation with any health care professional should be an opportunity to review reinforce and extend both knowledge and skills.

2. There is no doubt that increased allergen exposure in sensitised individuals is associated with an increase in asthma symptoms, bronchial hyperresponsiveness and deterioration in lung function (BTS/SIGN, 2009); this includes animal allergens. However, the removal of cats from the home has not been shown to always benefit individuals with asthma. The reduction of exposure to other allergens, such as house dust mite, may also be considered for their potential effect on asthma symptoms. There is no evidence for the effectiveness of dust mite reduction strategies (Getzsche and Johansen, 2008).

If Mrs LJ wishes to try and reduce the burden of allergens in her home, then the following can be considered:

- Complete barrier bed-covering systems
- Remove carpets
- Remove soft toys from beds for children
- High temperature washing of bed linen
- Use acaricides on soft furnishings
- Ensure good ventilation with or without dehumidification
- Use a high-efficiency vacuum cleaner with an inbuilt air filter to reduce cat allergens.

If these measures provide no benefit to asthma symptoms or quality of life after a trial of a few months, they should be stopped.

Case 25.3

Mr KM is a 49-year-old man who has been diagnosed with asthma since childhood. He also suffers from allergic rhinitis with symptoms following exposure to grass pollen in the early summer. He is also allergic to cats. Over the past 2 years his asthma has been steadily deteriorating with a marked reduction in his ability to walk without becoming breathless. He now experiences daily symptoms and is woken up at night several times a week with shortness of breath which is temporarily relieved using a salbutamol inhaler. His current medication is:

Salbutamol DPI 200 μcg when required (currently using three or four times every day)

Seretide-250® evohaler® 2 puffs twice daily
Montelukast 10 mg at night
Aminophylline m/r (Phyllocontin®) 450 mg twice daily

He has had five exacerbations in the past 18 months, requiring hospitalisation. His last admission was 1 month ago with a severe exacerbation requiring a short period of ventilation support. He was discharged with a course of prednisolone 40 mg daily for 14 days but has had to continue taking prednisolone and currently takes 10 mg daily.

··· .
Questions

1. At which step of the BTS/SIGN guidelines is Mr KM, and what is his likely diagnosis?
2. What should be the next step in his management?
3. Is there a link between asthma and allergic rhinitis?
4. Mr KM has a positive skin prick test for animal dander and his IgE titre measures 425 IU/L. Is Mr KM suitable for treatment for omalizumab and, if so, for how long should this be given?

··· .
Answers

1. He is at step 5, with uncontrolled asthma despite taking 1000 μcg of inhaled fluticasone daily (equivalent to 2000 μcg of beclometasone), a LABA, and three other medications, including oral steroids. It is likely that Mr KM has 'difficult to treat' asthma.
2. Mr KM should be referred to a respiratory specialist. He requires careful assessment which will include:

   - Confirmation or verification of the diagnosis of asthma, including asthma subsets such as steroid-resistant asthma (PEF increase less than 15% after 2 weeks of steroids), psychosocial asthma, premenstrual asthma, aspirin-induced asthma, rhinitis, occupational asthma, allergic bronchopulmonary aspergillosis
   - Identification of preventable causes of persistent symptoms
   - A review of inhaler technique
   - An assessment of adherence to treatment. A significant proportion of patients who may be considered difficult to treat are non-adherent with their corticosteroid therapy. The number of ICS and SABA inhalers dispensed per year can be an indicative measure of non-adherence
   - IgE titre.

3. Allergic rhinitis co-exists with asthma in the majority of patients. The rhinitis should be treated with intranasal steroids as this has been demonstrated to improve asthma morbidity.
4. Mr KM meets the criteria for omalizumab to be given. Omalizumab takes between 12 and 16 weeks to demonstrate effectiveness. Mr KM should be reviewed at 16 weeks and omalizumab only continued if there is a marked improvement in symptoms.

Chronic obstructive pulmonary disease

26

D. Cripps and K. P. Gibbs

Key points

- Chronic obstructive pulmonary disease (COPD) is a leading cause of morbidity and mortality worldwide.
- COPD is the most prevalent manifestation of obstructive lung disease and mainly comprises chronic bronchitis and emphysema.
- The reduction of exposure to tobacco smoke, occupational dusts, chemicals and pollutants is an important goal to prevent the onset and progression of COPD.
- Risk factors for COPD include host factors (α_1-antitrypsin deficiency and airway hyper-responsiveness) and exposures (tobacco smoke, occupational dusts and chemicals, indoor and outdoor pollutants, infections) and socio-economic status.
- Smoking cessation is the single most effective intervention to reduce the risk of developing COPD and slow disease progression. This should be the primary focus of management.
- The management of COPD should follow both national and international guidance.
- COPD care should be delivered by a multidisciplinary team; assessing and managing patients, advising patients on self-management strategies and exercise, identifying and monitoring patients at high risk of exacerbations and educating patients and other health professionals.
- Patients should undergo non-pharmacological pulmonary rehabilitation, such as breathing exercises.

Chronic obstructive pulmonary disease (COPD) is a disease state characterised by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases (GOLD, 2009).

COPD is a general term that covers a variety of other disease labels including chronic obstructive airways disease (COAD), chronic obstructive lung disease (COLD), chronic bronchitis and emphysema.

COPD has been defined (National Institute for Health and Clinical Excellence, 2010) as:

- Airflow obstruction with a reduced FEV_1/FVC ratio of less than 0.7.
- If FEV_1 is ≥80% of predicted normal, a diagnosis of COPD should only be made in the presence of respiratory symptoms, for example breathlessness or cough.

Epidemiology

COPD is the fifth leading cause of death in the UK and the fourth in the world. It is expected to rise to third position by 2020. It is estimated that over 3 million people have the disease in the UK, with 2 million having undiagnosed COPD (National Clinical Guideline Centre, 2010). COPD is the largest single cause of lost working days in the UK. It is accountable for more than 10% of all hospital admissions and directly costs the NHS around £491 m/year. The burden of COPD on the UK healthcare system exceeds that of asthma and is outlined in Table 26.1.

Respiratory diseases including chronic bronchitis are more common in areas of high atmospheric pollution and in people with dusty occupations such as foundry workers and coal miners. Areas that are highly industrialised generally have the highest incidence of COPD. The UK has around twice the rate of mortality from respiratory disease compared to the European average.

Pathology

The major pathological changes in COPD affect four different compartments of the lung and all are affected in most individuals to varying degrees (American Thoracic Society/ European Respiratory Society Task Force, 2004).

Central airways (<2 mm diameter, cartilaginous)

The bronchial glands hypertrophy and goblet cell proliferation occurs. This results in excessive mucus production (chronic bronchitis). Epidemiologically chronic bronchitis is defined as a chronic or recurrent cough with sputum production on most days for at least 3 months of the year during at least 2 consecutive years, in the absence of other diseases recognised to cause sputum production. There is a loss of ciliary function with increase in inflammatory cells, notably lymphocytes, macrophages and, later in the disease, neutrophils.

Table 26.1 Annual morbidity and mortality from COPD (National Clinical Guideline Centre, 2010)

	Hospital admissions	GP consultations	Deaths
England and Wales	130,000	1.4 million	30,000

Peripheral airways (<2 mm diameter, non-cartilaginous)

Bronchiolitis is present from early disease with a pathological increase in goblet cells and in inflammatory cells in the airway walls. With disease progression, fibrosis develops along with increased deposition of collagen in the airway walls.

Lung parenchyma (respiratory bronchioles, alveoli and capillaries)

In emphysema, elastases destroy elastin, thus resulting in dilation and destruction of the respiratory bronchioles and alveolar sacs and ducts. Because of this there is a loss of the alveolar wall attachments and peripheral airway collapse.

Emphysema is defined as an abnormal enlargement of the air spaces distal to the terminal bronchioles. There are two main forms: (1) centrilobular emphysema which involves dilation and destruction of respiratory bronchioles, alveolar ducts and alveoli and (2) panacinar emphysema which involves destruction of the whole acinus. The former predominates in COPD, the latter in patients with α_1-antitrypsin deficiency.

Pulmonary vasculature

Vessel walls thicken early in the course of the disease along with endothelial dysfunction. The vessel walls become infiltrated by inflammatory cells, including macrophages and lymphocytes, and there is increased vascular smooth muscle which can lead to pulmonary hypertension. In advanced disease, there is emphysematous destruction of the vascular bed and collagen deposition.

Aetiology

Tobacco smoking is the most important and dominant risk factor in the development of COPD but other noxious particles also contribute, such as occupational exposure to chemical fumes, irritants, dust and gases. A person's exposure can be thought of in terms of the total burden of inhaled particles. These cause a (normal) inflammatory response in the lungs. Smokers, however, seem to have an exaggerated response which eventually causes tissue destruction and impaired repair mechanisms. In addition to inflammation, the other main processes involved in the pathogenesis of COPD are an imbalance of proteinases and antiproteinases in the lungs, and oxidative stress.

Not all smokers go on to develop clinically significant COPD; genetic factors seem to modify each individual's risk. The age at which an individual begins smoking, total pack-years smoked and current smoking status are predictive of COPD mortality. Passive exposure to cigarette smoke may also contribute to respiratory symptoms and COPD by increasing the lungs' total burden of inhaled particles and gases (GOLD, 2009). Tobacco exposure is quantified in 'pack-years':

$$\text{Total pack years} = \frac{\text{Number of cigarettes smoked per day}}{20} \times \text{number of years of smoking}$$

Additional risk factors include the natural ageing process of the lungs. Males are currently more at risk of developing chronic bronchitis, but as the number of women who smoke increases, the incidence of chronic bronchitis in females will also rise. The major risk factors are summarised in Table 26.2.

Table 26.2 Risk factors for the development of COPD

Risk factor	Comment
Smoking	Risk increases with increasing consumption but there is also large interindividual variation in susceptibility
Age	Increasing age results in ventilatory impairment; most frequently related to cumulative smoking
Gender	Male gender was previously thought to be a risk factor but this may be due to a higher incidence of tobacco smoking in men. Women have greater airway reactivity and experience faster declines in FEV_1, so may be at more risk than men
Occupation	The development of COPD has been implicated with occupations such as coal and gold mining, farming, grain handling and the cement and cotton industries
Genetic factors	α_1-Antitrypsin deficiency is the strongest single genetic risk factor, accounting for 1–2% of COPD. Other genetic disorders involving tissue necrosis factor and epoxide hydrolase may also be risk factors
Air pollution	Death rates are higher in urban areas than in rural areas. Indoor air pollution from burning biomass fuel is also implicated as a risk factor, particularly in underdeveloped areas of the world
Socio-economic status	More common in individuals of low socio-economic status
Airway hyper-responsiveness and allergy	Smokers show increased levels of IgE, eosinophils and airway hyper-responsiveness but how these influence the development of COPD is unknown

Inflammation

COPD is characterised by chronic inflammation throughout the airways, parenchyma and pulmonary vasculature. This is a different pattern of inflammation from that of asthma, with an increase in neutrophils, macrophages and T-lymphocytes (particularly CD8[+]); increased eosinophils occur in some patients during exacerbations. These inflammatory cells cause the release of inflammatory mediators and cytokines such as leukotriene B4, interleukin-8 and tumour necrosis factor-α (TNF-α). Over time the actions of these mediators damages the lungs and leads to the characteristic pathological changes observed.

Proteinase and antiproteinase imbalance

The observation that α_1-antitrypsin-deficient individuals are at increased risk of developing emphysema has led to the theory that an imbalance between proteinases and antiproteinases leads to lung destruction. In COPD, there is either an increased production/activity of proteinases or a decreased production/activity of antiproteinases. The main proteinases, proteolytic enzymes such as neutrophil elastin are released by macrophages or neutrophils. The antiproteinases inhibit the damage caused by the proteolytic enzymes. The main antiproteinase is α_1-antitrypsin, also known as α_1-proteinase inhibitor. Cigarette smoke has been shown to inactivate this protein. Oxidative stress also decreases the activity of antiproteinases.

Oxidative stress

An imbalance of oxidants and antioxidants exists in COPD with the balance in favour of the oxidants. This state of oxidative stress contributes to the development of the disease by damaging the intracellular matrix, oxidising biological molecules which cause cell destruction and promoting histone acetylation. There also seems to be a link between oxidative stress and the poor response to corticosteroids seen in COPD. To work, corticosteroids must recruit histone deacetylase to switch off the transcription of inflammatory genes. In COPD, the activity of histone deacetylase is impaired by the oxidative stress, thereby reducing the responsiveness to corticosteroids. Cigarette smoke also impairs the function of histone deacetylase.

Pathophysiology

The pathogenic mechanisms and pathological changes described above lead to the physiological abnormalities of COPD: mucus hypersecretion, ciliary dysfunction, airflow limitation and hyperinflation, gas exchange abnormalities, pulmonary hypertension and systemic effects (American Thoracic Society/European Respiratory Society Task Force, 2004).

Mucus hypersecretion, ciliary dysfunction and complications

Enlarged mucus glands cause hypersecretion of mucus and the squamous metaplasia of epithelial cells results in ciliary dysfunction. These are typically the first physiological abnormalities in COPD.

Normally, cilia and mucus in the bronchi protect against inhaled irritants, which are trapped and expectorated. The persistent irritation caused by cigarette and other smoke causes an exaggeration in the response of these protective mechanisms and leads to inflammation of the small bronchioles (bronchiolitis) and alveoli (alveolitis). Cigarette smoke also inhibits mucociliary clearance, which causes a further build-up of mucus in the lungs. As a result, macrophages and neutrophils infiltrate the epithelium and trigger a degree of epithelial destruction. This, together with a proliferation of mucus-producing cells, leads to plugging of smaller bronchioles and alveoli with mucus and particulate matter.

This excessive mucus production causes distension of the alveoli and loss of their gas exchange function. Pus and infected mucus accumulate, leading to recurrent or chronic viral and bacterial infections. The primary pathogen is usually viral but bacterial infection often follows. Common bacterial pathogens include *Streptococcus pneumoniae*, *Moraxella catarrhalis* and *Haemophilus influenzae.*

Bronchiectasis is a pathological change in the lungs where the bronchi become permanently dilated. It is common after early attacks of acute bronchitis during which mucus both plugs and stretches the bronchial walls. In severe infections, the bronchioles and alveoli can become permanently damaged and do not return to their normal size and shape. The loss of muscle tone and loss of cilia can contribute to COPD because mucus has a tendency to accumulate in the dilated bronchi.

Airflow limitation and hyperinflation

Fibrosis and narrowing (airway remodelling) of the smaller conducting airways (<2 mm diameter) is the main site of expiratory airflow limitation in COPD. This is compounded by the loss of elastic recoil (destruction of alveolar walls), destruction of alveolar support/attachments and the accumulation of inflammatory cells mucus and plasma exudates during exercise. The degree of airflow limitation is measured by spirometry.

This progressive destructive enlargement of the respiratory bronchioles, alveolar ducts and alveolar sacs is referred to as emphysema. Adjacent alveoli can become indistinguishable from each other, with two main consequences. The first is loss of available gas exchange surfaces, which leads to an increase in dead space and impaired gas exchange. The second consequence is the loss of elastic recoil in the small airways, vital for maintaining the force of expiration, which leads to a tendency for them to collapse, particularly during expiration. Increased thoracic gas volume and hyperinflation of the lungs result. The causes of airflow limitation in COPD are summarised in Box 26.1.

Gas exchange abnormalities

This occurs in advanced disease and is characterised by arterial hypoxaemia with or without hypercarbia. The anatomical changes during COPD result in an abnormal distribution of ventilation and perfusion within the lungs and create the abnormal gaseous exchange.

Pulmonary hypertension and cor pulmonale

Pulmonary hypertension develops late in COPD after gas exchange abnormalities have developed. The thickening of the bronchiole and alveolar walls resulting from chronic inflammation and oedema leads to blockage and obstruction of the airways. Alveolar distension and destruction result in distortion of the blood vessels that are closely associated with the alveoli. This causes a rise in the blood pressure in the pulmonary circulation. Reduction in gas diffusion across the alveolar epithelium leads to a low partial pressure of oxygen in the blood vessels (hypoxaemia) due to an imbalance between ventilation and perfusion. By a mechanism that is not clearly established, chronic vasoconstriction results and causes a further increase in blood pressure and further compromises gas diffusion from air spaces into the bloodstream. The chronic low oxygen levels lead to polycythaemia, thereby increasing blood viscosity. In advanced disease, persistent hypoxaemia develops along with pathological changes in the pulmonary circulation. Sustained pulmonary hypertension results in a thickening of the walls of the pulmonary arterioles, with associated pulmonary remodelling and an increase in right ventricular pressure within the heart.

The consequence of continued high right ventricular pressure is eventual right ventricular hypertrophy, dilation and progressive right ventricular failure (cor pulmonale). Pulmonary oedema develops as a result of physiological changes subsequent to the hypoxaemia and hypercapnia, such as activation of the renin–angiotensin system, salt and water retention and a reduction in renal blood flow.

Systemic effects

Systemic inflammation and skeletal muscle wasting can occur in COPD which limit exercise capacity and worsen prognosis. Osteoporosis, depression, normocytic normochromic anaemia are potential sequelae, as well as increased risk of cardiovascular disease associated with elevated levels of C-reactive protein.

Clinical manifestations

Diagnosis

A diagnosis of COPD should be considered in any patient who has symptoms of cough, wheeze, regular sputum production or exertional dyspnoea and/or a history of exposure to COPD risk factors (see Table 26.2). Spirometry is then used to confirm the diagnosis. There is no single diagnostic test for COPD.

Clinical features

COPD is a progressive disorder, which passes through a potentially asymptomatic mild phase, before the moderate phase and then severe disease. The traditional description of COPD symptoms, particularly in severe disease, depends on whether bronchitis or emphysema predominate. Chronic bronchitic patients exhibit excess mucus production and a degree of bronchospasm, resulting in wheeze and dyspnoea. Hypoxia and hypercapnia (high levels of carbon dioxide in the tissues) are common. This type of patient has a productive cough, is often overweight and finds physical exertion difficult due to dyspnoea. The bronchitic patient is sometimes referred to as a 'blue bloater'. This term is used because of the tendency of the patient to retain carbon dioxide caused by a decreased responsiveness of the respiratory centre to prolonged hypoxaemia that leads to cyanosis, and also the tendency for peripheral oedema to occur. Bronchitic patients lose the ability to increase the rate and depth of ventilation in response to persistent hypoxaemia. The reason for this is not clear, but decreased ventilatory drive may result from abnormal peripheral or central respiratory receptors. As the disease progresses, patients will experience an increasing frequency of exacerbations of acute dyspnoea triggered by excess mucus production and obstruction. In severe disease, the chest diameter is often increased, giving the classic barrel chest. As obstruction worsens, hypoxaemia increases, leading to pulmonary hypertension. Right ventricular strain leads to right ventricular failure, which is characterised by jugular venous distension, hepatomegaly and peripheral oedema, all of which are consequences of an increase in systemic venous blood pressure. Recurrent lower respiratory tract infections can be severe and debilitating. Signs of infection include an increase in the volume of thick and viscous sputum, which is yellow or green in colour and may contain bacterial pathogens, squamous epithelial cells, alveolar macrophages and saliva, but pyrexia may not be present. Eventually, cardiorespiratory failure with hypercapnia will occur, which may be severe, unresponsive to treatment and result in death.

The clinical features of emphysema are different from those of bronchitis. A patient with emphysema will experience increasing dyspnoea even at rest, but often there is minimal cough and the sputum produced is scanty and mucoid. Generally,

bronchial infections tend to be less common in emphysema. The patient with emphysema is sometimes referred to as a 'pink puffer' because he or she hyperventilates to compensate for hypoxia by breathing in short puffs. As a result, the patient appears pink with little carbon dioxide retention and little evidence of oedema. The patient will breathe rapidly (tachypnoea), because the respiratory centres are responsive to mild hypoxaemia, and will have a flushed appearance. Typically, a patient with emphysema will be thin and have pursed lips in an effort to compensate for a lack of elastic recoil and exhale a larger volume of air. Such a patient will tend to use the accessory muscles of the chest and neck to assist in the work of breathing. Hypoxaemia is not a problem until the disease has progressed. Emphysema patients will become progressively dyspnoeic, without exacerbations triggered by increased sputum production. Eventually, cor pulmonale will develop very rapidly, usually in the late stages of the disease, leading to intractable hypercapnia and respiratory arrest. The bronchitic 'blue bloater' and emphysemic 'pink puffer' represent two ends of the COPD spectrum. In reality, the underlying pathophysiology may well be a mixture, and the resulting signs and symptoms somewhere between the two extremes described.

The clinical progress of COPD depends on whether bronchitis or emphysema predominates.

Additional specific problems are also common in patients with COPD:

- Obstructive sleep apnoea hypopnoea syndrome (OSAHS)
- Acute respiratory failure

The sleep apnoea syndrome is a respiratory disorder characterised by frequent or prolonged pauses in breathing during sleep. It leads to a deterioration in arterial blood gases and a decrease in the saturation of haemoglobin with oxygen. Hypoxaemia is often accompanied by pulmonary hypertension and cardiac arrhythmias, which may lead to premature cardiac failure.

Acute respiratory failure is said to have occurred if the PaO_2 suddenly drops and there is an increase in $PaCO_2$ that decreases the pH to 7.3 or less. The most common cause is an acute exacerbation of chronic bronchitis with an increase in volume and viscosity of sputum. This further impairs ventilation and causes more severe hypoxaemia and hypercapnia. The clinical signs and symptoms of acute respiratory failure include restlessness, confusion, tachycardia, cyanosis, sweating, hypotension and eventual unconsciousness.

Investigations

Lung function tests are used to assist in diagnosis. A spirometer is used to measure lung volumes and flow rates. The main measurement made is the forced expiratory volume in the first second of exhalation (FEV_1). Other tests can be performed, such as:

- *Vital capacity (VC)*: the volume of air inhaled and exhaled during maximal ventilation;

- *Forced vital capacity (FVC)*: the volume of air inhaled and exhaled during a forced maximal expiration after full inspiration;
- *Residual volume (RV)*: the volume of air left in the lungs after maximal exhalation.

Airflow obstruction is defined as:

- FEV_1 less than 80% of that predicted for the patient and
- FEV_1/FVC less than 0.7.

VC decreases in bronchitis and emphysema. RV increases in both cases but tends to be higher in patients with emphysema due to air being trapped distal to the terminal bronchioles. Total lung capacity is often normal in patients with bronchitis but is usually increased in emphysema, again due to air being trapped. Smoking increases the normal deterioration in FEV_1 over time, from about 30 mL/year to about 45 mL/year. The major criticism of measuring FEV_1 and FVC is that they detect changes only in airways greater than 2 mm in diameter. As airways less than 2 mm in diameter contribute only 10–20% of normal resistance to airflow, there is usually severe obstruction and extensive damage to the lungs by the time the lung function tests (FEV_1 and FVC) detect abnormalities. Additionally, lung function tends to deteriorate with age even in the absence of COPD, and so use of FEV_1/FVC can lead to overdiagnosis in the elderly. Underdiagnosis may also be a problem in patients under 45 years of age.

Both UK and international COPD guidelines use spirometry to categorise the severity of COPD. These are summarised in Table 26.3. Testing should be carried out after a dose of inhaled bronchodilator to prevent overdiagnosis or overestimation of severity.

At diagnosis and evaluation, patients may receive other investigations as outlined in Table 26.4.

Chest radiographs reveal differences between the two disease states. A patient with emphysema will have a flattened diaphragm with loss of peripheral vascular markings and the appearance of bullae. These are indicative of extensive trapping of air. A patient with bronchitis will have increased bronchovascular markings and may also have cardiomegaly (increased cardiac size due to right ventricular failure) with prominent pulmonary arteries.

Table 26.3 Assessment of severity of airflow obstruction (adapted from National Institute for Health and Clinical Excellence, 2010; GOLD, 2009)

FEV_1	Severity (NICE)	Severity (GOLD)
Greater than 80% predicted		Stage I: Mild
50–80% predicted	Mild	Stage II: Moderate
30–49% predicted	Moderate	Stage III: Severe
Less than 30% predicted	Severe	Stage IV: Very severe

Table 26.4 Additional investigations at the diagnosis of COPD

Investigation	Note
Chest X-ray	To exclude other pathologies
Full blood count	To identify anaemia or polycythaemia
Serial domiciliary peak flow measurements	To exclude asthma if there is a doubt about diagnosis
α_1-Antitrypsin	Particularly with early-onset disease or a minimal smoking/family history
Transfer factor for carbon monoxide	To investigate symptoms that seem disproportionate to the spirometric impairment
CT scan of the thorax	To investigate symptoms that seem disproportionate to the spirometric impairment To investigate abnormalities seen on the chest X-ray To assess suitability for surgery
ECG	To assess cardiac status if features of cor pulmonale
Echocardiogram	To assess cardiac status if features of cor pulmonale
Pulse oximetry	To assess need for oxygen therapy If cyanosis or cor pulmonale is present or if FEV_1 <50% of predicted value
Sputum culture	To identify organisms if sputum is persistently present and purulent

Treatment

Stable COPD

Drug treatments, together with other measures such as physiotherapy and artificial ventilation, have not been shown to improve the natural progression of COPD. Quality of life and symptoms will, however, improve with suitable treatment and it is likely that the correct management of the patient will lead to a reduction in hospital admissions and prevent premature death. In patients with severe COPD and hypoxaemia, long-term oxygen therapy (LTOT) is the only treatment known to improve the prognosis.

The aims of treatment for patients with COPD are shown in Box 26.2 and the common therapeutic problems associated with COPD in Box 26.3. Drug treatment itself can only relieve symptoms; it does not modify the underlying pathology. Most patients with COPD are considered to have irreversible obstruction, in contrast to patients with asthma, but a significant number do seem to respond to bronchodilators.

Smoking cessation

Smoking is the most important factor in the development of obstructive airways disease. All COPD patients who are still smoking, regardless of age, should be encouraged to stop and be offered help to do so, at every opportunity. Unless contraindicated, all patients who are planning to stop smoking should be offered nicotine replacement therapy (NRT), varenicline or bupropion, as appropriate along with a support programme (NRT) (National Institute for Health and Clinical Excellence, 2010). Individually targeted advice may prove to be more successful in persuading individuals to give up, especially in those who are well.

Bronchodilators

Bronchodilators in COPD are used to reverse airflow limitation. As the degree of limitation varies widely, their effectiveness should be assessed in each patient using respiratory function tests and by assessing any subjective improvement reported by the patient. Patients may experience

---

Box 26.2 Treatment aims for patients with COPD

- Prevent disease progression
- Relieve symptoms
- Improve exercise tolerance
- Improve health status
- Prevent and treat complications such as hypoxaemia and infections
- Prevent and treat exacerbations
- Reduce mortality

Box 26.3 Common therapeutic problems associated with COPD

- Failure of patient to stop smoking
- Inadequate inhaler technique leading to subtherapeutic dosing
- Poor adherence with treatment regimen
- Inappropriate prescribing of antibiotics in an acute exacerbation of COPD
- Failure to properly assess a patient for home nebuliser therapy
- Failure to ensure adherence to 15 h a day of home oxygen therapy

improvements in exercise tolerance or relief of symptoms such as wheeze and cough. Treatment options for the use of bronchodilators and inhaled corticosteroids (ICSs) are outlined in Fig. 26.1.

Initial empiric therapy with short-acting bronchodilators, prescribed 'when required', for the relief of breathlessness and exercise limitation are recommended for initial use (National Institute for Health and Clinical Excellence, 2010). If patients remain breathless or have exacerbations despite short-acting bronchodilators then maintenance therapy is recommended, with:

- $FEV_1 \geq 50\%$ predicted: long-acting β_2-adrenoceptor agonist (LABA) or long-acting antimuscarinic (LAMA)
- $FEV_1 < 50\%$ predicted: a combination of either LABA and ICSs or LABA and LAMA

If the patient remains breathless, or has exacerbations, then triple therapy should be considered (i.e. ICS and LABA in a combination inhaler together with a LAMA).

Short-acting bronchodilators (short-acting β_2-adrenoceptor agonist or short-acting antimuscarinic). Selective β_2-agonists provide rapid relief and have a low incidence of side effects. Inhaled treatment is as efficacious as oral agents and is, therefore, preferred because of fewer side effects. The dose–response curve for β_2-agonists in COPD is almost flat and there is little benefit in giving more than 1 mg. The effects of short-acting β_2-agonists last for 4 h and they should be used 'as required' for symptom relief. Used before exercise, they can improve exercise tolerance. Poor patient response to bronchodilators may be due to poor inhalation technique, so this should be checked as often as possible and the inhaler device changed if necessary.

In patients with COPD, parasympathetic (vagal) airway muscle tone is the major reversible component. Inhaled anticholinergic drugs reverse this vagal tone and have a significant bronchodilator effect, especially in the elderly.

Long-acting bronchodilators. Long-acting bronchodilators include LAMAs and LABAs. The only LAMA in the UK, tiotropium, has a 24-h duration of action and can reduce exacerbation rates, increase exercise tolerance and reduce rates of hospital admissions, though not the rate of decline in lung function. There is no strong evidence to favour either a LABA or LAMA for monotherapy (National Clinical Guideline Centre, 2010).

High-dose bronchodilators. Some patients with distressing or debilitating breathlessness despite maximal inhaled therapy may benefit from higher doses, either by inhaler or via a nebuliser. These patients should have their inhaled therapy optimised, possibly using a protocol as outlined in Box 26.4.

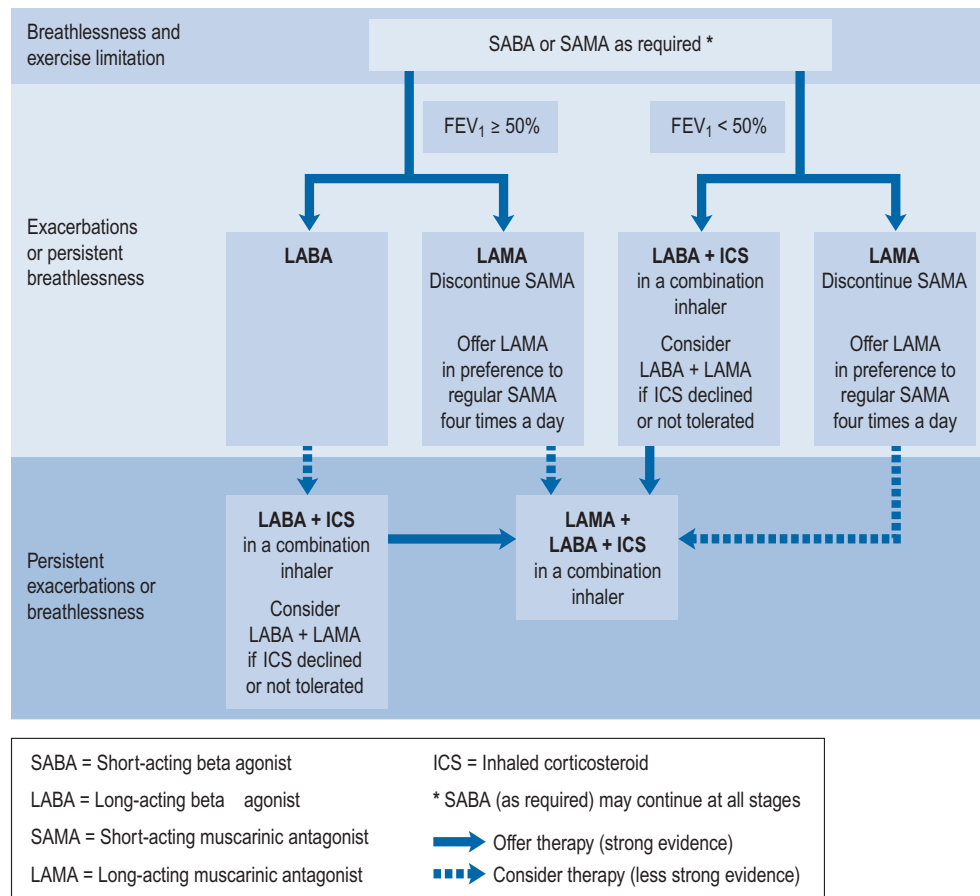
Theophylline. Theophylline is a weak bronchodilator but seems to have useful additional physiological effects in COPD


Fig. 26.1 Stepwise approach to the pharmacological management of chronic COPD (National Institute for Health and Clinical Excellence, 2010; with kind permission from National Institute for Health and Clinical Excellence).

1. Assessment by a respiratory specialist. Check diagnosis and confirm severity. Ensure optimal inhaler technique

2. Ensure all other therapies have been tried

3. Optimise hand-held inhaler dosing, for example:
   - Salbutamol 200–400 μcg four times a day
   - Ipratropium bromide 40 μcg four times a day or tiotropium 18 μcg once daily
   or a combination of these agents

4. Try further increasing the dose of the hand-held inhaler to:
   - Salbutamol up to 1 mg four times a day, and/or
   - Ipratropium bromide up to 160 μcg four times a day (although the effect of alternative use of tiotropium at this stage is unknown)
   These doses are unlicensed in the UK

5. If a poor response at step 4, consider a period of home nebulizer therapy with careful examination of patient response, over at least 2 weeks
   - Reduction in symptoms
   - An increase in the patient's ability to undertake activities of daily living
   - An increase in exercise capacity
   - An improvement in lung function
   - The occurrence of side effects such as tachycardia and tremor

6. Initial therapy: try nebulised salbutamol 2.5 mg or terbutaline 5 mg four times a day and assess response at 2 weeks

7. If the response to monotherapy is poor, consider one or more of the following:
   - Salbutamol 5 mg or terbutaline 10 mg four times a day, or
   - Iptratropium bromide 250–500 μcg four times a day, or the combination
   - Salbutamol 2.5–5 mg and ipratropium 500 μcg four times a day

8. Decide which treatment in step 7 was the most beneficial

such as increased respiratory drive, improved diaphragmatic function and improved cardiac output, although the exact clinical benefits have not been quantified. The use of theophylline should only be considered after a trial of short acting with long-acting bronchodilators. Whenever theophylline is tried in the management of COPD, an initial therapeutic trial of several weeks should be carried out. If subjective and objective measures of lung function show an improvement, then theophylline can be continued as maintenance therapy. Persistent nocturnal symptoms such as cough or wheeze may be helped by the night-time use of long-acting theophylline.

Care must be taken when prescribing theophylline. Its clearance is affected by many factors, including cigarette smoking, viral pneumonia, heart failure and concurrent drug treatment, such as macrolide antibiotics used during exacerbations (see Chapter 25).

Theophylline is being investigated in low concentrations for its ability to reverse the decrease in histone deacetylase

activity associated with oxidative stress. This may prove to be of benefit in reversing corticosteroid resistance.

Corticosteroids

Patients with COPD show a poor response to corticosteroids and have a largely steroid-resistant pattern of inflammation (Barnes, 2004). It is postulated that the oxidative stress of COPD inhibits the mechanism by which corticosteroids, acting through histone deacetylase, switch off activated inflammatory genes.

The long-term benefits of ICSs in COPD have only been shown in patients with moderate-to-severe disease, with an FEV_1 less than 50% of predicted value and who are having exacerbations requiring treatment with antibiotics and oral corticosteroids (National Institute for Health and Clinical Excellence, 2010). A reduction in the number of exacerbations and a slowing of the decline in health status have been shown, but these have no effect on improving lung function and result in an increased risk of pneumonia.

ICSs should be used, although there is no consensus over the minimum effective dose. In the UK, no inhaled steroid is licensed for use in COPD except when used with LABA in combination devices.

There is little place for oral steroids in stable COPD. Some patients with advanced disease may require maintenance oral therapy if this cannot be withdrawn after a short course prescribed to treat an exacerbation. In this instance, the lowest dose possible should be used. The patient should be regularly assessed for osteoporosis and the need for osteoporosis prevention. Patients over 65 years receiving maintenance therapy should automatically receive prophylactic treatment for osteoporosis.

Mucolytics

Mucolytics may be of benefit in stable COPD if there is a chronic cough productive of sputum. Benefit must be assessed, for example, with a reduction in the frequency of cough and/or sputum production. If there is no benefit, then mucolytics should be stopped.

Antibiotics and immunisation

Prophylactic antibiotics have no place in the management of COPD. Antibiotic therapy is, however, vital if a patient develops purulent sputum. If a patient frequently develops acute infective exacerbations of bronchitis then they should be given a supply of antibiotics to keep at home to start at the first sign of an exacerbation.

Initial routine sputum cultures are unhelpful in these patients as they are unreliable in identifying the pathogenic organisms.

The normal pathogens involved are *S. pneumoniae*, *H. influenzae* or *M. catarrhalis*. The usual antibiotics of choice are co-amoxiclav, amoxicillin, erythromycin or doxycycline. If the infection follows influenza, *Staphylococcus aureus* may be present and an anti-staphylococcal agent such as flucloxacillin should be added to the regimen. If the infection is considered atypical in presentation or if the purulent sputum is still present after 1 week of treatment, then sputum cultures

should be taken to try to identify the pathogenic organisms. A single dose of pneumococcal vaccine and annual influenza vaccinations have been shown to reduce hospitalisations and the risk of death in the elderly with chronic lung disease, and should be offered to those with chronic airflow obstruction. The prevalent strains of influenza change, so the vaccine composition is, correspondingly, altered annually.

Acute exacerbations of COPD

Patients with COPD suffer acute worsenings of the disease, referred to as acute exacerbations. These exacerbations can be spontaneous but are often precipitated by infection and lead to respiratory failure with hypoxaemia and retention of carbon dioxide. Many patients can be managed at home (see National Institute for Health and Clinical Excellence, 2010) but some will require admission to hospital.

Bronchodilators

Bronchodilators are used to treat the increased breathlessness that is associated with exacerbations. These can be given by metered-dose inhaler (MDI) or nebuliser, although practically breathless patients are often unable to use MDIs effectively. A β_2-agonist can be given with or without an anticholinergic agent, depending on the benefits obtained.

Antibiotics

Bacteria can be isolated from the sputum of patients with stable COPD but antibiotics can be used to treat exacerbations of COPD associated with a history of more purulent sputum. The choice of antibiotic should be dependent on local policy, sensitivity patterns and any previous treatments. An amino-penicillin or a macrolide with increased activity against *H. influenzae* or oxytetracycline is generally suitable as a first-line agent. Sputum should be sent for culture in order to check the appropriateness of initial therapy, and the antibiotic changed if necessary.

Corticosteroids

A short course of oral steroids has been shown to benefit FEV_1 and reduce the duration of hospitalisation. Patients managed at home who have increased breathlessness which interferes with daily activities and all those admitted to hospital should be treated. A suitable course is prednisolone 30 mg every morning, given for 7–14 days.

Other treatment

Intravenous aminophylline can be considered, if there is an inadequate response to bronchodilators. The loading dose and maintenance dose required should be carefully chosen as these depend on various factors (see Chapter 25).

Oxygen therapy is necessary to improve hypoxia. In about a quarter of patients with COPD, a predisposition to carbon dioxide retention will be present. Administration of high concentrations of oxygen to these individuals can lead to an increase in retention of carbon dioxide and, thus, to respiratory acidosis. The widely held view that this effect is due to loss of hypoxic ventilatory drive has been questioned; a more complex process involving a mismatch between ventilation and perfusion is now thought to play a significant role. The goal is an initial oxygen saturation of between 88% and 92% to avoid respiratory acidosis but to allow enough oxygen to be administered to overcome potentially life-threatening hypoxia (O'Driscoll et al., 2008). The initial concentration used should be 24–28% and then titrated to oxygen saturation. Arterial blood gases should be monitored regularly.

During an acute attack, pyrexia, hyperventilation and the excessive work of breathing can result in an inability to eat or drink. This can lead to dehydration which requires treatment with intravenous hydration.

Chest physiotherapy is employed to mobilise secretions, promote expectoration and expand collapsed lung segments. Nebulised 0.9% sodium chloride has also been used to help.

Although largely superseded by non-invasive ventilatory support, doxapram (as a continuous infusion at a rate of 1–4 mg/min) can be tried in patients with acute respiratory failure, carbon dioxide retention and depressed ventilation. Doxapram stimulates the respiratory and vasomotor centres in the medulla, increases the depth of breathing and may slightly increase the rate of breathing. Arterial oxygenation is usually not improved because of the increased work of breathing induced by doxapram. This agent has a narrow therapeutic index with side effects such as arrhythmias, vasoconstriction, dizziness and convulsions and may be harmful if used when the $PaCO_2$ is normal or low.

Treatment of hypoxaemia and cor pulmonale

COPD is responsible for over 90% of cases of cor pulmonale. Although patients often tolerate mild hypoxaemia, once the resting PaO_2 drops below 8 kPa signs of cor pulmonale develop. Treatment is symptomatic and involves managing the underlying airways obstruction, hypoxaemia and any pulmonary oedema that develops. Peripheral oedema is managed using thiazide or loop diuretics, although there are concerns over their metabolic effects reducing respiratory drive. Oxygen is used to treat hypoxaemia, and this should also promote a diuresis. All patients should be assessed for the need for LTOT.

Domiciliary oxygen therapy

The aim of therapy is to improve oxygen delivery to the cells, increase alveolar oxygen tension and decrease the work of breathing to maintain a given PaO_2. Domiciliary oxygen therapy can be given in two ways.

Intermittent (short burst) administration. Intermittent administration is used to increase mobility and capacity for exercise and to ease discomfort. Intermittent administration is of most benefit in patients with emphysema.

Continuous LTOT. LTOT for at least 15 h/day has been shown to improve survival in patients with severe, irreversible

airflow obstruction, hypoxaemia and peripheral oedema (MRC Working Party, 1981). LTOT can only be prescribed if specific conditions are met, as described in Box 26.5. The main aim of treatment is to achieve a PaO_2 of at least 8 kPa without causing a rise in $PaCO_2$ of more than 1 kPa, achieved by adjusting the oxygen flow rate. Before LTOT can be prescribed each individual must be assessed accordingly (see Box 26.5).

Oxygen can be prescribed as oxygen cylinders but 15 h/day at 2 L/min requires ten 1340-L cylinders a week. A more convenient system is to use a concentrator, which converts ambient air to 90% oxygen using a molecular sieve. The concentrator is sited in a well-ventilated area in the home with plastic tubing to terminals in rooms such as the living room and bedroom. Tubing from the terminals delivers oxygen to the patient, who wears a mask or uses the more convenient nasal prongs. This tubing should be long enough to allow some mobility.

Patient care

Pulmonary rehabilitation

Early pulmonary rehabilitation should be considered for patients at all stages of disease progression when symptoms and disability are present. Patients should participate in a co-coordinated programme of non-pharmacological treatment including:

- advice and support to stop smoking
- nutritional assessment
- aerobic exercise training to increase capacity and endurance for exercise
- strength training for upper and lower limbs
- relaxation techniques
- breathing retraining, for example, diaphragmatic and pursed lips breathing to improve the ventilatory pattern and improve gas exchange
- education about their medicines, nutrition, self-management of their disease and lifestyle issues
- psychological support because COPD patients often have decreased capacity to participate in social and recreational activities and can become anxious, depressed or fatigued.

A multidisciplinary team should deliver these programmes and should include a minimum of 6 and a maximum of 12 weeks of physical exercise, disease education, psychological and social interventions (National Institute for Health and Clinical Excellence, 2010).

Pulmonary rehabilitation programmes that include at least 4 weeks exercise training have been shown to improve dyspnoea and exercise capacity. The long-term effects, however, of these programmes has yet to be established, although personalised education to COPD patients about their condition has been shown to reduce their need for health services.

Stopping smoking

The health hazards associated with smoking are well known and publicised. To give up smoking, which has been described as a form of drug addiction, requires self-motivation. Stopping smoking does not, however, have an immediate effect. A reduction in COPD mortality is not seen until about 10 years or more after cessation of smoking.

Members of the healthcare team can educate smokers about the dangers and actively encourage and motivate those who want to give up. Brief conversations between individuals and health professionals about stopping smoking are both effective and cost-effective in encouraging individuals to quit (National Institute for Health and Clinical Excellence, 2006).

Once a decision to quit has been made, it is the degree of dependence rather than the level of motivation that will influence the success rate. Smokers need both initial advice from all healthcare professionals and follow-up support. For example, especially in the early stages, symptoms such as coughing increase after the cigarettes are stopped. The patient must be closely supported to avoid a return to the habit. Strategies such as individual behavioural counselling, group behaviour therapy and use of self-help materials and telephone counselling and 'quit lines' have been advocated as effective interventions.

There are a number of therapeutic options to help an individual to stop smoking and these include NRT, bupropion and varenicline.

Nicotine replacement

The major mode of action of NRT is thought to involve stimulation of nicotine receptors in the brain and the subsequent release of dopamine. This, together with the peripheral effects of nicotine, leads to a reduction in nicotine withdrawal symptoms. NRT may also act as a coping mechanism, making cigarette smoking less rewarding. NRT does not, however, completely eliminate the effects of withdrawal as none of the available products reproduces the rapid and high levels of nicotine obtained from cigarettes.

There is little research comparing the relative effectiveness of NRT products, but all seem to have similar success rates. Choice of product should be made on the number of cigarettes smoked (irrespective of the nicotine content), the smoker's personal preference and tolerance to side effects. An individual is more likely to adhere to the cessation programme if using a product which suits him or her. The types of NRT available are summarised in Table 26.5.

NRT approximately doubles smoking cessation rates compared with controls (either placebo or no NRT), irrespective of the intensity of adjunctive therapy. The strongest evidence is

Table 26.5 Comparison of selected nicotine replacement products

Formulation	Use and comments	Specific side effects
Patch: 24 h: 7, 14 and 21 mg; 16 h: 5, 10, 15 and 25 mg	One daily on clean, non-hairy, unbroken skin. Remove before morning (16 h) or next morning (24 h). Apply to fresh site or non-hairy skin, usually at the hip, trunk or upper arm. Should not be applied to broken skin	Local skin irritation and rashes, insomnia. Do not use with generalised skin disease
Gum: 2 and 4 mg	Chew until taste is strong then rest gum between gum and cheek; chew again when taste has faded. Repeat this for 30 min or until taste dissipates. Avoid acidic drinks for 15 min before and during chewing the gum	Jaw ache, headache and dyspnoea. Mild burning sensation in the mouth and throat
Sublingual tablet: 2 or 4 mg each	Rest under tongue until dissolved	
Lozenge: 1, 2 or 4 mg each	Place between gum and cheek and allow to dissolve. Delivers slightly more nicotine than the equivalent gum	Nasal irritation, rhinorrhoea, sneezing, throat irritation and cough. This usually dissipates with continued use
Inhalator: 10 mg per cartridge	Inhale as required. Helps to satisfy the hand-to-mouth ritual of using a cigarette which may help some people. The nicotine is absorbed through the mouth rather than the lungs. Use with caution in people with asthma	Nasal irritation, rhinorrhoea, sneezing, throat irritation and cough. This usually dissipates with continued use
Nasal spray: 500 μcg per spray	One spray into each nostril as needed. More rapidly absorbed than other forms of NRT so often used for acute relief of cravings. Not recommended for people with nasal or sinus conditions, allergies or asthma	

for use of patches and gum. The choice of product and initial dose is also influenced by the degree of tobacco dependence; heavy smokers (15 to 20+ cigarettes a day and/or smoking within 30 min of waking) will require higher NRT doses. The available types of NRT product are set out below:

Long acting. Long-acting transdermal patches are considered to be most suitable for people who smoke regularly through the day. The 24-h patch, worn overnight, is better for people who crave nicotine first thing in the morning. Use of the patch can cause insomnia or vivid dreams and so can either be removed before bedtime or a 16-h patch used instead. Heavy smokers should be started on the high-dose patches.

Short acting. There are several short-acting products available:

Gum. It is important to chew nicotine gum correctly. The gum should be chewed slowly until the taste becomes strong and then allowed to rest between the cheek and teeth to allow absorption. When the taste has faded the gum should be chewed again. Nicotine gum is not a good choice for people with dentures or other vulnerable dental work. Most gum users do not consume enough in a day to match the nicotine levels from smoking. Patients should be encouraged to use 10–15 pieces of gum a day, for example, as one piece an hour.

Lozenge. These are allowed to dissolve in the mouth and periodically moved around, until completely gone. One lozenge per hour is recommended during the initial period of use to provide adequate nicotine absorption.

Inhalator. Inhalators may be particularly useful for people who miss the physical act of smoking. Nicotine is absorbed via the buccal mucosa, peaking in 20–30 min. To achieve sufficient blood levels, the user should puff on the inhalator for 2 min each hour, changing the cartridge after three 20-min sessions.

Nasal spray. A nasal spray is most useful for people who smoke 20 or more cigarettes per day. The side effects of sneezing and a burning sensation in the nose usually wear off after a day or two, so patients should be encouraged to persevere.

Sublingual tablets. These tablets dissolve under the tongue and may be useful for people with dentures who have difficulty using nicotine gum. Hourly use should be recommended.

Bupropion (amfebutamone)

Originally used as an antidepressant, bupropion has been licensed for use in smoking cessation. It inhibits neuronal noradrenaline and dopamine uptake, reducing tobacco withdrawal symptoms by increasing CNS dopamine levels. Treatment should be started while the patient is still smoking with a target date to stop smoking set during the second week of use. The total treatment period should be for 7–9 weeks. The initial dose should be 150 mg daily for 6 days, increasing to 150 mg twice a day thereafter (with at least 8 h between doses). Bupropion is as effective as NRT and intensive behavioural support. There is no clear evidence of benefit over NRT but there is some evidence of better results if used in combination with NRT.

Bupropion should not be used in patients with a current or previous seizure disorder or in patients with bulimia, anorexia

nervosa, bipolar disorder, severe hepatic cirrhosis or those taking monoamine oxidase inhibitors; nor is it appropriate for use in smokers under the age of 18. Bupropion inhibits cytochrome P450 enzymes and so may inhibit the metabolism of other drugs. The main side effects experienced include dry mouth, insomnia (avoid bedtime dosing), headache, dizziness, allergic reactions, taste disorder and seizures.

Varenicline

Varenicline is an oral selective partial $\alpha_4\beta_2$ agonist at the neuronal nicotinic acetylcholine receptor. Varenicline alleviates the symptoms of craving and withdrawal, whilst reducing the rewarding and reinforcing effects of smoking by preventing nicotine binding to $\alpha_4\beta_2$ receptors. Trial evidence suggests use may result in a higher abstinence rate than either bupropion or NRT, although this may not be sustained after 12 months. Use is recommended as an option for smokers aged 18 or over wishing to quit, ideally in the context of a behavioural support programme (National Institute for Health and Clinical Excellence, 2007). Varenicline should be started 1–2 weeks before stopping smoking. The main side effects are nausea, vomiting, abnormal dreams and insomnia. Fears over a possible increased risk of depression and suicide have been allayed (Gunnell et al., 2009), although individuals who develop agitation, depressed mood or suicidal thoughts are required to seek prompt medical advice.

Combination therapy involving varenicline and bupropion (either with each other or in conjunction with NRT) is not recommended.

Use of inhaled therapy

For individuals suffering from obstructive airways disease with a degree of reversibility, the correct use of inhaled therapy is a vital part of overall management.

Medication counselling needs to highlight the modes of action of the bronchodilators, particularly the more rapid onset of the β_2-agonists to relieve breathlessness rather than the slower-acting anticholinergics. If inhaled steroids are prescribed, the importance of regular administration must be stressed. The incorrect use of any inhaler will lead to subtherapeutic dosing. The correct use of inhalers is, therefore, as vital in the management of COPD patients as it is for patients with asthma (see Chapter 25). The advantages and disadvantages of each type of inhaler device are summarised in Table 26.6.

Domiciliary oxygen therapy

Studies have shown that only about 50% of patients on LTOT comply with the requirement for 15 h of treatment a day. Counselling will be required to persuade the patient to comply with this minimum figure. Emphasis must be given to the improvement in quality of life gained from treatment rather than the idea of being continually 'tied' to the oxygen supply. If an oxygen concentrator is used, limited mobility can be gained by installing at least two terminals for the unit (usually in the living room and bedroom) with long tubing between the terminal and nasal prongs.

Patients should be actively encouraged to stop smoking if they still do; because of the fire risk if they use LTOT. Moreover, the carbon monoxide present in tobacco smoke binds to haemoglobin and forms carboxy-haemoglobin, which decreases the amount of oxygen that can be transported by the blood and will partially or completely negate the beneficial effects of LTOT.

The long-term, chronic nature of COPD may leave a patient with a fear of exercise as this will cause dyspnoea (breathlessness). Thus, the patient with COPD may decide not to undertake any exercise. Ambulatory oxygen cylinders can be used to encourage mobility and increase exercise tolerance during travel outside the home.

Patients using domiciliary oxygen are followed up to provide education and support, to assess the oxygen saturation of the patient and to assess the suitability of the delivery device for ambulatory oxygen if provided. Suitable devices have been suggested (National Institute for Health and Clinical Excellence, 2010) depending on the amount of time required for use (Table 26.7).

Table 26.6 Comparison of inhaler devices

Inhaler type	Compact	Hand–lung co-ordination required	Easy to use	Reduces oropharynx deposition
MDI	+	+	−	−
MDI + small spacer	+	±	±	+
MDI + large spacer	−	−	±	+
Breath-actuated MDI	+	−	+	−
Dry powder	+	−	±	−
Breath-actuated dry powder	+	−	+	−
Nebuliser	−	−	±	−

MDI, metered-dose inhaler; +, feature present; ±, feature present for some patients; −, feature absent.

Table 26.7 Oxygen delivery for ambulatory oxygen therapy (National Institute for Health and Clinical Excellence, 2010)

How long is the oxygen used by the patient?	Best type of delivery device
Less than 90 min	Small cylinder
90 min to 4 h	Small cylinder with oxygen-conserving device
More than 4 h	Liquid oxygen
More than 30 min, with flow rates greater than 2 L/min	Liquid oxygen

Case studies

Case 26.1

Mr JF, a 74-year-old man, has a long-standing history of COPD. He has a 70-pack-year history of smoking, but finally managed to give up 4 years ago, after numerous admissions to hospital for infective exacerbations. He is recovering on the respiratory ward from his first admission for 6 months. His consultant believes he may be a candidate for long-term oxygen therapy.

Questions

1. What criteria should Mr JF fill in order to be eligible for long-term oxygen therapy?
2. How is long-term oxygen therapy delivered?
3. Why might Mr JF be anxious about starting long-term oxygen therapy?
4. How would you allay these concerns?
5. What is the intended outcome of using long-term oxygen therapy?

Answers

1. In order to be eligible for long-term oxygen therapy, patients should have, when stable and on two separate occasions at least 3 weeks apart:
   pO_2 <7.3 kPa
   or
   pO_2 >7.3 kPa and <8.0 kPa as well as at least one of the following:

   • secondary polycythaemia
   • nocturnal hypoxaemia (O_2 saturations <90% for >30% of the time)
   • peripheral oedema
   • pulmonary hypertension

2. It is impractical to deliver long-term oxygen therapy using cylinders. Instead, an oxygen concentrator, a device which increases the relative concentration of oxygen in environmental air via a molecular 'sieving' process, is used. In most cases, a flow rate of 2 L/min is delivered via nasal cannulae. Patients must use the concentrator for at least 15 h, and preferably over 20 h a day to achieve intended therapeutic outcomes (see below).
3. Mr JF may be concerned for several reasons listed:

   • the length of time he will be tied to the machine each day
   • restrictions on leaving the house once he starts his 15 h a day
   • the cost of the electricity required to drive the concentrator
   • loss of supply if there is a power cut

4. Mr JF's concerns are logical but he can be reassured. The concentrator can be used while he is asleep (generally two outlets are installed, one in the living room and the other in the bedroom) and so this leaves him up to 9 h a day where he does not need to be using oxygen. The 15-h minimum does not have to be continuous, and so he can leave the house or interrupt the oxygen delivery as necessary to carry out activities of daily living. The cost of the electricity is covered by the oxygen contractor, who will monitor usage using a meter. Contractors are required to install a backup power supply which will continue to drive the concentrator for a minimum of 8 h should the mains supply fail.
5. Provided patients receive the required duration of therapy each day, beneficial effects on life expectancy, exercise tolerance and mental capacity can be anticipated.

Case 26.2

Mrs VL, a 58-year-old lady, has been brought into hospital by ambulance having been struggling with dyspnoea and significantly reduced exercise tolerance for several days. You review her chart and medical notes on the hospital admissions ward. The working diagnosis is an infective exacerbation of COPD. The patient presents with:
Thick green sputum which the patient reports is usually clear/white.
O_2 saturation of 82% on 28% oxygen delivered via a Venturi mask
Arterial blood gases (ABG):
   pH 7.33 (7.35–7.45)
   pO_2 7.24 kPa (10.7 kPa)
   pCO_2 7.1 kPa (4.7–6.0 kPa)
   Bicarbonate 46 mmol/L (22–26 mmol/L)
   D-dimer negative
Drug history:
   Salbutamol 2.5 mg via a nebuliser four times a day
   Symbicort® 200/6 2 puffs twice a day
   Tiotropium 18 μcg daily
   Furosemide 40 mg twice a day
   Ramipril 5 mg daily
   Alendronate 70 mg weekly on Saturdays
   Adcal D3 2 tablets daily
Mrs VL is commenced on:
   Salbutamol 5 mg via a nebuliser 4 hourly
   Ipratropium bromide 500 μcg via a nebuliser 6 hourly
   Prednisolone 30 mg daily
   Co-amoxiclav 1.2 g i.v. three times a day
   Doxycycline 200 mg stat then 100 mg od thereafter.

Questions

1. Explain the arterial blood gas profile.
2. What is the significance of the negative D-dimer result?

3. If she does not respond to initial therapy, what might it be appropriate to change or introduce?

Answers

1. The low pO_2 indicates significant hypoxia. A slightly low pH and slightly elevated pCO_2 suggest a respiratory acidosis. The high bicarbonate level indicates that this acid/base disturbance is compensated at this level. The bicarbonate is likely to have accumulated over a relatively prolonged period.

2. A negative D-dimer is a strong indicator that Mrs VL's dyspnoea is not as a result of a pulmonary embolism. Although a raised D-dimer is not a reliable means of confirming thromboembolic disease (low specificity – frequent false positives), it is far more reliable in excluding such conditions where the result falls within the normal range (high sensitivity – rare false negatives). It is important to exclude conditions such as pulmonary embolism or acute left ventricular failure when patients with COPD present with increased shortness of breath to avoid missed diagnoses.

3. The concentration of oxygen could be increased to 35%. Mrs VL may be at risk of developing hypercapnia as a result of her COPD, and so her arterial blood gases should be rechecked 30–60 min after the change in her oxygen therapy. Particular attention should be made to any increase in the carbon dioxide concentration. If Mrs VL's respiratory rate exceeds 30 breaths/min while using a Venturi mask, the oxygen flow rate should be increased by 50%. The target for oxygen therapy is to achieve a saturation of 88–92%.

   Inadequate response to nebulised bronchodilators is an indication where intravenous aminophylline should be considered. A loading dose of 5 mg/kg over at least 20 min followed by a continuous infusion of 500 μcg/kg/h can be administered. Levels should be checked within the first 24 h of therapy.

   There is no evidence that use of mucolytics at this acute stage will be of benefit.

Case 26.3

Mrs SS is a 61-year-old retired factory worker who has been recently diagnosed with COPD after admission to hospital. She was discharged a few days ago having been started on a nicotine patch, 14 mg every 24 h. She asks you for advice on the best way to give up smoking as she has tried several times in the past and failed to quit. She smokes around 25 cigarettes a day and has been smoking since she was 17. She has a history of oesophageal reflux and also has epilepsy.

Questions

1. Why is it important for Mrs SS to give up smoking?
2. How many pack-years has she smoked?
3. What aspects should be discussed when helping someone to stop smoking?
   When you question Mrs SS about her previous attempts to stop smoking, she confides that her husband smokes in the house and she finds it difficult not to smoke when he does. She has tried nicotine gum but finds it difficult to use with her dentures. Her current patch does not seem to be helping, it has reduced her craving but not eliminated it, especially when she wakes up in the morning.
4. Is the current management of Mrs SS appropriate?
5. What non-pharmacological support should be offered to Mrs SS?

Answers

1. Stopping smoking is the single most important way of affecting a patient's outcome at all stages of COPD. Giving up smoking will slow down the gradual decline in FEV_1 that is seen in smokers.

2.

$$\text{Total pack years} = \frac{\text{Number of cigarettes smoked per day}}{20} \times \text{number of years of smoking}$$

   Mrs SS has smoked approximately 55 pack-years.

3. There are five key steps in helping a smoker to stop smoking, the 'five As':

   * *Ask* about tobacco use. This should include an assessment of the degree of addiction
   * *Advise* to quit
   * *Assess* willingness to make an attempt
   * *Assist* in quit attempt
   * *Arrange* follow-up.

   Motivation from the patient is the key to giving up smoking but is related to the degree of dependence on tobacco. Heavy smokers may exhibit low motivation to quit as they lack confidence in their ability to do so.

4. Nicotine replacement patches are considered to be most suitable for people who smoke regularly through the day but a 21- to 25-mg patch would have been a more appropriate starting dose for someone smoking 20 or more cigarettes a day. Two of the most common side effects are insomnia or vivid dreams, if these occur the patch can either be removed before bedtime or a 16-h patch used. A suitable alternative would be the short-acting gum, lozenge or nasal spray. Mrs SS would require the 4-mg gum and should be encouraged to use the 8- to 12-pieces of gum a day to provide approximately 20 mg of absorbed nicotine per day. As the nasal spray is most useful for people who smoke 20 or more cigarettes per day, this may be the preferred formulation.
   Mrs SS may benefit from a combination of products. Although this practice is not specifically recommended by product manufacturers, it is considered suitable in highly dependent patients, or in those who have had unsuccessful quit attempts using a single nicotine replacement therapy preparation. If breakthrough cravings are felt despite a background patch then the addition of short-acting dosage forms may be used as 'rescue' medication.
   A date on which to quit smoking should be set. Nicotine replacement therapy should be prescribed in blocks of 2 weeks. Mrs SS should be seen and helped regularly throughout this process, before and after her quit date. The duration of nicotine replacement therapy in people who maintain an abstinence is usually 8–12 weeks, depending on the product, followed by a dose reduction.
   Another option would be to try varenicline. This may be more effective in achieving continuous abstinence (National Institute for Health and Clinical Excellence, 2007) than either nicotine replacement therapy or bupropion. Varenicline should be started 1–2 weeks before Mrs SS's quit date and is continued for a total of 12 weeks, although an additional 12 weeks' therapy may be required. Bupropion is contraindicated as this may increase Mrs SS's risk of seizures.

5. It is thought that around 3% of smokers quit every year on their own but that percentage increases when they are given simple advice whilst encouraging the quit attempt. Several non-pharmacological strategies exist to help:

   * Written self-help material.
   * Counselling and behavioural therapy. These aim to motivate the smoker and help with the skills and strategies required to cope with nicotine withdrawal, psychological pressures to smoke and situations of temptation to smoke.

In all cases, pharmacological therapy should also be offered as appropriate.

Several NHS, patient and charitable organisations can provide help and support to people wishing to stop smoking. Information can be obtained from the followed web sites:

27 Insomnia

S. Bleakley and M. Sie

Key points

- Hypnotic drugs do not cure insomnia but can provide useful short-term symptomatic treatment.
- Before starting medication, the primary cause of insomnia should be investigated and treated appropriately where possible.
- Hypnotic drugs should only be used short-term (2–4 weeks); long-term regular use leads to tolerance, dependence and other adverse effects.
- Sleep hygiene, relaxation techniques and psychological methods are more appropriate than hypnotics as long-term treatment for patients with insomnia.
- Non-benzodiazepine hypnotics such as zopiclone, zolpidem and zaleplon have similar pharmacological and adverse effects to benzodiazepines, offer few advantages and are more expensive.
- A melatonin preparation is available for primary insomnia. Its place in therapy is yet to be determined but it does not cause tolerance or dependence.

Definitions and epidemiology

Insomnia refers to difficulty in either falling asleep, remaining asleep or feeling refreshed from sleep. Complaints of poor sleep increase with increasing age and are twice as common in women as in men (Sateia and Nowell, 2004). Thus, by the age of 50, a quarter of the population are dissatisfied with their sleep, the proportion rising to 30–40% (two-thirds of them women) among individuals over 65 years.

Pathophysiology

Insomnia reflects a disturbance of arousal and/or sleep systems in the brain. These systems are functionally interrelated and their activity determines the degree and type of alertness during wakefulness and the depth and quality of sleep.

Sleep systems

The phenomenon of sleep is actively induced and maintained by neural mechanisms in several brain areas, including the lower brainstem, pons and parts of the limbic system. These mechanisms have reciprocal inhibitory connections with arousal systems, so that the activation of sleep systems inhibits waking and vice versa. Normal sleep includes two distinct levels of consciousness, orthodox sleep and paradoxical sleep, which are promoted from separate neural centres.

Orthodox sleep normally takes up about 75% of sleeping time. It is somewhat arbitrarily divided into four stages (1–4) which merge into each other, forming a continuum of decreasing cortical and behavioural arousal (see Fig. 27.1). Stages 3 and 4 represent the deepest phase of sleep and are also termed slow-wave sleep (SWS).

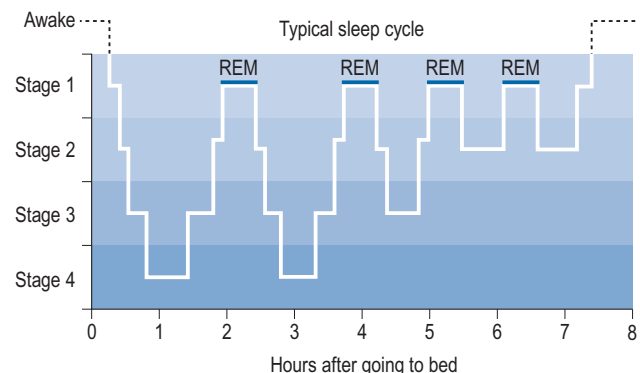
Paradoxical sleep, rapid eye movement (REM) sleep, normally takes up about 25% of sleeping time and has quite different characteristics to non-rapid eye movement (NREM) sleep. The EEG shows unsynchronised fast activity similar to that found in the alert conscious state and the eyes show rapid jerky movements. Peripheral autonomic activity is increased during REM sleep and there is an increased output of catecholamines and free fatty acids. Vivid dreams and nightmares most often occur during REM sleep, although brief frightening dreams (hypnagogic hallucinations) can occur in orthodox sleep, especially at the transition between sleeping and waking. Normally, stage 4 sleep occurs primarily in the first few hours of the night, while REM sleep is most prominent towards the morning. Brief awakenings during the night are normal. Both SWS and REM sleep are thought to be essential for brain function and both show a rebound after a period of deprivation, usually at the expense of lighter (stage 1 and 2) sleep which appears to be expendable. Many drugs can affect the different stages of sleep.


Fig. 27.1 The five stages of sleep. REM, rapid eye movement.

Benzodiazepines suppress stages 3 and 4 of sleep, but only cause a slight decrease in REM sleep. Z-hypnotics shorten stage 1 of sleep and prolong stage 2 of sleep but have little effect on stages 3, 4 and REM sleep. Chloral derivatives do not affect sleep architecture.

Aetiology and clinical manifestations

Insomnia may be caused by any factor which increases activity in arousal systems or decreases activity in sleep systems. Many causes act on both systems (Morin, 2003). Increased sensory stimulation activates arousal systems, resulting in difficulty in falling asleep. Common causes include chronic pain, gastric reflux, uncontrolled asthma and external stimuli such as noise, bright lights and extremes of temperature. Anxiety may also delay sleep onset as a result of increased emotional arousal.

Drugs are an important cause of insomnia. Difficulty in falling asleep may result directly from the action of stimulants, including caffeine, nicotine, theophylline, sympathomimetic amines, some antidepressants, levothyroxine and antimuscarinics. Some illicit substances, cocaine, amphetamines and anabolic steroids can also cause insomnia. Drug withdrawal after chronic use of central nervous system depressants, including hypnotics, anxiolytics and alcohol, commonly causes rebound insomnia with delayed or interrupted sleep, increased REM sleep and nightmares. With rapidly metabolised drugs, such as alcohol or short acting benzodiazepines, this rebound may occur in the latter part of the night, resulting in early waking. Certain drugs, including antipsychotics, tricyclic antidepressants and propranolol, may occasionally cause nightmares.

Difficulty in staying asleep is characteristic of depression. Patients typically complain of early waking but sleep records show frequent awakenings, early onset of REM sleep and reduced NREM sleep. Alteration of sleep stages, increased dreaming and nightmares may also occur in schizophrenia, while recurring nightmares are a feature of post-traumatic stress disorder (PTSD). Interference with circadian rhythms, as in shift work or rapid travel across time zones, can cause difficulty in falling asleep or early waking.

Frequent arousals from sleep are associated with myoclonus, 'restless legs syndrome', muscle cramps, bruxism (tooth grinding), head banging and sleep apnoea syndromes. Reversal of the sleep pattern, with a tendency for poor nocturnal sleep but a need for daytime naps, is common in the elderly, in whom it may be associated with cerebrovascular disease or dementia. In general, decreased duration of sleep has been shown to increase the risk of obesity (Kripke et al., 2002) and hypertension (Gangwisch et al., 2006). Sleep disturbances in the elderly are also associated with increased falls, cognitive decline and a higher rate of mortality (Cochen et al., 2009). There is growing concern that daytime sleepiness resulting from insomnia increases the risk of industrial, traffic and other accidents.

Investigations and differential diagnosis

Many patients complaining of insomnia overestimate their sleep requirements. Although most people sleep for 7–8 h daily, some healthy subjects require as little as 3 h of sleep and sleep requirements decline with age. Such 'physiological insomnia' does not usually cause daytime fatigue, although the elderly may take daytime naps. If insomnia is causing distress, primary causes such as pain, drugs which disturb sleep, psychiatric disturbance including anxiety and depression and organic causes such as sleep apnoea should be identified and treated before hypnotic therapy is prescribed.

Treatment

Non-drug therapies

Explanation of sleep requirements, attention to sleep hygiene (see Box 27.1), reduction in caffeine or alcohol intake and the use of analgesics where indicated may obviate the need for hypnotics (Anon, 2004). Medications that cause insomnia should also be avoided if possible. Psychological techniques such as relaxation therapy and cognitive behavioural therapy (CBT) are also helpful (Kierlin, 2008). However, studies comparing psychological approaches to hypnotics are scarce (Riemann and Perlis, 2009).

Hypnotic drugs

Hypnotic drugs provide only symptomatic treatment for insomnia. Although often efficacious in the short-term, they do little to alter the underlying cause which should be sought and treated where possible. About 20 million prescriptions for hypnotics are issued each year in the UK and these drugs can improve the quality of life if used rationally.

Box 27.1 Principles of typical advice for good sleep hygiene (Anon, 2004)

- Have a good bed time routine, go to bed and get up at the same time every day and avoid daytime naps.
- Avoid stimulants such as caffeine, nicotine, chocolate and alcohol 6 h before bedtime.
- Take regular exercise during the day, but avoid strenuous exercise within 4 h of bedtime.
- Avoid large meals close to bedtime.
- Associate bed with sleep. Do not watch TV or listen to music when retiring to bed.
- The bedroom should be a quiet, relaxing place to sleep; make sure the room is not too hot or too cold.
- If after 30 min you cannot get off to sleep, then get up. Leave the bedroom and try to do something else, return to bed when sleepy. This can be repeated as often as necessary until you are asleep.

The ideal hypnotic would

- gently suppress brain arousal systems while activating systems that promote deep and satisfying sleep,
- have a rapid onset of action with a duration of less than 8 h,
- have no hangover effect the next day,
- not induce tolerance or dependence if used long-term,
- not cause withdrawal effects when stopped,
- not depress respiration,
- be safe for use in the elderly patient.

Unfortunately, no such hypnotic exists; most available hypnotics are general central nervous system depressants which inhibit both arousal and sleep mechanisms. Thus, they do not induce normal sleep and often have adverse effects, including daytime sedation ('hangover') and rebound insomnia on withdrawal. They are unsuitable for long-term use because of the development of tolerance and dependence.

Benzodiazepines

By far the most commonly prescribed hypnotics are the benzodiazepines. A number of different benzodiazepines are available (see Table 27.1). These drugs differ considerably in potency (equivalent dosage) and in rate of elimination but only slightly in clinical effects. All benzodiazepines have sedative/hypnotic, anxiolytic, amnesic, muscular relaxant and anticonvulsant actions with minor differences in the relative potency of these effects.

Pharmacokinetics

Most benzodiazepines marketed as hypnotics are well absorbed and rapidly penetrate the brain, producing hypnotic effects within half an hour after oral administration. Rates of elimination vary, however, with elimination half-lives from 6 to 100 h (see Table 27.1). These drugs undergo hepatic metabolism via oxidation or conjugation and some form pharmacologically active metabolites with even longer elimination half-lives. Oxidation of benzodiazepines is decreased in the elderly, in patients with hepatic impairment and in the presence of some drugs, including alcohol.

Pharmacokinetic characteristics are important in selecting a hypnotic drug. A rapid onset of action combined with a medium duration of action (elimination half-life about 6–8 h) is usually desirable. Too short a duration of action may lead to, or fail to control, early morning waking, while a long duration of action (e.g. nitrazepam) may produce residual effects

Table 27.1 Overview of the medication used for insomnia

Drug	Usual dose at night (adult) (mg)	Half life in adults (h)	Licensed indication	Tolerance	Dependence
Benzodiazepines					
Diazepam	2–5	24–36	Insomnia (short-term use)	Yes	Yes
Loprazolam	1	11	Insomnia (short-term use)	Yes	Yes
Lorazepam	1	12–16	Insomnia (short-term use)	Yes	Yes
Lormetazepam	0.5–1.5	10	Insomnia (short-term use)	Yes	Yes
Nitrazepam	5–10	18–36	Insomnia (short-term use)	Yes	Yes
Temazepam	10–20	5–11	Insomnia (short-term use)	Yes	Yes
Z-Hypnotics					
Zaleplon	10	2	Insomnia (short-term use up to 2 weeks)	Yes	Yes
Zolpidem	5–10	2–3	Insomnia (short-term use up to 4 weeks)	Yes	Yes
Zopiclone	3.75–7.5	3.5–6	Insomnia (short-term use up to 4 weeks)	Yes	Yes
Chloral and Derivatives (rarely used)					
Cloral Betaine	707	Unclear	Insomnia (short-term use)	Yes	Yes
Clomethiazole					
Clomethiazole	192–384	4–5	Severe insomnia in elderly (short-term use)	Yes	Yes
Antihistamines					
Promethazine	25–50	10–19	Night sedation and insomnia (short-term use)	Yes	No
Melatonin					
Melatonin Circadin® Unlicensed products also available	2	3.5–4	Insomnia in adults over 55 years (short-term use)	No	No

the next day and may lead to accumulation if the drug is used regularly. However, frequency of use and dosage are also important. For example, diazepam (5–10 mg) produces few residual effects when used occasionally, despite its slow elimination, although chronic use impairs daytime performance. Large doses of short acting drugs may produce hangover effects, while small doses of longer acting drugs may cause little or no hangover.

Mechanism of action

Most of the effects of benzodiazepines result from their interaction with specific binding sites associated with postsynaptic GABA$_A$ receptors in the brain. All benzodiazepines bind to these sites, although with varying degrees of affinity, and potentiate the inhibitory actions of GABA at these sites.

GABA$_A$ receptors are multi-molecular complexes (see Figs. 27.2 and 27.3) that control a chloride ion channel and contain specific binding sites for GABA, benzodiazepines and several other drugs, including many non-benzodiazepine hypnotics and some anticonvulsant drugs (Haefely, 1990). The various effects of benzodiazepines (hypnotic, anxiolytic, anticonvulsant, amnesic, muscle relaxant) result from GABA potentiation in specific brain sites and at different types of GABA$_A$ receptor. There are multiple subtypes of GABA$_A$ receptor which may contain different combinations of at least 18 sub-units (including α_{1-6}, β_{1-3}, γ_{1-3} and others) and the subtypes are differentially distributed in the brain.
GABA$_A$ receptor

6 different α subunits

4 differnet β subunits

3 different γ subunits

Most common mammalian structure $(\alpha1)_2(\beta2)_2(\gamma1)$

Fig. 27.2 *The GABA$_A$ receptor and sub-units.* The GABA$_A$ receptor is a heteropentameric glycoprotein. A total of five distinct polypeptide sub-units have been cloned to date; α, β, γ, d and r, and multiple isoforms of these sub-units are reported in the literature. Different confirmations of the GABA$_A$ receptor are found throughout the brain, and the most common mammalian arrangements of sub-units is $(\alpha1)_2(\beta2)_2(\gamma1)$. The specific sub-units in the GABA$_A$ receptor confer functional diversity on the receptor. For example, the γ sub-unit needs to be co-expressed with the α and β sub-units to observe the potentiation of the GABA$_A$ receptor by benzodiazepines.
Fig. 27.3 *Schematic representation of the GABA$_A$ receptor.* GABA is the major inhibitory neurotransmitter in the central nervous system. The GABA$_A$ receptor is composed of five sub-units – two α, two β and one γ sub-unit. Two molecules of GABA activate the receptor by binding to the α sub-units. Once activated the receptor allows the passage of negatively charged ions (Cl–) into the cytoplasm, which results in hyper-polarisation and the inhibition of neurotransmission. Source: www.CNSforum.com.

Benzodiazepines bind to three or more subtypes and it appears that their combination with α_2-containing subtypes mediates their anxiolytic effects, α_1-containing subtypes their sedative and amnesic effects, and α_1 as well as α_2 and α_5 their anticonvulsant effects (Rudolph et al., 2001).

Zopiclone

In 1988, zopiclone, a cyclopyrrolone, was the first non-benzodiazepine to be approved for the treatment of insomnia in the European market. Although classed as a non-benzodiazepine, it still binds to benzodiazepine receptors but is said to be more selective for the α_1 subtype. It has hypnotic effects similar to benzodiazepines and carries a similar potential for adverse effects including tolerance, dependence and abstinence effects on withdrawal. Psychiatric reactions, including hallucinations, behavioural disturbances and nightmares, have been reported to occur shortly after the first dose. Other common adverse reactions include a bitter taste, a dry mouth and difficulty arising in the morning (Zammit, 2009). This drug appears to have no particular advantages over benzodiazepines, although it may cause less alteration of sleep stages and does not have the controlled drug requirements of the benzodiazepines. Eszopiclone the S- (+) isomer of zopiclone is available in the USA but there are no current plans to launch in the UK. What advantage, if any, the isomer incurs over zopiclone is unclear.

Zolpidem

Zolpidem is an imidazopyridine that binds preferentially to the α_1 benzodiazepine receptor sub-unit thought to mediate hypnotic effects. It is an effective hypnotic with only weak anticonvulsant and muscle relaxant properties. As it has a

short elimination half-life (2 h) hangover effects are rare but rebound effects may occur in the later part of the night, causing early morning waking and daytime anxiety. High doses have been reported to cause brief psychotic episodes, tolerance and withdrawal effects. Anecdotal case reports (mainly from the USA) have associated zolpidem with complex sleep related behaviours. These have included 'sleep-driving', making phone calls, preparing food and eating while asleep. The majority of these cases also involved ingestion of alcohol and should be interpreted with caution because they are not replicated in the wider medical literature (Zammit, 2009). A controlled release version of zolpidem (zolpidem-CR) is available in some countries.

Zaleplon

Zaleplon is a pyrazolopyrimidine which, like zolpidem, binds selectively to the α_1 benzodiazepine receptor. It is an effective hypnotic, has a very short elimination half-life (1 h) and appears to cause minimal residual effects on psychomotor or cognitive function after 5 h. There is little evidence of tolerance or withdrawal effects in short-term use and the drug appears suitable for use in the elderly (Doble et al., 2004).

All the 'Z-hypnotics' are recommended for short-term use only (2–4 weeks) and are more expensive than benzodiazepines. There is no compelling evidence to distinguish them from the shorter acting benzodiazepine hypnotics (National Institute of Health and Clinical Excellence, 2004). Patients who do not respond to either a benzodiazepine or z-hypnotic should not be prescribed the other.

Melatonin

Melatonin is a naturally occurring hormone, produced by the pineal gland, which regulates the circadian rhythm of sleep. It begins to be released once it becomes dark, and continues to be released until the first light of day. Melatonin release decreases with age which may in-part explain why older adults require less sleep. Melatonin supplementation promotes sleep initiation and helps to reset the circadian clock allowing uninterrupted sleep. It has also been shown to improve next day functioning. Contrary to most other hypnotics melatonin shows no abuse or tolerance potential and appears to have no next day sedation problems. Prolonged release melatonin (Circadin®) was launched in June 2008 and is available at a dose of 2 mg at night for up to 3 weeks. It is licensed as monotherapy in primary insomnia for adults over 55 years old. Whilst the adverse effect profile looks advantageous there are currently no trials comparing melatonin against psychological or other hypnotic treatments. Circadin® is also much more expensive than other currently prescribed hypnotics (Anon, 2009).

Other hypnotic drugs

The risk of adverse effects, including dependence and dangerous respiratory depression in overdose, generally outweighs the potential benefits of the older hypnotics, chloral derivatives, clomethiazole and barbiturate. Therefore, these drugs are best avoided. Antidepressants with sedative properties, such as amitriptyline, mirtazapine, trazodone and agomelatine may be helpful if sleep disturbance is secondary to depression. Sedative antihistamines, such as promethazine, diphenhydramine and chlorphenamine, which can be purchased over-the-counter, have mild-to-moderate hypnotic efficacy but commonly produce hangover effects and rebound insomnia can occur after prolonged use (Anon, 2004).

Potential adverse effects of hypnotic use

Tolerance and dependence

Tolerance to the hypnotic effects of benzodiazepines and probably z-hypnotics develops rapidly and may lead to dosage escalation. Nevertheless, poor sleepers may report continued efficacy and the drugs are often used long-term because of difficulties on withdrawal.

Rebound insomnia

Rebound insomnia, in which sleep is poorer than before drug treatment, is common on withdrawal of benzodiazepines. Sleep latency (time to onset of sleep) is prolonged, intra-sleep wakenings become more frequent and REM sleep duration and intensity are increased, with vivid dreams or nightmares which may add to frequent awakenings. These symptoms are most marked when the drugs have been taken in high doses or for long periods, but can occur after only a week of low dose administration. They are prominent with moderately, rapidly eliminated benzodiazepines (temazepam, lorazepam) and may last for many weeks. With slowly eliminated benzodiazepines (diazepam), SWS and REM sleep may remain depressed for some weeks and then slowly return to the baseline, sometimes without a rebound effect. Tolerance and rebound effects are reflections of a complex homeostatic response to regular drug use, involving desensitisation, uncoupling and internalisation of certain GABA/benzodiazepine receptors and sensitisation of receptors for excitatory neurotransmitters (Allison and Pratt, 2003). These changes encourage continued hypnotic usage and contribute to the development of drug dependence.

Oversedation and hangover effects

Many benzodiazepines used as hypnotics can give rise to a subjective 'hangover' effect and after most of them, even those with short elimination half-lives, psychomotor performance, including driving ability and memory, may be impaired on the following day. Over sedation is most likely with slowly eliminated benzodiazepines, especially if used chronically, and is most marked in the elderly in whom drowsiness, incoordination and ataxia, leading to falls and fractures, and acute confusional states may result even from small doses. Chronic use can

cause considerable cognitive impairment, sometimes suggesting dementia. Paradoxical excitement may occasionally occur.

Some benzodiazepines in hypnotic doses may decrease alveolar ventilation and depress the respiratory response to hypercapnia, increasing the risk of cerebral hypoxia, especially in the elderly and in patients with chronic respiratory disease.

Drug interactions

Benzodiazepines have additive effects with other central nervous system depressants. Combinations of benzodiazepines with alcohol, other hypnotics, sedative tricyclic antidepressants, antihistamines or opioids can cause marked sedation and may lead to accidents or severe respiratory depression.

Rational drug treatment of insomnia

A hypnotic drug may be indicated for insomnia when it is severe, disabling, unresponsive to other measures or likely to be temporary. In choosing an appropriate agent, individual variables relating to the patient and to the drug need to be considered (see Table 27.1).

Patient care

Type of insomnia

The duration of insomnia is important in deciding on a hypnotic regimen. Transient insomnia may be caused by changes of routine such as overnight travel, change in time zone, alteration of shift work or temporary admission to hospital. In these circumstances, a hypnotic with a rapid onset, medium duration of action and few residual effects could be used on one or two occasions.

Short-term insomnia may result from temporary environmental stress. In this case, a hypnotic may occasionally be indicated but should be prescribed in low dosage for 1 or 2 weeks only, preferably intermittently, on alternate nights or one night in three.

Chronic insomnia presents a much greater therapeutic problem. It is usually secondary to other conditions (organic or psychiatric) at which treatment should initially be aimed. In selected cases, a hypnotic may be helpful but it is recommended that such drugs should be prescribed at the minimal effective dosage and administered intermittently (one night in three) or temporarily (not more than 2 or 3 weeks). Occasionally it is necessary to repeat short, intermittent courses at intervals of a few months.

The elderly

The elderly are especially vulnerable both to insomnia and to adverse effects from hypnotic drugs. They may have reduced metabolism of some drugs and may be at risk of cumulative effects. They are also more susceptible than younger people to central nervous system depression, including cognitive impairment and ataxia (which may lead to falls and fractures). They are sensitive to respiratory depression, prone to sleep apnoea and other sleep disorders and are more likely to have 'sociological', psychiatric and somatic illnesses which both disturb sleep and may be aggravated by hypnotics. For some of these elderly patients, hypnotics can improve the quality of life but the dosage should be adjusted (usually half the recommended adult dose) and hypnotics with long elimination half-lives or active metabolites should be avoided.

A considerable number of elderly patients give a history of regular hypnotic use going back for 20 or 30 years. In many of these patients, gradual reduction of hypnotic dosage or even withdrawal may be indicated and can be carried out successfully, resulting in improved cognition and general health with no impairment of sleep or escalation of other symptoms (Curran et al., 2003).

The young

Traditional benzodiazepine-like are generally contraindicated for children. Where sedation is required, sedative antihistamines or melatonin are usually recommended.

Disease states

Hypnotics are contraindicated in patients with acute pulmonary insufficiency, significant respiratory depression, obstructive sleep apnoea or severe hepatic impairment. In patients with chronic pain or terminal conditions, suitable analgesics including non-steroidal anti-inflammatory agents or opiates, sometimes combined with neuroleptics, usually provide satisfactory sedation. In such patients, the possibility of drug dependence becomes a less important issue and regular use of hypnotics with a medium duration of action should not be denied if they provide symptomatic relief of insomnia.

Choice of drug

There is little difference in hypnotic efficacy between most of the available agents. The main factors to consider in the rational choice of a hypnotic regimen are duration of action and the risk of adverse effects, especially over sedation and the development of tolerance and dependence. Cost may also be a factor when prescribing melatonin.

Rate of elimination

Slowly eliminated drugs should be avoided because of the risk of over sedation and hangover effects. Very short acting drugs such as zaleplon carry the risk of late night rebound insomnia and daytime anxiety. Drugs with a medium elimination half-life (6–8 h) appear to have the most suitable profile for hypnotic use. These may include temazepam and loprazolam, as these are the drugs of first choice in most situations where hypnotics are indicated. Zopiclone is a

reasonable second choice and sedative antihistamine such as promethazine is a safe third choice. These are useful in children, although sedative antihistamine may produce daytime drowsiness.

Duration and timing of administration

To prevent the development of tolerance and dependence, the maximum duration of treatment should be limited to 2 or 3 weeks and treatment should, where possible, be intermittent (one night in two or three). Dosage should be tapered slowly if hypnotics have been taken regularly for more than a few weeks. Doses should be taken 20 min before retiring in order to allow dissolution in the stomach and absorption to commence before the patient lies down in bed.

Case studies

Case 27.1

Mr PH, aged 24, was hospitalised for 3 months after a serious motorcycle injury followed by painful complications. While in hospital he developed panic attacks and insomnia. He received no psychological support but was prescribed temazepam, initially in 20 mg doses but later increased to 60 mg because of continued insomnia. After discharge from hospital Mr PH continued to receive temazepam from his primary care doctor and the dosage was increased over a period of years until he was taking 80 mg temazepam each night and 40–80 mg during the day. At the age of 30, Mr PH was removed from the practice list of his doctor after he altered a prescription. He later attended several different primary care doctors, obtaining multiple temazepam prescriptions. When he could no longer satisfy his need from prescriptions he took to obtaining temazepam on the street, taking large and irregular doses by mouth. All this time, his anxiety levels increased. His behaviour became chaotic and he was twice imprisoned for credit card fraud but he was able to obtain temazepam and other drugs from his co-prisoners. When last heard of, Mr PH, aged 35, was again buying temazepam illicitly, as well as other addictive drugs, had started injecting intravenously and was involved in a court case for obtaining money under false pretences.

Question

How could this tragedy have been prevented?

Answer

Mr PH's downfall could have been averted at several stages.

- The hospital staff should not have allowed the temazepam dosage to escalate and should have provided psychological/psychiatric help for what was probably PTSD or panic disorder.
- An antidepressant drug could have been prescribed, along with psychological measures, instead of prolonged treatment with excessive doses of temazepam.
- On discharge from hospital, Mr PH's doctor should have been warned of his temazepam intake and a slow withdrawal schedule suggested.
- The series of primary care doctors who gave Mr PH prescriptions should have been aware that he was likely to obtain illicit supplies and should have referred him to a withdrawal clinic or drugs unit.

Case 27.2

Mrs AK, a recently widowed lady aged 65, had difficulty sleeping after her bereavement. She was prescribed nitrazepam in a bedtime dose of 5 mg, which was very effective and was continued for over 4 weeks. Mrs AK lived alone but was visited occasionally by her daughter. On a visit 2 weeks after the nitrazepam was started, Mrs AK seemed calm and said that she was sleeping well but the daughter noticed her mother was unsteady on her feet. A week later the daughter visited again and found her mother lying on the bedroom floor, in pain and unable to move. She said that she had lost her balance on getting out of bed. An ambulance was called and it was found in hospital that Mrs AK had broken her hip.

Question

Should the doctor have prescribed nitrazepam for this lady?

Answers

- Long acting benzodiazepines should be avoided in the elderly. The elimination half-life of nitrazepam is 15–38 h and the recommended dose for the elderly is 2.5–5 mg. Temazepam, loprazolam or lormetazepam would have been a better choice but for short-term use only (preferably only 2 weeks).
- The elderly are particularly prone to ataxia and light-headedness with benzodiazepines and this can lead to falls and fractures.
- Benzodiazepines are not recommended, except acutely, for bereavement. Their amnesic effects may interfere with subsequent psychological adjustment.

28 Anxiety disorders

S. Bleakley and D. Baldwin

Key points

- Benzodiazepines should only be used short-term (2–4 weeks) as long-term regular use can lead to tolerance, dependence and other adverse effects.
- If benzodiazepines are indicated, the smallest effective dose should be used along with intermittent dosing where possible. Start with small doses, increase if necessary. Use half the adult dose in elderly patients.
- Psychological therapies (talking therapies) are generally considered first-line treatments in all anxiety disorders because they may provide a longer lasting response and lower relapse rates than pharmacotherapy.
- Some antidepressants are appropriate long-term treatment for anxiety disorders.
- Selective serotonin reuptake inhibitors (SSRIs) are the recommended antidepressants in anxiety disorders but can worsen symptoms at the beginning of treatment and, therefore, should be initiated at half the usual dose used.

Definitions and epidemiology

Anxiety is a normal, protective, psychological response to an unpleasant or threatening situation. Mild to moderate anxiety can improve performance and ensure appropriate action is taken. However, excessive or prolonged symptoms can be disabling, lead to severe distress and cause much impairment to social functioning. Figure 28.1 shows that as anxiety levels increase performance/actions increase. However, as the anxiety level increases beyond acceptable or tolerated levels, the performance declines.

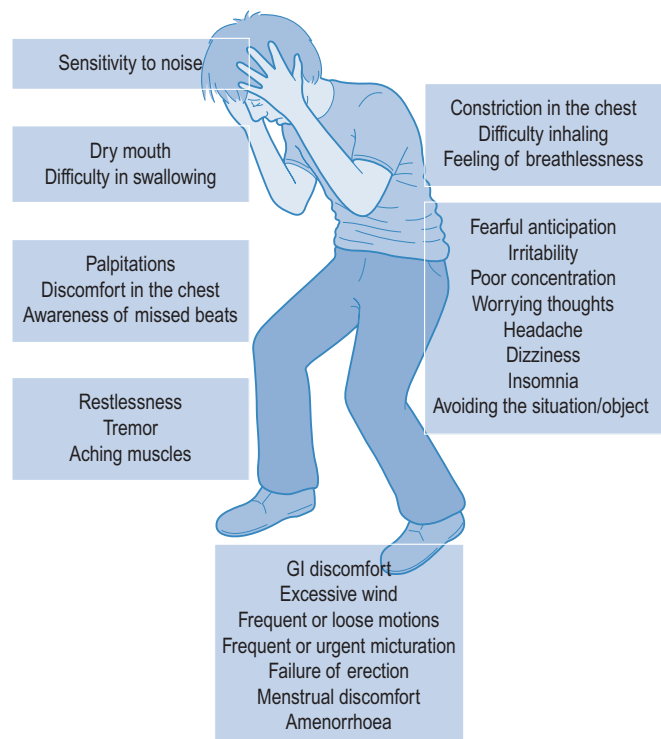
The term 'anxiety disorder' encompasses a variety of complaints which can either exist on their own or in conjunction with another psychiatric or physical illness. Symptoms of anxiety vary but generally present with a combination of psychological, physical and behavioural symptoms (Fig. 28.2). Some of these symptoms are common to many anxiety disorders while others are distinctive to a particular disorder. Anxiety disorders are broadly divided into generalised anxiety disorder (GAD), panic disorder, social phobia, specific phobias, post-traumatic stress disorder (PTSD) and obsessive-compulsive disorder (OCD), see Table 28.1. Patient testimonials are presented in Box 28.1. Approximately two-thirds of sufferers of an anxiety disorder will have another psychiatric illness. This is most commonly depression and often successful treatment of


Fig. 28.2 The symptoms of anxiety.

Table 28.1 A brief description of the common anxiety disorders

Symptoms common to all anxiety disorders	Fear or worry, sleep disturbances, concentration problems, dry mouth, sweating, palpitations, GI discomfort, restlessness, shortness of breath, avoidance behaviour
Generalised anxiety disorder (GAD)	Persistent (free floating), excessive and inappropriate anxiety on most days for at least 6 months. The anxiety is not restricted to a specific situation
Panic disorder (with or without agoraphobia)	Recurrent, unexplained surges of severe anxiety (panic attack). Most patients develop a fear of repeat attacks or the implications of an attack. Often seen in agoraphobia (fear in places or situations from which escape might be difficult)
Social phobia (or social anxiety disorder)	A marked, persistent and unreasonable fear of being observed, embarrassed or humiliated in a social or performance situation (e.g. public speaking or eating in front of others)
Specific phobia	Marked and persistent fear that is excessive or unrealistic, precipitated by the presence (or anticipation) of a specific object or situation (e.g. flying, spiders). Sufferers avoid the feared object/subject or endure it with intense anxiety
Post-traumatic stress disorder (PTSD)	Can occur after an exposure to a traumatic event which involved actual or threatened death, or serious injury or threats to the physical integrity of self or others. The person responds with intense fear, helplessness or horror. Sufferers can re-experience symptoms (flashbacks) and avoid situations associated with the trauma. Usually occurs within 6 months of the traumatic event
Obsessive-compulsive disorder (OCD)	Persistent thoughts, impulses or images (obsessions) that are intrusive and cause distress. The person attempts to get rid of these obsessions by completing repetitive time-consuming purposeful behaviours or actions (compulsions). Common obsessions include contamination while the compulsion may be repetitive washing or cleaning

Box 28.1 Patient testimonies (NICE, 2005a,b)

Symptoms described by a sufferer of post-traumatic stress disorder:

> I would feel angry at the way the crash happened and that there was nothing I could do to stop it or help. I was physically exhausted, but was finding it hard to sleep. As soon as the bedroom light went out at night a light would come on in my head and all I could do was lie there and think. When I would eventually fall asleep, I would wake up with nightmares of the crash. I could not get away from it. It was all I could think about in the day and all I would dream about at night.

Thoughts from a sufferer of obsessive-compulsive disorder:

> I've just arrived home from work. Tired and tense, I'm convinced my hands are contaminated with some hazardous substance and my primary concern now is to ensure that I don't spread that contamination to anything that I, or others, may subsequently touch. I will wash my hands, but first I will need to put a hand in my pocket to get my door keys, contaminating these, the pocket's other contents, and everything else I touch on my way to the sink. It will be late evening before I will have completed the whole decontamination ritual.

A slow recovery described by a post-traumatic stress disorder and panic attack sufferer:

> Slowly I gained ground and as each new insight came I was able to see my symptoms diminish. The panic attacks tapered off, the intensity of the flashbacks dwindled, and my irritable bowel began to loosen some of its hold on me. I was able to breathe again.

an underlying depression will significantly improve the symptoms of anxiety. Many patients will also present with more than one anxiety disorder at the same time which can further complicate treatment. Anxiety disorders are the most commonly reported mental illness and as a whole have a lifetime prevalence of 21% (Baldwin et al., 2005) with specific phobias the most commonly reported.

For all anxiety disorders together the overall female to male ratio is 2:1. The age of onset of most anxiety disorders is in young adulthood (20s and 30s), although the maximum prevalence of generalised anxiety and agoraphobia in the general population is in the 50–64 year age group.

Pathophysiology

Anxiety occurs when there is a disturbance of the arousal systems in the brain. Arousal is maintained by at least three interconnected systems: a general arousal system, an 'emotional' arousal system and an endocrine/autonomic arousal system (Fig. 28.3). The general arousal system, mediated by the brainstem reticular formation, thalamic nuclei and basal forebrain bundle, serves to link the cerebral cortex with incoming sensory stimuli and provides a tonic influence on cortical reactivity or alertness. Excessive activity in this system, due to internal or external stresses, can lead to a state of hyperarousal as seen in anxiety. Emotional aspects of arousal, such as fear and anxiety, are contributed by the limbic system which also serves to focus attention on selected aspects of the environment. There is evidence that increased activity in certain limbic pathways is associated with anxiety and panic attacks.

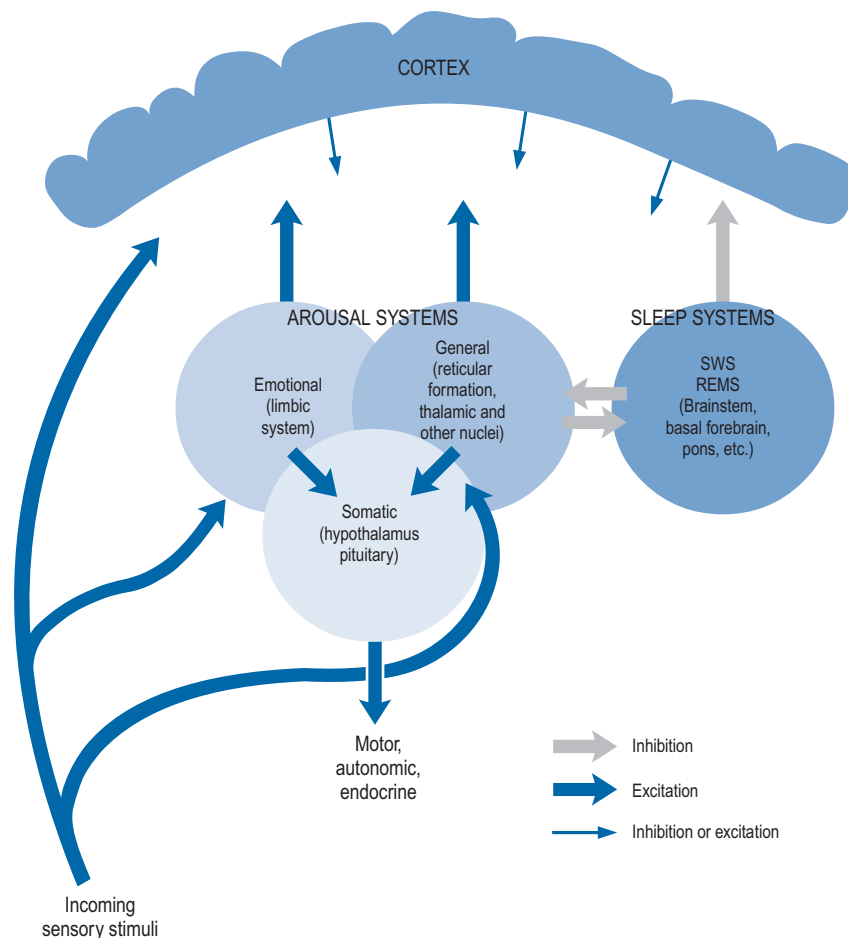
These arousal systems activate somatic responses to arousal, such as increased muscle tone, increased sympathetic activity and increased output of anterior and posterior pituitary hormones. Inappropriate increases in autonomic activity are


Fig. 28.3 Diagram of arousal and sleep systems. Arousal systems receive environmental and internal stimuli, cause cortical activation and mediate motor, autonomic and endocrine responses to arousal. Reciprocally connected sleep systems generate slow-wave sleep (SWS) and rapid eye movement sleep (REMS). Either system can be excited or inhibited by cognitive activity generated in the cortex.

often associated with anxiety states; the resulting symptoms (palpitations, sweating, tremor, etc.) may initiate a vicious circle that increases the anxiety.

Several neurotransmitters have been implicated in the arousal systems. Acetylcholine is the main transmitter maintaining general arousal but there is evidence that heightened emotional arousal is particularly associated with noradrenergic and serotonergic activity. Drugs which antagonise such activity have anxiolytic effects. In addition, the inhibitory neurotransmitter γ-aminobutyric acid (GABA) exerts an inhibitory control on other transmitter pathways and increased GABA activity may have a protective effect against excessive stress reactions. Many drugs which increase GABA activity, such as the benzodiazepines, are potent anxiolytics.

Aetiology and clinical manifestations

Anxiety is commonly precipitated by stress but vulnerability to stress appears to be linked to genetic factors such as trait anxiety. Many patients presenting for the first time with anxiety symptoms have a long history of high anxiety levels going back to childhood. Anxiety may also be induced by central stimulant drugs (caffeine, amphetamines), withdrawal from chronic use of central nervous system depressant drugs (alcohol, hypnotics, anxiolytics) and metabolic disturbances (hyperventilation, hypoglycaemia, thyrotoxicosis). It may form part of a depressive disorder and may occur in temporal lobe lesions and in rare hormone-secreting tumours such as phaeochromocytoma or carcinoid syndrome.

Apart from the psychological symptoms of apprehension and fear, somatic symptoms may be prominent in anxiety and include palpitations, chest pain, shortness of breath, dizziness, dysphagia, gastro-intestinal disturbances, loss of libido, headaches and tremor. Panic attacks are experienced as storms of increased autonomic activity combined with a fear of imminent death or loss of control. If panic becomes associated with a particular environment, commonly a crowded place with no easy escape route, the patient may actively avoid similar situations and eventually become agoraphobic. When anxiety is precipitated by a specific cause then behaviour can become altered to ensure the sufferer avoids the cause. This avoidance behaviour can maintain the often irrational fear and strengthen the desire to avoid the threat.

Investigations and differential diagnosis

In patients presenting with symptoms and clinical signs of anxiety, it is important to exclude organic causes such as thyrotoxicosis, excessive use of stimulant drugs such as caffeine and the possibility of alcoholism or withdrawal effects from benzodiazepines. However, unnecessary investigations should generally be avoided if possible. Extensive gastroenterological, cardiological and neurological tests may increase anxiety by reinforcing the patient's fear of a serious underlying physical disease.

Treatment

Treatment for anxiety disorders often requires multiple approaches. The patient may need short-term treatment with an anxiolytic, such as a benzodiazepine, to help reduce the immediate symptoms combined with psychological therapies and an antidepressant for longer term treatment and prevention of symptoms returning.

Psychotherapy

Psychological therapies (talking therapies) are generally considered first-line treatments in all anxiety disorders because they may provide a longer lasting response and lower relapse rates than pharmacotherapy. Psychotherapy, however, is less available, more demanding and takes longer time to work than pharmacotherapy. If the patient is unable to tolerate the anxiety or associated distress, then medicines are often used before psychotherapy or while awaiting psychotherapy. The ideal treatment should be tailored to the individual and may involve a combination of both psychotherapy and pharmacotherapy. The type of treatment should depend on symptoms, type of anxiety disorder, speed of response required, long-term goals and patient preference.

The specific psychotherapy with the most supporting evidence in anxiety disorders is cognitive behavioural therapy (CBT). Cognitive behaviour therapy focuses on the 'here and now' and explores how the individual feels about themselves and others and how behaviour is related to these thoughts. Through individual therapy or group work the patient and therapist identify and question maladaptive thoughts and help develop an alternative perspective. Individual goals and strategies are developed and evaluated with patients encouraged to practise what they have learned between sessions. Therapy usually lasts for around 60–90 minutes every week for 8–16 weeks, or longer in more resistant cases. Cognitive behavioural therapists are usually health professionals such as mental health nurses, psychologists, general practitioners, social workers, counsellors or occupational therapists who have undertaken specific training and supervision.

In PTSD, CBT is trauma focused, with the therapist helping the patient confront their traumatic memory and people or objects associated with this trauma. At the same time, patients are taught skills to help them cope with the emotional or physical response of this trauma. One such skill includes relaxation training which may involve systematically relaxing major muscle groups in a way that decreases anxiety. Another psychotherapy sometimes recommended in PTSD is eye movement desensitisation and reprocessing (EMDR). This involves briefly recounting the trauma or objects associated with the trauma to the therapist who will then simultaneously initiate another stimulus, for example, moving a finger continuously in front of the patient's eyes or hand tapping. Over time it enables the patient to focus on alternative thoughts when associations with the trauma occur. A single session of debriefing following a traumatic event is not thought effective to prevent PTSD and, therefore, not recommended.

In OCD, CBT includes exposure and response prevention (ERP). This involves the therapist and the patient repeatedly facing the fears, beginning with the easiest situations and progressing until all the fears have been faced. At the same time the person must not perform any rituals or checks.

Specific phobias are also almost exclusively treated using exposure techniques and most patients will respond to this treatment. Only a very few will require additional drug therapy.

Other psychotherapies, although occasionally tried, have a poorer evidence base than CBT and are, therefore, not usually recommended. Self-help is one alternative technique which is recommended (NICE, 2007) for GAD and panic disorder. It involves using materials either alone or in part under professional guidance to learn skills to help cope with the anxiety. The materials such as books, tapes or computer packages can be accessed at home and in the patients' own time. Some self-help material, however, is of poor quality, so it is probably best used in those who have mild symptoms and who do not need more intensive treatments.

Pharmacotherapy

Benzodiazepines

Benzodiazepines are commonly prescribed to provide immediate relief of the symptoms of severe anxiety. A number of different benzodiazepines are available (Table 28.2). These drugs differ considerably in potency (equivalent dosage) and in rate of elimination but only slightly in clinical effects. All benzodiazepines have sedative/hypnotic, anxiolytic, amnesic, muscular relaxant and anticonvulsant actions with minor differences in the relative potency of these effects.

Pharmacokinetics. Most benzodiazepines are well absorbed and rapidly penetrate the brain, producing an effect within half an hour after oral administration. Rates of elimination vary; however, with elimination half-lives from 8 to 35 h (see Table 28.2). The drugs undergo hepatic metabolism via oxidation or conjugation and some form pharmacologically active metabolites with even longer elimination half-lives. Oxidation of benzodiazepines is decreased in the elderly, in patients with hepatic impairment and in the presence of some drugs, including alcohol. Benzodiazepines are metabolised through the cytochrome P450 3A4/3 enzyme system in the liver, so

Table 28.2 Profile of selected benzodiazepines (Bazire, 2009; Taylor et al., 2009)

Drug	Usual daily dose (mg)	Half-life hours (range)	Equivalent dose to diazepam 10 mg
Alprazolam	0.5–1.5	13 (12–15)	Unknown
Chlordiazepoxide	30	12 (6–30)	30 mg
Clonazepam	2–4	35 (20–60)	1–2 mg
Diazepam	5–30	32 (21–50)	–
Lorazepam	1–4	12 (8–25)	1 mg
Oxazepam	30	8 (5–15)	30 mg
Temazepam	10–20	8 (5–11)	20 mg

significant enzyme inducers (such as carbamazepine) may reduce levels while enzyme inhibitors (e.g. erythromycin) may increase levels (Bazire, 2009).

Mechanism of action. Most of the effects of benzodiazepines result from their interaction with specific binding sites associated with postsynaptic $GABA_A$ receptors in the brain. All benzodiazepines bind to these sites, although with varying degrees of affinity, and potentiate the inhibitory actions of GABA at these sites. GABA is the most important inhibitory neurotransmitter in the central nervous system (CNS). Neuronal activity in the CNS is regulated by the balance between GABA inhibitory activity and excitatory neurotransmitters such as glutamate. If the balance swings towards more GABA activity, sedation, ataxia and amnesia occur. Conversely, when GABA is reduced arousal, anxiety and restlessness occur. $GABA_A$ receptors are multimolecular complexes that control a chloride ion channel and contain specific binding sites for GABA, benzodiazepines and several other drugs, including many non-benzodiazepine hypnotics and some anticonvulsant drugs (Haefely, 1990) (Fig. 28.4). The various effects of benzodiazepines (hypnotic, anxiolytic, anticonvulsant, amnesic, myo-relaxant) result from GABA potentiation in specific brain sites and at different $GABA_A$ receptor types. There are multiple subtypes of $GABA_A$ receptor which may contain different combinations of at least 17 subunits (including α_{1-6}, β_{1-3}, γ_{1-3} and others) and the subtypes are differentially distributed in the brain (Christmas et al., 2008). Benzodiazepines bind to two or more subtypes and it appears that combination with α_2-containing subtypes mediates their anxiolytic effects and α_1-containing subtypes their sedative and amnesic effects. There is some evidence that patients with anxiety disorders

GABA activation of receptor opens channel gate, an effect enhanced by benzodiazepine binding to receptor subunits
Fig. 28.4 Schematic diagram of the $GABA_A$ receptor. This consists of five subunits arranged around a central chloride ion channel (one subunit has been removed in the diagram to reveal the ion channel, shown in the closed position). Some of the subunits have binding sites for benzodiazepines (B) and other hypnotics and anticonvulsants. Activation of the receptor by GABA opens the chloride channel, allowing chloride ions (Cl⁻) to enter the cell, resulting in hyperpolarisation (inhibition) of the neurone. Occupation of the benzodiazepine site, along with GABA, potentiates the inhibitory actions of GABA.

have reduced numbers of benzodiazepine receptors in key brain areas that regulate anxiety responses (Roy-Byrne, 2005). Secondary suppression of noradrenergic and/or serotonergic and other excitatory systems may also be of importance in relation to the anxiolytic effects of benzodiazepines.

Role in treating anxiety. The benzodiazepines have been used for over 40 years in the treatment of anxiety and can provide rapid symptomatic relief from acute anxiety states. Concerns over dependence and tolerance restrict use to short-term use only. Many clinical trials have shown short-term efficacy in patients with anxiety disorders, although the efficacy shown is in part dependent on the year of publication of the study. Older randomised controlled trials appear to show a larger effect than more recent ones (Martin et al., 2007). Anxiolytic effects have also been reported in normal volunteers with high trait anxiety and in patients with anticipatory anxiety before surgery. However, in subjects with low trait anxiety and in non-stressful conditions, benzodiazepines may paradoxically increase anxiety and impair psychomotor performance.

Although useful for many anxiety disorders, benzodiazepines are not generally recommended for those with panic disorder as the long-term outcome is poor (NICE, 2007). Some patients report worse panic attacks after the benzodiazepines are stopped. Benzodiazepines are also useful at the start of SSRI treatment in OCD and as hypnotics in PTSD (NICE, 2005a,b). They should, however, be used at the lowest effective dose prescribed intermittently where possible and used for no longer than 2–4 weeks.

Choice of benzodiazepine in anxiety. The choice of benzodiazepine depends largely on pharmacokinetic characteristics. Potent benzodiazepines such as lorazepam and alprazolam (Table 28.2) have been widely used for anxiety disorders but are probably inappropriate. Both are rapidly eliminated and need to be taken several times a day. Declining blood concentrations may lead to interdose anxiety as the anxiolytic effect of each tablet wears off. The high potency of lorazepam (~10 times that of diazepam), and the fact that it is available only in 1 and 2.5 mg tablet strengths, has often led to excessive dosage. Similarly, alprazolam (~20 times more potent than diazepam) has often been used in excessive dosage, particularly in the USA. Such doses lead to adverse effects, a high probability of dependence and difficulties in withdrawal.

A slowly eliminated benzodiazepine such as diazepam is more appropriate in most cases. Diazepam has a rapid onset of action and its slow elimination ensures a steady blood concentration. Clonazepam, although long acting, is more potent than diazepam and in practice is often difficult to withdraw from. It is only indicated for epilepsy in the UK, but is commonly used as an anxiolytic.

Parenteral administration of lorazepam or diazepam may occasionally be indicated for severely agitated psychiatric patients.

Adverse effects. Adverse effects include drowsiness, lightheadedness, confusion, ataxia, amnesia, a paradoxical increase in aggression, an increased risk of falls and fractures in the elderly and an increased risk of road traffic accidents. They are also widely acknowledged as addictive and cause tolerance after more than 2–4 weeks of continuous use (Taylor et al., 2009). Respiratory depression is rare, but possible following high oral doses or parenteral use. Flumazenil, a benzodiazepine receptor antagonist, can reverse the effects of severe reactions but requires repeated dosing and close monitoring because of its short half-life.

Psychomotor and cognitive impairment. Although oversedation is not usually a problem in anxious patients, there is evidence that long-term use of benzodiazepines results in psychomotor impairment and has adverse effects on memory. Many patients on long-term benzodiazepines complain of poor memory and incidents of shoplifting have been attributed to memory lapses caused by benzodiazepine use. In elderly patients, the amnesic effects may falsely suggest the development of dementia. There is some evidence that benzodiazepines also inhibit the learning of alternative stress-coping strategies, such as behavioural treatments for agoraphobia. Additive effects with other CNS depressants including alcohol occur and may contribute to road traffic and other accidents.

Disinhibition, paradoxical effects. Occasionally, benzodiazepines produce paradoxical stimulant effects. These effects are most marked in anxious subjects and include excitement, increased anxiety, irritability and outbursts of rage. Violent behaviour has sometimes been attributed to disinhibition by benzodiazepines. This behaviour is normally suppressed by social restraints, fear or anxiety. Increased day-time anxiety can also occur with rapidly eliminated benzodiazepines and may be a withdrawal effect.

Affective reactions. Chronic use of benzodiazepines can aggravate depression, may sometimes provoke suicide attempts in impulsive patients, and can cause depression in patients with no previous history of depressive disorder. Aggravation of depression is a particular risk in anxious patients who often have mixed anxiety/depression. Benzodiazepines are taken alone or in combination with other drugs in 40% of self-poisoning incidents. Although relatively non-toxic in overdose, they can cause fatalities as a result of drug interactions and in those with respiratory disease.

Some patients on long-term benzodiazepines complain of 'emotional anaesthesia' with inability to experience either pleasure or distress. However, in some patients, benzodiazepines induce euphoria and they are occasionally used as drugs of abuse.

Dependence. The greatest drawback of chronic benzodiazepine use is the development of drug dependence. It is generally agreed that the regular use of therapeutic doses of benzodiazepines as hypnotics or anxiolytics for more than a few weeks (2–4 weeks) can give rise to dependence, with withdrawal symptoms on cessation of drug use in over 40% of patients. It is estimated that there are about 1 million long-term benzodiazepine users in the UK and many of these are likely to be dependent. People with substance misuse histories, anxious or 'passive-dependent' personalities seem to be most vulnerable to dependence and withdrawal symptoms. Such individuals make up a large proportion of anxious patients in psychiatric practice, are often described as suffering from 'chronic anxiety' and are the type of patient for whom benzodiazepines are most likely to be prescribed.

Such patients often continue to take benzodiazepines for many years because attempts at dosage reduction or drug withdrawal result in abstinence symptoms, which they are unable to tolerate. Nevertheless, these patients continue to suffer from anxiety symptoms despite continued benzodiazepine use, possibly because they have become tolerant to the anxiolytic effects and may also suffer from other adverse effects of long-term benzodiazepine use such as depression or psychomotor impairment.

Abuse. In the last 15 years, there has been much concern about benzodiazepine abuse. Some patients escalate their prescribed dosage and may obtain prescriptions from several doctors. These tend to be anxious patients with 'passive-dependent' personalities who may have a history of alcohol misuse; they often combine large doses of benzodiazepines with excessive alcohol consumption. In addition, a high proportion (30–90%) of illicit recreational drug abusers also use benzodiazepines and some take them as euphoriants in their own right. Recreational use of most benzodiazepines has been reported in various countries; in the UK, temazepam is most commonly abused. Exceedingly large doses (over 1 g) may be taken and sometimes injected intravenously. Benzodiazepines became easily available due to widespread prescribing which favoured their entrance into the illicit drug scene. Abusers become dependent and suffer the same adverse effects and withdrawal symptoms as prescribed dose users.

Benzodiazepine withdrawal. Many patients on long-term benzodiazepines seek help with drug withdrawal. Clinical experience shows that withdrawal is feasible in most patients if carried out with care. Abrupt withdrawal in dependent subjects is dangerous and can induce acute anxiety, psychosis or convulsions. However, gradual withdrawal, coupled where necessary with psychological treatments, can be successful in the majority of patients. The duration of withdrawal should be tailored to individual needs and may last many months. Dosage reductions may be of the order of 1–2 mg of diazepam per month. Even with slow dosage reduction, a variety of withdrawal symptoms may be experienced, including increased anxiety, insomnia, hypersensitivity to sensory stimuli, perceptual distortions, paraesthesia, muscle twitching, depression and many others (Box 28.2). These may last for many weeks, though diminishing in intensity, but occasionally the withdrawal syndrome is protracted for a year or more. Transfer to diazepam, because of its slow elimination and availability as a liquid and in low dosage forms, may be indicated for patients taking other benzodiazepines. Useful guidelines for benzodiazepine withdrawal are given in the British National Formulary and detailed withdrawal schedules are also available (Lader et al., 2009).

The eventual outcome does not appear to be influenced by dosage, type of benzodiazepine, duration of use, personality disorder, psychiatric history, age, severity of withdrawal symptoms or rate of withdrawal. Hence, benzodiazepine withdrawal is worth attempting in patients who are motivated to stop and most patients report that they feel better after withdrawal than when they were taking the benzodiazepine. Community pharmacists may be ideally suited to advise doc-

Box 28.2 Some common benzodiazepine withdrawal symptoms	
Symptoms common to anxiety states	**Symptoms relatively specific to benzodiazepine withdrawal**
Anxiety, panic	Perceptual distortions, sense of
Agoraphobia	movement
Insomnia, nightmares	Depersonalisation, derealisation
Depression, dysphoria	Hallucinations
Excitability, restlessness	Distortion of body image
Poor memory and	Tingling, numbness, altered
concentration	sensation
Dizziness, light-headedness	Skin prickling (formication)
Weakness, 'jelly legs'	Sensory hypersensitivity
Tremor	Muscle twitches, jerks
Muscle pain, stiffness	Tinnitus
Sweating, night sweats	Psychosis[a]
Palpitations	Confusion, delirium[a]
Blurred or double vision	Convulsions[a]
Gastro-intestinal and urinary	
symptoms	

[a]Usually only on rapid or abrupt withdrawal from high doses.

tors and patients on the management of benzodiazepine withdrawal. Leading a benzodiazepine withdrawal clinic may also be a useful role for pharmacist or nurse prescribers.

Drug interactions. In addition to the pharmacokinetic interactions listed earlier, benzodiazepines have additive effects with other CNS depressants. Combinations of benzodiazepines with alcohol, other hypnotics, sedative tricyclic antidepressants (TCAs), antihistamines or opioids can cause marked sedation and may lead to accidents, collapse or severe respiratory depression.

Pregnancy and lactation. The regular use of benzodiazepines is not recommended in pregnancy since the drugs are concentrated in fetal tissue where hepatic metabolism is minimal. They have been associated with an increased risk of oral clefts following first trimester exposure, a low birth weight, neonatal depression, feeding difficulties and withdrawal symptoms if given in late pregnancy. They also enter breast milk and may cause sedation, lethargy and weight loss in the infant. Long-acting benzodiazepines should particularly be avoided during lactation because of the potential for the infant to accumulate the drug. Short- to medium-acting benzodiazepines are occasionally used with enhanced monitoring of the infant.

Antidepressant drugs

Antidepressants can provide a long-term treatment option for those with an anxiety disorder. They are generally recommended for those who are unable to commit to or have not responded to psychological therapies. In addition, antidepressants are considered first-line treatment option either alone or in combination with CBT in patients suffering from OCD with moderate or severe impairment (NICE, 2005a). The number needed to treat (NNT) to see one benefit with antidepressants is around five in PTSD and GAD (NICE, 2005b, 2007).

The response rate to antidepressants in anxiety is often lower and takes longer than that seen in depression. Initial worsening of symptoms can occur and high therapeutic doses are often required to improve response (Baldwin et al., 2005).

Selective serotonin reuptake inhibitors. The selective serotonin reuptake inhibitors (SSRIs) have a broad anxiolytic effect and are considered the first drug options in GAD, panic disorder, social phobia, PTSD and OCD (NICE, 2005a,b, 2007; Baldwin et al., 2005). Individual SSRIs have varying licensed indications across the anxiety disorders but this does not necessarily mean others have no supporting evidence. Where more than one SSRI is licensed in a particular disorder it is not possible to conclude which SSRI would be more effective because of the lack of direct head to head trials. The SSRIs do differ in their interaction potential, side effect profile and ease of discontinuation. Initial worsening of symptoms is common when starting an SSRI in anxiety, so beginning with half the dose than that used in depression is recommended as is reassuring the patient that this is usually only experienced for the first few weeks of treatment. In view of these concerns, the NICE (2007) guidelines for GAD and panic disorder recommend that patients are reviewed every 2 weeks for the first 6 weeks of treatment to monitor for efficacy and tolerability.

Tricyclic antidepressants. Certain TCAs such as clomipramine, imipramine and amitriptyline are efficacious in some anxiety disorders. They are, however, associated with a greater burden of adverse reactions such as anticholinergic effects, hypotension and weight gain. Of particular concern is the TCAs' cardiac toxicity in overdose which relegates their use to second line following the failure of an SSRI. They should be avoided in any patient at risk of suicide or those with an underlying cardiac disease. TCAs commonly cause sedation which occasionally can prove useful in anxiety disorders. Clomipramine may also be slightly more effective in OCD compared with SSRIs.

Monoamine-oxidase inhibitors. The monoamine-oxidase inhibitors (MAOIs) are rarely used in practice because of their potential interactions with other medicines and tyramine in the diet. Moclobemide is a reversible MAOI, so causes fewer problematic interactions. Phenelzine and moclobemide are occasionally used by specialists in social phobia following the failure of an SSRI. Phenelzine is also recommended as a third-line treatment option in PTSD (NICE, 2005b).

Other antidepressants. The selective and noradrenaline reuptake inhibitor (SNRI) venlafaxine has some evidence to support its use in almost all the anxiety disorders, but it is only licensed for use in GAD and social phobia at a dose of 75 mg/day in the extended release form. Discontinuation symptoms are common following venlafaxine withdrawal and can be experienced after missing a single dose. Patients prescribed venlafaxine should be reminded of the importance of a slow withdrawal (over at least 4 weeks) when discontinuation is necessary. Venlafaxine can increase blood pressure at higher doses and so is contraindicated in patients with a very high risk of cardiac ventricular arrhythmia or uncontrolled hypertension. Duloxetine, another SNRI, is also licensed in GAD and can similarly increase blood pressure.

Mirtazapine, an α_2-adrenoreceptor antagonist, is recommended as an option for PTSD if patients do not wish to participate in trauma focused CBT (NICE, 2005b). Mirtazapine has a lower incidence of nausea, vomiting and sexual dysfunction than the SSRIs but can commonly cause weight gain and sedation.

No other antidepressants are routinely recommended for anxiety disorders, although some such as agomelatine are under clinical trials in anxiety to investigate potential future uses. To reduce the risk of symptoms returning patients should be advised to continue the antidepressant for at least 6 months following improvement of symptoms in GAD and panic disorder and for 12 months in PTSD, OCD and social phobia (NICE, 2005a, 2007; Baldwin et al., 2005). Those with an enduring and recurrent illness, however, may continue for many years, depending on the risk of relapse and severity of symptoms.

For a complete review of the antidepressants, including adverse effects and interactions, see Chapter 29.

Other medications occasionally used in anxiety

Hydroxyzine, a sedating antihistamine, is licensed for the short-term treatment of anxiety in adults at a dose of 50–100 mg four times a day. The clinical evidence only supports its use in GAD (for up to 4 weeks) if sedation is required. NICE supports the use of a sedating antihistamine in the immediate management of GAD but state they should not be used in panic disorders (NICE, 2007).

Antipsychotics have limited evidence and a high side effect burden when used in anxiety disorders. The first-generation (typical) antipsychotics are associated with movement disorders such as akathisia and tardive dyskinesia and so are rarely used in anxiety. The second-generation (atypical) antipsychotics are less likely to cause movement disorders but can have other physical health concerns. The majority of the evidence only supports antipsychotics (specifically risperidone and quetiapine) in combination with an SSRI in OCD in those who have failed to respond to the SSRI alone. Olanzapine augmentation has also been used in PTSD and social phobia.

Pregabalin is licensed for GAD and has shown an anxiolytic effect over placebo after 1 week in adults or 2 weeks in the elderly (Montgomery et al., 2008). Two short-term studies (4 and 6 weeks) suggest that pregabalin 400–600 mg/day is as effective but better tolerated than venlafaxine 75 mg/day XL or lorazepam 6 mg/day. Pregabalin, however, commonly causes dizziness, somnolence and nausea and is more expensive than other medication options in GAD and should be limited to specialist use only after other treatments have failed.

Buspirone, a $5HT_{1A}$ partial agonist, is licensed for short-term use in anxiety. It is not a benzodiazepine and so does not treat or prevent benzodiazepine withdrawal problems. In GAD, buspirone and other azapirones are superior to placebo in short-term studies (4–9 weeks) but less effective or acceptable than benzodiazepines (Chessick et al., 2006). NICE have said the evidence for buspirone in GAD is equivocal and, therefore, presumably not recommended (NICE, 2007). There is no evidence supporting buspirone in other anxiety disorders.

Table 28.3   Overview of the recommended drug treatments in anxiety

	Generalised anxiety disorder (GAD)	Panic disorder	Social phobia (social anxiety disorder)	Obsessive-compulsive disorder (OCD)	Post-traumatic stress disorder (PTSD)
Immediate management/ short-term treatment	Benzodiazepines (2–4 weeks only) Hydroxyzine	Benzodiazepines not recommended by NICE	Benzodiazepines (2–4 weeks only)	Benzodiazepines (only to counter initial worsening of symptoms with SSRIs)	Hypnotics may be considered for short-term use for insomnia
First-line pharmacotherapy[a]	SSRI Escitalopram Paroxetine Sertraline	SSRI Citalopram Escitalopram Paroxetine	SSRI Escitalopram Paroxetine	SSRI Escitalopram Fluoxetine Fluvoxamine Paroxetine Sertraline	SSRI Paroxetine Sertraline
Other drug treatments with some supporting evidence	Buspirone Duloxetine Imipramine Pregabalin[c] Venlafaxine	Clomipramine[b] Imipramine[b] Mirtazapine Moclobemide Venlafaxine	Moclobemide[c] Phenelzine[c] Venlafaxine	Clomipramine Augmentation with quetiapine or risperidone[c]	Amitriptyline[c] Augmentation with olanzapine or risperidone[c] Imipramine Mirtazapine[b] Phenelzine[c] Venlafaxine

[a]The licensed SSRI is indicated but other SSRIs may also be beneficial.
[b]Unlicensed but recommended by NICE (2005a,b, 2007).
[c]Usually prescribed by mental health specialists only.

Propranolol and oxprenolol are both licensed for anxiety symptoms but are probably only useful for physical symptoms such as palpitations, tremor, sweating and shortness of breath. β-Blockers do not have sufficient evidence to support their inclusion in NICE guidelines but intriguingly small pilot studies indicate that giving an immediate course of propranolol following a traumatic event may prevent emerging PTSD (Pitman et al., 2002; Vaiva et al., 2003).

An overview of the recommended drug treatments in anxiety is provided in Table 28.3.

Case studies

Case 28.1

Mrs DW is a 32-year-old with a 10-year history of 'emotional problems'. These have largely been dealt with by her primary care doctor who has prescribed low dose TCAs for the last 3 years. Mrs DW's life is severely restricted by a number of rituals which she obsessively carries out. They include washing of sinks, baths and toilets, disinfection of kitchen surfaces, and vacuuming. These activities occupy up to 8 hours a day.

Current prescribed medication:
Diazepam 10 mg three times a day
Amitriptyline 25 mg twice a day
Both have been prescribed for 3 years

Mrs DW is concerned about possible addiction to her medication, as previous attempts to stop it have been unsuccessful. In addition, both she and her family feel that more can be achieved and are willing to work at solving the problems faced by Mrs DW.

Questions

1. Is this appropriate therapy for OCD and if not what would be a better first choice?
2. Suggest possible drug therapies for Mrs DW and indicate for how long they should be continued?
3. Providing an alternative therapy is commenced, recommend an appropriate scheme for withdrawal of the diazepam.

Answers

1. Benzodiazepines are not recommended in OCD. First choice is cognitive behaviour therapy or an SSRI.
2. Potential drug treatments include high dose SSRIs or clomipramine. Augmentation strategies (e.g. antipsychotics) would also be a possibility. Treatment may need to be continued for a year before a dose reduction is tried.
3. As Mrs DW is on a dose of 30 mg diazepam daily, it would be appropriate to consider reducing the diazepam by 2 mg/day every 1–2 weeks until 20 mg/day dose is reached. Further reductions may need to be 1 mg every 1–2 weeks until stopped. Longer intervals between dose reduction may be necessary as the dose reduces towards zero. Patient may wish to adopt faster withdrawal and accept the consequences. All patients should be monitored for increased anxiety, restlessness, agitation, etc., and may need slow withdrawal.

Case 28.2

Mrs AB, a previously well 30-year-old woman, had been treated with paroxetine 40 mg daily for anxiety/depression which had been precipitated by a traumatic marriage break-up. After taking paroxetine for 18 months, Mrs AB's problems had

mainly resolved and she was feeling well. She decided that she no longer needed the drug and stopped taking it. Within 3 days her anxiety/depression returned with insomnia and nightmares. Her mood lowered and she became irritable and found herself weeping for no reason. A week later she returned to her doctor complaining of these symptoms as well as depersonalisation and strange electric shock sensations. The doctor thought the original depression had returned and reinstated paroxetine which cleared up her symptoms within a few days.

Questions

1. What alternative explanation could there be for Mrs AB's symptoms and what other decision could the doctor have made?
2. What would be a suitable withdrawal schedule for her paroxetine?

Answers

1. All antidepressants can cause a discontinuation reaction. Mrs AB's symptoms were typical of SSRI withdrawal. This occurs most commonly with paroxetine, perhaps partly due to its rapid rate of elimination (half-life 21 h in chronic users).
2. In this previously well lady no longer under marital stress, the doctor, after reinstating paroxetine, could have supplied a gradual tapering schedule of drug withdrawal, that is, reducing the dose by 10 mg/week, aiming to withdrawal in 4 weeks.

Case 28.3

Mr SB is a 22-year-old soldier. He has recently returned from his second active tour where he was injured by a roadside bomb. Two of his squad were killed in the same blast and, although his physical injuries healed quickly, he has persistent and intense episodes of panic and flashbacks. He is especially aroused at night and has great difficulty getting to sleep. An initial prescription of an SSRI has proved ineffective and he is currently on the waiting list for psychological therapies.

Question

1. What alternative drug treatment may be appropriate?

Answer

1. A sedating antidepressant such as mirtazapine or amitriptyline may be appropriate, ensuring adequate duration of therapy and effective dose. A short cause of a benzodiazepine may prove useful but for no longer than 2–4 weeks. Alternatively, augmenting the antidepressant with a sedating antipsychotic such as olanzapine may be useful. For prolonged symptom treatment and relapse prevention it is likely that the patient will need to fully engage with psychological therapies.

Case 28.4

Ms AC is a 32-year-old personal assistant to a director of a leading investment company. She has recently been promoted to this role and is now expected to entertain potential clients by dining out with the director at local restaurants. She has always preferred eating alone in the comfort of her own home and the thought of eating in public while promoting the business fills her with dread, which brings on palpitations and shortness of breath.

Questions

1. What drug therapy is available which may provide some immediate relief of her anxiety symptoms?
2. What would be an appropriate choice of treatment for long-term control and prevention of symptoms?

Answers

1. β-Blockers such as propranolol may help with the shortness of breath and palpitations but will not treat the fear and dread. Benzodiazepines may be appropriate but may affect her performance and cause other adverse reactions.
2. For long-term control, a course of cognitive behavioural therapy including exposure techniques is appropriate or treatment with an SSRI such as escitalopram.

Affective disorders 29

J. P. Pratt

Key points

- Diagnosis should be made using standardised criteria, for example, DSM IV, ICD 10.
- Target symptoms should be recorded and response to treatment monitored against these symptoms.
- In patients with depression of mild severity, non-pharmacological strategies should be considered as first-line intervention.
- The evidence base for determining the use of a particular antidepressant in an individual patient does not exist. For most patients, when an antidepressant is indicated, a generic SSRI should be considered as a first-line treatment option.
- Currently, all antidepressants are considered equally effective but differ in their side effect profile, toxicity in overdose, need for dose titration and monitoring.
- In the absence of a previous response or contraindication, antidepressant choice should be guided by evidence-based clinical guidelines and the clinician and the patient's perception of the risks and benefits of available options. Resource implications should not be ignored.
- Emerging evidence and a greater understanding of the clinical application of pharmacogenomics may increase the ability to individualise treatments in the future.
- Comprehensive assessment, accurate diagnosis, adequate duration of pharmacotherapy and involvement of the patient in the treatment regimen are the cornerstones of effective management of affective disorders.
- Valproate, antipsychotics and benzodiazepines, sometimes in combination, are the treatments of choice in acute mania.
- Either lithium, valproate or specific antipsychotics may be considered to be the first-line prophylactic agent of choice in bipolar I disorder.

This chapter focuses on affective disorders in adults. The issues of affective disorders in children and adolescents are more complex and beyond the scope of this section.

The central feature of an affective disorder is an alteration in mood. The most common presentation is that of a low mood or depression. Less commonly, the mood may become high or elated, as in mania.

Classification

Depression

The term 'depression' can in itself be misleading. Everyone in the normal course of daily life will experience alterations in mood. Depressed mood in this context does not represent a disorder or illness; in fact, lowered mood as a response to the ups and downs of living is considered normal and termed sadness or unhappiness. Sometimes clinical depression may present in a mild form, so it is important to differentiate this from normal unhappiness.

Mania

If the mood becomes elated or irritable this may be a symptom of mania. The term 'mania' is used to describe severe cases, frequently associated with psychotic symptoms. Hypomania describes a less severe form of the disorder. In clinical practice, this distinction often becomes blurred, with hypomania being seen as patients develop, or recover from, mania.

Bipolar and unipolar disorders

If a patient develops one or more severe episodes of a mood disorder which includes a manic episode, the condition may be termed a bipolar disorder. The existence of repeated manic episodes alone is sufficient to be termed a bipolar disorder. The disorder can be further categorised as bipolar I, where full-blown episodes of mania occur, and bipolar II, where depressive episodes are interspersed with less severe hypomanic episodes. The term 'manic-depressive' is now outdated. Rapid cycling describes the existence of four or more episodes within a year. Unipolar mood disorder is used to describe single episodes of depression.

Epidemiology

Differences in diagnosis, particularly of depression, make it difficult to estimate the true incidence of affective disorders. The lifetime risk of developing a bipolar I disorder is said to be about 1% (0.3–1.5%). An accurate estimate for the more broadly defined bipolar II disorder is more difficult and it may be much more common, with studies suggesting a lifetime prevalence of between 0.2% and 10.9%. The incidence of bipolar I is generally reported to be the same for both men and women, whereas some studies suggest that bipolar II may be slightly more common in women. By comparison, the overall incidence of depression is much higher and there does appear to be a significant difference between the sexes. Studies from America and Europe, using standard assessment tools, found a lifetime prevalence of between 16% and 17%,

with a 6-month prevalence of about 6%. Higher rates are consistently found in women but social, economic and ethnic factors are also likely to be influential. Although depression may occur at any age, including early childhood, it is estimated that the average age of onset of depression is in the mid-20s. Some earlier studies found the incidence and prevalence of depression in women peaking at the age of 35–45 years. In bipolar disorder, an earlier age of onset is suggested, perhaps in late adolescence, with most people experiencing their first episodes before 30 years of age.

Aetiology

Like most psychiatric disorders, the causes of affective disorders remain unknown. In depression, it is likely that genetic, hormonal, biochemical, environmental and social factors all have some role in determining an individual's susceptibility to developing the disorder, with major life events sometimes, but not always, acting as a precipitant for a particular episode. Although pharmacological treatments are clearly effective, there is no simple relationship between biochemical abnormalities and affective disorders.

Genetic causes

In depression, one theory suggests that a variant of the gene responsible for encoding the serotonin transporter protein could account for early childhood experiences being translated into an increased risk of depression through stress sensitivity in adulthood. In bipolar disorder, some genetic linkage has been proposed, but a precise marker remains elusive.

The incidence of affective disorder in first-degree relatives of someone with severe depression may be about 20%, which is almost three times the risk for relatives in control groups. Comparisons of the risk of affective disorder in the children of both parents with an affective disorder show a four times greater risk, and the risk is doubled in children with one parent with an affective disorder. Studies looking at twins have found fairly strong evidence for a genetic factor. Evidence of a genetic link has also been found in studies of children from parents with affective disorder who were adopted by healthy parents. A higher incidence of affective disorder was found in the biological parents of adopted children with affective disorder than in the adoptive parents.

Environmental factors

Although environmental stresses can often be identified prior to an episode of mania or depression, a causal relationship between a major event in someone's life and the development of an affective disorder has not been firmly established. It may be that life events described as 'threatening' are more likely to be associated with depression. The lack of prospective studies makes it difficult to interpret data linking early life events, such as loss of a parent, to the development of an affective disorder. The fact that specific environmental stresses have not

been identified should not lead to the conclusion that the environment or lifestyle is irrelevant to the course or development of affective disorders. Employment, higher socio-economic status and the existence of a close and confiding relationship have been consistently noted to offer some protection against the development of an episode.

Biochemical factors

In its simplistic form, the biochemical theory of depression postulates a deficiency of neurotransmitter amines in certain areas of the brain. This theory has been developed to suggest that receptor sensitivity changes may be important. Alternative propositions suggest a central role of acetylcholine arising from dysregulation of the cholinergic and noradrenergic neurotransmitter systems. Although many neurotransmitters may be implicated, the theory focuses on an involvement of the neurotransmitters noradrenaline (norepinephrine), serotonin (5-hydroxytryptamine) and dopamine. This theory emerged from the findings that both monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants appeared to increase neurotransmitter amines, particularly noradrenaline (norepinephrine), at important sites in the brain. When it was found that reserpine, previously used as an antihypertensive, caused both a depletion of neurotransmitter and also induced depression, this was taken as an apparent confirmation of the theory.

Although less attention has been paid to dopaminergic activity, some studies have found reduced activity in depressed patients, and an overactivity has been postulated in mania.

The concept of noradrenergic (norepinephrinergic) and serotonergic forms of depression has not gained widespread support, and there is no justification in measuring the activity of neurotransmitters such as noradrenaline (norepinephrine) or serotonin metabolites in routine clinical practice.

Endocrine factors

The endocrine system, particularly the hypothalamic-pituitary-adrenal (HPA) axis and the hypothalamic-pituitary-thyroid (HPT) axis, is felt to be implicated in the development of affective disorders. Some endocrine disorders such as hypothyroidism and Cushing's syndrome have also been associated with changes in mood. People with depression have been found to have increased cortisol levels, which also supported the proposition that mood disorders may be linked to dysfunction within the HPA axis. This led to the development of a dexamethasone suppression test for depression in the 1970s. The relationship between cortisol and symptoms of depression is complex which severely limits the clinical utility of such a test.

Physical illness and side effects of medication

Disorders of mood, particularly depression, have been associated with several types of medication and a number of physical illnesses (Box 29.1). Depression can affect the outcome in people with a range of physical problems. An increase in death rates has been found in those patients with co-morbid depression.

Drugs
Analgesics
Antidepressants
Antihypertensives
Anticonvulsants
Opiate withdrawal
Amfetamine withdrawal
Benzodiazepine withdrawal
Antipsychotics
Benzodiazepines
Antiparkinsonism agents
Steroids
Oral contraceptives

Physical illness
Viral illness
Carcinoma
Neurological disorders
Diabetes
Multiple sclerosis
Thyroid disease
Addison's disease
Systemic lupus erythematosus
Pernicious anaemia

Box 29.2   ICD 10 diagnostic criteria for bipolar affective disorder (WHO, 1992)

Characterised by repeated (at least two) episodes in which the patient's mood and activity levels are significantly disturbed. This disturbance consisting on some occasions of an elevation in mood and increased energy and activity (mania or hypomania), and on others of a lowering of mood and decreased energy and activity (depression).

Manic episodes usually begin abruptly and last for between 2 weeks and 4–6 months (median 4 months). Depression tends to last longer (median about 6 months). Episodes of both kinds often follow stressful life events or other mental trauma, but the presence of such stress is not essential for the diagnosis.

Clinical manifestations

Depression

A low mood is the central feature of depression. This is often accompanied by a loss of interest or pleasure in normally enjoyable activities. Thinking is pessimistic and in some cases suicidal. A depressed person may complain they have little or no energy. In severe cases, psychotic symptoms such as mood congruent hallucination or delusion may be present. Anxiety or agitation frequently accompany the disorder, and the so-called biological features of sleep disturbances, weight loss and loss of appetite are often present. Depressed people typically complain of somatic symptoms, particularly gastric problems, and non-specific aches are common. Sexual drive is often reduced, and some people may lose interest in sex altogether. In some cases, the biological symptoms are reversed and excessive eating and sleeping may occur. In contrast to agitation, psychomotor retardation may be a presenting feature.

Bipolar disorder

Standardised diagnostic criteria vary. For an ICD 10 diagnosis of bipolar disorder, at least two mood episodes must occur, one of which must be manic or hypomanic (Box 29.2). According to DSM IV, at least one episode of mania must have occurred for a diagnosis of bipolar I disorder to be made; depression may also occur, but it is not essential.

Mania

In mania, the mood is described as elated or irritable and the accompanying overactivity is usually unproductive. Disinhibition may result in excessive spending sprees, inappropriate sexual activity and other high-risk behaviours. Driving may be particularly dangerous. Manic people may describe their thoughts as racing, with ideas rapidly changing from one topic to another. Speech may be very rapid with frequent punning and rhyming. Ideas may become grandiose with patients embarking on fantastic projects which lead nowhere and inevitably are left incomplete and disjointed. Clothing is usually flamboyant, and if make-up is worn it is usually excessive and involves bright colours.

Severity

The severity of the disorder may vary from mild through moderate to severe. In most circumstances, it would be inappropriate for people with mild forms of the disorders to be seen by specialist services and treated with pharmacotherapy. In the absence of a risk of serious self-harm, people with less severe forms of the disorder should be treated by the primary health care team. Guidelines advise that a stepwise approach is taken on the management of depression, with increasing evidence supporting the fact that antidepressant therapy is more likely to be effective in the more severe episodes (NICE, 2009).

If left untreated, it is important to remember that affective disorders carry a risk of mortality. In addition to suicidal attempts by someone who is depressed, the lack of self-care and physical exhaustion resulting from mania may be life-threatening. The social and financial consequences can have a devastating effect on both the patient with mania or hypomania and their family. Depression may also contribute to exacerbation of physical problems such as increased pain and worsening outcomes from cardiac disease (Nicholson et al., 2006).

Investigations

There are no universally accepted biochemical or genetic tests which will confirm the presence of an affective disorder. Various rating scales have been developed that may help to

demonstrate the severity of depressive disorder or distinguish a predominantly anxious patient from a depressed patient. Within the limits of our current understanding of the technology, biochemical or genetic tests are unlikely to be helpful in determining the treatment plan or management of affective disorders.

In the UK, mental and behavioural disorders are commonly classified using the *International Classification of Diseases*, ICD 10 (WHO, 1992). The American Psychiatric Association has developed a precise system of diagnosis, based on the description of symptoms in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM IV TR), now in its revised, fourth edition (American Psychiatric Association, 2000).

A systematic approach to the diagnosis of affective disorders is important when considering the effectiveness of medication. Most new clinical trials for antidepressants or antipsychotics require a DSM diagnosis as an entry criterion. In the UK, the ICD 10 classification is commonly used, with the severity of depression determined by the presence of the number of symptoms (see Boxes 29.2 and 29.3). More recently, use of the symptom count as a single factor upon which to base treatment decisions has been cautioned against (NICE, 2009). Account should also be taken of the extent of impairment and disability associated with depression.

National guidelines provide a sound framework for the management of depression (NICE, 2009) and bipolar disorder (NICE, 2006). It is important that people with depression are identified. A simple screening process for the presence of depression could involve asking the patient two questions about their mood and interest. For example, the patient could be asked 'During the last month, have you often been bothered by feeling down, depressed or hopeless?' and 'During the last month, have you often been bothered by having little interest or pleasure in doing things?'. If the answer to either question is 'no', it is unlikely the patient will be considered to have a depressive disorder. Patients who answer 'yes' warrant further investigation.

Identification of target symptoms may be useful in evaluating the response to treatment. In routine clinical practice, antidepressant medication should not generally be used to treat patients with mild depression. Non-pharmacological strategies are preferable in this group.

Rating scales

Various rating scales can be used to assist with the assessment of the severity of the disorder. Two of the more commonly used rating scales are the Beck Depression Inventory and the Hamilton Depression Rating Scale.

Beck Depression Inventory

This is a self-reporting scale looking at 21 depressive symptoms. The subject is asked to read a series of statements and mark on a scale of 1–4 how severe their symptoms are.

Box 29.3 ICD 10 diagnostic criteria for a depressive episode (WHO, 1992)

Usual symptoms
Depressed mood, loss of interest and enjoyment, and reduced energy leading to increased fatiguability and diminished activity

Common symptoms
Reduced concentration and attention
Reduced self-esteem and self-confidence
Ideas of guilt and unworthiness (even in a mild type of episode)
Bleak and pessimistic views of the future
Ideas or acts of self-harm or suicide
Disturbed sleep
Diminished appetite

In a depressive episode, the mood varies little from day to day and is often unresponsive to circumstances, yet may show characteristic diurnal variation as the day goes on. The clinical picture shows marked individual variations, and atypical presentations are particularly common in adolescence. In some cases, anxiety, distress and motor agitation may be more prominent at times than the depression.

For depressive episodes of all grades of severity, a duration of 2 weeks is usually required for diagnosis, but shorter periods may be reasonable if symptoms are unusually severe and of rapid onset.

Mild depressive episode: For at least 2 weeks, at least two of the usual symptoms of a depressive episode plus at least two of the common symptoms listed above.

An individual with a mild depressive episode is usually distressed by the symptoms and has some difficulty in continuing with ordinary work and social activities, but will probably not cease to function completely.

Moderate depressive episode: For at least 2 weeks, at least two or three of the usual symptoms of a depressive episode plus at least three (preferably four) of the common symptoms listed above.

An individual with moderately severe depressive episode will have these symptoms to a marked degree, but this is not essential if a particularly wide variety of symptoms is present overall. They will usually have considerable difficulties in continuing with social, work or domestic activities.

Severe depressive episode: For at least 2 weeks, all three of the usual symptoms of a depressive episode plus at least four of the common symptoms listed above, some of which should be of severe intensity.

An individual with severe depressive episode may be unable or unwilling to describe many symptoms in detail, but an overall grading of severe may still be justified. They will usually show considerable distress or agitation, unless retardation is a marked feature. Loss of self-esteem or feelings of uselessness or guilt are likely to be prominent. Suicide is a distinct danger, particularly in severe cases.

The higher the score, the more severely depressed a person may be.

Hamilton Depression Rating Scale

This rating scale is used by a health care professional at the end of an interview to rate the severity of depression.

Treatment

The aim of treatment is to prevent harm and to relieve distress or to be prophylactic. It is important to differentiate symptoms of the disorder from the premorbid personality. In general, the drugs which are used to control the symptoms of mania are not specifically antimanic. These agents are also used to treat other disorders. This means the diagnosis will primarily influence the way in which these drugs are used rather than the choice of drug per se. Clinicians should be aware of the licensed indication of treatments, so that any 'off label' use is done knowingly and in line with current best practice.

In the treatment of depression, all the antidepressants currently available in the UK may be considered to be equally effective. There is increasing evidence that patients with more severe episodes of depression are more likely to respond to antidepressant drugs, as opposed to placebo, than those with less severe forms of the disorder (Fournier et al., 2010). There is also some evidence to suggest that sertraline and escitalopram may have a more favourably risk/benefit profile than some other antidepressants (Cipriani et al., 2009). However, it is unclear if the magnitude of the difference between these drugs is sufficient to direct treatment choice for most depressed patients.

There are some generalisations which may help individualise the choice of antidepressant. Females may have a poorer tolerance of migraine than males and tricyclic antidepressants are less well tolerated and more likely to be toxic in overdose than the selective serotonin reuptake inhibitors (SSRIs). Patients may prefer one drug over another based on their past experience of benefit or side effects. Overall, the major difference between antidepressant agents is in their side effect profile and toxicity in overdose. There can also be significant variations in the costs of different agents.

Treatment of depression

In moderate and severe depression, pharmacological intervention is important, but this should never be considered in isolation from the social, cultural and environmental influences on the patient. Non-pharmacological therapies are effective and in mild depression they are considered preferable to drug treatment. Non-drug treatments and antidepressant medication are not mutually exclusive and in some cases it is preferable to use both in combination.

Drug treatment

Despite the availability of many new antidepressants, the therapeutic effectiveness of these agents has changed little since the discovery of the antidepressant properties of drugs used to prevent migraine in the late 1950s. Further research may reveal differences between antidepressants. Advances in the clinical utility of pharmacogenomics may, in time, provide clinicians with a tool to individualise pharmacotherapy. Overall, the SSRI antidepressants appear to be better tolerated than tricyclics and their safety profile in overdose should be an important consideration for use.

A strong response to placebo is found in most of the studies of antidepressants. Tolerability is, therefore, an important factor in the choice of drug; patients who are unable to tolerate the side effects of antidepressants are likely to discontinue these drugs. Antidepressants should be taken in adequate doses for some 4–6 weeks, and up to 12 weeks in older people, to achieve a full response. Following a single episode of depression, treatment should be continued for 6 months, at the same dose at which the patient achieved remission, before attempting withdrawal. In patients experiencing multiple episodes of depression, treatment should be continued for longer periods (2 years).

Withdrawal of antidepressants should normally be undertaken gradually. Following abrupt discontinuation, patients may experience symptoms of withdrawal that include gastro-intestinal symptoms, together with headache, giddiness, sweating, shaking and insomnia. In addition, extrapyramidal reactions may be associated with abrupt withdrawal from some of the SSRI antidepressants. Following successful treatment, antidepressants should be gradually reduced over a period of 4 weeks. This period should be increased if patients experience problems, or where medication has been given for extended periods.

Generally, the long half-life of fluoxetine enables the drug to be stopped without the need for tapering from the standard antidepressant dose of 20 mg. Patients taking MAOIs may experience psychomotor agitation following discontinuation.

As patients do not experience the craving typically associated with drugs of addiction, most health care professionals do not class antidepressants as addictive. Patients should be warned that there is a risk of problems with abrupt discontinuation, but use of emotive words like addiction or dependence is best avoided. In moderate or severe depression, the balance of risks and benefits is usually in favour of using antidepressants. Occasionally, some patients report that they have become dependent on their antidepressants and feel unable to stop taking them. These concerns should not be dismissed lightly, but the focus of discussion with the patient should be on the overall risks and benefits of the treatment in the context of their individual circumstances.

As discussed earlier, there is no strong evidence for the existence of a particular biochemical subtype of depression. However, some patients do respond better to particular antidepressants. This has led to the widely held view that previous response to treatment is a strong indication to use that particular drug in the treatment of a future episode.

In addition to previous response, the other important considerations to take into account when selecting an antidepressant are side effects, contraindications, toxicity in overdose, patient preference and clinician familiarity.

Generally speaking, the older drugs have a poorer side effect (Barbui et al., 2001; Geddes et al., 2002) and toxicity profile than the more recently introduced agents. Traditionally, the antidepressant drugs are categorised by their chemical structure, for example, tricyclic, or their predominant pharmacological action, for example, MAOI, SSRI.

Tricyclic antidepressants. A greater understanding of the pharmacology of antidepressants has given much support to the so-called biochemical theory of depression. Although substantial data on the pharmacological effects of the tricyclic antidepressants exist, it is still not clear how the drugs relieve the symptoms of depression. This is an important point often overlooked when discussing the issue with patients. The notion that depression is a simple lack of, or imbalance of, chemicals has little basis in fact. It merely provides a useful framework from which to discuss the benefits and harms of antidepressants.

It was thought originally that the primary effect of these drugs was related to their ability to block the reuptake of noradrenaline (norepinephrine) and/or 5HT following their release and action as neurotransmitters. As this effect occurs some weeks before the antidepressant response, clearly this is not the whole story. Following chronic administration, further biochemical changes take place, particularly with pre- and postsynaptic receptor sensitivity. Reduction of presynaptic α_2-inhibitory receptor sensitivity occurs, and this increases the production of noradrenaline (norepinephrine). Other effects which may be relevant include an increase in α_1 and β_1 receptor sensitivity. It is now felt that these receptor changes in the cerebral cortex and hippocampus may be more relevant to the antidepressant response than simple reuptake inhibition.

There are a number of tricyclic antidepressants in current clinical use. The basic chemical structures of these compounds are similar but there are differences between them. All the tricyclic antidepressants block the reuptake of noradrenaline (norepinephrine) and 5HT to a greater or lesser degree. In view of the risks associated with cardiac abnormalities, an ECG is advised prior to initiating treatment with this group of drugs.

Imipramine. The antidepressant effect of imipramine was demonstrated around 50 years ago and it has been widely prescribed in subsequent years. Although imipramine is less sedating than other tricyclic drugs, some patients may still experience problems. As well as cardiovascular problems, significant antimuscarinic effects such as dry mouth, blurred vision and constipation occur. Females tend to tolerate imipramine less well than males. At one time it was felt to be important that the drug should be prescribed at the full therapeutic dose. Recent analysis of clinical trials suggests this is not the case. If patients respond to lower doses, there is no rationale for increasing the dose further. Tolerance may develop to some of the unpleasant side effects, and this may be facilitated by starting with a lower dose of the drug and gradually increasing the dose over a week.

In addition to the unpleasant side effect profile, imipramine is toxic following overdose. Considering that the drug is used to treat a disorder which involves suicide, this relative lack of safety is an important disadvantage. As with all tricyclics, imipramine should only be used in circumstances where cardiac tolerability can be assured and intentional overdose can be prevented. Imipramine is metabolised by demethylation to an active metabolite, desipramine. Both the parent drug and its metabolite have long half-lives, of 9–20 and 10–35h, respectively, that permit single daily dosing.

Amitriptyline. Also developed in the late 1950s, amitriptyline has a similar poor side effect and toxicity profile to imipramine but is more sedative. Additional sedative properties are sometimes considered an advantage in selected patients. The widespread use of low doses of amitriptyline commonly relate to its use in the management of pain, rather than depressive disorders. Like imipramine, the drug and its active metabolite (nortriptyline) have long half-lives, of 9–46 and 18–56h, respectively. The dose range is similar to imipramine.

Clomipramine. This was one of the first antidepressants found to be a potent 5HT reuptake inhibitor. Some clinicians believed that the drug was more effective than other antidepressants, but little evidence exists to support this anecdotal view. However, the effects on 5HT may explain the benefit of this drug in the management of obsessive-compulsive disorder.

Data from a fatal toxicity index (Buckley and McManus, 2002) show clomipramine to have a lower than expected toxicity index. It is unlikely that clomipramine is inherently less toxic than other antidepressants, so this finding could be accounted for by other factors, such as the relatively high rate of prescribing in non-depressive states.

Dosulepin. Guidelines for the management of depression (NICE, 2009) advise that dosulepin should not be prescribed because of the risks associated with cardiac problems and toxicity in overdose compared to other available treatments.

Doxepin. Doxepin has similar effects and side effects to the traditional tricyclics. Limited evidence suggests that it may have fewer cardiac effects in patients with pre-existing cardiac disease than other traditional tricyclics. However, direct comparisons do not exist and a newer, alternative agent should be considered in preference to doxepin in patients with cardiac disease.

Lofepramine. Although desipramine is a metabolite of lofepramine, the latter should not be considered purely as a prodrug. Important differences exist between lofepramine and the other traditional tricyclics. Antimuscarinic effects do occur with lofepramine, but these are less severe than with other tricyclics. In addition, despite being metabolised to desipramine, lofepramine is significantly safer in overdose than the traditional agents. This may be due to lofepramine antagonising the cardiac effects of desipramine. Lofepramine does not have a significant sedative effect, which may be an advantage in some patients, but in others the lack of sedation may be seen as a disadvantage. Some patients may complain of an alerting effect from lofepramine, particularly if the majority of the dose is given at bedtime. Despite a few reports of hepatic problems, given the favourable side effect profile and low toxicity in overdose, lofepramine may be considered as a reasonable option if an SSRI is ineffective or not tolerated.

Nortriptyline. Nortriptyline is the major metabolite of amitriptyline, but appears to have little effect on blood pressure. Nortriptyline shares many of the properties of the traditional tricyclic antidepressants.

Trimipramine. This is a particularly sedative tricyclic antidepressant with few differences from the rest of the traditional tricyclics.

Monoamine oxidase inhibitors. Two types of MAOI are available: the traditional MAOIs, which are both non-selective and irreversible, and moclobemide, which is a selective reversible inhibitor of monoamine oxidase type A (RIMA). In clinical

practice, the traditional MAOIs are not widely prescribed. If patients are able to tolerate adequate doses, they are effective antidepressants, particularly in patients with atypical symptoms of depression. Due to the potential for drug and food interactions, MAOIs should be reserved for use in situations where a first-line SSRI antidepressant has failed. The potential for MAOIs to interact with other drugs and tyramine-containing foods has been well known since the 1960s. It is important that patients are made aware of the dietary restrictions and potential for serious drug interactions. These can be found in standard texts such as the British National Formulary.

Although the inhibitory effect of these drugs on monoamine oxidase is well understood, as with other antidepressants it is still not clear exactly how the MAOIs exert their antidepressant effect. MAOIs inhibit the enzymes responsible for the oxidation of noradrenaline (norepinephrine), 5HT and other biogenic amines. Two forms of monoamine oxidase have been found to exist, MAO-A and MAO-B. The traditional MAOIs are all non-selective and inhibit both forms of the enzyme.

Inhibition of MAO-A is thought to be responsible for the antidepressant effects. It is also responsible for metabolising tyramine and producing the cheese interaction. Moclobemide is an antidepressant that acts as a reversible inhibitor of MAO-A. As tyramine is metabolised by both forms of the enzyme, if tyramine-containing foods are consumed, tyramine is metabolised by MAO-B enzymes as well as being able to reverse the inhibition of MAO-A. Unless very large quantities of tyramine are ingested, this appears to prevent the typical hypertensive reaction seen with conventional MAOIs and tyramine-containing foods.

Traditional MAOIs. The traditional MAOIs and moclobemide have little anticholinergic effect. Nevertheless, some patients do experience dry mouth, constipation and urinary retention. In contrast to the hypertension which follows the interaction of tyramine-rich foods with the traditional MAOIs, these drugs are liable to cause postural hypotension as a side effect. This side effect may be particularly problematic with phenelzine and may prevent adequate dosages being achieved.

Tranylcypromine. Tranylcypromine has a structure that closely resembles amfetamine. It has a significant stimulant effect, and because of this could be more likely to give rise to problems around dependence. Unlike the other MAOIs, it does not irreversibly inhibit monoamine oxidase, which is said to recover some 5 days after withdrawal of the drug. Even so, the precautions associated with the MAOIs must still be continued for 2 weeks after discontinuing the drug. Due to the amfetamine-like alerting effect of tranylcypromine, the last dose should not be given after about 3 p.m. The risk of severe interaction is also said to be greater with tranylcypromine than with other MAOIs.

Phenelzine. Phenelzine has a hydrazine structure and because hydrazines have been associated with hepatocellular jaundice, it is recommended that phenelzine should be avoided in patients with hepatic impairment or abnormal liver function tests.

Reversible inhibitors of monoamine oxidase. Although moclobemide is an effective antidepressant, with less propensity for interactions with tyramine-rich foods, caution should still be exercised as other drug interactions do occur. It could be considered, after a suitable wash-out period, as an option if a first- or second-line SSRI is ineffective.

Selective serotonin reuptake inhibitors. These agents were developed in an attempt to reduce some of the problems associated with the tricyclic antidepressants. Overall, the SSRIs are better tolerated by most patients and coupled with the fact that they are considerably less toxic in overdose; this means that they should be the first-line choice for the pharmacological management of moderate or severe depression (NICE, 2009). As generic versions of the drugs are available, the financial impact of using SSRIs first line has reduced in recent years. The SSRIs have a broadly similar range of side effects, but there are variations in the intensity or duration. The degree of specificity for serotonin reuptake differs between the SSRIs, but this does not correlate with clinical efficacy. If given in adequate doses for an adequate period of time, all the drugs in this class appear to be equally effective.

They do not appear to be significantly more or less effective than traditional tricyclics. They are, however, better tolerated than tricyclics and importantly much less toxic if taken in overdose. There are differences between SSRI's effect on the cytochrome P450 isoenzyme system. This may also be an important factor to consider when individualising treatment.

Fluvoxamine. Although patients experience few antimuscarinic side effects, other problems related to serotonergic enhancement such as nausea, headache and nervousness have been reported.

Fluoxetine. The main difference between fluoxetine and the other SSRIs is the long half-lives of both the parent drug and its primary active metabolite, desmethylfluoxetine. In the initial stages of treatment, some patients may experience a greater feeling of nervousness with fluoxetine than with the other SSRIs, but in most cases tolerance to this develops. The long half-life of fluoxetine and its major metabolite is a problem if severe side effects develop. In other situations, the long half-life means that the risks of discontinuation syndrome is reduced. Formulations of fluoxetine that can be taken on a weekly basis are available in some parts of the world.

Paroxetine. Although all the SSRIs have been reported to cause extrapyramidal-type movements, paroxetine appears to be more commonly implicated. The problem may be particularly severe following abrupt discontinuation of high doses.

Sertraline. Like the other SSRIs, sertraline is an effective antidepressant. Although doses of up to 200 mg have been used, doses of 150 mg and above should not be given for longer than 8 weeks.

Citalopram. The efficacy and side effect profile of citalopram appear similar to the other agents but, like sertraline, the reduced propensity for interactions with drugs metabolised by the cyctochrome P450 2D6 isoenzyme may be an advantage in some cases.

Escitalopram. Escitalopram is thought to be the active *S* enantiomer of citalopram, which is a racemic mixture of *R*- and *S*-citalopram. The use of escitalopram has been advocated on the basis that the *R* enantiomer has no antidepressant effect, and may even counteract some of the antidepressant effects of the *S* enantiomer of escitalopram.

Lithium. Lithium does have antidepressant properties but will be discussed in more detail in the antimanic section.

Other drugs

Trazodone. In vitro, trazodone appears to operate as a mixed serotonin agonist/antagonist, but clinically it is thought to operate as a serotonin agonist. Trazodone is much safer than the tricyclics following overdose but causes pronounced sedative and hypotensive effects in some patients. Priapism has also been noted as a rare but distressing side effect. This is probably due to its potent α-receptor blocking properties.

Mianserin. Mianserin was one of the first antidepressants to demonstrate an improved toxicity profile following overdose. Like many of the newer drugs, it has fewer antimuscarinic side effects than the traditional tricyclics. One drawback in using mianserin is the need for monthly blood counts during the first 3 months of treatment, due to a high reported incidence of blood dyscrasias, particularly in the elderly. Mianserin is no longer widely prescribed in the UK.

Venlafaxine. Venlafaxine was reported to be the first in a new class of antidepressants, the serotonin-noradrenaline reuptake inhibitors (SNRIs). These antidepressants were developed in an attempt to improve efficacy over the standard agents. As the name suggests, they prevent the reuptake of both serotonin and noradrenaline (norepinephrine), a mechanism they have in common with the tricyclic antidepressants. It was hoped this would result in a drug with similar efficacy to the tricyclics in more severe cases but without the antimuscarinic, cardiac or toxic effects of the older drugs. Guidelines for depression (NICE, 2009) highlight the relative poor tolerability and increased risks of toxicity compared to the SSRIs. In view of this, venlafaxine is not recommended as a first-line treatment for patients with moderate or severe depression.

Duloxetine. Like venlafaxine, duloxetine is an SNRI. It weakly inhibits dopamine reuptake and may be less well tolerated than SSRIs. Given the relative benefit/tolerability profile, the drug is considered to be a second-line treatment option.

Reboxetine. Reboxetine is a specific noradrenergic (norepinephrinergic) reuptake inhibitor (NARI). Response rates appear similar to other antidepressants. This casts further doubt on the existence of particular subtypes of depression likely to respond to particular antidepressants. Patients experiencing problems with serotonergic-related side effects may benefit from a switch to reboxetine.

Mirtazapine. Mirtazapine is a noradrenergic and specific serotonergic antidepressant (NaSSA). It enhances both noradrenergic (norepinephrinergic) and $5HT_1$ serotonergic transmission. Specific $5HT_1$ neurotransmission is achieved as the drug also acts as a $5HT_2$ and $5HT_3$ antagonist. The receptor-specific effects of mirtazapine may explain some reduction in sexual dysfunction and nausea compared to other SSRIs. Despite this novel pharmacology, mirtazapine appears little different from other antidepressants in terms of efficacy.

Agomelatine. Agomelatine is structurally related to melatonin, it gained regulatory approval for use as an antidepressant in Europe in 2009. It is thought to act as an agonist at melatonin MT_1 and MT_2 and antagonist at $5HT_{2c}$ (Kasper and Hamon, 2009). In contrast to other antidepressants, it has no effect on monoamine uptake systems. Liver function tests are required prior to commencement and at intervals during treatment as rare cases of hepatic dysfunction have been reported. As yet there is insufficient evidence to comment on the place of this drug in the management of depression, but its relatively high cost may limit its use within the UK.

Choice of antidepressant. Whilst it has been suggested (Cipriani et al., 2009) that sertraline and escitalopram should be considered first-choice antidepressants for the majority of patients, it is unclear whether this will be translated into routine practice. The severity of the disorder, patient preference and previous experience should also play a part as they are also likely to affect outcome. In some areas, cost has become a critical factor in choice. For most people with moderate-to-severe depression, unless otherwise contraindicated, the use of a generic SSRI as the first-line choice is appropriate. Previous response, tolerance and the likelihood of drug interactions should also be considered.

In clinical practice, the identification of patients at high risk of suicide is difficult, and all patients with severe depression should be considered at risk of self-harm. The quantities of medication supplied to these patients should be carefully monitored.

Other treatments

Non-drug treatments. In addition to drug treatment, it is important to consider the patient's wider social, cultural and environmental circumstances. Although most patients with moderate to severe symptoms of depression will be offered pharmacological treatment, all patients and their close family should be offered help and support to cope with depression. Specific non-pharmacological interventions such as cognitive behaviour therapy (CBT) can be as effective as drug treatments. For people with more severe symptoms of depression, a combination of antidepressants and CBT is recommended. For mild-to-moderate forms of depression or persistent sub-threshold symptoms, then non-drug strategies based on the principals of CBT should be considered as the first-line treatment (NICE, 2009).

The basis of CBT was developed over 50 years ago and subsequently refined into a specific therapy in the 1970s. This type of treatment helps patients to address their unhelpful thoughts and actions associated with depression. Over a series of up to 20 sessions the CBT therapist works with the patient either alone or in groups, to replace negative or self-critical thoughts and actions with more positive and helpful ones. CBT is not a 'quick fix' solution to depression, patients are often given 'homework' between sessions to try and put their positive actions into place. Interpersonal psychotherapy (IPT) is another form of psychotherapy which may help patients overcome symptoms of depression. This type of therapy aims to improve the patient's social functioning by linking their mood with interpersonal contacts so that their depressive mood and relationships can simultaneously improve.

Electroconvulsive therapy. Electroconvulsive therapy (ECT) would only be considered after referral to a psychiatrist. Although it is said to have a faster onset of action, its effects

are fairly short-lived and antidepressants are normally required to prevent relapse. Although the treatment itself is considered safe, there are risks from the anaesthetic agent, and some patients suffer short-term memory loss following treatment.

St John's wort (*Hypericum perforatum*). Extracts of hypericum have been shown to be as effective as standard antidepressants in the management of major depression (Linde et al., 2008). In England and Wales, prescribers are advised against prescribing hypericum because of uncertainty about appropriate doses and persistence of effect. Problems can also be caused due to the variation in the nature of preparations available and the potential for serious interactions with other drugs.

Treatment of mania

Valproate semisodium (divalproate) is licensed in the UK as a specific treatment for mania associated with bipolar disorder. Other antipsychotics, including lithium and benzodiazepines, may also have a role in the management of mania. There appears to be insufficient evidence to differentiate between the various antipsychotics licensed for use in the acute management of mania and as a consequence the side effect profile, tolerability, previous experience and patient preference should all be considered when selecting the agent to use. Short-term adjunctive treatment with a benzodiazepine may be also be required.

Lithium may be used as an antimanic agent but it takes longer than other agents to produce its full effect and few would consider lithium as their agent of choice for acute antimanic treatment. However, it remains a drug of choice for long-term use to prevent recurrence or relapse. Valproate, certain antipsychotics, carbamazepine and lamotrigine (off-label use) may also be considered for this indication. In the future, further evidence or new technologies may emerge that permit better individualisation of treatment.

When used prophylactically the antimanic agents are commonly referred to as mood stabilisers.

If an episode of mania occurs in patients taking antidepressants, the antidepressant should be withdrawn. If mania occurs in patients already taking an antimanic agent for prophylaxis, attention should be given to maximising the dose and, if necessary, adding a second agent.

Valproate semisodium

This is a 1:1 molar combination of sodium valproate and valproic acid. Following administration, valproate ion is released and subsequently absorbed. The therapeutic differences between sodium valproate and valproate semisodium have not been established. However, the latter is the only form of valproate licensed for the acute treatment of mania. The mechanism of action in mania is unclear but may be related to increased levels of GABA. The antimanic effects of valproate are seen within 3 days, but the full benefit of treatment may not be apparent for up to 3 weeks. Dose should be rapidly titrated to between 1000 and 2000 mg per day. Routine valproate serum levels are not necessary, but levels between 50 and 100 mg/L have been reported to be associated

with optimal response in some patients. Although the risks of liver damage are greater in young children, liver function tests should be performed prior to initiation of therapy and periodically thereafter in all patients. In addition, the patient must be instructed to report any problems, such as unexplained bruising, that may indicate abnormalities in coagulation. Although valproate is well established as a prophylactic treatment to prevent relapse, this is an off-label use and should not be used in patients likely to become pregnant because of its teratogenic potential.

Antipsychotics

All the antipsychotics share a common effect of blocking dopamine D_2 postsynaptic receptors to some degree. Most of the newer antipsychotics, for example olanzapine, risperidone, quetiapine and aripiprazole, are licensed for use in the management of acute mania and prevention of new manic episodes.

Concerns about the side effect profiles of antipsychotic drugs often limit use, but in reality individual patients vary in their concern for and susceptibility to different side effects. Therefore, it is important that treatment choices are individualised and patients monitored regularly for side effects. Haloperidol, in an appropriate dose, is still commonly prescribed as part of the acute management of mania. It is less sedating than other antipsychotics which means it may occasionally be necessary to control severe behaviour disturbances with additional sedatives such as lorazepam, either orally or by injection. When a single agent is not considered to be effective, consideration should be given to augmenting the antipsychotic with valproate. Dose and duration of treatment are important considerations when treating acute mania. The dose of antipsychotic should be reviewed as the patient improves and where necessary consideration given to switching to an alternative prophylactic agent or continuing treatment to prevent relapse.

Lithium

Although lithium is effective in the acute management of mania, other treatments are generally preferred. This is due to the delay in response and variability of physical exertion and fluid intake which may compromise the safe use of lithium. In the acute situation, lithium may take up to 10–14 days to exert an effect. Dose is adjusted to achieve a target serum lithium concentration of 0.8–1 mmol/L for the management of acute episodes of mania, and for patients who have previously or have subsyndromal symptoms.

Antipsychotics or valproate semisodium, either alone or in combination, along with benzodiazepines should be considered the first-line treatment in the acute phase of mania.

Following an acute episode, lithium is a well-established treatment that may be considered as a first-line option for prophylaxis (Baldessarini and Tondo, 2000). Continuation therapy with a prophylactic mood stabiliser should be considered in all bipolar patients who have had two or more

acute episodes within 2–4 years. It may also be reasonable to consider prophylaxis in any patient following a severe manic episode. As treatment is long term, the cooperation of the patient is essential and so a thorough explanation of the risks and benefits of the treatment is vital.

Before lithium treatment is initiated, an assessment of the patient's physical state is essential. Thyroid, renal and cardiac function should all be within normal limits. It is, however, still possible to use lithium, with caution, in patients with mild-to-moderate renal failure or cardiovascular impairment. Any thyroid deficiency should be corrected before lithium treatment is commenced. Patients should be informed of the need for monitoring and cautioned about the consequences of dehydration and risks of drug interactions.

Serum levels. There is a narrow therapeutic window for lithium serum levels and variation in the reference ranges reported. Some of this variation can be accounted for by variation in dose schedules. In the main, 12-h (post-dose) levels above 1.2 mmol/L are considered to be toxic and levels below 0.4 mmol/L are not considered to be effective. In adults, if lithium serum levels are kept in the range 0.4–0.8 mmol/L, then lithium is usually well tolerated with minimal side effects. Levels at or above 0.7 mmol/L are reported as being more effective than lower doses.

For most patients the range of 0.4–0.8 mmol/L is appropriate for prophylaxis, but if lithium is used to control the acute phase, levels may need to be around 1.0 mmol/L. To accurately interpret lithium levels, it is important that the correct schedule is followed and to establish consistent results, the 12-h standard serum lithium protocol has been devised. This means that lithium levels should be taken in the morning as near as possible to 12 h after the last dose of lithium.

As the absorption and bioavailability of lithium may vary from brand to brand, it is important that patients do not inadvertently change brands or dosage forms without levels being checked. Lithium not only has a narrow therapeutic range but is particularly toxic in overdose. Common side effects reported by patients are gastro-intestinal disturbances, tremor, thirst, polyuria, weight gain and lethargy. In addition to complaints of side effects, some patients prefer to remain untreated as they feel lithium 'damps down' their creativity and they miss the slight 'highs' that occur as part of their illness.

Patients taking a prophylactic mood stabiliser may occasionally stop taking their medication when they feel they no longer need it, or want to see if they can overcome the disorder without the need for drugs. Patients commonly have several trials on a mood stabiliser before they accept that the balance of risks and benefits is usually in favour of longer term treatment. There is a significant risk of relapse if lithium is discontinued abruptly.

Other anticonvulsants

Carbamazepine is generally considered as a second-line prophylactic treatment, when first-line therapy is either not tolerated or is ineffective. Emerging evidence continues to support the use of lamotrigine as an alternative in patients with bipolar depression (Geddes et al., 2009).

Treatment combinations

In patients who cannot be controlled on a single mood stabiliser, consideration should be given to combining treatments. Although not entirely without risks, all the above drugs have been used in various combinations in resistant cases.

Patient care

In the acute phase of an affective disorder, a patient will have little or no insight into his or her condition. This often makes it difficult to prescribe medication following an informed discussion on the risks and benefits of treatment. Depressed patients may say they are not worth treating; most manic patients will find it impossible to engage in meaningful dialogue, or they may insist they do not need medication and consistently refuse treatment. Thus, in the initial stages of treatment, some patients are treated against their will. As patients respond to treatment, it is crucial that the benefits and risks of treatment are explained. This may need to be repeated and backed up by written information. Engaging the patient and including them in the choice of treatment not only supports their basic human rights but is also likely to lead to a better therapeutic outcome. The discussion should also allow the patient to record their preference for future treatment. This may include drug regimens they would prefer to receive should they relapse as well as medication they would find objectionable.

During the acute phase of their illness, patients may often forget what they have been told about their medication. It is, therefore, important to regularly offer information or reassurance about medication, even if the patient is reported to have fully discussed the actions and effects with a health care professional.

Many patients are frightened by the notion of taking medication that will affect their mind. Taking an antidepressant is often felt to be a sign of failure or weakness by the patient as well as their family and friends. This often leads people to try and deal with their depression without medication. This is fine for the milder forms of the disorder and is sometimes referred to as 'watchful waiting'. In more severe cases, such an approach could have life-threatening consequences for the patient.

Patients should always be offered the opportunity of discussing their medication. The use of patient information leaflets and the involvement of the family or close friends may help patients understand the risks and benefits of their treatment. Many of the drugs used in the treatment of affective disorders have the potential to interact with other drugs that have been prescribed or purchased. Some of these are summarised in Table 29.1.

Common therapeutic problems in the management of affective disorder are outlined in Table 29.2.

Table 29.1 Examples of important drug interactions with drugs used in the management of affective disorders

Antidepressant	Interacting drug	Effect
Tricyclics	Adrenaline (epinephrine) and other directly acting sympathomimetics	Greatly enhances effect. Dangerous acting sympathomimetics
	Alcohol	Enhanced sedation
	Antiarrhythmics	Risk of ventricular arrhythmias
	Anticonvulsants	Lowered seizure threshold and possible lowered tricyclic levels
	MAOIs	Severe hypertension
	Fluoxetine	Increased tricyclic serum levels
SSRIs	Anticoagulants	Enhanced effects
	MAOIs	Dangerous
	Lithium	Possible serotonin syndrome
MAOIs	Alcohol, fermented beverages, tyramine-rich foods	Hypertensive crisis
	Antihypertensives	Increased effect
	Anticonvulsants	Lowered seizure threshold
	Levodopa	Hypertensive crisis
	Sympathomimetics	Hypertensive crisis
Antipsychotics	Anaesthetic agents	Hypotension
	Anticonvulsants	Lowered seizure threshold
	Antiarrhythmics	Risk of ventricular arrhythmias
	Astemizole and terfenadine	Risk of ventricular arrhythmias
Lithium	Non-steroidal anti-inflammatory drugs (NSAIDs)	Enhanced lithium serum levels
	SSRIs	Possible serotonin syndrome
	Diuretics	Enhanced lithium serum levels particularly with thiazides
	Angiotensin-converting enzyme (ACE) inhibitors	Enhanced lithium serum levels
	Sumatriptan	Possible central nervous system toxicity
St John's wort	Induces cytochrome P450 enzymes, particularly 1A2, 2C9 and 3A4	
	Indinavir	Reduced serum concentration (avoid)
	Warfarin	Reduced anticoagulant effect (avoid)
	SSRIs	Increased serotonergic effect (avoid)
	Carbamazepine (and other anticonvulsants)	Reduced serum concentrations (avoid)
	Digoxin	Reduced serum concentration (avoid)
	Oestrogens and progestogens	Reduced contraceptive effect (avoid)
	Theophylline	Reduced serum concentration (avoid)
	Ciclosporin	Reduced serum concentration (avoid)

Table 29.2 Common therapeutic problems in the management of affective disorder

Problem	Possible solution
Antidepressants	
Treatment failure (30–40% of patients will not respond to first antidepressant)	Ensure adequate dose and duration of treatment
	Check adherence, engage the patient, develop therapeutic alliance
	Reassess response against target symptoms
Risk of self-harm	Reconfirm diagnosis and identify compounding factors, for example, high levels of alcohol consumption in unsupervised situations
Withdrawal reactions	Ensure gradual withdrawal
Relapse on discontinuation	Consider long-term treatment
Intolerance	Consider changing to a different class
Antimanic agents	
Treatment failure	Ensure adequate dose, check serum levels and adherence; consider drug combinations
Toxicity adverse effects	Determine dose by clinical response, guided by serum levels
	Ensure patient is well informed and able to recognise impending toxicity and adverse effects of treatment
Weight gain	Dietary advice; consider alternative pharmacotherapy
Lithium levels	Ensure serum levels are 12h post-dose, taken in the morning. Regular monitoring is important

Case studies

Case 29.1

Ms PS is a 17-year-old woman who presented to her primary care doctor with a 2-month history of difficulty in getting to sleep. She described herself as feeling generally unhappy. She had lost interest in socialising but was able to perform most of her usual daily routines. She sometimes felt as though she had little energy and was spending more time just watching the television.

Question

What diagnosis is likely to be given to Ms PS and what are the important factors to take into account when advising on treatment?

Answer

On further questioning by her primary care doctor, Ms PS does not reveal any ideas of self-harm. She is in a supportive relationship and, although she has some financial concerns, these are not excessive. It is likely that her depression is sub-threshold or of mild severity. Referral to specialist services is not appropriate. The patient should be given advice on sleep hygiene, including the removal of the television from her bedroom. A watching brief should be maintained and the patient asked to attend for a follow-up appointment within 2 weeks.

Antidepressants should not be prescribed. The risk/benefit balance is generally against prescribing antidepressants in people under 18 years of age. There is also little evidence to support the use of antidepressants in this case. More appropriate treatment options to consider would be a structured group exercise programme, guided self-help based on the principles of cognitive behavioural therapy or computerised cognitive behavioural therapy. The specific intervention should be guided by Ms PS's preferences.

Case 29.2

Mr DD is a 50-year-old unemployed man with a long-standing history of bipolar I disorder. He was admitted, as a voluntary patient, to an acute psychiatric ward by his community psychiatric nurse (CPN). The admission followed a short period of increasingly disturbed behaviour. Mr DD's daughter had contacted the CPN when she discovered that her father had just spent over £5000 on scientific instruments from an Internet auction site. Over the same period she had noticed that her father had lost interest in his self-care and become elated at the prospect of being on the verge of developing a special formula to solve the fuel crisis. On the ward Mr DD said he felt 'fine, fine all the time'. He told staff on the ward that he didn't need to be in hospital and it was keeping him away from his top secret mission. He also told ward staff that they could not keep him on the ward and insisted he was within his rights to go home. Mr DD's speech was sometimes very rapid, and it was sometimes difficult to understand what he was saying. His records showed that on his last admission he had been treated with haloperidol.

Question

What treatment is appropriate for Mr DD?

Answer

Before initiating treatment it is important to rule out any organic or physical causes for Mr DD's presentation. Following a thorough physical and psychiatric examination, it was established that Mr DD had been relatively well since commencing treatment with lithium almost 4 years previously.

It is important that symptoms of mania are brought under control. Haloperidol would be a suitable choice, in view of his previous response. However, a review of Mr DD's medication history revealed that he had experienced several acute dystonic reactions to haloperidol during previous admissions. His daughter also reported that her father had commented on how awful it felt being given haloperidol during his last admission. Mr DD was, therefore, given the option to discuss alternative antipsychotic treatment. He agreed to take olanzapine which was prescribed at a dose of 15 mg daily.

When Mr DD's manic symptoms are controlled, prophylactic treatment should be discussed with him. This should include a discussion about why he had discontinued lithium several months earlier. The opportunity should be taken to provide written information with the offer of a further discussion that should include his daughter.

Mr DD had stopped lithium as he felt he no longer needed it but after discussion was prepared to restart treatment. Renal, thyroid and cardiac function should be assessed, and if within normal limits, lithium carbonate 400 mg at night may be prescribed.

One week later a 12-h standard serum lithium level should be performed and the dose of lithium adjusted to achieve the same lithium levels as before (0.6 mmol/L).

The side effects and signs of impending toxicity from lithium should be explained to Mr DD and if possible his daughter. They should be given written information about the side effects, potential interactions, signs of toxicity and provided with a booklet to enable them to record the results of regular investigation. The arrangements for future prescribing and monitoring of lithium should be clarified so that Mr DD's care is not compromised by moving across organisational boundaries.

Case 29.3

Mrs FA is a 40-year-old designer. She was admitted to an acute psychiatric unit from the emergency department of the local hospital. She had taken an overdose of 32 co-codamol tablets when her husband told her he was going to leave her. On the ward she told staff she hated her life, and that everything was going wrong. She was angry that she had not been successful in killing herself as there was no point in living. She could see no hope for the future and had no interest in anything, not even eating.

Question

What course of action would you advise?

Answer

Mrs FA has a severe episode of depression. Antidepressant drug treatment should be initiated immediately. In line with guidelines for the management of depression, one of the SSRIs, for example, citalopram, should be considered as a suitable choice. Although Mrs FA may be reluctant to take medication, it should be explained that the drug does relieve the symptoms of depression. As soon as practical, the explanation should be followed up by discussing the importance of taking treatment for 4–6 weeks before the full benefit

is realised and the likely time course of antidepressant treatment being in the region of 6 months. Mrs FA should also be given the opportunity to discuss any concerns she may have about becoming dependent on the antidepressant as well as a general explanation about possible side effects.

Case 29.4

Mr MA is a 49-year-old unemployed man. He was admitted to a psychiatric unit at the request of the crisis intervention team. Mr MA had been prescribed fluoxetine 20 mg 2 months ago, and after no apparent response the prescriber in the crisis team had changed this to citalopram 4 weeks earlier. On admission he was noted to be withdrawn, lacking motivation and just gave 'yes' or 'no' in response to questioning. He reported no interests in his life, and it was noted that he had attempted to harm himself in the past. Two weeks after admission there was no significant improvement in his symptoms.

Question

What treatment options are appropriate for Mr MA?

Answer

Before considering a change in treatment, it should be confirmed that Mr MA has regularly taken his antidepressant medication. Serum levels are not generally available, or particularly helpful. Scrutiny of the medicine charts, discussion with nursing staff, relatives, key workers and the patient will enable a reasonable judgement to be reached. A dose increase could be considered if the patient had shown a limited response. In this case, the patient had received no apparent benefit and a change in treatment was warranted.

An in-depth review of his physical condition and previous medication should be undertaken. This should include discussion with the patient about any previous antidepressant treatment he had found to be particularly effective, or troublesome.

This review revealed that Mr MA had received several different antidepressants over the past 20 years. Three years ago he was treated with venlafaxine S/R 75 mg twice daily. The medical records confirmed Mr MA's view that this medication had helped him in the past, but on further questioning he stated that he had not taken medication for long after discharge from hospital as he did not want to get 'hooked' on it.

The importance of long-term treatment and the proposed treatment plan should be discussed with Mr MA. Particular issues to be addressed include an assessment of physical functioning including base line blood pressure and the need for ongoing periodic monitoring. In view of Mr MA's concerns about dependence, particular attention should be given to discussion around this issue. Based on Mr MA's agreement to the treatment plan, his previous response, the lack of any physical contraindication and the ability to organise ongoing, periodic blood pressure monitoring would be a reasonable treatment option.

Case 29.5

Ms YS is a 28-year-old student with a history of bipolar I disorder. She had recently moved to the area in the hope of continuing her studies. She was admitted to an acute psychiatric unit at the request of her key worker who reported that Ms YS had recently become increasingly elated and her partner was very concerned about the increased credit card bills she was incurring.

Whilst on the ward she attempted to develop sexual relationships with several young male patients.

Question

Describe the treatment options available for Ms YS.

Answer

There is insufficient information to determine whether or not Ms YS was being treated adequately with a prophylactic mood stabiliser. It is important to determine if the current episode was related to inadequate prophylactic treatment.

The current episode of hypomania must be treated. She is currently at risk through her promiscuity and the excessive use of her credit card. Both behaviours are likely to affect her ability to maintain a relationship with her partner.

As Ms YS was taking adequate contraceptive precautions and was adamant that she had no intention or desire to become pregnant, initially treatment with valproate semisodium should be considered. Olanzapine or another antipsychotic could also be considered, but Ms YS did not want to be treated with an antipsychotic. An assessment of liver function, prothrombin rate and full blood count should be performed prior to initiating therapy.

The patient should be informed of the important adverse effects of therapy. In particular, she should be advised to report any unexplained bruising and to avoid the use of salicylates. Treatment should be commenced at 250 mg three times daily and increased in accordance with response and tolerability. Benzodiazepines may also be considered as a short-term adjunct if additional sedation is required.

Following resolution of the acute episode, long-term prophylaxis must be considered. In this case, Ms YS had previously been treated with lithium, but had refused to continue as this had caused significant weight gain.

In view of the patient's refusal to consider lithium, prophylactic options include carbamazepine or valproate semisodium (valproate semisodium is not licensed for prophylactic use in the UK). Little hard evidence currently exists to guide the choice. It is important to take the patient's view into account. Even though valproate does not have a UK marketing authorisation for prophylaxis in bipolar disorder, on the basis of informed choice, prophylactic treatment with valproate was agreed with Ms YS.

Case 29.6

Ms AB is a 55-year-old unemployed lady with a long-standing history of depression. She has been treated with several antidepressants over the years and is currently under the care of the community mental health team.

The only treatment that appears to have had any effect on her depressive episodes has been dosulepin. She has taken several overdoses in the past and her psychiatrist is reluctant to prescribe this drug.

Question

What measures could be taken to enable Ms AB to be treated effectively?

....

Answer

Ms AB does not have treatment-resistant depression. She has been successfully treated with dosulepin in the past, but impulsively takes an overdose as a way of dealing with difficult circumstances even when she is not depressed.

Non-drug strategies by the mental health team should be directed at enabling Ms AB to find alternative ways of dealing with these difficulties.

In view of the obvious risk of fatality, alternative antidepressant treatment should be considered. Dosulepin could remain as an option for Ms AB due to her previous response to this drug and the lack of response to other antidepressants, but this would fall outside current guidance for the management of depression (NICE, 2009). Practical measures of controlling the quantities of medication should be introduced such as ensuring she only receives sufficient medication for 2 or 3 days treatment.

Communication between all those involved in the care of Ms AB is crucial. When individualizing the supply of medication in this way, all those involved must be alert to the possibility that the system of supply may break down. In this case, an apparently routine prescription for 1 month's supply of medication may have fatal consequences.

Schizophrenia 30

D. Branford

Key points

- Schizophrenia is a complex illness which varies greatly in presentation.
- Positive symptoms such as hallucinations, delusions and thought disorder, which commonly occur in the acute phase of the illness, usually respond to treatment with antipsychotic drugs.
- Negative symptoms such as apathy, social withdrawal and lack of drive, which occur commonly in the chronic phase of the illness, are more resistant to drug treatment.
- The term 'atypical' is used to describe the newer antipsychotic drugs that do not cause extrapyramidal side effects.
- The atypical antipsychotics are associated with a range of metabolic side effects including weight gain and diabetes.
- Typical antipsychotic drugs are often associated with anticholinergic, sedative and cardiovascular side effects in addition to extrapyramidal side effects.
- Long-term treatment with typical antipsychotic drugs is associated with the development of tardive dyskinesia.
- Most typical and atypical antipsychotic drugs have similar efficacy in the treatment of schizophrenia.
- Decisions about which antipsychotic drug to use should be a mutual decision based on an informed discussion involving individual preference, previous efficacy and side effects.
- Clozapine has a broader spectrum of activity than traditional antipsychotic drugs with some efficacy for treatment-resistant schizophrenia and negative symptoms.

The concept of schizophrenia can be difficult to understand. People who do not suffer from schizophrenia can have little idea of what the experience of hallucinations and delusions is like. The presentation of schizophrenia can be extremely varied, with a great range of possible symptoms. There are also many misconceptions about the condition of schizophrenia that have led to prejudice against sufferers of the illness. People with schizophrenia are commonly thought to have low intelligence and to be dangerous. In fact, only a minority shows violent behaviour, with social withdrawal being a more common picture. Up to 10% of people with schizophrenia commit suicide.

Classification

Since the late nineteenth century there have been frequent attempts to define the illness we now call schizophrenia. Kraepelin, in the late 1890s, coined the term 'dementia praecox' (early madness) to describe an illness where there was a deterioration of the personality at a young age. Kraepelin also coined the terms 'catatonic' (where motor symptoms are prevalent and changes in activity vary), 'hebephrenic' (silly, childish behaviour, affective symptoms and thought disorder prominence) and 'paranoid' (clinical picture dominated by paranoid delusions). A few years later Bleuler, a Swiss psychiatrist introduced the term 'schizophrenia', derived from the Greek words *skhizo* (to split) and *phren* (mind), meaning the split between the emotions and the intellect.

Two systems for the classification of schizophrenia are widely used: the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM IV; American Psychiatric Association, 1994) and the *International Classification of Diseases*, 10th edition (ICD 10; World Health Organization, 1992).

Symptoms and diagnosis

Acute psychotic illness

To establish a definite diagnosis of schizophrenia it is important to follow the diagnostic criteria in either DSM IV or ICD 10, but symptoms which commonly occur in the acute phase of a psychotic illness include the following:

- awkward social behaviour, appearing preoccupied, perplexed and withdrawn, or showing unexpected changes in behaviour
- initial vagueness in speech which can progress to disorders of the stream of thought or poverty of thought
- abnormality of mood such as anxiety, depression, irritability or euphoria
- auditory hallucinations, the most common of which are referred to as 'voices'; such voices can give commands to patients or may discuss the person in the third person, or comment on their actions
- delusions, of which those relating to control of thoughts are the most diagnostic; for example, patients feel that thoughts are being inserted into or withdrawn from their mind
- lack of insight into the illness.

These symptoms are commonly called positive symptoms.

Factors affecting diagnosis and prognosis

There is a reluctance to classify people as suffering schizophrenia on the basis of one acute psychotic illness, but there are a number of features which aid prediction of whether an acute illness will become chronic. These features include:

- age of onset, which, typically for schizophrenia, is late teenage to 30 years
- reports of a childhood which indicate the individual did not mix or was a rather shy and withdrawn personality
- a poor work record
- a desire for social isolation
- being single and not seeming to have sexual relationships
- a gradual onset of the illness and deterioration from the previous level of functioning
- grossly disorganised behaviour

Treatment

There is a wide range of antipsychotic drugs available for the treatment of a psychotic illness. Although most antipsychotic drugs are equally effective in the treatment of psychotic symptoms, some individuals respond better to one drug than another.

There is controversy over how long people should remain on an antipsychotic drug following their first acute illness. Some would argue that, if the prognosis is poor, long-term therapy should be advocated. Others would want to see a second illness before advocating long-term therapy.

Chronic schizophrenia

Between 60% and 80% of patients who suffer from an acute psychotic illness will suffer further illness and become chronically affected. For these patients the diagnosis of schizophrenia can be applied.

As schizophrenia progresses, there may be periods of relapse with acute symptoms but the underlying trend is towards symptoms of lack of drive, social withdrawal and emotional apathy. Such symptoms are sometimes called negative symptoms and respond poorly to most antipsychotic drugs.

Causes of schizophrenia

Although the cause of schizophrenia remains unknown, there are many theories and models.

Vulnerability model

The vulnerability model postulates that the persistent characteristic of schizophrenia is not the schizophrenic episode itself but the vulnerability to the development of such episodes of the disorder. The episodes of the illness are time limited but the vulnerability remains, awaiting the trigger of some stress. Such vulnerability can depend on premorbid personality, the individual's social network or the environment. Manipulation and avoidance of stress can abort a potential schizophrenic episode.

Developmental model

The developmental model postulates that there are critical periods in the development of neuronal cells which, if adversely affected, may result in schizophrenia. Two such critical periods are postulated to occur when migrant neural cells do not reach their goal in fetal development and when supernumerary neural cells slough off at adolescence. This model is supported by neuroimaging studies which show structural brain abnormalities in patients with schizophrenia.

Ecological model

The ecological model postulates that external factors involving social, cultural and physical forces in the environment, such as population density, individual space, socio-economic status and racial status, influence the development of the disorder. The evidence in support of such a model remains weak.

Genetic model

There is undoubtably a genetic component to schizophrenia, with a higher incidence in the siblings of schizophrenics. However, even in monozygotic twins there are many cases where only one sibling has developed schizophrenia.

Transmitter abnormality model

The suggestion that schizophrenia is caused primarily by an abnormality of dopamine receptors and, in particular, D_2 receptors, has largely emerged from research into the effect of antipsychotic drugs. Such a theory is increasingly being questioned.

Other factors

Numerous other factors have been implicated in the development and cause of schizophrenia. These include migration, socio-economic factors, perinatal insult, infections, season of birth, viruses, toxins and family environment.

In reality, all of these factors may influence both the development and progression of schizophrenia. Social, familial and biological factors may lead to premorbid vulnerability and subsequently influence both the acute psychosis and the progression to chronic states. What is then likely is that the illness will feed back to influence social, familial and biological factors, thus leading to future vulnerability.

Drug treatment

Mode of action of antipsychotic drugs

Although the cause of schizophrenia is the subject of controversy, an understanding of the mode of action of antipsychotic drugs has led to the dopamine theory of schizophrenia. This theory postulates that the symptoms experienced in schizophrenia are caused by an alteration to the level of dopamine activity in the brain. It is based on knowledge that

dopamine receptor antagonists are often effective antipsychotics while drugs which increase dopamine activity, such as amfetamine, can either induce psychosis or exacerbate a schizophrenic illness.

At least six dopamine receptors exist in the brain, with much activity being focused on the D_2 receptor as being responsible for antipsychotic drug action. However, drugs such as pimozide, that claim to have a more specific effect on D_2 receptors, do not appear superior in antipsychotic effect when compared to other agents.

Research into the mode of action of clozapine has caused a change of attention to the mesolimbic system in the brain and to different receptors. Clozapine does not chronically alter striatal D_2 receptors but does appear to affect striatal D_1 receptors. It also appears to have more effect on the limbic system and on serotonin ($5HT_2$) receptors, which may explain its reduced risk of extrapyramidal symptoms. The term 'atypical' is used to categorise those antipsychotic drugs that, like clozapine, rarely produce extrapyramidal side effects (EPSEs).

Although the reason for the superiority of clozapine in schizophrenia treatment remains an enigma, a variety of theories have led to the development of a new family of antipsychotic drugs. Some mimic the impact of clozapine on a wide range of dopamine and serotonin receptors, for example, olanzapine, others mimic the impact on particular receptors, for example, $5HT_2/D_2$ receptor antagonists such as risperidone, others focus on limited occupancy of D_2 receptors, for example, quetiapine, while others focus on alternative theories such as partial agonism (aripiprazole).

Rationale for use of drugs

Although a variety of social and psychological therapies are helpful in the treatment of schizophrenia, drugs form the essential cornerstone. The aim of all therapies is to minimise the level of handicap and achieve the best level of mental functioning. Drugs do not cure schizophrenia and are only partially effective at eradicating some symptoms such as delusions and negative symptoms. At the same time, benefits have to be balanced against side effects and whether the need to suppress particular symptoms is important. For example, if the person has a delusion that he or she is responsible for famine in Africa, but this does not in any way influence that person's behaviour or mood, a common view would be that there would be little point in increasing antipsychotic drug therapy. However, others would argue that this 'untreated' delusion would make the person stand out or be subject to social stigma and the delusion should be more aggressively treated. If, on the other hand, this delusion led to great distress, or violent or dangerous behaviour, then an increase in antipsychotic drugs would usually be indicated.

It is now accepted that antipsychotic drugs can control or modify symptoms such as hallucinations and delusions that are evident in the acute episode of illness. Except for clozapine and the other atypicals, there is little evidence for antipsychotic drugs being of value in the treatment of the negative symptoms, although the matter remains controversial (Chakos et al., 2001). Antipsychotic drugs increase the length of time between breakdowns and shorten the length of the acute episode in most patients.

Drug selection and dose

Over the years there have been many changes to the range of antipsychotic drugs available. Despite the availability of newer agents many of the issues relevant to drug selection and dose have remained similar for the last 50 years and include:

Individual response

Drug selection should not be based on chemical group alone, since individual response to a particular drug or dose may be more important.

Side effects

For older, typical antipsychotic drugs, side effects such as hypotension, extrapyramidal symptoms and anticholinergic effects are key factors in the choice of drug. In contrast, with the newer atypical drugs, side effects such as diabetes, sexual dysfunction and weight gain affect adherence in many patients. Sedation remains a factor for all antipsychotic drugs.

The key side effects of concern are those categorised as EPSEs. Those that caused these side effects were called typical antipsychotic drugs and those that did not were called atypical. This classification system, however, has always remained subject to criticism as some atypicals will cause EPSEs when used at higher doses and the side effects of the different atypicals can vary considerably. EPSEs include:

Akathisia or motor restlessness. This causes patients to pace up and down, constantly shift their leg position or tap their feet.

Dystonia is the result of sustained muscle contraction. It can present as grimacing and facial distortion, neck twisting and laboured breathing. Occasionally the patient may have an oculogyric crisis in which, after a few moments of fixed staring, the eyeballs move upwards and then sideways, remaining in that position. In addition to these eye movements, the mouth is usually wide open, the tongue protruding and the head tilting backwards.

Parkinson-like side effects usually present as tremor, rigidity and poverty of facial expression. Drooling and excessive salivation are also common. A shuffling gait may be seen and the patient may show signs of fatigue when performing repetitive motor activities.

Another movement disorder more commonly associated with typical antipsychotics is tardive dyskinesia. Tardive dyskinesia normally affects the tongue, facial and neck muscles but can also affect the extremities. Individuals with tardive dyskinesia often have abnormalities of posture and movement of the fingers in addition to the oral-lingual-masticatory movements.

Epidemiological studies support the association between the prescribing of typical antipsychotic drugs and the development of tardive dyskinesia. Other factors which also appear to be associated include the duration of exposure to

antipsychotic drugs, the co-prescribing of anticholinergic drugs, the co-prescribing of lithium, advanced age, prior experience of acute extrapyramidal symptoms and brain damage. Many other factors have been postulated to be associated with tardive dyskinesia such as depot formulations of antipsychotic drugs, dosage of antipsychotic drug and antipsychotic drugs with high anticholinergic activity, but such associations remain unproven.

Although the mechanism by which tardive dyskinesia arises is unclear, the leading hypothesis is that after prolonged blockade of dopamine receptors, there is a paradoxical increase in the functional activity of dopamine in the basal ganglia occurs. This increased functional state is thought to come about through a phenomenon of disuse supersensitivity of dopamine receptors. The primary clinical evidence to support this theory arises because tardive dyskinesia is late in onset following prolonged exposure to antipsychotic drugs and has a tendency to worsen upon abrupt discontinuation of the antipsychotic drug.

Attempts to treat tardive dyskinesia have been many and varied. Treatments include use of dopamine-depleting agents such as reserpine and tetrabenazine, dopamine-blocking agents such as antipsychotic drugs, interference with catecholamine synthesis by drugs such as methyldopa, cholinergic agents such as choline and lecithin, use of GABA mimetic agents such as sodium valproate and baclofen, and the provision of drug holidays. Rarely are these strategies successful. Most successful strategies currently involve a gradual withdrawal of the typical antipsychotic drug and replacement with an atypical antipsychotic drug.

Concerns about the EPSEs and toxicity of typical antipsychotic drugs led to calls over the past 10 years for the 'atypicals' to be prescribed more widely. This approach was supported in national guidance which advocated that atypical antipsychotic drugs should be used for the treatment of a first illness. However, increasing concern about the side effects of the atypical antipsychotic drugs, which includes weight gain, diabetes and sexual dysfunction, has led many clinicians to question the benefits of the newer and more expensive atypical antipsychotics. In more recent guidance (National Institute for Health and Clinical Excellence, 2009), it has been advocated that:

- Oral antipsychotic medication should be offered to people with newly diagnosed schizophrenia.
- Information on the benefits and side effects of each antipsychotic agent should be provided and discussed with the patient.
- The decision as to which antipsychotic to use should be made in partnership with the patient and carer as appropriate.
- When deciding on the most suitable medication, the relative potential of the individual antipsychotics to cause EPSEs such as akathisia, metabolic side effects such as weight gain and other side effects including unpleasant subjective experiences should be considered.
- Combined antipsychotic medication should not be started, except for short periods (e.g. when changing medication).

Information on the advantages and disadvantages of the various antipsychotic drugs can be found in Table 30.1.

A significant factor that has influenced prescribing practice in schizophrenia in recent years has been an improved understanding of the role of clozapine in treatment-resistant schizophrenia.

Clozapine and refractory illness

Clozapine was developed as an antipsychotic drug during the 1960s. Unfortunately, use is associated with a 1–2% incidence of neutropenia and this initially resulted in the withdrawal of the drug from clinical practice. However, it was noted even at an early stage in the drug's history that it was free of the extrapyramidal side frequently seen with the other antipsychotic drugs. In the 1980s, clozapine was demonstrated to have a greater efficacy than other antipsychotics (Kane et al., 1988; Lieberman et al., 1994) and was subsequently reintroduced into clinical practice but with routine monitoring of blood mandatory.

Clozapine is now established as the drug of choice in treatment-resistant schizophrenia but it is not without problems (Tuunainen et al., 2000). In addition to neutropenia, it is associated with a greater risk of seizures, particularly if doses are above 600 mg daily. Some guidelines recommend the co-prescribing of sodium valproate to reduce this risk. In addition, use is associated with excessive drooling, hypotension and sedation during the early stages of treatment, requiring slow dose increases initially.

A regimen of gradual dose increases starting at 12.5 mg twice daily aiming to reach 300 mg in 2–3 weeks is normally recommended. However, this rate of dose increase is frequently too rapid, with tachycardia being a particular problem. In such cases, it is usual to slow down the rate of dose increase to a half or a quarter of that recommended. Although tachycardia is a common problem with clozapine initiation, if use is associated with fever, chest pain or hypotension this may indicate a high risk of myocarditis and the drug should be stopped (Committee on Safety of Medicines, 2002).

Polypharmacy

Polypharmacy remains a matter of concern in the management of individuals with schizophrenia. It usually arises because:

- There is a poor response to standard drug treatment.
- There are unrealistic expectations about the onset of action and the extent of treatment control.
- Prescribers feel inhibited about using high doses and resort to prescribing two or more antipsychotic drugs to achieve control, particularly in the acute situation. The consensus is that very high doses of antipsychotics do not improve the overall level of response (Royal College of Psychiatrists, 2006). Increasingly, though, prescribers are being encouraged to use clozapine at an earlier stage for patients who do not fully respond to treatment.

Table 30.1 Neuroleptics/antipsychotics and their commonly associated attributes and problems

Drug group	Drug	Comment
Butyrophenones	Haloperidol	Regarded as the gold standard reference antipsychotic Extrapyramidal side effects of parkinsonian rigidity, dystonia, akathisia Tardive dyskinesia with long-term use Drug most associated with neuroleptic malignant syndrome Sedation common Hormonal effects common Wide range of formulations including long-acting injection
	Benperidol	As haloperidol Claimed to reduce sexual drive, although little evidence to support the claim
Phenothiazines Piperidine	Pericyazine	Marked anticholinergic side effects of dry mouth, blurred vision and constipation Postural hypotension and falls in the elderly Lower incidence of extrapyramidal side effects
	Pipotiazine	As pericyazine but only available as depot formulation
Aliphatic	Chlorpromazine	As haloperidol but in addition postural hypotension, low body temperature, rashes and photosensitivity Increased sedative effects
	Promazine	As chlorpromazine but low potency Considered by some to have weak antipsychotic effect
	Levomepromazine (methotrimeprazine)	Very sedative and postural hypotension common Mostly used in terminal illness
Piperazine	Trifluoperazine	As chlorpromazine but greater incidence of extrapyramidal side effects and lower incidence of anticholinergic effects Tardive dyskinesia with long-term use Some antiemetic properties
	Fluphenazine	As trifluoperazine but also available as depot formulation
	Perphenazine	As trifluoperazine
Thioxanthines	Flupentixol	Similar to fluphenazine but also available as depot formulation
	Zuclopenthixol	Similar to chlorpromazine but also available as depot formulation
Diphenylbutylpiperidines	Pimozide	As haloperidol but concerns about cardiac effects at high dose limits use
Benzamides	Sulpiride	Lower incidence of extrapyramidal effects Few anticholinergic effects Useful adjunct to clozapine in refractory illness
	Amisulpride	As sulpiride
Dibenoxazepine tricyclics	Clozapine	Drug of choice for treatment-resistant schizophrenia Low incidence of extrapyramidal side effects or tardive dyskinesia Neutropenia in 1–2% of cases Enhanced efficacy against both positive and negative symptoms Sedation, dribbling, drooling, weight gain and diabetes
Thienobenzodiazepines	Olanzapine	Sedation, weight gain and diabetes Low incidence of extrapyramidal side effects and low impact on prolactin
	Quetiapine	Low incidence of extrapyramidal side effects and low impact on prolactin
	Zotepine	Similar to olanzapine but higher rate of prolactin elevation and higher rate of drug-induced seizures
Serotonin–dopamine antagonists	Risperidone	Extrapyramidal side effects at higher doses. High rate of prolactin elevation
	Paliperidone	As risperidone
	Ziprasidone	As risperidone
	Sertindole	Available on named patient basis only due to risk of sudden cardiac events
Partial dopamine agonist	Aripiprazole	Low level of side effects but light-headedness and blurred vision common

- Once control has been achieved there may be reluctance to reduce either dose or the number of drugs an individual is receiving for fear of re-emergence of symptoms.
- There is an imbalance between the perceived need in the hospital ward setting for sedation rather than an antipsychotic effect. The sedating side effects of antipsychotic drugs may be evident within hours; they are rapid in onset but may begin to wear off after 2–3 weeks. The antipsychotic effects on thought disorder, hallucinations and delusions may take some weeks to appear, although if there has been no response within 2–3 weeks a change of antipsychotic or change of dose may be indicated.

Neuroleptic equivalence

Although antipsychotic drugs vary in potency, studies on relative dopamine receptor binding have led to the concept of chlorpromazine equivalents as a useful method of transferring dosage from one product to another. Concern has been expressed about the variation between sources for such values, in particular about the quoted chlorpromazine equivalents of the butyrophenones and the conversion of depot doses to oral doses (Table 30.2). Likewise, there is no agreement on the equivalent doses of the atypicals.

For research purposes the concept of proportion of the maximum dose stated in the British National Formulary (BNF) has been developed as a standardised method for calculating average doses used in practice. However, this may not be a useful way of determining a dose when transferring a patient from one antipsychotic to another.

Table 30.2 Equivalence of typical antipsychotic drugs to 100 mg chlorpromazine (from Foster, 1989)

Drug	Usual dose (mg) equivalent of to 100 mg chlorpromazine	Variations in quoted dosage (mg) equivalent to 100 mg of chlorpromazine
Oral antipsychotics		
Promazine	200	100–250
Thioridazine	100	50–120
Trifluoperazine	5	3.5–7.5
Haloperidol	2	1.5–5
Sulpiride	200	–
Depot antipsychotics administered every 2 weeks (all administered as the decanoate)		
Zuclopenthixol	200	80–200
Flupentixol	40	16–40
Fluphenazine	25	10–25
Haloperidol	20	–

Augmentation strategies and polytherapy

Schizophrenia is a complex illness with a very varied presentation. In addition to the core symptoms, elements of other mental illnesses such as mania, depression and anxiety may predominate. Controversy remains about whether these associated symptoms should be treated separately or as a part of schizophrenia. In addition, there is debate about whether these presentations represent an alternative diagnosis, for example, schizoaffective disorder when the mood disorder is a primary component of the presentation. The current fashion is for these components of the illness to be treated separately, with much resulting polytherapy with SSRI antidepressants and antiepileptic drugs for mood control.

In addition to the above, complex prescriptions can arise when treatment with clozapine is perceived to be inadequate or doses are limited due to side effects. The theory behind the addition of a further drug can be either that the plasma concentration of the clozapine will be enhanced by the addition of another drug, or the second drug will enhance a particular receptor blockade which may be considered necessary in a specific patient (Cipriani et al., 2009; Paton et al., 2007). The augmentation strategy with the best evidence to support its use is the addition of sulpiride or amisulpride to clozapine. Other strategies include the addition of risperidone, lamotrigine or Ω3 fatty acids. However, many of the trials that support these augmentation strategies are small scale and a meta-analysis concluded that no single strategy was superior to another (Paton et al., 2007).

Long-acting formulations of antipsychotic drugs

Most long-acting (depot) formulations, including the long-acting olanzapine formulation, are synthesised by esterification of the hydroxyl group of the antipsychotic drug to a long chain fatty acid such as decanoic acid. The esters which are more lipophilic and soluble are dissolved in an oily vehicle such as sesame oil or a vegetable oil (viscoleo). Once the drug is injected into muscle it is slowly released from the oil vehicle. Active drug becomes available following hydrolysis for distribution to the site of the action. A long-acting injection of olanzapine has been marketed which contains a salt of olanzapine and pamoic acid suspended in an aqueous vehicle. This also is designed for intramuscular injection every 2–4 weeks.

Although the ideal long-acting antipsychotic formulation should release the drug at a constant rate so that plasma level fluctuations are kept to a minimum, all the available products produce significant variations (Table 30.3). This can result in increased side effects at the time of peak plasma concentrations, usually after 5–7 days, for oil-based depots and increased patient irritability towards the end of the period, as plasma concentrations decline. For many patients though, oil-based long-acting formulations result in a very slow decline in drug availability after a period of chronic administration (Altamura et al., 2003). When transferring a patient from depot formulations to oral administration, it may be many months before the effect of the depot finally wears off.

Table 30.3 Comparison of depot antipsychotics

Drug	Ester	Vehicle	Time to peak (days) from single dose	Half-life (days)
Haloperidol	Decanoate	Sesame oil	3–9	21
Flupentixol	Decanoate	Viscoleo oil	7	17
Zuclopenthixol	Decanoate	Viscoleo oil	4–7	19
Fluphenazine	Decanoate	Sesame oil	0.3–1.5	6–9
Pipotiazine	Palmitate	Sesame oil	10–15	15
Risperidone		Microspheres	32	8–9
Olanzapine	Pamoate	Aqueous	3	10
Paliperidone	Palmitate	Microspheres	13	25–49

Long-acting risperidone injection involves a microsphere formulation. The microspheres delay the release of risperidone for 3–4 weeks. Once release has commenced, the risperidone reaches a maximum concentration 4–5 weeks after the injection with a decline over the subsequent 2–3 weeks. This more rapid decline has an advantage that by 2 months after the last injection, little of the risperidone will remain. The delay in onset is often a reason for relapse as it is necessary to maintain oral supplementation for at least 6 weeks and this may be overlooked.

In addition to the principles of drug choice and dosage selection that apply to oral drugs, with depot therapy there is also a need to consider the future habitation of the patient. If the patient is to live an independent lifestyle, depot formulations are indicated, but if the person is to remain in staffed accommodation and receive other medicines routinely administered by a nurse, the use of depot formulations may not be logical.

Advantages and disadvantages of long-acting formulations

Non-adherence with oral medicines is a major problem in patients with any long-term illness and the administration of depot formulations guarantees drug delivery. It has been argued that, although depot injections are expensive, they have economic advantages because they reduce hospital admissions, improve drug bioavailability by avoiding the deactivating processes which occur in the gut and liver, and result in more consistent plasma levels of drug.

Depot formulations have the disadvantage of reduced flexibility of dosage, the painful nature of administration and, for the older depots, a high incidence of EPSEs. In addition, risperidone long-acting injection has the disadvantage of considerable delay in onset, whilst the olanzapine depot is associated with a post-injection syndrome consistent with olanzapine overdose. Although this side effect is relatively rare there is a requirement for patients to be observed for 3 hours following injection thereby limiting its acceptability.

Anticholinergic drugs

Anticholinergic drugs are prescribed to counter the EPSEs of typical antipsychotics, and at one time were routinely prescribed. It is generally accepted that, with the possible exception of the first few weeks of treatment with antipsychotic drugs known to have a high incidence of EPSEs, anticholinergic drugs should only be prescribed when a need has been shown. A number of studies have looked at the discontinuation of anticholinergic agents and reported re-emergence of the symptoms. Up to 60% of patients may be affected by re-emergence of symptoms and between 25% and 30% of patients will have a continuing need for anticholinergic drugs. The anticholinergic drugs are not without problems, having their own range of side effects that include dry mouth, constipation and blurred vision. Trihexyphenidyl in particular, is renowned for its euphoric effects and withdrawal problems can include cholinergic rebound. One of the benefits of the atypical antipsychotic drugs is the reduced need for co-prescription of anticholinergic drugs. However, EPSEs can still occur with atypical antipsychotic drugs, particularly at high dose.

Interactions and antipsychotic drugs

There are claimed to be many interactions involving antipsychotic drugs but few appear to be clinically significant. Propranolol increases the plasma concentration of chlorpromazine, and carbamazepine accelerates the metabolism of haloperidol, risperidone and olanzapine. When tricyclic antidepressants are administered with phenothiazines, increased antimuscarinic effects such as dry mouth and blurred vision can occur and most antipsychotic drugs increase the sedative effect of alcohol. The SSRI antidepressants fluvoxamine, fluoxetine and paroxetine interact with clozapine, resulting in increases in clozapine plasma concentration.

Therapeutic drug monitoring

Therapeutic drug monitoring is only of value if there is a reliable laboratory assay and a correlation exists between the concentration of the drug in any particular body compartment, usually

blood/plasma, and its clinical effectiveness. Unfortunately, this is not the case for most antipsychotic drugs and the measurement of drug concentrations is not a part of routine clinical practice. In recent years, however, it has become common to measure clozapine levels although even with this drug there is only a weak correlation between plasma levels and clinical effect. The general guidance is that individuals who have not adequately responded to clozapine and have a plasma level below 350–500 μcg/L may benefit from a dose increase and those who suffer side effects and have a plasma level above this range may benefit from a dose reduction. Those with a plasma level above 1000 μcg/L are more likely to suffer seizures and cover using sodium valproate should be considered.

Adverse effects and antipsychotic medicines

There are a large number of adverse effects associated with antipsychotic medicines. Some of these effects, such as sedation, antilibido effects and weight gain may be considered to be of value with particular patients, but the susceptibility to such adverse effects is often a major factor in determining drug choice. Prescribing guidelines are available (Bazire, 2009; Taylor et al., 2009) which provide details of the relative likelihood of side effects with the various antipsychotic drugs. The major side effects are set out below.

Sedation

Although sedation is most commonly associated with chlorpromazine and clozapine, it is primarily related to dosage with other antipsychotics. Products claiming to be less sedating can often only substantiate this when used at low doses.

Weight gain and diabetes

Weight gain was a common feature of the first phenothiazine antipsychotics. It was originally thought this side effect was caused by a direct effect on metabolism. This side effect has also become a feature of some of the newer atypical antipsychotic medicines, particularly olanzapine and clozapine. This re-emergence of an old side effect with the new drugs has rekindled interest in the cause, which is now thought to be more associated with loss of control of food intake, rather than a direct effect on food metabolism. In addition to weight gain, these two atypical antipsychotic drugs have also been associated with increased incidence of diabetes. Controversy remains about whether there is a link between the weight gain and onset of diabetes, and whether the development of diabetes is more associated with the illness of schizophrenia than the drugs. Whatever the link, the controversy has led to the acceptance that people with schizophrenia often suffer poor physical health in addition to poor mental health and require regular monitoring of physical health risk factors. Increased concern about the physical and metabolic side effects of the antipsychotic medicines has led to increased requirements to monitor urea and electrolytes, blood lipids, full blood count, plasma glucose and blood pressure.

QT prolongation and cardiac risk

Some antipsychotic drugs are associated with changes to the QT interval measured on the elecrocardiogram (ECG) and, if given in high doses, may increase the risk of sudden cardiac death. Although, overall, the risk is low, monitoring the ECG has become part of normal practice, especially if high doses are used.

Anticholinergic side effects

Side effects such as dry mouth, constipation and blurred vision are particularly associated with piperidine phenothiazines.

Extrapyramidal side effects

Side effects such as akathisia, dystonia and parkinsonian effects are associated with typical antipsychotic drugs and occur frequently, particularly with depot antipsychotics, piperazine phenothiazines such as trifluoperazine and fluphenazine, and butyrophenones such as haloperidol. These side effects are reversible by using anticholinergic drugs or by dosage reduction. The common extrapyramidal effects include akathisia, dystonia and parkinson-like side effects (see the previous section)

Hormonal effects and sexual dysfunction

These side effects are primarily influenced by the effect on prolactin. This may result in galactorrhoea, missed menstrual periods and loss of libido. Some studies have suggested very high levels of sexual dysfunction with some antipsychotic drugs such as typical antipsychotic drugs and the atypical antipsychotics risperidone and amisulpride. However, in many of these studies the background level of such dysfunction is unclear. In addition, there has been a debate about the extent to which the long-term elevation of prolactin, particularly in the young, may be a cause of osteoporosis. What remains controversial though is at what point an elevated prolactin level should result in a discussion about choosing an alternative antipsychotic.

Postural hypotension and photosensitivity

Postural hypotension and photosensitivity are particularly associated with the aliphatic phenothiazines such as chlorpromazine.

Neuroleptic malignant syndrome (NMS)

The NMS is a rare but serious complication of antipsychotic drug treatment. The primary symptoms are rigidity, fever, diaphoresis, confusion and fluctuating consciousness. Confirmation can be sought through detection of elevated levels of creatinine kinase. The onset is particularly associated with high-potency typical drugs such as haloperidol, recent and rapid changes to dose and abrupt withdrawal of anticholinergic drugs. Treatment usually requires admission to a medical ward and withdrawal of all antipsychotic drugs.

Case studies

Case 30.1

Lee is a 20-year-old man. His childhood was disrupted by constant changes to family membership. From an early age his behaviour was difficult but despite such changes by the age of 16 he was achieving well at school. Aged 17, he became involved with the illicit drug culture and increasingly lost interest in his studies. His parents became concerned as he appeared to undergo a change of personality, communicating with them very little. He eventually dropped out of school and took various short-term jobs. He was unable to sustain any long-term employment. He moved into a flat and seemed to live a twilight existence involving illicit drugs and all-night raves. Police were called to his flat following a violent disturbance. They found Lee living in squalor. He was surrounded by pieces of paper containing incomprehensible messages and was incoherent. He sat with a fixed stare, appearing quite inaccessible. He kept laughing and responding to imaginary people. He was very resistant to hospital admission, and had to be admitted under a section of the Mental Health Act 2007. On the ward he has remained quiet but appears to be in conversation with people who are not there.

Questions

1. Outline the drug(s) of choice for Lee and the rationale for selection.
2. What factors would influence the likely prognosis?
3. Outline the drug(s) of choice if there is the need to control aggressive behaviour.

Answers

1. The first need is to ascertain whether the patient's behaviour results from abuse of illicit substances or the onset of a schizophrenic illness. If the former, he would be expected to recover within a few days with little or no drug treatment. If, however, this is the first presentation of a schizophrenic illness, the symptoms are likely to persist and it would be appropriate to prescribe an antipsychotic drug. The choice of antipsychotic drug for first-illness psychosis may partly depend on the formulation acceptable to the situation but would usually be an atypical antipsychotic drug. If oral medicines were refused the intramuscular formulation of olanzapine may be the drug of choice. If there were concerns that he may not swallow the drug, aripiprazole, olanzapine and risperidone are formulated as orodispersible formulations.
2. A number of factors in Lee's history indicate a poor prognosis:

   - there has been a deterioration in function
   - his age, which is typical for a first breakdown
   - his poor work record
   - grossly disorganised behaviour
   - a number of positive symptoms such as hallucinations

3. If Lee becomes aggressive and there was a need to use medicines to control the aggression a decision would have to be made about whether to use antipsychotic drugs or benzodiazepines. In the past, sedative antipsychotic drugs such as chlorpromazine, haloperidol or zuclopenthixol were favoured, but increasing concern about sudden death has led to a move to use benzodiazepines such as lorazepam or diazepam. However, the introduction of intramuscular olanzapine has resulted in some swing back to using antipsychotic drugs for the control of violent and aggressive behaviour.

Case 30.2

Gordon has relapsed for the third time this year, the pattern for the last two relapses being the same. His positive symptoms responded rapidly on both previous occasions. On the first he suffered severe extrapyramidal side effects with 30 mg daily of haloperidol and was subsequently stabilised and discharged on sulpiride 400 mg twice daily and procyclidine 5 mg twice daily. He almost immediately stopped taking the sulpiride, claiming not to be ill. During his second relapse he was successfully treated with risperidone 4 mg daily but again stopped the medicine.

Questions

1. Was Gordon's drug treatment appropriate?
2. What strategies could be adopted to maintain Gordon in treatment?

Answers

1. Gordon's initial treatment was not according to current guidelines. The initial treatment with a large dose of haloperidol in a drug-naive patient would now be regarded as excessive. The initial choice of a low-dose typical antipsychotic followed by a second choice of an atypical after the patient suffered extrapyramidal side effects was common practice prior to the publication of national guidance (National Institute for Health and Clinical Excellence, 2009). An atypical antipsychotic would be regarded as the drug of choice for first illness.
2. Gordon has no insight into his illness or the need for continuing treatment. This could be for a number of reasons:

   - It is part of the illness, and his failure to gain insight is symptomatic of incomplete recovery.
   - He lacks a supportive environment to ensure that he takes medicines.
   - He is suffering from side effects that deter him from taking the medicines.

   In most cases, the use of a depot antipsychotic injection would be the easiest way to ensure adherence, although if Gordon is determined to avoid drug treatment this strategy is unlikely to be successful. In his case, the history of good response to oral risperidone and severe extrapyramidal side effects with a typical antipsychotic drug would indicate that the long-acting intramuscular formulation of risperidone may be a good choice.

Case 30.3

Sharon, aged 25, has a 3-year history of schizophrenia with many admissions to hospital. Throughout the period of her illness she has received a range of different oral antipsychotic drugs including chlorpromazine, haloperidol, sulpiride, risperidone and olanzapine, as well as the depot formulations of haloperidol and zuclopenthixol. For most of this time she has had a fixed belief that she is involved with a range of mythical beasts that sexually assault her. When she is ill these beings torment her. She currently receives zuclopenthixol decanoate 500 mg by intramuscular injection every week, olanzapine 10 mg at night, carbamazepine 200 mg three times daily, haloperidol 10 mg four times daily, and procyclidine 10 mg three times daily. She has remained on the ward for the last 4 months with no sign of improvement. She has greatly increased in weight, now approaching 20 stone. The team wishes to consider clozapine for Sharon.

....

Questions

1. Comment on the current drug therapy Sharon is receiving.
2. What action is required before Sharon can receive clozapine?

....

Answers

1. Although it is not uncommon for polypharmacy to occur when there has been poor response, the practice is frowned upon. Additional medicines are often added in a crisis or in the hope of achieving a greater degree of response. As in this case, the strategy is often unsuccessful. The particular issues of note with this patient's drug regimen are

   - The combination of a typical and an atypical antipsychotic drug reduces the potential benefit of using a drug with a low incidence of extrapyramidal side effects because the patient still suffers extrapyramidal side effects, requires procyclidine, and is at risk of developing tardive dyskinesia.
   - The very large total dose she is receiving from the combination of antipsychotic drugs.
   - The dose of anticholinergic drug (procyclidine) is high and likely to result in its own side effects.

   - The need for such frequent dosing of the intramuscular depot might not be necessary; administration at 2-week intervals would normally be appropriate.
   - There is little evidence to support the value of carbamazepine, either for schizophrenia or as an adjunctive treatment.
   - She is suffering severe weight gain.
   - The interaction between carbamazepine and the antipsychotic drugs may be reducing their potential efficacy.

2. The preparation for treatment with clozapine involves a number of steps. These include

   - registration with the clozapine monitoring scheme
   - background blood tests to ensure that the patient is not already suffering from neutropenia or another blood disorder
   - stopping the depot antipsychotic drug; this would usually occur some weeks before starting clozapine
   - stopping carbamazepine as this interacts with clozapine
   - slowly reducing haloperidol
   - gradually stopping procyclidine

   Ideally all other treatments would be stopped and clozapine prescribed alone. Sometimes the final step of withdrawing other medicines may occur during the initiation phase with clozapine.

Epilepsy 31

J. W. Sander and S. Dhillon

Key points

- An epileptic seizure is a transient paroxysm of uncontrolled discharges of neurones causing an event which is discernible by the person experiencing the seizure and/or an observer.
- The incidence of epileptic seizures is around 50 cases per 100,000 of the population.
- About 70–80% of all those who develop epilepsy will become seizure free on treatment and about 50% will eventually withdraw their medication successfully.
- Generalised seizures result in impairment of consciousness from the onset; they include tonic clonic convulsions, absence attacks and myoclonic seizures.
- Focal seizures include simple partial seizures, complex partial seizures and secondarily generalised seizures.
- Treatment of epilepsy is usually for at least 3 years and, depending on circumstances, sometimes for life.
- Treatment aims to control seizures using one drug without causing side effects and minimising the use of polypharmacy.
- Management of epilepsy requires empowering patients to understand their condition and medication and helping them develop effective partnerships with health professionals.

An epileptic seizure is a transient paroxysm of uncontrolled discharges of neurones causing an event that is discernible by the person experiencing the seizure and/or by an observer. The tendency to have recurrent attacks is known as epilepsy; by definition, a single attack does not usually constitute epilepsy. Epileptic seizures or attacks are a symptom of many different diseases, and the term epilepsy is loosely applied to a number of conditions that have in common a tendency to have recurrent epileptic attacks. A patient with epilepsy will show recurrent epileptic seizures that occur unexpectedly and stop spontaneously.

Epidemiology

There are problems in establishing precise epidemiological information for a heterogeneous condition such as epilepsy. Unlike most ailments, epilepsy is episodic; between seizures, patients may be perfectly normal and have normal investigations. Thus, the diagnosis is essentially clinical, relying heavily on eyewitness descriptions of the attacks. In addition, there are a number of other conditions in which consciousness may be transiently impaired and which may be confused with epilepsy. Another problem area is that of case identification. Sometimes the person may be unaware of the nature of the attacks and so may not seek medical help. People with milder epilepsy may also not be receiving ongoing medical care and so may be missed in epidemiological surveys. Furthermore, since there is some degree of stigma attached to epilepsy, people may sometimes be reluctant to admit their condition. Indeed, epilepsy is still one of the world's most stigmatised conditions. In today's society, in both developed and developing countries, fear, misunderstanding, discrimination and social stigma still exist and these affect the quality of life for people with the disorder and their families.

Epilepsy does impact on an individual's human rights, for example, access to health and life insurance is affected. A person who suffers from epilepsy may not be able to obtain a driving licence and it has an impact on the choice of career. In addition, legislation can impact on the life of individuals with epilepsy, for example, in some countries epilepsy may deter marriages. Legislation based on internationally accepted human rights standards can prevent discrimination and rights violations, improve access to health care services and raise quality of life (WHO, 2009). A global campaign has been established to raise awareness about epilepsy, provide information and highlight the need to improve care and reduce the disorder's impact through public and private collaboration. This is supported through a partnership established between WHO, the International League Against Epilepsy (ILAE) and the International Bureau for Epilepsy (IBE).

Epilepsy is recognised as a priority in effective health care delivery and there are still a number of issues that health professionals should consider:

- Epilepsy is a chronic neurological disorder that affects people of all ages.
- Around 50 million people worldwide have epilepsy.
- Nearly 90% of the people with epilepsy are found in developing regions.
- Epilepsy responds to treatment 70% of the time. Despite this, approximately 75% of affected people in developing countries do not get the treatment they need.
- People with epilepsy and their families suffer from stigma and discrimination in many parts of the world.

Incidence and prevalence

Epileptic seizures are common. The incidence (number of new cases per given population per year) has been estimated at between 20 and 70 cases per 100,000 persons, and the cumulative incidence (the risk of having the condition at some point in life) at 2–5%. The incidence is higher in the first two decades of life but falls over the next few decades, only to increase again in late life, due mainly to cerebrovascular diseases. Currently, the elderly are the group in the populations with the highest incidence of epilepsy. Most studies of the prevalence of active epilepsy (the number of cases in the population at any given time) in developed countries cite figures of 4–10 per 1000 with a rate of 5 per 1000 population most commonly quoted. In developed countries, annual new cases are between 0.4 and 0.7 per 1000 general population.

In developing countries, the prevalence of epilepsy is higher with rates of 6–10 per 1000 population cited and reported annual new cases twice those seen in developed countries, presumably due to the higher risk of experiencing conditions that can lead to permanent brain damage. Overall, nearly 90% of epilepsy cases worldwide are found in developing regions.

Prognosis

Up to 5% of people will suffer at least one seizure in their lifetime. The prevalence of active epilepsy is, however, much lower and most patients who develop seizures have a very good prognosis. About 70–80% of all people developing epilepsy will eventually become seizure free, and about half will successfully withdraw their medication. Once a substantial period of remission has been achieved, the risk of further seizures is greatly reduced. A minority of people (20–30%) will develop chronic epilepsy and in such cases, treatment is more difficult. People with symptomatic epilepsy, more than one seizure type, associated learning disabilities or neurological or psychiatric disorders are more likely to have a poor outcome. Of people with chronic epilepsy, fewer than 5% will be unable to live in the community or will depend on others for their day-to-day needs. Most people with epilepsy are entirely normal between seizures but a small minority of patients with severe epilepsy may suffer physical and intellectual deterioration.

Mortality

People with epilepsy, especially younger patients and those with severe epilepsy are at an increased risk of premature death. Most studies have given overall standardised mortality ratios between two and three times that of the general population. Common causes of death in people with epilepsy include accidents such as drowning, head injury, road traffic accidents, status epilepticus, tumours, cerebrovascular disease, pneumonia and suicide. Sudden unexpected death, an entity which remains unexplained, is common in chronic epilepsy, particularly among the young who have convulsive forms of epilepsy.

Aetiology

Epileptic seizures are produced by abnormal discharges of neurones that may be caused by any pathological process which affects the cortical layer of the brain. The idiopathic epilepsies are those in which there is a clear genetic component, and they probably account for a third of all new cases of epilepsy. In a significant proportion of cases, however, no cause can be determined and these are known as the cryptogenic epilepsies. Possible explanations for cryptogenic epilepsy include as yet unexplained metabolic or biochemical abnormalities and microscopic lesions in the brain resulting from brain malformation or trauma during birth or other injury. The term 'symptomatic epilepsy' indicates that a probable cause has been identified.

The likely aetiology of epilepsy depends upon the age of the patient and the type of seizure. The commonest causes in young infants are hypoxia or birth asphyxia, intracranial trauma during birth, metabolic disturbances and congenital malformations of the brain or infection. In young children and adolescents, idiopathic seizures account for the majority of the epilepsies, although trauma and infection also play a role. In this age group, particularly in children aged between 6 months and 5 years, seizures may occur in association with febrile illness. These are usually short, generalised tonic clonic convulsions that occur during the early phase of a febrile disease. They must be distinguished from seizures that are triggered by central nervous system infections which produce fever, for example, meningitis or encephalitis. Unless febrile seizures are prolonged, focal, recurrent or there is a background of neurological handicap, the prognosis is excellent and it is unlikely that the child will develop epilepsy.

The range of causes of adult-onset epilepsy is very wide. Both idiopathic epilepsy and epilepsy due to birth trauma may also begin in early adulthood. Other important causes are head injury, alcohol abuse, cortical dysplasias, brain tumours and cerebrovascular diseases. Brain tumours are responsible for the development of epilepsy in up to a third of patients between the ages of 30 and 50 years. Over the age of 50 years, cerebrovascular disease is the commonest cause of epilepsy, and may be present in up to half of patients.

Pathophysiology

Epilepsy differs from most neurological conditions as it has no pathognomonic lesion. A variety of different electrical or chemical stimuli can easily give rise to a seizure in any normal brain. The hallmark of epilepsy is a rather rhythmic and repetitive hyper-synchronous discharge of neurones, either localised in an area of the cerebral cortex or generalised throughout the cortex, which can be observed on an electroencephalogram (EEG).

Neurones are interconnected in a complex network in which each individual neurone is linked through synapses with hundreds of others. A small electrical current is discharged by neurones to release neurotransmitters at synaptic levels to

permit communication with each other. Neurotransmitters fall into two basic categories: inhibitory or excitatory. Therefore, a neurone discharging can either excite or inhibit neurones connected to it. An excited neurone will activate the next neurone whereas an inhibited neurone will not. In this manner, information is conveyed, transmitted and processed throughout the central nervous system.

A normal neurone discharges repetitively at a low baseline frequency, and it is the integrated electrical activity generated by the neurones of the superficial layers of the cortex that is recorded in a normal EEG. If neurones are damaged, injured or suffer a chemical or metabolic insult, a change in the discharge pattern may develop. In the case of epilepsy, regular low-frequency discharges are replaced by bursts of high-frequency discharges usually followed by periods of inactivity. A single neurone discharging in an abnormal manner usually has no clinical significance. It is only when a whole population of neurones discharge synchronously in an abnormal way that an epileptic seizure may be triggered. This abnormal discharge may remain localised or it may spread to adjacent areas, recruiting more neurones as it expands. It may also generalise throughout the brain via cortical and subcortical routes, including collosal and thalamocortical pathways. The area from which the abnormal discharge originates is known as the epileptic focus. An EEG recording carried out during one of these abnormal discharges may show a variety of atypical signs, depending on which area of the brain is involved, its progression and how the discharging areas project to the superficial cortex.

Clinical manifestations

The clinical manifestation of a seizure will depend on the location of the focus and the pathways involved in its spread. An international seizure classification scheme based on the clinical features of seizures combined with EEG data is widely used to describe seizures. It divides seizures into two main groups according to the area of the brain in which the abnormal discharge originates. If it involves initial activation of both hemispheres of the brain simultaneously, the seizures are termed 'generalised'. If a discharge starts in a localised area of the brain, the seizure is termed 'partial' or 'focal'.

Generalised seizures

Generalised seizures result in impairment of consciousness from the onset. There are various types of generalised seizures.

Tonic clonic convulsions

Often called 'grand mal' attacks, these are the commonest of all epileptic seizures. Without warning, the patient suddenly goes stiff, falls and convulses, with laboured breathing and salivation. Cyanosis, incontinence and tongue biting may occur. The convulsion ceases after a few minutes and may often be followed by a period of drowsiness, confusion, headache and sleep.

Absence attacks

Often called 'petit mal', these are a much rarer form of generalised seizure. They happen almost exclusively in childhood and early adolescence. The child goes blank and stares; fluttering of the eyelids and flopping of the head may occur. The attacks last only a few seconds and often go unrecognised even by the child experiencing them.

Myoclonic seizures

These are abrupt, very brief involuntary shock-like jerks, which may involve the whole body, or the arms or the head. They usually happen in the morning, shortly after waking. They may sometimes cause the person to fall, but recovery is immediate. It should be noted that there are forms of non-epileptic myoclonic jerks that occur in a variety of other neurological diseases and may also occur in healthy people, particularly when they are just going off to sleep.

Atonic seizures

These comprise a sudden loss of muscle tone, causing the person to collapse to the ground. Recovery afterwards is quick. They are rare, accounting for less than 1% of the epileptic seizures seen in the general population, but much commoner in patients with severe epilepsy starting in infancy.

Partial or focal seizures

Simple partial seizures

In these seizures, the discharge remains localised and consciousness is fully preserved. Simple partial attacks on their own are rare and they usually progress to the other forms of partial seizure. What actually happens during a simple partial seizure depends on the area of the discharge and may vary widely from person to person but will always be stereotyped in one person. Localised jerking of a limb or the face, stiffness or twitching of one part of the body, numbness or abnormal sensations are examples of what may occur during a simple partial seizure. If the seizure progresses with impairment of consciousness, it is termed a complex partial seizure. If it develops further and a convulsive seizure occurs, it is then called a partial seizure with secondary generalisation. In attacks which progress, the early part of the seizure, in which consciousness is preserved, may manifest as a sensation or abnormal feeling and is called the aura or warning.

Complex partial seizures

The person may present with altered or 'automatic' behaviour: plucking his or her clothes, fiddling with various objects and acting in a confused manner. Lip smacking or chewing movements, grimacing, undressing, performing aimless activities,

and wandering around in a drunken fashion may occur on their own or in different combinations during complex partial seizures. Most of these seizures originate in the frontal or temporal lobes of the brain and can sometimes progress to secondarily generalised seizures.

Secondarily generalised seizures

These are partial seizures, either simple or complex, in which the discharge spreads to the entire brain. The person may have a warning, but this is not always the case. The spread of the discharge can occur so quickly that no feature of the localised onset is apparent to the person or an observer, and only an EEG can demonstrate the partial nature of the seizure. The involvement of the entire brain leads to a convulsive attack with the same characteristics as a generalised tonic clonic convulsion.

There have been recent proposals to revise the concepts, terminology and approaches for classifying seizures and forms of epilepsy (Berg et al., 2010). In this proposal, the so-called natural classes, for example, specific underlying cause, age at onset, associated seizure type; or pragmatic groupings, for example, epileptic encephalopathies, self-limited electroclinical syndromes, serve as the basis for classification.

Diagnosis

Diagnosing epilepsy can be difficult as it is first necessary to demonstrate a tendency to recurrent epileptic seizures. The one feature that distinguishes epilepsy from all other conditions is its unpredictability and transient nature. The diagnosis of epilepsy is clinical and depends on a reliable account of what happened during the attacks, if possible both from the patient and from an eyewitness. Investigations may help and the EEG is usually one of them. These investigations, however, cannot conclusively confirm or refute the diagnosis of epilepsy.

There are other conditions that may cause impairment or loss of consciousness and which can be misdiagnosed as epilepsy; these include syncope, breath-holding attacks, transient ischaemic attacks, psychogenic attacks, etc. In addition, people may present with acute symptomatic seizures or provoked seizures as a result of other problems such as drug intake, metabolic dysfunction, infection, head trauma or flashing lights (photosensitive seizures). These conditions have to be clearly ruled out before a diagnosis of epilepsy is made. Epilepsy must only be diagnosed when seizures occur spontaneously and are recurrent. The diagnosis must be accurate since the label 'suffering with epilepsy' carries a social stigma that has tremendous implications for the person.

The EEG is often the only examination required, particularly in generalised epilepsies, and it aims to record abnormal neuronal discharges. EEGs have, however, limitations that should be clearly understood. Up to 5% of people without epilepsy may have non-specific abnormalities in their EEG recording, while up to 40% of people with epilepsy may have a normal EEG recording between seizures. Therefore,

the diagnosis of epilepsy should be strongly supported by a bona fide history of epileptic attacks. Nevertheless, the EEG is invaluable in classifying seizures.

The chance of recording the discharges of an actual seizure during a routine EEG, which usually takes 20–30 min, is slight and because of this, ambulatory EEG monitoring and EEG video-telemetry are sometimes required. Ambulatory EEG allows recording in day-to-day circumstances using a small cassette recorder. EEG video-telemetry is useful in the assessment of difficult cases, particularly if surgery is considered. The person is usually admitted to hospital and remains under continuous monitoring. This is only helpful in a very few cases, and it is best suited for people who have frequent seizures.

Neuroimaging with magnetic resonance imaging (MRI) is the most valuable investigation when structural abnormalities such as stroke, tumour, congenital abnormalities or hydrochephalus are suspected. MRI should be carried out in anyone presenting with partial seizures or where a structural lesion on the brain may be responsible for seizures.

Treatment

National Institute for Health and Clinical Excellence (2004a) issued guidance on the diagnosis and treatment of the epilepsies in adults and children in primary and secondary care. The guidance covered issues such as when a person with epilepsy should be referred to a specialist centre, the special considerations concerning the care and treatment of women with epilepsy and the management of people with learning disabilities. The key points of the guidance are summarised in Box 31.1.

Box 31.1 Key points on the diagnosis and management of epilepsy (National Institute for Health and Clinical Excellence, 2004a)

- Diagnosis to be made urgently by a specialist with an interest in epilepsy
- EEG to be used to support diagnosis
- MRI to be used in people who develop epilepsy as adults, in whom focal onset is suspected, or in whom seizures persist
- Seizure type(s) and epilepsy syndrome, aetiology and co-morbidity to be determined
- Initiation of appropriate treatment to be recommended by a specialist
- Treatment individualised according to seizure type, epilepsy syndrome, co-medication and co-morbidity, the individual's lifestyle and personal preferences
- The individual with epilepsy, and their family and/or carers, to participate in all decisions about care, taking into account any specific need
- Comprehensive care plans to be agreed
- Comprehensive provision of information about all aspects of condition
- Regular structured review at least once a year
- Patient to be referred back to secondary or tertiary care if:
  - Epilepsy inadequately controlled
  - Pregnancy considered or pregnant
  - Antiepileptic drug withdrawal considered
- MRI, magnetic resonance imaging; EEG, electroencephalogram.

Treatment during seizures

Convulsive seizures may look frightening but the person is not in pain, will usually have no recollection of the event afterwards and is usually not seriously injured. Emergency treatment is seldom necessary. People should, however, be made as comfortable as possible, preferably lying down (ease to the floor if sitting), cushioning the head and loosening any tight clothing or neckwear. During seizures, people should not be moved unless they are in a dangerous place, for example, in a road, by a fire or hot radiator, at the top of stairs or by the edge of water. No attempt should be made to open the person's mouth or force anything between the teeth. This usually results in damage, and broken teeth may be inhaled, causing secondary lung damage. When the seizure stops, people should be turned over into the recovery position and the airway checked for any blockage.

Partial attacks are usually less dramatic. During automatisms, people may behave in a confused fashion and should generally be left undisturbed. Gentle restraint may be necessary if the automatism leads to dangerous wandering. Attempts at firm restraint, however, may increase agitation and confusion. No drinks should be given after an attack, nor should extra antiepileptic drugs (AEDs) be administered. It is commonly felt that seizures may be life-threatening, but this is seldom the case. After a seizure, it is important to stay with the person and offer reassurance until the confused period has completely subsided and the person has recovered fully.

If a seizure persists for more than 10 min, if a series of seizures occur or if the seizure is particularly severe, then intravenous or rectal administration of 10–20 mg diazepam for adults, with lower doses being used in children, is advisable.

Status epilepticus

Initial management of status epilepticus is supportive and may include:

- positioning the person to avoid injury
- supporting respiration
- maintaining blood pressure
- correcting hypoglycaemia

Drugs used include intravenous lorazepam or diazepam. Alternative medicines include midazolam in cases where the person has not responded to first-line drugs. Alternatively, buccal midazolam has been advocated and is increasingly being used, although it is not licensed in the UK. In severe cases, phenytoin, clonazepam or phenobarbital sodium may be required.

Febrile convulsions

Convulsions associated with fever are termed febrile convulsions and may occur in the young. Brief febrile convulsions are managed conservatively with the primary aim of reducing the temperature of the child. Tepid sponging and use of paracetamol is usual. Prolonged febrile convulsions lasting 10–15 min or longer or in a child with risk factors require active management to avoid brain damage. The drug of choice is diazepam by intravenous or rectal (rectal solution) administration. Prophylactic management of febrile convulsions may be required in some children, such as those with pre-existing risk factors or a history of previous prolonged seizures.

Long-term treatment

In most cases, epilepsy can only be treated by long-term, regular drug therapy. The objective of therapy is to suppress epileptic discharges and prevent the development of epileptic seizures. In the majority of cases, full seizure control can be obtained, and in other patients drugs may reduce the frequency or severity of seizures.

Initiating treatment with an AED is a major event in the life of a person, and the diagnosis should be unequivocal. Treatment options must be considered with careful evaluation of all relevant factors, including the number and frequency of attacks, the presence of precipitating factors such as alcohol, drugs or flashing lights, and the presence of other medical conditions (Feely, 1999). Single seizures do not require treatment unless they are associated with a structural abnormality in the brain, a progressive brain disorder or there is a clearly abnormal EEG recording. If there are long intervals between seizures (over 2 years), there is a case for not starting treatment. If there are more than two attacks that are clearly associated with a precipitating factor, fever or alcohol for instance, then treatment may not be necessary.

Therapy is long-term, usually for at least 3 years and, depending on circumstances, sometimes for life. A full explanation of all the implications must be given to the person and they must be involved in all stages of the treatment plan. It is vital that the person understands the implications of treatment and agrees with the treatment goals. Empowerment of the person with epilepsy to be actively involved in the decision-making process will encourage adherence and is essential for effective clinical management. Support for people so that they understand the implications of the condition and why drug therapy is so important is crucial to ensure effective clinical management.

Health professionals have a key role in supporting people with epilepsy to ensure they are able to manage their medicines appropriately. AED treatment will fail unless the patient fully understands the importance of regular therapy and the objectives of treatment. Poor adherence is still a major factor which results in hospital admissions and poor seizure control and leads to the clinical use of multiple AEDs.

General principles of treatment

Therapy aims to control seizures using one drug, with the lowest possible dose that causes the fewest side effects possible. The established AEDs, carbamazepine, ethosuximide and sodium valproate, are still important parts of the antiepileptic armamentarium. Acetazolamide, clobazam, clonazepam, phenobarbital phenytoin and primidone are also still used. In the last two decades, new AEDs such as vigabatrin, lamotrigine, gabapentin, topiramate, tiagabine, oxcarbazepine,

levetiracetam, pregabalin, zonisamide, lacosamide and eslicar-bazepine acetate have been introduced. The choice of drugs depends largely on the seizure type, and so correct diagnosis and classification are essential. Table 31.1 lists the main indications for the more commonly used AEDs, and Table 31.2 summarises the clinical use of the newer AEDs.

Initiation of therapy in newly diagnosed patients

The first-line AED most suitable for the person's seizure type should be introduced slowly, starting with a small dose. This is because too rapid an introduction may induce side effects that will lose the person's confidence. For most drugs, this gradual introduction will produce a therapeutic effect just as fast as a rapid introduction, and the person should be reassured about this.

Maintenance dosage

There is no single optimum dose of any AED that suits all patients. The required dose varies from person to person, and from drug to drug. Drugs should be introduced slowly and then increased incrementally to an initial maintenance dosage. Seizure control should then be assessed, and the dose of drug changed if necessary. For most AEDs, dosage increments are constant over a wide range. More care is, however, needed with phenytoin as the serum level–dose relationship is not linear, and small dose changes may result in considerable serum level changes. Generic prescribing for epilepsy remains controversial. Most specialists would prefer people to remain on the same brand of medication, and this is also preferred by

the majority of people with epilepsy. This is obviously important in those people in whom the dosage has been carefully titrated to achieve optimal control.

Altering drug regimens

If the maximal tolerated dose of a drug does not control seizures, or if side effects develop, the first drug can be replaced with another first-line AED. To do this, the second drug should be added gradually to the first. Once a good dose of the new drug is established, the first drug should then slowly be withdrawn.

Withdrawal of drugs

AEDs should not be withdrawn abruptly. With barbiturates and benzodiazepines, in particular, rebound seizures may occur. Withdrawal of individual AEDs should be carried out in a slow stepwise fashion to avoid the precipitation of withdrawal seizures (e.g. over 2–3 months). This risk is particularly great with barbiturates, for example, phenobarbital and primidone, and benzodiazepines, for example, clobazam and clonazepam. If a drug needs to be withdrawn rapidly, for example, if there are life-threatening side effects, then diazepam or another benzodiazepine can be used to cover the withdrawal phase.

Examples of withdrawal regimens are given below.

- Carbamazepine
  100–200 mg every 2 weeks (as part of a drug change)
  100–200 mg every 4 weeks (total withdrawal)

- Phenobarbital
  15–30 mg every 2 weeks (as part of a drug change)
  15–30 mg every 4 weeks (total withdrawal)

- Phenytoin
  50 mg every 2 weeks (as part of a drug change)
  50 mg every 4 weeks (total withdrawal)

- Sodium valproate
  200–400 mg every 2 weeks (as part of a drug change)
  200–400 mg every 4 weeks (total withdrawal)

- Ethosuximide
  125–250 mg every 2 weeks (as part of a drug change)
  125–250 mg every 4 weeks (total withdrawal)

Variations in the above regimens may be used in different settings. People must be monitored closely for any change in seizure frequency. The pace of withdrawal may be slower if the person is within the higher end of the quoted dose range. The pace of withdrawal may be faster if the person is an inpatient.

When to make dose changes

Some AEDs have long half-lives and it may, therefore, take some time, normally five half-lives, before a change in dose results in a stable blood level. For example, phenobarbital has a half-life of up to 6 days and will take more than 4 weeks to

Table 31.1 Antiepileptic drugs for different seizure types

Seizure type	First-line treatment	Second-line treatment
Partial seizures		
	Carbamazepine	Topiramate
	Lamotrigine	Valproate
	Oxcarbazepine	Clobazam
	Levetiracetam	Zonisamide
		Pregabalin
		Phenytoin
		Gabapentin
		Lacosamide
		Eslicarbazepine
Generalised seizures		
Tonic clonic	Valproate sodium	Lamotrigine
Tonic	Carbamazepine	Clobazam
Clonic	Lamotrigine	Phenobarbital
Absence	Ethosuximide	Clonazepam
	Sodium valproate	Lamotrigine
Atypical absences	Sodium valproate	
Atonic	Clonazepam	Lamotrigine
	Clobazam	Carbamazepine
		Phenytoin
		Acetazolamide
		Topiramate
Myoclonic	Sodium valproate	Levetiracetam
	Clonazepam	Acetazolamide
		Topiramate

Table 31.2 Summary of newer antiepileptic agents

Antiepileptic drugs	Clinical use	Available formulation	Side effect profile
Lamotrigine	Monotherapy and adjunctive treatment of partial seizures, primary and secondary generalised tonic clonic seizure, Lennox–Gastaut syndrome	Tablets: 25, 50, 100, 200 mg Dispersible tablets: 5, 25, 100 mg	Dizziness, headache, diplopia, ataxia, nausea, somnolence, vomiting, rash. Rare: Stevens–Johnson syndrome, hematological
Vigabatrin	Adjunctive treatment of partial seizures with or without secondary generalisation, monotherapy for West's syndrome	Tablets: 500 mg Powder: 500 mg/sachet	Drowsiness, fatigue, dizziness, visual field defects nystagmus, abnormal vision, agitation, amnesia, depression, psychosis, increased weight, withdrawal seizures
Gabapentin	Adjunctive treatment of partial seizures with or without secondary generalisation, neuropathic pain	Capsules: 100, 300, 400 mg Tablets: 600, 800 mg	Somnolence, dizziness, ataxia, headache, fatigue, nystagmus, tremor, nausea, vomiting, increased weight
Tiagabine	Adjunctive treatment of partial seizures with or without secondary generalisation	Tablets: 5, 10, 15 mg	Dizziness, asthenia, nervousness, tremor, diarrhoea, depression, emotional liability, confusion, abnormal thinking, decreased weight
Topiramate	Adjunctive treatment of partial seizures with or without secondary generalisation, Lennox–Gastaut syndrome, primary generalised tonic clonic seizures	Tablets: 25, 50, 100, 200 mg Sprinkle capsules: 15, 25 mg	Dizziness, abnormal thinking, somnolence, ataxia, fatigue, confusion, impaired concentration, paresthesia, decreased weight, nephrolithiasis (1.5%)
Zonisamide	Adjunctive therapy in treatment of partial seizures with or without secondary generalisation	Capsule: 25, 50, 100 mg	Somnolence, anorexia, dizziness, headache, nausea, agitation/irritability, confusional state, depression
Lacosamide	Adjunctive for partial epilepsy with or without secondary generalisation	Tablets: 50, 100, 150, 200 mg Syrup: 15 mg/mL	Dizziness, headache, depression, diplopia nystagmus, impaired co-ordination, impaired memory, drowsiness, tremor, fatigue, pruritus

produce a stable blood level. For this reason an assessment of the effectiveness of any dose change should be undertaken several weeks after the dose change has been made and be informed by knowledge of the half-life of the drug.

Newer AEDs

The newer AEDs are generally used as second-line drugs when treatment with established first-line drugs has failed. Exceptions to this are lamotrigine, levetiracetam, topiramate and oxcarbazepine, which have indications for first-line use in the UK. Lamotrigine is considered the first-line option in women of child-bearing potential who have idiopathic generalised epilepsy because of the teratogenic profile of sodium valproate, otherwise the first-line drug for this indication. Oxcarbazepine has the same indications as carbamazepine, although the latter is probably more cost-effective.

There is no evidence that the newer AEDs are more effective than the established drugs, although it could be argued that they might be better tolerated. The chronic side effect profile of the new AEDs has not yet been fully established and this is the main reason why use should be reserved for those cases where benefit outweighs risk. Guidance has been issued that covers the use of the newer AEDs in adults (National Institute for Health and Clinical Excellence, 2004b):

- Newer drugs, for example, lamotrigine, oxcarbazepine and topiramate, suitable for the type of epilepsy to be treated can be used in patients where older drugs, for example, sodium valproate or carbamazepine, do not provide effective clinical control or cause untolerable side effects.
- Gabapentin, levetiracetam, tiagabine and vigabatrin are generally used in combination with another drug.
- Newer drugs can be used where older drugs are unsuitable for the person, for example, liver disease, or where unwanted effects cannot be tolerated.
- The aim should be to treat people with just one AED where possible.

The guidance for adults was followed up by advice for use of the newer AEDs in children (National Institute for Health

and Clinical Excellence, 2004c). This advice reflected that issued for adults and included:

- Lamotrigine, oxcarbazepine or topiramate can be given to children as sole treatment for epilepsy.
- Gabapentin, tiagabine and vigabatrin are generally used as combination therapy with another drug.
- Vigabatrin is suitable for first-line treatment of young children with a rare type of infantile spasm called West's syndrome.
- Newer drugs are indicated if older drugs are unsuitable, for example, in liver disease, or if patients cannot tolerate unwanted effects.
- Children should be treated with just one AED where possible.

A third set of national guidance was issued on the diagnoses and management of the epilepsies in adults and children in primary and secondary care (National Institute for Health and Clinical Excellence, 2004a). A recent report on the implementation of this guidance (National Institute for Health and Clinical Excellence, 2009) revealed:

- No major change was noticed in the rate of increase for prescriptions for newer AEDs.
- Use of the newer AEDs had increased at a faster rate than the older drugs.
- Over 70% of patients received mono-therapy for their epilepsy during the period monitored. Of these patients, 60% received an 'old' epilepsy drug. Of newly diagnosed patients, 80% received mono-therapy as their treatment.
- 68% of adults received a medication review within 12 months of being prescribed a drug for their epilepsy.

Follow-up and monitoring of treatment

It is essential to follow up patients in whom AED treatment has been started. The reason for this is essentially to monitor the efficacy and side effects of treatment, upon which drug dosage will depend, but also to encourage good adherence to the treatment. This follow-up is particularly important in the early stages of treatment, when an effective maintenance dose may not have been fully established, when the importance of regular adherence may not have been recognised by the person, and when the psychological adjustment to regular treatment may not be resolved.

Chronic epilepsy

The drug treatment of people with established epilepsy that is uncontrolled despite initial attempts is much more difficult than that of newly diagnosed patients. Prognosis is worse, drug resistance may have developed, and there may be additional neurological, psychological or social problems.

Assessment. The diagnosis of epilepsy should be reassessed before assuming seizures are intractable. A significant proportion of patients may have been incorrectly diagnosed. The aetiology of the epilepsy should also be considered, and the question of a progressive neurological condition addressed. A treatment history should be obtained and note made of previous drugs used which were helpful, unhelpful or of uncertain benefit. Serum level measurements should be obtained where appropriate and drugs not previously tried should be identified.

Choice of drug and dosage. Treatment should always be started with one AED appropriate for seizure type and suitable for the individual. Only when attempts at monotherapy fail should a combination of two AEDs be tried. In the majority of patients, there is no place for therapy with more than two drugs. The choice of drugs should be made according to seizure type and previous treatment history. Drugs that were helpful in the past or found to be of uncertain benefit, or which have not been used before, should be tried if appropriate to seizure type. The use of sedative AEDs should be minimised where possible.

Intractable epilepsy. It is important to realise that there are limits to AED treatment and that in some people, albeit a small group, seizure control is not possible with the drugs currently available. In such cases, the goal of drug treatment changes, and the objectives are to reduce medication to minimise toxicity while providing partial control. The sedative drugs, for example, barbiturates or benzodiazepines, should be used only where absolutely necessary. In these persons, surgical treatment or the use of experimental antiepileptic agents may be considered. However, only a relatively small number of people with partial epilepsy are suitable for curative surgical treatment.

Stopping treatment

Withdrawing therapy should be considered in people who have been seizure free for a considerable period of time. In no individual case, however, can the safety of drug withdrawal be guaranteed, and the risk of relapse on withdrawal of medication in a person who has been seizure free for more than 2 years is about 40%. The longer the person has been free of seizures, the lower the risk of seizure recurrence when drugs are withdrawn. If a person has a learning disability, partial seizures or symptomatic epilepsy, neurological signs or other evidence of cerebral damage, this risk is much higher and in such cases it may be best to continue drug treatment indefinitely. Drug withdrawal should be carried out only very slowly in staged decrements, and only one drug at a time should be withdrawn.

The risks of drug withdrawal should be clearly explained to the person, and the possible medical and social implications taken into account. There may be serious social or domestic consequences should seizures recur, and the attacks may be subsequently difficult to control, even if the original AED regimen is re-established. In the final analysis, the decision to withdraw therapy is an individual one, and the person should be made aware of the risks and benefits of withdrawal.

Monitoring antiepileptic therapy

Therapeutic drug monitoring (TDM) involves the measurement of serum drug levels and their pharmacokinetic interpretation. It is an integral component in the management of

people taking phenytoin and carbamazepine but is less useful in people receiving other AEDs. Indeed, TDM has a very limited use for new AEDs except in people who are acutely unwell, pregnant or elderly. It is also very useful to document AED side effects and in managing drug interactions. Adherence may also be a problem in these patients and hence TDM may be useful to establish adherence with the treatment.

TDM is indicated:

- at the onset of therapy
- if seizure control is poor or sudden changes in seizure control occur
- if toxicity is suspected
- if poor or non-adherence is suspected
- to monitor the time-scale of drug interactions
- when changing AED therapy or making changes to other aspects of a person's drug regimen that may interact with the AED.

The frequency of undertaking TDM varies. Stabilised patients may require their serum levels to be checked only once or twice a year. TDM may be used more often in some people, for one or more of the above indications. A number of the newer AEDs do not require routine TDM. However, since most are used as adjuvant therapy, it is useful to establish baseline levels of existing drugs before the new agent is introduced. Clinical effects should be monitored and TDM, where appropriate, carried out at 6–12 month intervals.

Drug development and action

The older, more established AEDs were developed in animal models in which the potential drugs were assessed in terms of their ability to raise seizure threshold or prevent spread of seizure discharge. The animals involved in these tests would not have epilepsy but would have seizures induced by, for instance, maximal electroshock or subcutaneous pentylenetetrazole. As a consequence the relevance of these models to epilepsy can be questioned.

Established AEDs such as phenytoin, phenobarbital, sodium valproate, carbamazepine, ethosuximide, clonazepam and diazepam are effective but have poor side effect profiles, are involved in many interactions and have complex pharmacokinetics. Over the past 10–15 years, there has been renewed interest in the development of new AEDs, based on a better understanding of excitatory and inhibitory pathways in the brain. The main mechanisms of current drugs are thought to involve enhancement of the inhibitory GABA-ergic system, for example, benzodiazepines, barbiturates, tiagabine, vigabatrin or use-dependent blockers of sodium channels, for example, carbamazepine, oxcarbazepine, lamotrigine and phenytoin (Fig. 31.1).

New drugs include lamotrigine, pregabalin, levetiracetam, topiramate, felbamate, lacosamide, oxcarbazepine, eslicarbazepine and zonisamide. Unlike most of the older agents, vigabatrin, lamotrigine, levetiracetam, lacosamide, gabapentin, pregabalin and zonisamide are devoid of clinically significant enzyme-inhibiting or enzyme-inducing properties. Oral contraceptives may increase the metabolism of lamotrigine and topiramate, and oxcarbazepine may induce cytochrome P450 CYP3A4 which is responsible for the metabolism of oral contraceptives (Sabers and Gram, 2000).

AED profiles

The maintenance doses for the more widely used AEDs are given in Table 31.3, while their pharmacokinetic profile is presented in Table 31.4. Drug interactions are summarised in Table 31.5, and common side effects in Table 31.6.

Acetazolamide

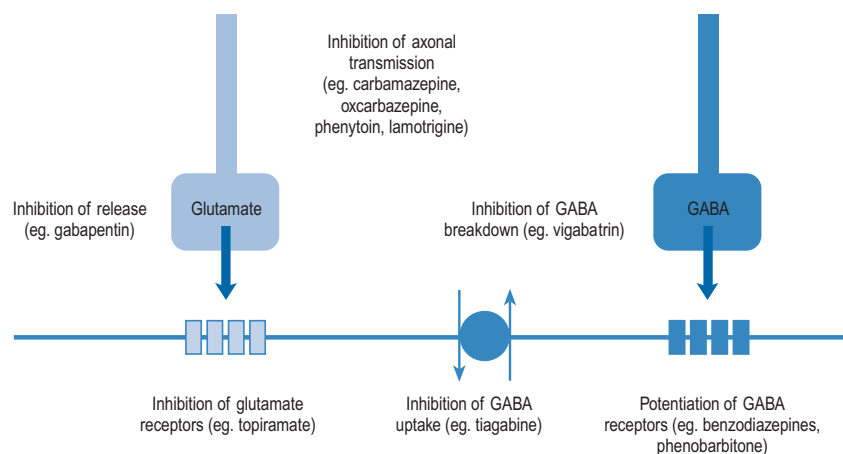
Acetazolamide is occasionally used as an AED. It can be prescribed as a second-line drug for most types of seizures, but particularly for partial seizures, absence seizures and myoclonic seizures. Its intermittent use in catamenial seizures has also been suggested. Acetazolamide has only limited use as long-term therapy because of the development of tolerance in the majority of patients. Side effects include skin rashes, weight loss, paraesthesia, drowsiness and depression. Routine TDM is not available for this drug.


Fig. 31.1 Action of antiepileptic drugs (from Duncan et al., 2006).

Table 31.3 Commonly used starting and maintenance doses of antiepileptic drugs for adults

Antiepileptic drug	Starting dose (mg)	Average maintenance	Doses/day (total mg/day)
Acetazolamide	250	500–1500	2
Carbamazepine	100	600–2400	2–4 (retard 2)
Clobazam	10	10–30	1–2
Clonazepam	0.5	0.5–3	1–2
Ethosuximide	250	500–1500	1–2
Gabapentin	300	900–1200	3
Lacosamide	50	200–400	2
Lamotrigine	50[a]	100–500[a]	2
Levetiracetam	1000	2000–3000	2
Oxcarbazepine	300	900–1800	2–3
Phenobarbital	60	60–180	1
Phenytoin	200–300	200–400	1–2
Sodium valproate	500	2000–2500	1–2
Tiagabine	5[b]	30–45	3
Vigabatrin	500	2000–4000	1–2
Zonisamide	50	300–500 or 200–300[c]	2

[a]Reduce by 50% if on sodium valproate.
[b]If taking enzyme inducer.
[c]If taking enzyme inducer or have impaired renal or liver function.

Carbamazepine

Carbamazepine is a drug of first choice in tonic clonic and partial seizures, and may be of benefit in all other seizure types except generalised absence seizures and myoclonic seizures. Tolerance to its beneficial effect does not usually develop. Adverse events may occur in up to a third of patients treated with carbamazepine but only about 5% of these events will require drug withdrawal, usually due to skin rash, gastro-intestinal disturbances or hyponatraemia. Dose-related adverse reactions including ataxia, dizziness, blurred vision and diplopia are common. Serious adverse events including hepatic failure and bone marrow depression are extremely uncommon.

Carbamazepine exhibits autoinduction, that is, induces its own metabolism as well as inducing the metabolism of other drugs. It should, therefore, be introduced at low dosage and this should be steadily increased over a period of a month. The target serum concentration therapeutic range is 4–12μcg/mL. In addition, a number of clinically important pharmacokinetic interactions may occur, and caution should be exercised when co-medication is instituted (see Table 31.5). For patients requiring higher doses, the slow-release preparation of carbamazepine has distinct advantages, allowing twice-daily ingestion and avoiding high peak serum concentrations. A 'chewtab' formulation is also available and pharmacokinetic studies have shown that it performs well even if inadvertently swallowed whole. Carbamazepine retard offers paediatric patients in particular a dosage form that reduces fluctuations in the peak to trough serum levels and hence allows a twice-daily regimen, which can assist compliance.

Clobazam

Clobazam is a 1,5-benzodiazepine that is said to be less sedative than 1,4-benzodiazepine drugs such as clonazepam and diazepam. Although the development of tolerance is common, clobazam is used as an adjunctive therapy for patients

Table 31.4 Pharmacokinetic data of antiepileptic drugs

Drug	Absorption F (%)	T_{peak} (h)	V_d (L/kg)	Protein binding (% bound)	Elimination $T_{1/2}$ (h)	Renal excretion (%)	Active metabolite
Carbamazepine	75–85	1–5 (chronic dose)	0.8–1.6	70–78	24–45 (single), 8–24 (chronic)	<1	Yes
Diazepam	90	1–2	1–2	96	20–95	2	Yes
Clonazepam	80–90	1–2	2.1–4.3	80–90	19–40	2	–
Gabapentin	51–59	2–3	57.7	0	5–7	100	No
Lamotrigine	100	2–3	0.92–1.22	55	24–35 (induces its own metabolism)	<10	No
Ethosuximide	90–95	3–7	0.6–0.9	0	20–60	10–20	No
Phenobarbital	95–100	1–3	0.6	40–50	50–144	20–40	No

Table 31.4 Pharmacokinetic data of antiepileptic drugs—cont'd

Drug	Absorption			Protein binding (% bound)	Elimination		
	F (%)	T_{peak} (h)	V_d (L/kg)		$T_{½}$ (h)	Renal excretion (%)	Active metabolite
Phenytoin	85–95	4–7	0.5–0.7	90–95	9–40 (non-linear kinetics)	<5	No
Primidone	90–100	1–3	0.4–1.1	20–30	3–19	40	Yes
Sodium valproate	100	0.5–1.0	0.1–0.5	88–92	7–17	<5	No
Vigabatrin	60–80	2	0.6–1.0	0	5–7	100	No
Zonisamide	100	2–4	1.1–1.7	40	52–69	30	Yes

F, bioavailability; T_{peak}, time to peak; V_d, volume of distribution.

Table 31.5 Examples of drug interactions involving antiepileptic drugs

Drug affected	Effect on serum level	Drug implicated	Possible mechanism
Carbamazepine	Increase	Valproate sodium Cimetidine Dextropropoxyphene Erythromycin Isoniazid Troleandomycin Danazol	Enzyme inhibition
	Decrease	Phenytoin, phenobarbital	Enzyme induction
Ethosuximide	Increase	Valproate sodium	Enzyme inhibition
	Decrease	Carbamazepine	Enzyme induction
Lamotrigine	Increase	Valproate sodium	Enzyme inhibition
	Decrease	Phenytoin, carbamazepine	Enzyme induction
Phenobarbital	Increase	Valproate sodium	Enzyme inhibition
	Decrease	Rifampicin	Enzyme induction
Phenytoin	Increase	Valproate sodium Chloramphenicol Isoniazid Disulfiram Fluconazole Flu vaccine Amiodarone Fluoxetine	Enzyme inhibition
			Mechanism unclear
	Decrease	Phenobarbital Rifampicin Carbamazepine	Enzyme induction
		Furosemide Acetazolamide	Decreased responsiveness of renal tubules. Increased osteomalacia
Sodium valproate	Increase	Salicylates	Displacement from protein binding sites and possible enzyme inhibition
Topiramate	Decrease	Phenytoin, carbamazepine	Enzyme induction
	Decrease	Potential enzyme inducers	Enzyme induction
Zonisamide	Decrease	Carbamazepine, phenytoin, phenobarbital and primidone	Enzyme induction

Table 31.6 Side effect profile of antiepileptic drugs

Drug	Dose related (predictable)	Non-dose related (idiosyncratic)
Carbamazepine	Diplopia, drowsiness, headache, nausea, orofacial dyskinesia, arrhythmias	Photosensitivity, Stevens–Johnson syndrome, agranulocytosis, aplastic anaemia, hepatotoxicity
Clonazepam	Fatigue, drowsiness, ataxia	Rash, thrombocytopenia
Ethosuximide	Nausea, vomiting, drowsiness, headache, lethargy	Rash, erythema multiforme, Stevens–Johnson syndrome
Gabapentin	Drowsiness, diplopia, ataxia, headache	Not reported
Lacosamide	Nausea, vomiting, dizziness, headache, drowsiness, depression, diplopia (double vision), impaired memory, impaired coordination, tremor, fatigue (tiredness), asthenia (muscle weakness), pruritus (itching).	Not reported
Lamotrigine	Headaches, drowsiness, diplopia, ataxia	Liver failure, disseminated intravascular coagulation
Levetiracetam	Dizziness, drowsiness, irritability, behavioural problems, insomnia, ataxia (unsteadiness), tremor, headache, nausea	Not reported
Oxcarbazepine	Diplopia (double vision), ataxia (unsteadiness), headache, nausea, confusion and vomiting	Skin rash
Phenobarbital	Fatigue, listlessness, depression, poor memory, impotence	Maculopapular rash, exfoliation, hepatotoxicity hypocalcaemia, osteomalacia, folate deficiency
Phenytoin	Ataxia, nystagmus, drowsiness, gingival hyperplasia, hirsutism, diplopia, asterixis, orofacial dyskinesia, folate deficiency	Blood dyscrasias, rash, Dupuytren's contracture, hepatotoxicity
Sodium valproate	Dyspepsia, nausea, vomiting, hair loss, anorexia, drowsiness	Acute pancreatitis, aplastic anaemia, thrombocytopenia, hepatotoxicity
Tigabine		Dizziness, fatigue (tiredness), nervousness, tremor, concentration difficulties, depression of mood, agitation
Topiramate	Dizziness, drowsiness, nervousness, fatigue, weight loss	Not reported
Vigabatrin	Drowsiness, dizziness, weight gain	Behavioural disturbances, severe psychosis
Zonisamide	Ataxia, dizziness, somnolence, anorexia	Hypersensitivity, weight decrease, rash, gastro-intestinal problems

with partial or generalised seizures who have proved unresponsive to other antiepileptic medication. Its intermittent use in catamenial epilepsy has also been suggested. Clobazam may produce less sedation than other benzodiazepines, but otherwise its adverse effects are similar, including dizziness, behavioural disturbances and dry mouth. Withdrawal may be difficult.

Clonazepam

Clonazepam, a 1,4-benzodiazepine, is a second-line drug for generalised tonic clonic seizures, absences, myoclonic seizures and as adjunctive therapy for partial seizures but, as with clobazam, effectiveness often wears off with time as tolerance develops. Parenteral clonazepam is useful in status epilepticus. It has an adverse effect profile similar to that of clobazam, but may be more sedating.

Diazepam

Diazepam is used mainly in the treatment of status epilepticus, intravenously or in the acute management of febrile convulsions as a rectal solution. Absorption from suppositories or following intramuscular injection is slow and erratic. The rectal solution may also be useful in status epilepticus if it is not possible to give the drug intravenously.

Eslicarbazepine acetate

Eslicarbazepine acetate is a drug which is similar to oxcarbazepine and which is licensed as a second-line treatment for partial seizures. As with oxcarbazepine, its mode of action is thought to be by interacting with voltage-gated sodium channels. Currently it is only available in a 800-mg tablet. It has a long half-life and can be used once per day. Its pharmacokinetics profile and side effects are also similar to those of oxcarbazepine.

Ethosuximide

Ethosuximide is a drug of first choice for generalised absence seizures, and has no useful effect against any other seizure type. Tolerance does not seem to be a problem. The most commonly encountered adverse effects are gastro-intestinal symptoms, which occur frequently at the beginning of therapy. Behaviour disorders, anorexia, fatigue, sleep disturbances and headaches may also occur. The therapeutic range commonly quoted is 40–100 µcg/mL, but some patients may require higher concentrations, sometimes as high as 150 µcg/mL. The absorption of ethosuximide is complete, the bioavailability of the syrup and capsule formulations being equivalent. An increase in daily dose may lead to disproportionately higher increases in average serum concentrations; therefore, careful monitoring is indicated at high doses.

Felbamate

Felbamate may be used as a drug of last resort in people with intractable epilepsy. It is licensed in the USA and most countries of the European Union but not in the UK. Its mechanism of action is unknown. The usual dose is between 1200 and 3600 mg/day. Felbamate exhibits significant pharmacokinetic interactions with phenytoin, carbamazepine and valproic acid. Side effects of felbamate include diplopia, insomnia, dizziness, headache, ataxia, anorexia, nausea and vomiting. A major limiting problem is its potential to cause aplastic anaemia and liver failure, affecting up to 1 in 4000 patients exposed to the drug. It, therefore, seems prudent to limit use to specialist centres and severe intractable cases.

Gabapentin

Gabapentin is occasionally used as a second-line treatment of partial seizures. Although initially developed as an AED, its main use currently is for the treatment of neuropathic pain. In view of its pharmacokinetic profile, a three times daily dosage must be used. To date, no clinically significant interactions with other AEDs, or other drugs, have been reported. The most frequently reported side effects are drowsiness, dizziness, diplopia, ataxia and headache.

Lacosamide

Lacosamide, a functionalised amino acid, is a second-line drug for partial epilepsy in patients over the age of 16 years. Its putative mode of action is not shared with any other currently available AEDs. It is said to enhance the slow inactivation of sodium channels and to modulate collapsing response mediator protein-2 (CRMP-2), although it is not known how this contributes to its antiepileptic action. The recommended doses are between 200 and 400 mg/day divided in two doses. It should be started at 50–100 mg/day and increased by 50 mg/day every 1 or 2 weeks. No drug–drug interactions are known. Its commonest side effects are dizziness, headaches, nausea and diplopia. No idiosyncratic side effects have yet been associated with this drug. The drug should be used with caution in patients with a history of cardiac conduction problems as it is know to increase the PR interval in some patients.

Lamotrigine

Lamotrigine may be used as a first-line drug in patients with partial seizures, with or without secondary generalisation, and in tonic clonic convulsions. The recommended starting dose is 50 mg when used as monotherapy, and 25 mg when used as an add-on therapy; the latter dose is given on alternate days in patients receiving concomitant sodium valproate and daily in patients receiving other AEDs, with a maximum recommended dose of 400 mg/day in two divided doses. It should be slowly titrated as too rapid a titration may be associated with an increased incidence of skin rash. Lamotrigine does not seem to interact with other concomitantly administered AEDs. However, hepatic enzyme inducers increase the metabolism of lamotrigine, reducing its half-life. Therefore, higher doses of lamotrigine need to be administered if it is used in conjunction with enzyme inducers such as phenytoin and carbamazepine. Inhibitors of hepatic enzymes such as sodium valproate block the metabolism of lamotrigine and reduced doses of lamotrigine need to be used if both drugs are given in combination.

Headaches, drowsiness, ataxia and diplopia, usually transient, are the most commonly reported acute adverse effects, particularly during dose escalation. A skin rash is the commonest idiosyncratic side effect of lamotrigine and affects up to 3% of patients.

Levetiracetam

Levetiracetam is indicated for the treatment of refractory partial epilepsy. Placebo-controlled trials in refractory partial epilepsy have shown a 50% seizure reduction in up to 40% of patients. In these trials, 8% of participants became seizure free compared to none on placebo. The usual dose is between 1500 and 3000 mg a day. It is usually started at 500 mg a day and the dose titrated upwards in incremental steps of 500 mg every 1 or 2 weeks. It is well tolerated and the most frequent central nervous system adverse events are dizziness, irritability, asthenia and somnolence. No idiosyncratic adverse events have yet been reported.

Oxcarbazepine

Oxcarbazepine is an analogue of carbamazepine. It is an inactive pro-drug that is converted in the liver to the active 10-hydroxy metabolite and bypasses the 10,11-epoxide, the

primary metabolite of carbamazepine. The usual dose is between 900 and 2400 mg/day. The spectrum of efficacy and side effects is broadly comparable to carbamazepine. The principal advantage of oxcarbazepine over carbamazepine is the lack of induction of hepatic enzymes, with the consequence that there is no auto-induction of the metabolism of the drug and fewer pharmacokinetic interactions. In addition, two-thirds of patients who are allergic to carbamazepine can tolerate oxcarbazepine.

Phenobarbital

Phenobarbital, a barbiturate, may be used for the treatment of tonic clonic, tonic and partial seizures. It may also be used in other seizure types. Its antiepileptic efficacy is similar to that of phenytoin or carbamazepine. Adverse effects on cognitive function, the propensity to produce tolerance and the risk of serious seizure exacerbation on withdrawal make it an unattractive option, and it should be used only as a last resort. In addition to cognitive effects, barbiturates may cause skin rashes, ataxia, folate deficiency, osteomalacia, behavioural disturbances (particularly in children) and an increased risk of connective tissue disorders such as Dupuytren's contracture and frozen shoulder. Phenobarbital is a potent enzyme inducer and is implicated in several clinically important drug interactions (see Table 31.5).

Phenytoin

In current practice, phenytoin is now a second-line drug for partial seizures, tonic clonic seizures as well atonic seizures and atypical absences. It is not effective in typical generalised absences and myoclonic seizures. Tolerance to its antiepileptic action does not usually occur. Phenytoin has non-linear kinetics and a low therapeutic index, and in some patients frequent drug serum level measurements may be necessary. Drug interactions (see Table 31.5) are common as phenytoin metabolism is very susceptible to inhibition by some drugs, while it may enhance the metabolism of others. Caution should be exercised when other medication is introduced or withdrawn.

Adverse events may occur in up to a half of patients treated with phenytoin, but only about 10% will necessitate drug withdrawal, most commonly due to skin rash. Dose-related adverse reactions including nystagmus, ataxia and lethargy are common. Cosmetic effects such as gum hypertrophy, hirsutism and acne are well-recognised adverse effects, and should be taken into account when prescribing for children and young women. Chronic adverse effects include folate deficiency, osteomalacia, Dupuytren's contractures and cerebellar atrophy. Serious idiosyncratic adverse events, including hepatic failure and bone marrow depression, are extremely uncommon.

Pregabalin

This drug has been licensed for the adjunctive treatment of refractory partial epilepsy. It is closely related to gabapentin and a structural analogue of the neurotransmitter GABA but does not seem to affect transmitter response. It modulates calcium channels by binding to a subunit of Ca^{2+} and this action is thought to be the basis of its antiepileptic mechanism. The recommended doses for pregabalin are between 150 and 600 mg divided into two doses, although some people may respond to doses outside this range. Pregabalin would normally be started at 50 or 75 mg twice daily and increased in incremental steps of 50 mg every 2 weeks up to 600 mg according to clinical need. Pregabalin is available in 25, 50, 75, 100, 150, 200 and 300 mg tablets.

Overall, pregabalin is well tolerated and so far no idiosyncratic side effects have been described. Dizziness, drowsiness, ataxia, tremor and diplopia are the most common side effects. Weight gain, particularly with higher doses, seems to be a chronic side effect of this medication. No pharmacokinetic interactions have yet been identified. In addition to its use in epilepsy, pregabalin has also been indicated for neuropathic pain and there are studies to suggest that it might be useful in generalised anxiety disorders.

Primidone

Primidone is principally metabolised to phenobarbital *in vivo* and has similar effects but a more severe side effect profile than phenobarbital. There is nothing to recommend primidone as an AED over phenobarbital.

Rufinamide

Rufinamide is licensed as an orphan drug for the adjunctive treatment of seizures in Lennox-Gastaut syndrome. It is a triazole derivative and is structurally unrelated to any other AED. Its mode of action is unknown. A serious hypersensitivity syndrome that may include rash, fever, lymphadenopathy, hepatic dysfunction, haematuria and multi-organ dysfunction has been reported upon initiation of therapy. Individuals should be warned to seek immediate medical assistance if signs or symptoms of hypersensitivity develop.

Sodium valproate

Sodium valproate is a drug of first choice for the treatment of generalised absence seizures, myoclonic seizures and generalised tonic clonic seizures, especially if these occur as part of the syndrome of primary generalised epilepsy. Tolerance to its anti-epileptic action does not usually occur. Drug interactions with other AEDs may be problematic. Phenobarbital levels increase following co-medication with valproate, and a combination of these two drugs may result in severe sedation. Sodium valproate may also inhibit the metabolism of lamotrigine, phenytoin and carbamazepine. Enzyme-inducing drugs enhance the metabolism of sodium valproate, so caution should be exercised when other AEDs are introduced or withdrawn.

Up to a third of patients may experience adverse effects, but fewer than 5% will require the drug to be stopped. Adverse effects include anorexia, nausea, diarrhoea, weight gain, alopecia, skin rash and thrombocytopenia. Confusion, stupor,

tremor and hyper-ammonaemia are usually dose related. Serious adverse events, including fatal pancreatic and hepatic failure, are extremely uncommon. In children under 2 years, on other AEDs and with pre-existing neurological deficit, the risk of this is 1/500. In adults on valproate monotherapy, the risk is 1/37,000.

The usual therapeutic range quoted is 50–100 μcg/mL, although because of the lack of a good correlation between total valproate concentrations and effect, serum level monitoring of the drug has limited use. TDM should only be performed in cases of suspected toxicity, deterioration in seizure control, to check adherence or to monitor drug interactions. Routine monitoring of this drug is not necessary. Sodium valproate is more teratogenic than other commonly used AEDs and should be used cautiously in women of child-bearing age.

Stiripentol

Stiripentol is licensed as an orphan drug for severe myoclonic epilepsy of infancy (SMEI) when used in conjunction with sodium valproate and clobazam. It is an aromatic alcohol and is unrelated to any other AED. Its mode of action is unknown.

Tiagabine

Tiagabine is a drug with mild efficacy in seizure control. It is used as a second-line drug in partial seizures with or without secondary generalisation. The usual dose is between 30 and 45 mg a day, and it is normally started at 10 mg/day in two divided doses, with incremental steps of 5 mg every 2 weeks. The most common adverse events are on the central nervous system and consist of sedation, tremor, headache, mental slowing, tiredness and dizziness. Confusion, irritability and depression may occur. Increases in seizure frequency and episodes of non-convulsive status have also been reported.

So far, no life-threatening idiosyncratic reactions have been reported. Use in pregnancy is not recommended, although no teratogenicity has been reported in humans.

Topiramate

Topiramate is chemically unrelated to other AEDs and is used as a second-line drug for patients with partial seizures. Usual doses are between 200 and 600 mg/day. It has to be titrated slowly, and the recommended starting dose is 25 mg once daily, titrating upwards in 25 mg/day increments every 2 weeks up to 200 mg/day in two divided doses. After that the dose should be increased by 50 mg every 2 weeks until seizure control is achieved or side effects develop. It has no clinically significant interactions with other AEDs, although hepatic enzyme inducers accelerate its metabolism and topiramate doses need to be adjusted downwards if patients are coming off carbamazepine or phenytoin.

Side effects of topiramate include dizziness, drowsiness, nervousness, impaired concentration, paraesthesias, nephrolithiasis and fatigue. Patients starting topiramate should increase their fluid intake to reduce the risk of kidney stones. Weight loss is seen in up to 30% of patients receiving topiramate.

Vigabatrin

Vigabatrin is an inhibitor of GABA transaminase but because of a poor safety profile, it is a last resort drug for partial seizures. Vigabatrin may also be useful in West's syndrome, particularly if associated with tuberous sclerosis. Vigabatrin does not interact with other drugs apart from decreasing phenytoin levels, probably by blocking its absorption. The most common adverse events associated with vigabatrin are behavioural disturbances, ranging from agitation and confusion to frank psychosis and visual field defects. Other known adverse effects include drowsiness, headaches, ataxia, weight gain, depression and tremor. Careful monitoring for side effects, particularly ophthalmological, on initiation of therapy is essential. Routine TDM is not available for this drug.

Zonisamide

Zonisamide, a sulphonamide analogue which inhibits carbonic anhydrase, is a potent blocker of the spread of epileptic discharges. This effect is believed to be mediated through action at voltage-sensitive sodium channels.

It is used as a second-line drug for patients with partial seizures with or without secondary generalisation. Anecdotal reports of its efficacy in other seizure types, particularly myoclonic seizures, need to be formally tested. Recommended doses are between 200 and 500 mg/day, although some patients may derive benefit from doses outside this range. The recommended starting dose for most patients is 100 mg once daily, titrating upwards every 2 weeks in 100 mg/day increments until seizure control is achieved or side effects develop. Its long elimination half-life allows once-daily dosing.

Zonisamide does not affect levels of carbamazepine, barbiturates or valproate, but may increase the serum concentration of phenytoin by about 10–15%. Zonisamide metabolism is, however, induced by carbamazepine, barbiturates and phenytoin and higher zonisamide doses may be necessary during co-administration with these AEDs.

Side effects of zonisamide include dizziness, drowsiness, headaches, hyporexia, nausea and vomiting, weight loss, skin rashes, irritability, impaired concentration and fatigue. These are mostly transient and seem to be related to the dose and rate of titration. Nephrolithiasis has also been reported, particularly in caucasians. It is not recommended for women of child-bearing age as there are issues about its teratogenic potential (Table 31.7).

Evidence for clinical use of newer drugs

The evidence for the efficacy, tolerability, and safety of seven new AEDs (gabapentin, lamotrigine, topiramate, tiagabine, oxcarbazepine, levetiracetam and zonisamide) in the treatment

Table 31.7 Common therapeutic problems in epilepsy

Problem	Comment
Hepatic enzyme induction	Enzyme induction occurs with carbamazepine, phenytoin, phenobarbital, primidone and topiramate Interactions occur with a large number of drugs including oral contraceptives
Use of progesterone-only contraceptives with enzyme-inducing antiepileptic drug	Best avoided. If no acceptable alternative, patient should take at least double usual dose of progesterone-only pill
Use of combined oral contraceptive with enzyme-inducing antiepileptic drug	Preparations containing 50 µcg of oestrogen should be used
Continuation of antiepileptic drug during pregnancy	Ideally review before attempting pregnancy to determine if reducing or discontinuing treatment is possible
Use of phenytoin as monotherapy	Less frequently considered first-line monotherapy due to poor side effect profile, narrow therapeutic index and saturation pharmacokinetics
Prescribing of branded antiepileptic drugs	Debate continues about whether significant differences exist between generic and branded antiepileptic drugs

of children and adults with refractory partial and generalised epilepsies was assessed by French et al. (2004). All drugs demonstrated efficacy as add-on therapy in patients with refractory partial epilepsy. The relative efficacy of the various agents could not, however, be determined due to the differing populations and dose ranges employed in the various studies. The analysis did, however, show that for all drugs, efficacy and side effects increased with increasing dose. A slower titration of dosage improved tolerability and hence the guidance remains to start with a low dose and increase slowly until side effects occur. For efficacy it appears useful to push to maximal tolerated dose.

Wilby et al. (2005) evaluated the clinical effectiveness, tolerability and cost-effectiveness of gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate and vigabatrin for epilepsy in adults. They included randomised controlled trials (RCTs) and systematic reviews for the newer AEDs when used in the treatment of adults with newly diagnosed or refractory epilepsy and relevant comparator studies which employed older AEDs, other newer AEDs and placebo. The overall findings revealed the following:

- Minimal good-quality evidence exists to support the use of newer AEDs as part of monotherapy or adjunctive therapy over older AEDs, or to support the use of one new AED in preference to another.
- Data relating to clinical effectiveness, safety and tolerability failed to demonstrate consistent and statistically significant differences between the newer and older drugs. The exception being comparisons between newer adjunctive AEDs and placebo, where a significant difference favoured use of the newer AEDs.
- Newer AEDs used as monotherapy may be cost-effective for the treatment of patients who have experienced adverse events with older AEDs, who have failed to respond to the older drugs, or where such drugs are contraindicated.

- An integrated economic analysis suggested that newer AEDs used as adjunctive therapy were cost-effective when compared with continuing current treatment alone.

Case studies

Case 31.1

JB is a 31-year-old woman with a history of early morning myoclonic jerks starting at the age of 16. When she was 18 years old she had her first generalised tonic clonic convulsive seizure. A diagnosis of juvenile myoclonic epilepsy was made and she was started on sodium valproate 1200 mg a day which controlled her seizures.

At the age of 21 the patient had a healthy baby and experienced no problems with epilepsy control. Aged 22, she had her second pregnancy and delivered a healthy baby girl. Three weeks after delivery early morning myoclonic seizures returned. The dose of sodium valproate was increased to 1500 mg to control jerks. However, 6 months later she experienced a recurrence of her convulsive attacks with no clear precipitating factor. Sodium valproate was increased to 2000 mg a day. Early morning myoclonic seizures crept back and she had further convulsive seizures. Lamotrigine was started at 200 mg daily. She has been completely seizure-free for the last 2 years and is now driving again.

JB wants to discuss her medication with you and would like to stop treatment. She has no plans to increase her family.

Question

What advice would you give JB?

Answers

JB should be advised to continue on medication. She has juvenile myoclonic epilepsy, which tends to recur when medication is withdrawn. The patient has no intention of having further children and, therefore, pregnancy need not be a consideration in the choice of her continued drug therapy. She is generally well and hence it would be sensible to advise her to continue with the

present regimen, as sodium valproate and lamotrigine have a synergistic effect in juvenile myoclonic epilepsy. If, however, she wants to reduce medication, then a slow decrease of valproate with optimisation of treatment with lamotrigine should be considered.

Case 31.2

Mr OB is a 44-year-old man who suffers from partial epilepsy. An MRI scan shows a choroid cyst on the right temporal lobe, bilateral hippocampal sclerosis and cerebral atrophy. Seizures take the form of complex partial attacks and at night secondary generalisations occur. He has had trials of treatment with every single drug in the book and almost every combination.

Six months ago, he was taking 225 mg of topiramate (could not tolerate more), 400 mg of phenytoin and 10 mg of clobazam each day. At this point levetiracetam was added and titrated up to 2000 mg a day. This led to a significant improvement in seizure control. Indeed, seizures have almost completely been abolished and he is only having occasional nocturnal events. He is, however, complaining of drowsiness and periods of unsteadiness.

Question

What treatment is appropriate for this patient?

Answer

Mr OB needs his drug regimen optimising. The decision should be made to reduce either the dose of topiramate or that of phenytoin. The consensus view is that phenytoin should probably be reduced first. However, this patient had a bad experience in the past when an attempt was made to discontinue phenytoin, at which time he had a significant increase in seizure frequency. It would, therefore, be more appropriate to discontinue topiramate in Mr OB. This was done and his improvement has been maintained.

Case 31.3

Ms GD is a 28-year-old woman with a history of early morning myoclonic jerks since age 14 years. At 16 years of age she presented with her first generalised tonic clonic convulsive seizure and was referred to a hospital specialist who diagnosed juvenile myoclonic epilepsy. At that time Ms GD was started on sodium valproate 1200 mg a day and within a few weeks her seizures were totally controlled. Ms GD has since remained on the same medication and has been well controlled. However, she now wishes to start a family and is concerned about the effects of the valproate on her baby.

Question

What advice would you give Ms GD?

Answer

The available evidence indicates sodium valproate is teratogenic, with the most common malformation reported being neural tube defects. Ms GD has had no seizures for over 5 years and it must, therefore, be determined whether she still needs medication. The risk of recurrence is low since she has been fit free for well over 5 years. An important consideration is whether or not she is a driver since if she is taken off medication and has a seizure, she will be unable to hold a licence. The other issue is the effect of pregnancy on her seizure threshold as there is some evidence that up to 20% of women may experience an increase in fits during pregnancy. The

options that need to be considered include change of medication. The following medicines need to be reviewed: lamotrigine, topiramate and levetiracetam.

Case 31.4

TD is a 41-year-old patient who has cryptogenic partial epilepsy. He experienced his first seizure at age 14 and this was diagnosed as a secondary generalised attack, although discussing his history revealed he might have had complex partial seizures. Two years ago TD was referred for assessment but it was felt that he was not a candidate for surgery. TD was taking carbamazepine 1200 mg a day and could not tolerate higher doses. Previous trials of valproate, phenytoin, phenobarbital, vigabatrin, lamotrigine, oxcarbazepine and topiramate had demonstrated little benefit. Levetiracetam was started and increased to 2500 mg. Improvement in seizure control has been noted over the past 2 years with only two nocturnal complex partial seizures recorded. His current medication is levetiracetam 2500 mg/day and carbamazepine 1200 mg/day.

Question

What should be done next? Should TD's therapy be reduced to levetiracetam monotherapy?

Answer

There is a need to discuss with TD whether he wishes to continue with his medication. Issues of relevance include a long history of epilepsy, the diagnosis and the range of drugs previously tried. It also needs to be clear whether he wishes to drive or not. If patients have been seizure free for 2 years, it is usual to review therapy.

Case 31.5

Mr FD is a 23-year-old student who was involved in a road traffic accident and admitted to hospital with a head trauma. He was stabilised but during his admission had a seizure and was then discharged on no medication. At 3 months he attends an out-patient hospital follow-up appointment and has had no further seizures.

Question

With regard to his clinical management was this appropriate; is there a role for prophylactic anticonvulsant medication?

Answer

Mr FD requires a full neurological review. The long-term use of antiepileptics following head injury is not indicated unless the patient has a history of seizures and Mr FD has had no seizures post-discharge.

Case 31.6

RA is a 75-year-old retired teacher who lives alone. He has long-standing epilepsy and his current medication includes phenytoin 300 mg daily. RA is in general good health but suffered a recent fall and was rushed to hospital with a suspected fractured neck of femur. On admission he was stabilised and found not to have sustained a fracture. His other medication included furosemide 40 mg mane and enalapril 5 mg twice daily. Routine blood levels of the anticonvulsants revealed a toxic level of phenytoin of 40 mg/L (normal therapeutic range 10–20 mg/L).

Question

How long will it take for the toxic levels of phenytoin to fall within the therapeutic range?

Answer

Phenytoin exhibits non-linear pharmacokinetics. Usual management will involve withholding phenytoin and monitoring serum levels each day. One assumption that can be made is that if the hepatic enzymes are fully saturated with phenytoin then at maximum metabolic capacity, approximately 10 mg/L of the drug will be eliminated each day. Initially, however, the drug will redistribute into serum so for the first few days phenytoin levels will fall slowly. It is usual for the levels to take 6–7 days to fall within the therapeutic range. Therapy will then need to be reviewed. On further investigation it was revealed the patient had a severe chest infection and was prescribed ciprofloxacin. His antibiotic regimen was completed 5 days ago. He was suffering from phenytoin toxicity which may have resulted in ataxia and contributed to his fall.

Parkinson's disease 32

D. J. Burn

Key points

- Parkinson's disease is the second most common neurodegenerative disease, affecting 1% of the population over the age of 65.
- Parkinson's disease is characterised by bradykinesia, rest tremor, rigidity and, later in the disease course, postural instability.
- Neuronal loss in the brainstem (substantia nigra) leads to a profound dopamine deficiency in the striatum. This provides the rationale for dopaminergic replacement therapies.
- Depression is common in Parkinson's disease. It is the major determinant of quality of life and is often missed. The depression of Parkinson's disease can be readily treated.
- Levodopa, coupled with a dopa-decarboxylase inhibitor, remains the most potent oral treatment for Parkinson's disease. There is debate as to whether levodopa should be deferred in biologically young patients, in an attempt to delay the onset of motor complications.
- Several other drug treatments are available for the management of Parkinson's disease. When given as adjunctive therapy to levodopa, the primary aim of these agents is to smooth out motor fluctuations.
- End-of-dose deterioration and the on–off phenomenon are motor complications synonymous with the use of levodopa, usually after a number of years. Despite advances in oral pharmacotherapy, the on–off phenomenon remains difficult to treat effectively.
- Surgical treatments of Parkinson's disease, using deep brain stimulation, are effective in highly selected cases.
- Advanced Parkinson's disease is difficult to manage, particularly dementia and neuropsychiatric problems. Reduction of dopaminergic therapy may be the best compromise. Rivastigmine may be useful for dementia associated with Parkinson's disease.

Parkinson's disease is the most common cause of Parkinsonism and is the second most common neurodegenerative disease, after Alzheimer's disease. Although descriptions of the condition appeared before the nineteenth century, it was James Parkinson's eloquent account in 1817 that fully documented the clinical features of the illness now bearing his name. The identification of dopamine deficiency in the brains of people with Parkinson's disease and the subsequent introduction of replacement therapy with levodopa represent a considerable success story in the treatment of neurodegenerative illness in general. There remain, however, a number of significant management problems in Parkinson's disease, particularly in the advanced stages of the condition.

Epidemiology

Parkinson's disease affects 1% of the population over 65 years of age, rising to 2% over the age of 80. One in 20 patients is, however, diagnosed before their 40th year. It is estimated that 110,000 people have Parkinson's disease in the UK. The condition is found worldwide, with variability in prevalence estimates most likely reflecting study methodology, rather than real differences. Most epidemiological studies have indicated a small male-to-female predominance.

Other causes of Parkinsonism include neurodegenerative conditions, multiple system atrophy and progressive supranuclear palsy. The prevalence for these conditions is approximately 5.0 per 100,000. Drug-induced Parkinsonism is a common form of so-called symptomatic Parkinsonism. It affects 10–15% of individuals exposed to dopamine receptor-blocking agents including neuroleptics and some labyrinthine sedatives.

Aetiology

Both genetic and environmental factors have been implicated as a cause of Parkinson's disease. While opinions were initially polarised, it now seems probable that in the majority of cases there is an admixture of influences, with environmental factors precipitating the onset of Parkinson's disease in a genetically susceptible individual.

Environmental factors became pre-eminent in the 1980s, when drug addicts attempting to manufacture pethidine accidently produced a toxin called MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine). Ingestion or inhalation of MPTP rapidly produced a severe Parkinsonian state, indistinguishable from advanced Parkinson's disease. Notably, not all individuals exposed to MPTP developed Parkinsonism, either acutely or on subsequent follow-up, suggesting inter-individual susceptibility to the toxic effects. MPTP is a relatively simple compound and is quite similar to paraquat. The more recent demonstration that chronic systemic exposure to the pesticide rotenone can reproduce the clinical and pathological features of Parkinson's disease in rats has generated considerable interest.

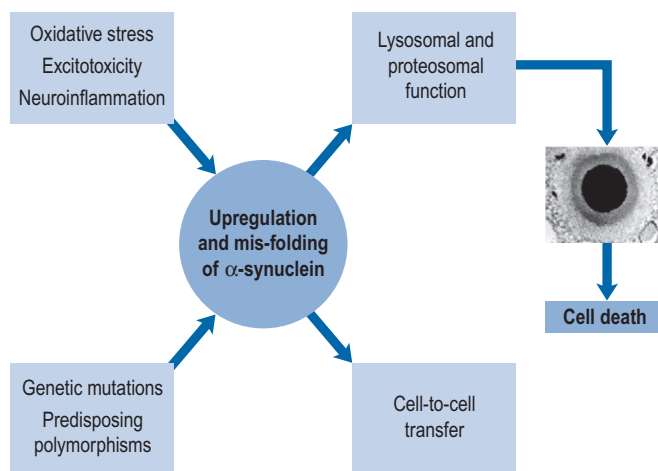
In a small number of patients, genetic factors are dominant. The discovery of a mutation in the gene coding for a synaptic protein called α-synuclein has provided tremendous

507

impetus for further research. Such mutations have been described in fewer than 10 families worldwide. Nevertheless, because α-synuclein is a major component of the pathological hallmark of Parkinson's disease, the Lewy body (see below), the challenge is to discover how a mutation in this protein in a tiny minority can relate to the formation of Lewy bodies in the vast majority. In recent years, eight genetic loci and a further four genes (*parkin, DJ-1, PINK1* and *LRRK-2*) have been identified (Healy et al., 2004). The intriguing thing is that the protein products of these genes are involved in a cellular system called the ubiquitin-proteasome system, which plays a crucial role in removing and recycling abnormal or damaged proteins. Current thinking is that abnormalities in the way in which the cell handles mutated or abnormal proteins may ultimately lead to its death, through increased oxidative stress and/or reduced mitochondrial energy production. The Lewy body may actually represent a defence mechanism by the cell to 'parcel up' potentially damaging proteinaceous material (Olanow et al., 2004).

More recently, cell-to-cell transfer of α-synuclein has been demonstrated *in vitro* and also in engrafted stem cell tissue. This suggests that the pathology of Parkinson's disease may be propagated between neurones and could have major implications for the spread of Lewy body pathology within the brain, as well as its treatment (Olanow and Prusiner, 2009) (Fig. 32.1).

Pathophysiology

The characteristic pathological features of Parkinson's disease are neuronal loss in pigmented brainstem nuclei, together with the presence of eosinophilic inclusion bodies, called Lewy bodies, in surviving cells. The pars compacta of the substantia nigra in the midbrain is particularly affected. Dopaminergic neurones within this nucleus project to the striatum, which is, therefore, deprived of the neurotransmitter dopamine. In Parkinson's disease, there is a loss of


over 80% of nigral neurones before symptoms appear. The 'Braak hypothesis' has been proposed to account for spread of pathology within the Parkinsonian brain and suggests that α-synuclein may first accumulate in the lower brainstem and then gradually ascend rostrally to affect critical brain regions including the substantia nigra and ultimately the cerebral cortex (Braak et al., 2003).

Dopaminergic neurones are not the only cells to die within the brainstem, and a plethora of other nuclei and neurotransmitter systems are also involved. For example, cholinergic neurones within the pedunculopontine nucleus degenerate, providing potential clinicopathological correlates with postural instability, swallowing difficulty (dysphagia) and sleep disturbance (REM sleep behavioural disturbance). The involvement of this nucleus in Parkinson's disease may explain why dopaminergic therapy is relatively ineffective in treating these particular clinical problems. Within the striatum, changes occur within γ-aminobutyric acid-containing neurones, as a consequence of nigrostriatal dopaminergic deficiency and also non-physiological dopaminergic replacement. These changes are thought to play a key role in mediating the development of involuntary movements (dyskinesias) which develop after a number of years of levodopa treatment. The loss of noradrenergic and serotonergic neurones within the locus coeruleus and the raphé nucleus, respectively, may provide a pathophysiological basis for depression, which is common in Parkinson's disease.

Clinical features

Motor features

Bradykinesia is a sine qua non for Parkinsonism in general. If a person does not have slowness of movement, they cannot have either Parkinsonism or Parkinson's disease. Rest tremor, extrapyramidal rigidity (so-called lead pipe and/or cog-wheel) and postural instability comprise the remaining classic tetrad of clinical features for Parkinson's disease. Asymmetry of signs at disease onset is very common. The rest tremor is a rhythmic movement with a frequency of 4–6 Hz (cycles/s), typically noticed with the patient at rest. It is sometimes described as 'pill-rolling' in nature, from the movement of the thumb across the fingers. However, 15–20% of patients do not develop a tremor. Further, up to 60% of people with Parkinson's disease may have a dominant postural tremor, worse with the arms held outstretched, which can cause diagnostic confusion with essential tremor (see below). Postural instability is a late feature of Parkinson's disease and comprises an impairment of righting reflexes with a tendency to fall. There may be a flexed truncal posture and loss of arm swing when walking. There is reduced blink frequency and facial expression, which, together with rather reduced volume (hypophonic) and monotonous speech, may lead to significant difficulties in communication. Writing becomes small (micrographia) and barely legible.

Fig. 32.1 Summary of pathophysiological processes believed to be central to Parkinson's disease.

Non-motor features

Autonomic dysfunction may occur in Parkinson's disease. The patient may drool and have greasy skin (seborrhoea). Urogenital difficulties, with erectile dysfunction in males and urinary urgency in both sexes, are commonly encountered. Frank incontinence is, however, rare. Constipation is invariable and is multifactorial in origin. Falling blood pressure on standing (postural hypotension) may contribute to falls later in the disease course. Depression affects approximately 40% of people with Parkinson's disease and is a major determinant of both carer stress and nursing home placement. It can be a very early feature, and may precede the onset, of Parkinson's disease. Recent studies have demonstrated that depression, above any other factor, is the most significant determinant of quality of life in the person with Parkinson's disease, yet it is generally underdiagnosed. The occurrence of dementia in Parkinson's disease is related predominantly to the age of the patient. Longitudinal community-based studies indicate that dementia may ultimately develop in 80% of people with Parkinson's disease. The cognitive impairment may be accompanied by hallucinations that are often visual, delusional misinterpretation, including paranoid ideation, and rapid fluctuations in attention.

Differential diagnosis

It is important to remember that, while Parkinson's disease is a common form of Parkinsonism, there are numerous other degenerative and symptomatic causes. Further, 'all that shakes is not Parkinson's disease'. Table 32.1 gives a differential diagnosis for causes of Parkinsonism. These are separated into degenerative and symptomatic categories. The list is not exhaustive and excludes, for instance, rare Parkinsonian manifestations in uncommon diseases. A detailed description of these different causes of Parkinsonism is beyond the scope of this chapter, but a few points should be highlighted. Essential tremor is not included in Table 32.1, as this common condition does not cause bradykinesia. Nevertheless, it may be very difficult to differentiate from tremor-dominant Parkinson's disease. A positive family history and good response to alcohol may provide vital clues towards the diagnosis of essential tremor, although in practice these are not always reliable.

Several clinical and clinicopathological series have confirmed our fallibility in not making a correct diagnosis of Parkinson's disease. If clinical criteria, such as those produced by the UK Parkinson's Disease Brain Bank, are not applied, then the error rate (false-negative diagnosis) may be as high

Table 32.1	Differential diagnosis of Parkinsonism	
Degenerative causes	**Symptomatic causes**
Parkinson's disease	Dopamine receptor blocking agents

Box 32.1 Clinical criteria for diagnosis of Parkinson's disease

Step 1 Diagnosis of Parkinsonian syndrome
The patient has bradykinesia, plus one or more of the following:
(a) classic rest tremor
(b) muscular rigidity
(c) postural instability, without other explanation

Step 2 Exclusion criteria for Parkinson's disease
(a) history of repeated strokes
(b) history of repeated head injury
(c) history of definite encephalitis
(d) oculogyric crises
(e) dopamine receptor blocking agent exposure at onset of symptoms
(f) more than one affected relative
(g) sustained remission
(h) strictly unilateral features after 3 years
(i) supranuclear gaze palsy
(j) cerebellar signs
(k) early severe autonomic involvement
(l) early severe dementia
(m) extensor plantar
(n) cerebral tumour or hydrocephalus on CT
(o) negative response to large doses of levodopa
(p) MPTP exposure

Step 3 Supportive prospective positive criteria for Parkinson's disease (three or more required for diagnosis of definite Parkinson's disease)
(a) unilateral onset
(b) rest tremor present
(c) progressive disorder
(d) progressive persistent asymmetry
(e) an excellent (>70%) response to levodopa
(f) a sustained (>5 years) response to levodopa
(g) severe levodopa-induced dyskinesias
(h) clinical course >10 years

CT, computed tomography.

---

as 25–30%. These criteria are listed in Box 32.1. Degenerative conditions commonly masquerading as Parkinson's disease include progressive supranuclear palsy, multiple system atrophy and Alzheimer's disease.

Drug-Induced Parkinsonism

Perhaps the most important differential diagnosis to consider when a patient presents with Parkinsonism is whether their symptoms and signs may be drug induced. This is because drug-induced Parkinsonism is potentially reversible upon cessation of the offending agent. Reports linking drug-induced Parkinsonism with the neuroleptic chlorpromazine were first published in the 1950s. Since then, numerous other agents have been associated with drug-induced Parkinsonism. Many of these are widely recognised, although others are not (Box 32.2). Compound antidepressants were a problem in the past because they contained neuroleptic drugs. For example, fluphenazine was found with nortriptyline in Motival® (discontinued in the UK in 2006) and often overlooked as a potential culprit. Repeat prescription of vestibular sedatives and anti-emetics

---

Box 32.2 Examples of non-neuroleptic drugs associated with drug-induced Parkinsonism

Sodium valproate
Tetrabenazine
Calcium channel blockers (e.g. cinnarizine)
Amiodarone
Lithium[a]
Phenelzine[b]
Amphotericin B[c]
5-Fluorouracil[b]
Vincristine–adriamycin[b]
Pethidine[b]

[a]Lithium causes postural tremor. Reports of Parkinsonism occurring with lithium have usually been in the context of prior exposure to neuroleptics.
[b]Only single case reports of drug-induced Parkinsonism with these drugs.
[c]One case report of drug-induced Parkinsonism in a child after bone marrow transplantation and a second in association with cytosine arabinoside therapy.

---

such as prochlorperazine and cinnarizine are other commonly encountered causes of drug-induced Parkinsonism. The pathogenesis of drug-induced Parkinsonism is unlikely to be only due to dopamine receptor blockade. If this were the case, the incidence and severity should correlate with the drug dosage and length of exposure, and this is not clearly observed. Sodium valproate is also now recognised to cause an encephalopathy dominated by Parkinsonism and cognitive impairment which is reversible upon drug cessation. Again, there is considerable idiosyncrasy in who develops this encephalopathy when exposed to valproate.

Drug-induced Parkinsonism is more common in the elderly and in women. The clinical features can be indistinguishable from Parkinson's disease, although the signs in drug-induced Parkinsonism are more likely to be bilateral at the onset. Withdrawal of the offending agent will lead to improvement and resolution of symptoms and signs in approximately 80% of patients within 8 weeks of discontinuation. Drug-induced Parkinsonism may, however, take up to 18 months to fully resolve in some cases. Further, in other patients, the Parkinsonism may improve after stopping the drug, only to then deteriorate. In this situation, the drug may have unmasked previously latent Parkinson's disease. This contention is supported by a study which noted an increased risk of Parkinson's disease in subjects who had experienced a previous reversible episode of drug-induced Parkinsonism.

Investigations

The diagnosis of Parkinson's disease is a clinical one and should be based, preferably, upon validated criteria. In young-onset or clinically atypical Parkinson's disease, a number of investigations may be appropriate. These include copper studies and DNA testing to exclude Wilson's disease and Huntington's
Fig. 32.2 A normal FP-CIT SPECT scan image, showing symmetric tracer uptake in both striata (mirror image commas). In Parkinson's disease, the tail of the comma is lost at an early stage, with the most severe loss being contralateral to the side most affected clinically.

disease, respectively. Brain imaging by computed tomography (CT) or magnetic resonance imaging (MRI) may be necessary to exclude hydrocephalus, cerebrovascular disease or basal ganglia abnormalities suggestive of an underlying metabolic cause. When there is difficulty in distinguishing Parkinson's disease from essential tremor, a form of functional imaging called FP-CIT SPECT (also known as *DaTSCAN*) may be useful, as this technique can sensitively identify loss of nigrostriatal dopaminergic terminals in the striatum (Fig. 32.2). Thus, in essential tremor, the SPECT scan is normal, whereas in Parkinson's disease, reduced tracer uptake is seen (Jennings et al., 2004).

Differentiating Parkinson's disease from multiple system atrophy and progressive supranuclear palsy is a not uncommon clinical problem and may be very difficult, particularly in the early disease stages. FP-CIT SPECT cannot differentiate Parkinson's disease from these other forms of degenerative Parkinsonism. MRI brain scanning, anal sphincter electromyography, tilt table testing for orthostatic hypotension and eye movement recordings may all be of some help, although they are rarely diagnostic in their own right.

Treatment

General approach

When treatment becomes necessary, it is impossible to generalise about which drug should be commenced. All currently available drugs for Parkinson's disease are symptomatic, as no agent has yet been shown, beyond reasonable doubt, to have disease-modifying or neuroprotective properties. There is no accepted algorithm for the treatment of Parkinson's disease, although a clinical management guideline has been produced (NICE, 2006).

A number of factors, including patient preference, age, severity and type of disease (tremor-dominant versus bradykinesia-dominant) and co-morbidity, need to be taken into account. The efficacy and tolerability of levodopa in Parkinson's disease was first described 1967, when the drug was started in low doses and gradually increased thereafter (Cotzias et al., 1967).

Unfortunately, despite dramatic initial benefits, the limitations of levodopa treatment were quickly realised and a phenomenon termed the 'long-term levodopa syndrome' was recognised. This syndrome comprises premature wearing off of the anti-Parkinsonian effects of levodopa, and response fluctuations. The wearing-off effect is the time before a patient is due their next dose of medication, during which they become increasingly bradykinetic. Response fluctuations can include dramatic swings between gross involuntary movements (dyskinesias) and a frozen, immobile state. The rapid and sudden switching between the dyskinetic state and profound akinesia is also termed the 'on–off' phenomenon. If this occurs rapidly and repeatedly, the term 'yo-yo-ing' is sometimes used. These problems emerge at a rate of approximately 10% per year, so that by 10 years into their illness all Parkinson's disease patients can expect to experience such unpredictable responses. Notably, however, levodopa-induced dyskinesias and fluctuations develop earlier in younger Parkinson's disease patients than in older patients. On–off episodes may be extremely disabling and remain a major therapeutic challenge in the management of Parkinson's disease.

Current management trends have, therefore, shifted towards either later administration of levodopa, provided alternative treatments can give adequate symptomatic control, or the use of combination therapies, in an effort to reduce the cumulative dose of levodopa given. The benefit for such 'levodopa-sparing' strategies beyond 5 years into the illness remains a matter of debate.

Drug treatment

Levodopa preparations

Immediate-release levodopa. Irrespective of the debate regarding early or late levodopa therapy, there is no doubt that levodopa remains the most effective oral symptomatic treatment for Parkinson's disease. It is administered with the peripheral dopa-decarboxylase inhibitors carbidopa or benserazide, where carbidopa plus levodopa is known as co-careldopa (Sinemet®) and benserazide plus levodopa is co-beneldopa (Madopar®). The decarboxylase inhibitor blocks the peripheral conversion of levodopa to dopamine and thereby allows a lower dose of levodopa to be administered. Levodopa readily crosses the blood–brain barrier and is converted by endogenous aromatic amino acid decarboxylase to dopamine and then stored in surviving nigrostriatal nerve terminals.

Immediate-release levodopa is usually commenced in a dose of 50 mg/day, increasing every 3–4 days until a dose of 50 mg three times daily is reached. The patient should be instructed in the early stage of the illness to take the drug with food to minimise nausea. Paradoxically, in more advanced Parkinson's disease, it may be beneficial to take levodopa 30 min or so before food, as dietary protein can critically interfere with the absorption of the drug. If there is little or no response to 50 mg three times daily, the unit dose may be doubled to 100 mg. Should the patient's levodopa dose escalate to 600 mg/day with no significant response, the diagnosis of Parkinson's disease should be reviewed. Levodopa, commenced in the above way,

is usually well tolerated. Nausea, vomiting and orthostatic hypotension are the most commonly encountered side effects. These adverse events may be circumvented by increasing the levodopa dose even more slowly, or co-prescribing domperidone 10 or 20 mg three times daily. Later in the illness, and in common with all anti-Parkinsonian drugs, levodopa may cause vivid dreams, nightmares or even a toxic confusional state.

Clinically relevant drug interactions with levodopa include hypertensive crises with monoamine oxidase type A inhibitors. Levodopa should, therefore, be avoided for at least 2 weeks after stopping the inhibitor. Levodopa can also enhance the hypotensive effects of antihypertensive agents and may antagonise the action of antipsychotics. The absorption of levodopa may be reduced by concomitant administration of oral iron preparations.

Controlled-release levodopa. Both Sinemet® and Madopar® are available as controlled-release (CR) preparations. The nomenclature for Sinemet CR® is confusing, as the drug is marketed as Sinemet CR® (carbidopa/levodopa 50/200) and also as Half Sinemet CR® (carbidopa/levodopa 25/100). Trying to prescribe Half Sinemet CR® unambiguously can be difficult. If the instruction is misinterpreted and a tablet of Sinemet CR® is halved, the slow-release mechanism is actually disrupted.

Levodopa in controlled release preparations has a bioavailability of 60–70%, which is less than the 90–100% obtained from immediate-release formulations. Controlled release preparations have a response duration of 2–4 h, compared with 1–3 h for immediate release.

Two large studies in early Parkinson's disease over 5 years have not shown any benefit for controlled release use over immediate-release levodopa in terms of dyskinesias and response fluctuation frequency. However, controlled release preparations may be of help in simplifying drug regimens, in relieving nocturnal akinesia, and in co-prescribing with immediate-release levodopa during the day to relieve end-of-dose deterioration.

Two commonly encountered problems with controlled release preparations are, first, changing the patient from all immediate release to all controlled release levodopa. This is poorly tolerated, as controlled release levodopa has a longer latency than immediate-release levodopa to turn the patient 'on' (typically 60–90 vs. 30–50 min), and the patient's perception is that the quality of their 'on' period is poorer. Second, controlled release preparations should not be prescribed more than four times a day, as the levodopa may accumulate, causing unpredictable motor fluctuations.

Co-careldopa intestinal gel. An intestinal gel preparation of levodopa and carbidopa (Duodopa®) is available that is administered directly into the small bowel (specifically, the jejunum) via a percutaneous route, using a portable electronic pump. Through continuous delivery in this way, motor fluctuations may be significantly reduced. Although effective, this treatment modality requires careful patient selection. The endoscopic insertion of a percutaneous jejunostomy carries a definite morbidity and mortality. The treatment is also very expensive while mechanical problems with tube detachment and blockage have been reported.

Dopamine agonists

In theory, dopamine agonists, which stimulate dopamine receptors both post- and presynaptically, would seem to be a very attractive therapeutic option in Parkinson's disease, as they may bypass the degenerating nigrostriatal dopaminergic neurones. Unfortunately, experience to date with the oral agents available has usually shown them to be less potent than levodopa and less well tolerated. One drug in this class, apomorphine, is used in a parenteral form. It is particularly potent and is described in detail below.

Dopamine agonists differ in their affinity for a number of receptors, including the dopamine receptor family. It is not known whether these differences are clinically significant, but experience to date would suggest not. Cabergoline is an ergot dopamine agonist with a much longer plasma half-life of 63–68 h than other agents in this class. This means that once-daily dosing is possible. Ropinirole and pramipexole are non-ergot derivatives that originally had to be administered three times daily. Slow release preparations of ropinirole (XL) and pramipexole (PR) are now available for once-daily dosing. A transdermally administered non-ergot dopamine agonist, rotigotine, is also available as a 24-h adhesive patch.

Four double-blind, randomised and controlled studies of up to 5 years duration have compared the use of a dopamine agonist (cabergoline, ropinirole, pramipexole and pergolide) with levodopa in the treatment of early Parkinson's disease. Although the studies differed in a number of ways, such as levodopa supplementation not being permitted in the pergolide study, the results produced a consistent message that use of dopamine agonists in early Parkinson's disease is associated with a lower incidence of dyskinesias when compared with levodopa. Supplementary levodopa was, however, required in a significant number of patients in the cabergoline (65% of patients initially randomised to cabergoline), ropinirole (66% of patients initially randomised to ropinirole) and pramipexole (53% of patients initially randomised to pramipexole) studies, suggesting that only a subgroup of patients derive adequate benefit from agonist monotherapy alone. Follow-up studies suggest that the addition of levodopa is required in the vast majority of patients and that any initial benefits in terms of lower dyskinesia incidence on agonist alone may be lost when levodopa is then introduced.

There have been very few comparative studies performed between the dopamine agonists, so it is not possible to be definitive as to which drug should be recommended. In practice, it is often worth changing from one agonist to another if side effects are a problem, since there is variability in a given patient's tolerance to the different drugs.

Dopamine agonist side effects. The principal side effect of the dopamine agonists are nausea and vomiting, postural hypotension, hallucinations and confusion, and exacerbation of dyskinesias. Ergot derivatives run the risk of causing pleuropulmonary fibrosis, which occurs in 2–6% of patients on long-term bromocriptine treatment. Annual monitoring with chest X-ray and erythrocyte sedimentation rate (ESR) has been suggested for patients taking ergot derivative agonists, although the utility and cost-effectiveness of this recommendation have not been established. More recently, concern has been expressed over the high frequency of cardiac valvulopathy, notably of the tricuspid valve, found in patients exposed to the ergot derivatives pergolide and cabergoline. Neither drug should be used as first-line agonists in Parkinson's disease. If prescribed, regular echocardiographic monitoring should be undertaken. There is also an increased risk of toxicity when erythromycin is co-prescribed with a dopamine agonist.

Ropinirole and pramipexole were previously implicated in causing 'sleep attacks', with sudden onset of drowsiness, leading to driving accidents in some cases. The term 'sleep attack' is almost certainly a misnomer, however, as patients do have warning of impending sleepiness, although they may subsequently be amnesic for up to several minutes while in this state. Excessive sleepiness attributable to anti-Parkinsonian drugs is actually not a new phenomenon and is almost certainly a 'class effect' of all dopaminergic therapies. It is essential to advise patients taking all anti-Parkinsonian agents that they may be prone to excessive drowsiness. This may be compounded by the use of other sedative drugs and alcohol.

Dopamine agonists have also been associated with impulse control disorders (ICDs). These disorders include pathological gambling, hypersexuality and excessive shopping. The onset may relate to dopamine D2/3 receptor stimulation in predisposed individuals. The patient and their carer should be warned about these potential problems before the drug is prescribed and regularly screened for abnormal behaviours while taking the agonist.

Catechol-*O*-methyl transferase inhibitors

Inhibitors of the enzyme catechol-*O*-methyl transferase (COMT) represent a novel addition to the range of therapies available for Parkinson's disease (Schrag, 2005). Use of the first agent in this class, tolcapone, was originally suspended in Europe because of fears over hepatotoxicity, although the drug became available again in 2005, accompanied by strict prescribing and monitoring guidelines. Entacapone is also available and studies have not shown derangement of liver function with this drug.

COMT itself is a ubiquitous enzyme, found in gut, liver, kidney and brain among other sites. In theory, COMT inhibition may occur both centrally, where the degradation of dopamine to homovanillic acid is inhibited, and peripherally, where conversion of levodopa to the inert 3-*O*-methyldopa is inhibited, to benefit the patient with Parkinson's disease. In practice, both tolcapone and entacapone act primarily as peripheral COMT inhibitors.

Placebo-controlled studies in patients with fluctuating Parkinson's disease have confirmed the efficacy of entacapone in decreasing 'off' time and permitting a concomitant reduction in levodopa dose. A 20% reduction in 'off' time is reported, translating into nearly 1.5 h less immobility per day. This reduction tends to occur towards the end of the day, a time when many Parkinson's disease patients are at their worst in terms of motor function. A comparison of entacapone and tolcapone

suggested that tolcapone may be the more potent COMT inhibitor, achieving up to an extra 1.5 h of 'on' time per day.

When entacapone is prescribed, a 200 mg dose is used with each dose of levodopa administered, up to a frequency of 10 doses/day. Because of increased dyskinesias, an overall reduction of 10–30% in the daily dose of levodopa may be anticipated. Entacapone can be employed with any other anti-Parkinsonian drug, although caution may be needed with apomorphine. More recently, entacapone has been marketed as a compound tablet with levodopa and carbidopa (Stalevo®). Although each tablet contains 200 mg of the COMT inhibitor, there are six different doses of levodopa available (50, 75, 100, 125, 150 and 200 mg), to provide flexibility. The compound tablet may help adherence by significantly reducing the total daily number of tablets a patient needs to take.

Tolcapone is prescribed as a fixed 100 mg three times a day regimen, increasing if necessary to 200 mg three times a day. It may only be used after the patient has tried and failed entacapone and where provision for 2-weekly monitoring of liver function tests for the first 12 months, reducing in frequency thereafter, is available. Again, a concomitant reduction in levodopa may be necessary to offset an increase in dyskinesias.

The optimal way to use COMT inhibition is unknown. A patient experiencing end-of-dose deterioration, or generally underdosed, would seem to be the ideal candidate. However, there are few comparative studies of COMT inhibitors versus dopamine agonists available to provide guidance as to which class of drug is best to use, and when. The STRIDE-PD study (Stocchi et al., 2010) assessed the potential benefit of combined treatment with levodopa and entacapone in *de novo* Parkinson's disease patients to address whether this combined treatment was associated with a lower incidence of dyskinesias. Unfortunately, the opposite was actually found, with a higher incidence of dyskinesias in patients randomised to levodopa and entacapone compared with levodopa alone.

Other than exacerbation of dyskinesias, COMT inhibitors may also cause diarrhoea, abdominal pain and dryness of the mouth. Urine discolouration is reported in approximately 8% of patients taking entacapone.

It is best to avoid non-selective monoamine oxidase inhibitors or a daily dose of selegiline in excess of 10 mg when using entacapone. In addition, the co-prescribing of venlafaxine and other noradrenaline (norepinephrine) reuptake inhibitors is best avoided. Entacapone may potentiate the action of apomorphine. Patients taking iron preparations should be advised to separate this medication and entacapone by at least 2 h.

Monoamine oxidase type B inhibitors

The propargylamines selegiline and rasagiline are inhibitors of monoamine oxidase type B. Inhibition of this enzyme slows the breakdown of dopamine in the striatum. These agents effectively have a 'levodopa-sparing' effect and may delay the onset of, or reduce existing, motor complications. Both drugs may also have an antiapoptotic effect (apoptosis is a form of programmed cell death thought to be important in several neurodegenerative conditions, including Parkinson's disease). Whether or not the drugs have a neuroprotective effect by this or some other means remains controversial. A recent study suggested that 1 mg of rasagiline may have a disease-modifying benefit in early Parkinson's disease, although this study was difficult to interpret since the same effect was not seen with the 2 mg dose (Olanow et al., 2009). Further, the magnitude of effect was very modest and of uncertain clinical relevance. The findings, therefore, need to be interpreted with caution but do offer some cause for optimism.

A single daily dose of 5 or 10 mg of selegiline is prescribed. Higher doses are associated with only minimal additional inhibition of monoamine oxidase. Selegiline may also be administered as a lyophilised freeze-dried buccal preparation. The dose of rasagiline is 1 mg daily.

Both selegiline and rasagiline may be used as *de novo* or adjunctive treatments in Parkinson's disease, although trial data for the latter indication are strongest for rasagiline and buccal selegiline.

Following publication of a study (Lees, 1995) which showed excess mortality in a group of patients taking selegiline, it was suggested that the drug was best avoided in patients with falls, confusion and postural hypotension. A subsequent meta-analysis, including nine trials of selegiline, did not, however, identify any excess mortality in patients taking selegiline (Ives et al., 2004). Selegiline can cause hallucinations and confusion, particularly in moderate-to-advanced disease. The withdrawal of selegiline may then be associated with significant deterioration in motor function. Unlike selegiline, rasagiline is not metabolised to amfetamine-like products, so neuropsychiatric side effects are less frequent. Selegiline should not be co-prescribed with selective serotonin reuptake inhibitors, as a serotonin syndrome, including hypertension and neuropsychiatric features, has been reported in a small minority of cases. Caution is also required for rasagiline when co-prescribing with a selective serotonin reuptake inhibitor.

Amantadine

Amantadine was introduced as an anti-Parkinsonian treatment in the late 1960s. It has a number of possible modes of action, including facilitation of presynaptic dopamine release, blocking dopamine reuptake, an anticholinergic effect, and also as a *N*-methyl-D-aspartate (NMDA) receptor antagonist. Initially employed in the early stages of treatment, where its effects are mild and relatively short-lived, interest has focused more recently upon the use of amantadine as an antidyskinetic agent in advanced disease (Blanchet et al., 2003).

Daily doses of 100–300 mg amantadine may be used. Some recommend even higher doses for improved antidyskinetic effect, although side effects become much more frequent at higher doses. These side effects include a toxic confusional state, peripheral oedema and livedo reticularis (a persistent patchy reddish-blue mottling of the legs, and occasionally the arms). There may be significant rebound worsening of Parkinsonism when amantadine is withdrawn. The mechanism for this is unknown.

Anticholinergic drugs

The availability of anticholinergic drugs such as trihexyphenidyl and orphenadrine predated the introduction of levodopa by nearly 90 years. Anticholinergic drugs have a moderate effect in reducing tremor but do not have any significant benefit upon bradykinesia.

The use of anticholinergic agents has declined because of troublesome side effects, including constipation, urinary retention, cognitive impairment and toxic confusional states. In selected younger patients, an anticholinergic drug may still be helpful but close monitoring is advised. Postmortem studies have suggested that long-term anticholinergic use may have adverse disease-modifying effects in Parkinson's disease, by increasing cortical levels of Alzheimer-type pathology (Perry et al., 2003).

Tricyclic antidepressants have anticholinergic properties, normally regarded as a disadvantage in the treatment of depression. These drugs are generally longer acting than other anticholinergic agents and may have a potential benefit in Parkinson's disease, both for their anticholinergic effects and also their effect in inhibiting monoamine reuptake at adrenergic nerve endings. A low dose of a tricyclic antidepressant, for example, amitriptyline 10–25 mg, at night is sometimes useful in alleviating nocturnal akinesia, improving sleep and improving performance early in the morning.

Apomorphine

Apomorphine is a specialised, but almost certainly underused, drug in the treatment of Parkinson's disease. It is the most potent dopamine agonist available and is administered either by bolus subcutaneous injection or by continuous subcutaneous infusion. The drug is acidic and is generally difficult to administer in a stable form which does not lead to irritation of skin or mucosal surfaces. Alternative methods of administration, including transdermal and intranasal routes and the use of an implantable copolymer-based apomorphine matrix, are being evaluated.

The drug produces a reliable 'on' effect with short latency of action. A single bolus lasts for up to 60 min, depending upon the dose given. Continuous subcutaneous apomorphine may significantly improve dyskinesias in advanced Parkinson's disease, as well as lessening akinesia and rigidity. This may allow oral anti-Parkinsonian medications to be reduced.

Apomorphine causes profound nausea, vomiting and orthostatic hypotension. These problems are counteracted by pre-dosing for 2–3 days with domperidone 20 mg three times daily. Neuropsychiatric disturbance, probably at a lower frequency than with oral agonists, and skin reactions, including nodule formation, are other potential side effects. Apomorphine, in conjunction with levodopa, may cause a Coomb's positive haemolytic anaemia, which is reversible. It is recommended that patients be screened before beginning treatment and at 6-monthly intervals thereafter.

Surgical treatment

There has been renewed interest in the use of neurosurgical techniques for the treatment of Parkinson's disease (Walter and Vitek, 2004). This has resulted not only from recognition of the shortcomings of medical treatment currently available but also from an improved understanding of basal ganglia circuitry and better neuroimaging methods. Table 32.2. summarises techniques currently being employed and evaluated. The functional effects of lesioning (-otomy) and the use of deep brain stimulation are similar, in that the high frequency used in stimulation is believed to act by blocking, or 'jamming' neurones. Deep brain stimulation has the advantage of being reversible but is costly, and programming the stimulator may be very time consuming.

The subthalamic nucleus target is the current target of choice in most centres and the number of published patient-years experience with this surgical approach has increased rapidly over the past decade. Several randomised controlled studies have confirmed the benefits that may be gained from deep brain stimulation of the subthalamic nucleus, in terms of impairment, activities of daily living, and quality of life. Careful case selection is essential for all forms of surgical intervention for Parkinson's disease: older and less biologically fit patients, those with active cognitive and/or neuropsychiatric problems, and patients with a suboptimal levodopa response are generally regarded as poor surgical candidates.

Surgery may also play a role in neurorestorative treatments. Such approaches include stem cell and fetal cell transplantation, and also gene transfer using viral vectors. To date, there have been conflicting results regarding the efficacy of fetal cell

Table 32.2 Summary of anatomical targets for surgical treatment of Parkinson's disease

Target	Bradykinesia	Tremor	Dyskinesia	Comments
Thalamus	–	+++	–	Bilateral thalamotomy is not recommended because of a high incidence of bulbar dysfunction
Globus pallidus	++	++	+++	10–15% incidence of persistent adverse events with unilateral pallidotomy; no reliable data for bilateral procedures
Subthalamic nucleus	+++	+++	++	Weight gain, contralateral dyskinesia, involuntary eyelid closure and speech disturbance reported

+ to +++ refers to the relative efficacy of the procedure for the clinical feature; – refers no benefit for the procedure for the clinical feature.
For each of the three targets listed, both ablation and stimulation procedures have been evaluated.

transplants. These differences may well reflect transplantation technique, the nature of the tissue being implanted, whether immunosuppression is prescribed, and how patients are selected and assessed. Despite the negative results from two double-blind studies of embryonic cell implantation, researchers continue to explore the potential benefits from this approach.

Patient care

Common therapeutic solutions to problems encountered in the management of people with Parkinson's disease are presented in Table 32.3. After diagnosis, the provision of an explanation of the condition, education and support are essential. The Parkinson's Disease Society (www.parkinsons.org.uk) produces an excellent range of literature to help the newly diagnosed patient come to terms with the condition. In accordance with advice given by the Society itself, patients who drive are advised to inform their insurance company and also the Driver and Vehicle Licensing Agency.

A doctor will record impairments in the clinic, while the patient is more concerned with their disability and handicap. Thus, a patient can be noted to have seemingly marked impairment and yet may not complain about significant disability. The converse may also be true. Not all patients, therefore, require immediate treatment. Further, concomitant depression may distort the patient's perception of their disability, leading to inappropriate prescribing of anti-Parkinsonian therapy. In this situation, the use of an antidepressant may be more helpful. There is no good evidence base for which antidepressant should be used, and both the tricyclic agents and selective serotonin reuptake inhibitors have their advocates.

Accurate adherence with the timing of therapy may be particularly important in patients who are beginning to develop long-term treatment complications. It can be helpful for patients to keep diary cards when they begin to experience problems with either bradykinesia or dyskinesia, so that these symptoms can be related to drug and food intake. Careful changes in timing of drug therapy or meals may initially be sufficient to reduce variation in performance. Some patients experience troublesome early morning bradykinesia. It may then be beneficial to prescribe an initial dose of a rapidly acting agent, such as dispersible oral co-beneldopa, to take on first wakening so that the patient can then get up and dress. A combination of levodopa with dopamine agonists, which are more slow acting, may be useful in the patient with motor fluctuations. A combination of levodopa and a COMT inhibitor may be more appropriate in a patient with end-of-dose deterioration.

Other factors that need to be considered in patients with Parkinson's disease are the benefits of adequate sleep and rest at night, which may be made more difficult if they have urinary frequency or problems with nocturnal bradykinesia. Judicious use of hypnotic therapy may be appropriate, while a tricyclic antidepressant may offer the dual benefit of sedation with anti-cholinergic effect. Low friction sheets to assist turning in bed and encouragement of mobility through physiotherapy may also be helpful. The treatment of the patient with severe disease remains one of the greatest challenges in the management of Parkinson's disease. On–off fluctuations may be refractory to oral dopaminergic therapies. Sudden freezing episodes compound failing postural stability, leading

Table 32.3 Common therapeutic solutions in the management of Parkinson's disease

Problem	Cause	Possible Solution
Early-onset dyskinesias in young Parkinson's disease patient	Exposure to levodopa? Biological factors?	Delay introduction of levodopa, or use lowest possible dose, or use alternative agent (e.g. agonist, MAOB inhibitor)
One dose of levodopa does not last until the next (wearing off)	Advanced disease (pre- and post-synaptic changes)	More frequent, smaller doses of levodopa, COMT inhibitor, dopamine agonist or MAOB-inhibitor
Pain and immobility during the night	Evening dose of levodopa not lasting long enough	Use slow release levodopa preparation or dopamine agonist
Freezing episodes and/or unpredictable motor fluctuations	Advanced disease (pre- and post-synaptic changes)	Apomorphine, duodopa or surgery Physiotherapy helpful for freezing
Mismatch between patient's symptoms and signs	Underlying depression?	Consider antidepressant
Confusion and hallucinations with preserved cognition	Toxic (drug-related) psychosis	Exclude intercurrent infection or other medical problem Review and reduce anti-Parkinsonian therapy Consider atypical anti-psychotic agent
Confusion and hallucinations with impaired cognition	Underlying brain pathology, and cholinergic deficit	Reduce anti-Parkinsonian therapy Cholinesterase inhibitor

to increasing falls and injuries. In select patients, the use of apomorphine, either as bolus injection (via a 'Penject' device) or as a continuous subcutaneous infusion, may be helpful.

The presence of reduced dexterity in virtually all people with Parkinson's disease means that thought needs to be given to the way in which medication is dispensed and stored. If the patient is taking a complex regimen of drugs or has early cognitive problems, the use of pre-packaged therapies may improve adherence.

Patients' relatives also need emotional and social support through what can be a very demanding period. The loss of physical mobility, together with a personality change, can be very difficult for relatives to cope with. The involvement of occupational therapists, social workers and specialists in palliative care in this situation is important.

Psychosis and dementia

When cognitive impairment is problematic, the use of conventional antipsychotic medication is inappropriate because such drugs can precipitate a catastrophic worsening of Parkinsonism. Behavioural disturbances require discussion with carers and, if possible, with the patient him- or herself. A graded withdrawal of anti-Parkinsonian drugs is often indicated, aiming to simplify the regimen to levodopa monotherapy. In rare cases, it may be necessary to reduce the dose or even completely withdraw levodopa therapy in order to control aggressive, sexually demanding or psychotic features. When reduction in dopaminergic therapy is ineffective or not tolerated because of unacceptable immobility, an atypical antipsychotic drug may be considered. In practice, the choice narrows down to quetiapine or clozapine, since risperidone and olanzepine are associated with worsening Parkinsonism, even in low doses. Further, both risperidone and olanzepine should not be used in cognitively impaired elderly people because of an increased risk of stroke. Clozapine is difficult to use for Parkinson's disease-associated psychosis because of the need to register the patient with a blood-monitoring programme. When quetiapine is used, it should be commenced in a low dose of 25 or 50 mg at night and increased slowly. The sedative effects may be helpful in promoting sleep.

Cholinesterase inhibitors have shown promise in treating the neuropsychiatric features of Parkinson's disease and may also have modest cognitive-enhancing benefits. Visual hallucinations, delusions, apathy and depression seem to be particularly responsive to these agents. These effects have been demonstrated for rivastigmine in dementia associated with Parkinson's disease in a large, multicentre, double-blind, placebo-controlled study (Emre et al., 2004). A randomised controlled trial of memantine in dementia associated with Parkinson's disease (and also patients with the closely related dementia with Lewy bodies) showed a modest benefit for memantine in the primary end-point, the Clinician's Global Impression of Change (Aarsland et al., 2009).

Autonomic problems

Other complications that may need attention include disorders of gut motility, which present as constipation or difficulty with swallowing, disturbances of micturition, sometimes presenting as nocturia, and postural hypotension. Constipation can be managed in the usual way with bulking agents and, if necessary, stimulant laxatives and stool-softening agents. The management of postural hypotension includes assessment of the patient's autonomic function in order to establish whether this is primarily drug related or associated with autonomic neuropathy. If the patient is dizzy on standing, simple measures such as advice on rising slowly may be adequate. The use of elastic stockings, to reduce pooling of the blood in the lower limbs, is sometimes helpful. Pharmacological approaches include the use of fludrocortisone or occasionally midodrine (a selective α_1-adrenergic agonist). It is also important to consider other therapies the patient is receiving that might contribute to such symptoms, for example, diuretics, and to stop these if possible.

Case studies

Case 32.1

A 48-year-old man, Mr V, has a 2-year history of Parkinson's disease. He is still working in an office. His wife confides in the Parkinson's Disease Nurse Specialist that she is concerned about his gambling. Whilst never a problem before his diagnosis, he is now spending huge sums of money on on-line casinos. They are getting into financial difficulties on account of this habit. She is upset and desperate for help.

Questions

1. What might be responsible for this gentleman's behaviour?
2. What would be the most appropriate management?

Answers

1. The most likely cause of Mr V's pathological gambling (so-called because of the adverse effect this is having on his family and life in general) relates to his medication. He was, in fact, taking the dopamine agonist pramipexole, as well as rasagiline to control his Parkinsonian symptoms. Dopamine agonists have been associated with impulse control disorders.
2. Mr V's dopamine agonist should be withdrawn as quickly as possible, via down-titration of the dose over a few weeks. This will, of course, worsen his motor symptoms. In Mr V's case, he required the use of co-careldopa to regain adequate control of his Parkinsonism, but off the agonist his gambling habit ceased completely. His wife was delighted. Had the patient and his wife been warned of this possible problem prior to starting the agonist the situation may not have got to such a near-disastrous social level. It is, therefore, essential to warn all patients starting dopamine agonists about the risk of impulse control disorders and to document this in writing in the medical records.

Case 32.2

A 70-year-old man, Mr W, was diagnosed as having mild Parkinson's disease 6 months ago. This did not require any treatment. He has no past medical history of note. He returns to clinic and it is clear that both his impairment and disability have worsened.

Questions

1. What initial treatment options should be considered for Mr W?
2. What considerations should be given to the initial drug choice?

Answers

1. There is no evidence to suggest that Mr W is depressed; a masked depression should always be considered when there is a 'mismatch' between impairment and reported disability. This was not the case here. A number of first-line anti-Parkinsonian drugs might, therefore, be considered, including immediate-release levodopa preparations, dopamine agonists and monoamine oxidase type B inhibitors.
2. Co-morbid illness or a life-shortening problem, such as cancer, usually mean that levodopa would be first choice, simply because it is most potent, with a good risk:benefit ratio. If the patient is biologically fit, then either a dopamine agonist or a monoamine oxidase type B inhibitor might be appropriate, so long as the disability is not too severe and there are no other contraindications. Dopamine agonists and selegiline, in particular, have the potential to cause or exacerbate neuropsychiatric problems and the patient and their family should be warned of such side effects. In particular, the patient and their family should be informed of the risk of impulse control disorders, generally associated with dopamine agonists, and this warning recorded in the medical records. By using these 'levodopa-sparing' agents, the onset of dyskinesias may be delayed by several years.

Case 32.3

A 59-year-old gentleman, Mr X, has had Parkinson's disease for 8 years. This was initially treated with selegiline and ropinirole. Due to progressive functional disability and his wish to keep working, levodopa was introduced 5 years previously. He is now experiencing severe motor fluctuations during the day, with periods of marked dyskinesia and also increasingly unpredictable 'off' periods, during which he is stiff, immobile and anxious. Unsuccessful attempts to smooth out these fluctuations have been made by manipulating his levodopa unit dose and frequency, the use of entacapone, and changing his dopamine agonist.

Questions

1. What therapeutic options could be considered in Mr X's case?
2. What factors would influence the choice of treatment?

Answers

1. A relatively simple option that has not yet been considered is amantadine. This agent may have useful antidyskinetic effects in advanced Parkinson's disease. It is usually administered as 100 mg daily initially, increasing gradually to two or three times daily. The dose of levodopa therapy is left unchanged, to avoid worsening 'off' periods. Neuropsychiatric problems and/or a livedinous rash may complicate the use of amantadine, although younger patients are often able to tolerate the drug better. An alternative approach which may well be required is the use of continuous subcutaneous apomorphine with or without amantadine, as this may have a significant antidyskinetic effect and also effectively manage freezing episodes. Duodopa® therapy, administered via a percutaneous jejunostomy, may also be a consideration. Finally, deep brain stimulation of the subthalamic nucleus may be appropriate for Mr X.

2. Patient choice, after being given the relevant options, is clearly important, as the treatments involved are potentially invasive and associated with morbidity. A previous history of neuropsychiatric problems, active psychosis or severe depression, or cognitive impairment would be relative contraindications to surgery. Severe needle phobia or the lack of an appropriately experienced and committed local nurse specialist would compromise the effective administration of apomorphine.

Case 32.4

A 63-year-old lady, Mrs Y, is referred by a colleague because of suspected Parkinson's disease. There is also evidence of some cognitive decline in the past 12 months. She has a background history of epilepsy which was quiescent until three years ago. At that stage, she presented to the neurology department, and her anticonvulsant regimen adjusted to good effect. Examination confirms a mini-mental state examination (MMSE) score of 22/30, symmetric bradykinesia and some rigidity.

Questions

1. Which question might give additional diagnostic help in this lady's history?
2. What would be the best management?

Answers

1. Given this lady's history of epilepsy, and the subsequent evolution of Parkinsonism and cognitive decline, one would be suspicious of the change in her anticonvulsant medication. A drug history confirmed that she had been switched from phenytoin to sodium valproate, raising the possibility of a 'valproate encephalopathy'.
2. Discontinuation of the valproate is definitely worth attempting and converting to an alternative anticonvulsant. If there is doubt over the diagnosis, an FP-CIT SPECT scan can be helpful; in Parkinson's disease, the scan is abnormal, whereas in drug-induced Parkinsonism, because the problem is caused by postsynaptic blockade of dopamine receptors, tracer uptake will be normal. In this case, Mrs Y's Parkinsonism resolved completely and on repeat testing 6 months later her MMSE had risen to 29/30. She was taking lamotrigine to control her seizures at review.

Case 32.5

Mr Z has an 8-year history of Parkinson's disease. He is 77 years old. His motor symptoms are well controlled on a combination of one tablet of co-careldopa (25/100), three times a day and selegiline 10 mg daily. His wife comes to clinic with him and reports that he has recently been confused at night. Further, he has been hallucinating, seeing his long-dead mother at the bottom of the bed.

Question

What should be done?

Answer

The problem here is to what extent the features of Mr Z's psychosis relates to his drugs or to the underlying disease process. Dementia associated with Parkinson's disease is more common in the older patient with long-standing disease.

An MMSE to assess cognitive function in more detail would be appropriate (although note that this scale is relatively insensitive in detecting dementia associated with Parkinson's disease). Intercurrent infection and metabolic derangements, for example, hypothyroidism, should also be excluded.

Selegiline is best avoided in cases like this and should be discontinued. This may lead to an improvement in Mr Z's psychotic features, without any other action being necessary. The use of a typical antipsychotic agent for Mr Z is absolutely contraindicated, as it will only serve to worsen his Parkinson's disease. If cognitive function is well preserved and discontinuing selegiline fails to improve the situation, then a low dose of the atypical antipsychotic quetiapine could be considered. If there is evidence of dementia, a cholinesterase inhibitor would be a better therapeutic choice.

Pain 33

R. D. Knaggs and G. J. Hobbs

Key points

- Pain is multifactorial in its aetiology.
- Treatment often requires use of a combination of drugs with different mechanisms of action.
- For cancer pain, the World Health Organization (WHO) analgesic ladder forms the basis for the use of analgesic drugs. Some clinicians prefer to omit weak opioids and start strong opioid therapy earlier.
- Opioids are not effective for all types of pain. Adjuvant drugs, such as tricyclic antidepressants or anti-epileptic drugs, should be considered.
- Breakthrough pain is treated with doses of immediate-release opioids, usually prescribed in addition to modified release opioids.
- Antiemetics and laxatives may need to be prescribed for patients taking opioids.
- Cancer pain may vary as the disease progresses. Drug therapy should be reviewed regularly to ensure that the most appropriate agent is being used for the type, site and intensity of pain.
- Most drugs exist in a range of different formulations but, whenever possible, the oral route should be used.

Pain can be defined as:

'An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage'.

Acute pain may be thought of as a physiological process having a biological function, allowing the patient to avoid or minimise injury. Persistent pain, on the other hand, may be described more as a disease than a symptom (Woolf, 2004).

Aetiology and neurophysiology

Neuroanatomy of pain transmission

The majority of tissues and organs are innervated by special sensory receptors (nociceptors) connected to primary afferent nerve fibres of differing diameters. Small myelinated Aδ fibres and unmyelinated C fibres are responsible for the transmission of painful stimuli to the spinal cord where these afferent primary fibres terminate in the dorsal horn.

Pain transmission further within the Central Nervous System (CNS) is far more complex and understood less well.

The most important parts of this process are the wide dynamic range cells in the spinothalamic tract that project to the thalamus and to the somatosensory cortex beyond. Modulation or inhibition of these neurones within the spinal cord result in less activity in the pain pathway. This modulatory action can be activated by stress or certain analgesic drugs such as morphine and is an important component of the gate theory of pain (Fig. 33.1). The gate control theory recognises the pivotal role the spinal cord plays in the continual modulation of neuronal activity by the relative activity of large (Aβ) and small (Aδ and C) fibres and by descending messages from the brain. Conversely, other influences can lead to an increased sensitivity to noxious stimuli. The most important of these is pain itself and further painful stimuli can lead to increased pain from relatively trivial insults. This occurs through neurochemical and anatomical changes within the CNS that have been termed central sensitisation.

Neurotransmitters and pain

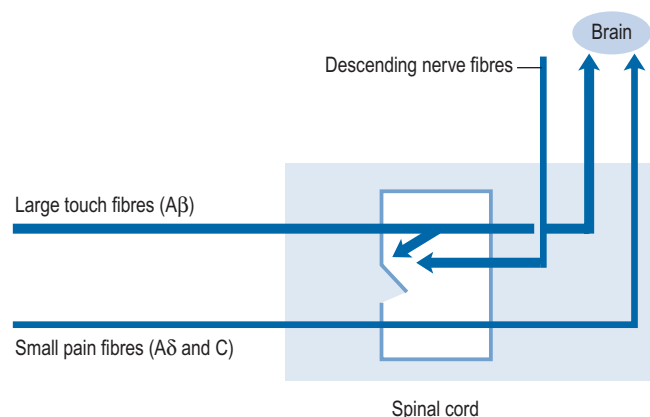
Various neurotransmitters in the dorsal horn of the spinal cord are involved in pain modulation. These include amino acids such as glutamate and γ-aminobutyric acid (GABA), monoamines such as noradrenaline and 5-hydroxytryptamine (5-HT, serotonin) and peptide molecules, of which the opioid peptides are the most important. Opioid receptors are found in both the CNS and the periphery; in the CNS they are found in high concentrations in the limbic system, the brainstem and the spinal cord. The natural ligands (molecules that bind to


Fig. 33.1 Gate control theory of pain.

the receptor) at opioid receptors are a group of neuropeptides including the endorphins. Opioid analgesics mimic the actions of these natural ligands and exert their effect through the μ, δ and, to a lesser extent, the κ receptors. These receptors mediate the analgesic effect of morphine-like drugs.

Assessment of pain

Evaluation of pain should include a detailed description of the pain and an assessment of its consequences. There should be a full history, psychosocial assessment, medication history and assessment of previous pain problems, paying attention to factors that influence the pain. Diagnostic laboratory tests, imaging, including plain radiography, computer tomography (CT) and magnetic resonance imaging (MRI), and diagnostic nerve blocks may aid confirmation of the diagnosis.

Pain is a subjective phenomenon and quantitative assessment is difficult (Breivik et al., 2008). The most commonly used instruments are visual analogue and verbal rating scales. Visual analogue scales are 10 cm long lines labelled with an extreme at each end; usually 'no pain at all' and 'worst pain imaginable'. The patient is required to mark the severity of the pain between the two extremes of the scale. Verbal rating scales use descriptors such as 'none', 'mild', 'moderate' and 'excruciating'. More elaborate questionnaires such as the Brief Pain Inventory and the McGill Pain Questionnaire help to describe other aspects of the pain, and pain diaries record the influence of activity and medication on pain.

Management

Acute pain usually results from noxious stimulation as a result of tissue damage or injury. It can be managed effectively using analgesic drugs and is often self-limiting.

Persistent pain may be considered as pain which continues beyond the usual time required for tissue healing. Treatment may involve specialist pain management services, hospices and a multidisciplinary approach that assesses and manages patients using a biopsychosocial approach. Initial treatment is usually directed at the underlying disease process where possible, for example, medication, surgery or anti-tumour therapy. However, non-medical treatments such as physical therapy and various psychological techniques including cognitive behavioural therapy may also form part of a multimodal treatment programme. Pain can be modulated using non-pharmacological techniques: for example, stimulation-produced analgesia such as transcutaneous electrical nerve stimulation (TENS), acupuncture and massage, or invasive procedures such as neurosurgery or neurolytic nerve blocks.

Analgesic ladder

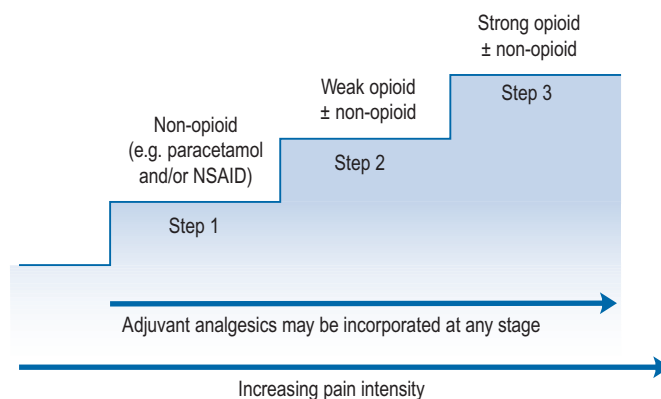
The World Health Organization (WHO) analgesic ladder (Fig. 33.2) forms the basis of many approaches to the use of analgesic drugs. There are essentially three steps: non-opioid


Fig. 33.2 WHO three-step analgesic ladder.

analgesics, weak opioids and strong opioids. The analgesic efficacy of non-opioids, such as paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs) (e.g. aspirin, ibuprofen and diclofenac), is limited by side effects and ceiling effects, that is, beyond a certain dose, no further pharmacological effect is seen. If pain remains uncontrolled, then a weak opioid, such as codeine or dihydrocodeine, may be helpful. There may be additional benefit in combining a weak opioid with a non-opioid drug, although many commercial preparations contain inadequate quantities of both components and are no more effective than a non-opioid alone. Strong opioids, of which morphine is considered the gold standard, have no ceiling effect and therefore increased dosage continues to give increased analgesia but side effects often limit effectiveness. Adjuvant drugs, such as corticosteroids, antidepressants or anti-epileptics, may be considered at any step of the ladder.

Analgesic drugs

Paracetamol

Despite being used in clinical practice for over 50 years and much investigation, the mechanism by which paracetamol exerts its analgesic effect remains uncertain. Inhibition of prostaglandin synthesis within the CNS has been proposed, although this is probably not the only mechanism. Interaction with the serotonin (Tjolsen et al., 1991) and endocannabinoid (Högestätt et al., 2005) neurotransmitter systems have been demonstrated in animal models.

Following oral administration the bioavailability of paracetamol is around 60%, but if given by the rectal route it is much lower and much more variable. A formulation for intravenous infusion has been promoted over the last few years and this has largely replaced the rectal route of administration. Therapeutic plasma levels are reached within 30 min of oral administration. The elimination half-life of paracetamol is relatively short ($t_{1/2}$ = 2–4 h); hence, frequent dosing is required to maintain its analgesic effect.

With normal doses, the majority of paracetamols are metabolised and inactivated in the liver, undergoing a phase II conjugation reaction with glucuronic acid (Fig. 33.3). A small

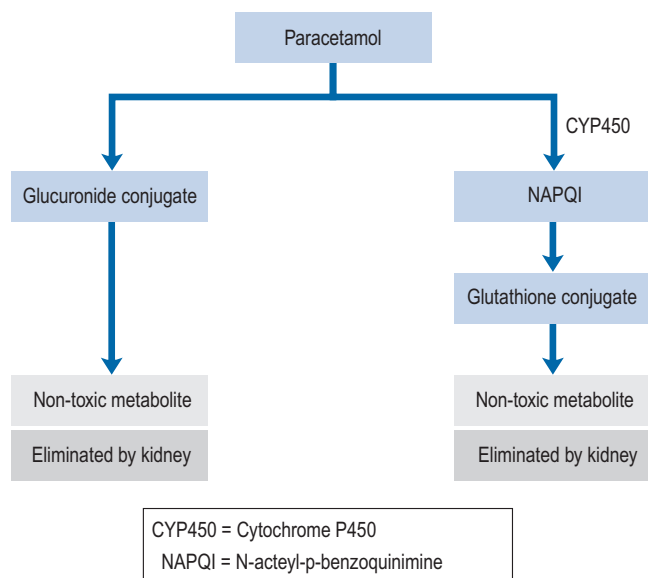
CYP450 = Cytochrome P450
NAPQI = N-acteyl-p-benzoquinimine


Fig. 33.3 Paracetamol metabolism in humans.

proportion of a dose is metabolised using a cytochrome P450 mediated reaction that forms a reactive intermediate, *N*-acteyl-*p*-benzoquinimine (NAPQI). Usually, NAPQI can be deactivated by conjugation with glutathione in the liver. However, following ingestion of a large amount of paracetamol the hepatic stores of both glucuronic acid and glutathione become depleted leaving free NAPQI, which causes liver damage.

The usual therapeutic dose for adults is paracetamol 1 g taken four times daily. It is very important that this dose is not exceeded, otherwise hepatotoxicity is more common. This may be particularly problematic for malnourished adults with low body weight (Claridge et al., 2010). A reduced maximum daily infusion dose (3 g/24 hours) is recommended for patients with hepatocellular insufficiency, chronic alcoholism or dehydration. Paracetamol is also available as an over-the-counter (OTC) medicine and is a component of many cold and influenza remedies. Compared with other analgesics, paracetamol is not as potent; however, when taken in combination with a NSAID or opioid, there is an additive analgesic effect.

Non-steroidal anti-inflammatory drugs

Mode of action

NSAIDs exert their analgesic and anti-inflammatory effects through inhibition of the enzyme cyclo-oxygenase. NSAIDs are used widely to relieve pain, with or without inflammation, in people with acute and persistent musculoskeletal disorders. In single doses, NSAIDs have superior analgesic activity compared to paracetamol (Hyllested et al., 2002). In regular higher dosages, they have both analgesic and anti-inflammatory effects, which makes them particularly useful for the treatment of continuous or regular pain associated with inflammation. NSAIDs have been shown to be suitable for the relief of pain in dysmenorrhoea, toothache and some headaches and to treat pain caused by secondary bone tumours, which result from lysis of bone and release of prostaglandins.

Clinical considerations

Differences in anti-inflammatory activity between NSAIDs are small, but there is considerable variation in individual patient response as well as the incidence and type of side effects. About 60% of patients will respond to any NSAID. Of the remaining patients, those who do not respond to one NSAID may well respond to another. An analgesic effect should normally be seen within a week, whereas an anti-inflammatory effect may not be achieved or assessable clinically for up to 3 weeks.

The potential treatment benefits of an NSAID must be weighed against the risks. NSAIDs are contraindicated in patients with known active peptic ulceration and should be used with caution in the elderly and in those with renal impairment or asthma.

COX-2 selective drugs

Cyclo-oxygenase exists in two forms: cyclo-oxygenase-1 (COX-1) and cyclo-oxygenase-2 (COX-2). COX-1 is a constitutive enzyme that is expressed under normal conditions in a variety of tissues, including the gastro-intestinal tract and kidney, where it catalyses the formation of prostaglandins required for homeostatic functions. It does not have a role in nociception or inflammation. COX-2 is an inducible enzyme that appears in damaged tissues shortly after injury and leads to the formation of inflammatory prostaglandins within these tissues. COX-2 selective NSAIDs should, theoretically, inhibit the formation of inflammatory prostaglandins without affecting the activity of COX-1 in areas such as the gut. In practice, use of COX-2 specific drugs is associated with reduced risks of gastro-intestinal side effects when compared with non-selective drugs. However, their use has also been linked with adverse effects including ischaemic cardiac events and this now limits their use.

Guidance on NSAID use

The lowest effective dose of NSAID or COX-2 selective inhibitor should be prescribed for the shortest time necessary. The need for long-term treatment should be reviewed periodically. Prescribing should be based on the safety profiles of individual NSAIDs or COX-2 selective inhibitors, on individual patient risk profiles, for example, gastro-intestinal and cardiovascular. Prescribers should not switch between NSAIDs without careful consideration of the overall safety profile of the products and the patient's individual risk factors, as well as the patient's preference (Medicines and Healthcare Regulatory Agency, 2006).

Concomitant aspirin, and possibly other antiplatelet drugs, greatly increases the gastro-intestinal risks of NSAIDs and severely reduces any gastro-intestinal safety advantages of COX-2 selective inhibitors. Aspirin should only be co-prescribed if absolutely necessary.

Weak opioids

Weak opioids are prescribed frequently, either alone or in combination with other analgesics, for a wide variety of painful disorders. There are three major drugs in this group,

codeine, dihydrocodeine and dextropropoxyphene, which are recommended as step 2 of the WHO analgesic ladder for pain that has not responded to non-opioid analgesics. Despite this recommendation, there is little data which demonstrates that weak opioids are of any benefit in the relief of persistent pain, and it may be more beneficial to use a smaller dose of a strong opioid.

Co-proxamol, a combination of dextropropoxyphene and paracetamol, was withdrawn in the UK in 2007 following safety concerns, particularly toxicity in overdose. An unlicensed product remains available for patients who find it difficult to change to alternative treatment.

Codeine

Codeine is the prototypical drug in this group. It is structurally similar to morphine and about 10% of the codeine is demethylated to form morphine, and the analgesic effect may be due to this, at least in part. It is a powerful cough suppressant as well as being very constipating. In combination with NSAIDs, the analgesic effects are usually additive but the variability in response is considerable. A degree of genetic polymorphism occurs within the population such that the hepatic microsomal enzyme CYP2D6 that is responsible for the conversion of codeine to morphine does not catalyse this conversion in approximately 8% of the Caucasian population. The duration of analgesic action is about 3 h.

Dihydrocodeine

Dihydrocodeine is only available in a few countries and is chemically similar to codeine. It has similar properties to codeine when used at the same dosage and may be slightly more potent.

Dextropropoxyphene

Historically, dextropropoxyphene was prescribed in combination with other analgesics such as paracetamol (co-proxamol). There are few data on its therapeutic value, and at least one review concluded that analgesic efficacy is less than aspirin and barely more than placebo. At best, dextropropoxyphene failed to show any superiority over paracetamol (Li Wan Po and Zhang, 1997). At worst, it is a dangerous drug which has the potential for steadily developing toxicity. Patients with hepatic dysfunction and poor renal function are particularly at risk. It is associated with problems in overdose, notably a non-naloxone reversible depression of the cardiac conducting system. Dextropropoxyphene interacts unpredictably with a number of drugs, including carbamazepine and warfarin. In 2005, the Medicines and Healthcare products Regulatory Agency (MHRA) announced concerns about the safety and effectiveness of co-proxamol and directed that it should be withdrawn from clinical use in the UK; however, it still remains available as an unlicensed medicine for the small number of patients who do not obtain analgesia with other analgesic medicines.

Strong opioids

Morphine

Morphine is the 'gold standard' strong opioid analgesic. It is available for administration by a range of administration routes, including oral, rectal and injectable formulations and has a duration of action of about 4 h after oral administration. There is no ceiling effect when the dose is increased. A general protocol for morphine use to obtain rapid relief from acute pain is to use intravenous bolus doses of 2–5 mg titrated until pain relief is achieved. In the initial management of persistent non-cancer pain or cancer pain, an oral regimen is more appropriate using an immediate-release formulation. A usual starting dose is 5–10 mg every 4 h, and the patient should be advised to take the same dose as often as is necessary for breakthrough pain. It may be necessary to double the dose every 24 h until pain relief is achieved, although a slower dose escalation will often suffice. After control is achieved, it is usual to change to an oral modified release formulation, which allows less frequent dosing, either daily or twice-daily. There is no ceiling dose for the analgesic effect of morphine; daily doses of up to 1 or 2 g of morphine may be required for some cancer patients, but relatively few require more than about 200 mg daily. Morphine is metabolised in the liver and one metabolite, morphine 6-glucuronide, is pharmacologically active and this should be taken into consideration in patients who have renal failure.

Other strong opioids

Opioids such as pethidine and dextromoramide offer little advantage over morphine in that they are generally weaker in action with a relatively short duration of action (2 h). Dipipanone is only available in a preparation which contains an antiemetic (cyclizine), and increasing doses lead to sedation and the risk of developing a tardive dyskinesia with long-term use. Methadone has a long elimination half-life of 15–25 h, and accumulation occurs in the early stages of use. It has minimal side effects with long-term use and some patients who experience serious adverse effects with morphine may tolerate methadone.

Hydromorphone and oxycodone are synthetic opioids that have been used for many years in North America and more recently in Europe. They are available in both immediate and modified release preparations. Some patients appear to tolerate hydromorphone or oxycodone better than morphine but there is no evidence to suggest which patients achieve the best effect with either of these drugs.

Fentanyl is available as a transdermal formulation for long-term use. The patch is designed to release the drug continuously over 3 days. When starting the drug, alternative analgesic therapy should be continued for at least the first 12 h until therapeutic levels are achieved, and an immediate acting opioid should be available for breakthrough pain. Patches are replaced every 72 h.

The relative potencies of the commonly used opioids are summarised in Table 33.1.

Table 33.1 Relative potencies of opioid drugs

Drug	Potency (morphine = 1)
Codeine	0.1
Dihydrocodeine	0.1
Tramadol	0.2
Pethidine	0.1
Morphine	1
Diamorphine	2.5
Hydromorphone	7
Methadone	2–10 (with repeat dosing)
Fentanyl (transdermal)	150

Clinical considerations

Use of opioids is almost universally accepted in cancer pain but many patients with persistent non-cancer pain can find considerable relief with strong opioids; however, barriers to their use in this context appear to be based more on ignorance and political fashions than clinical evidence (Ballantyne and Mao, 2003). As a general rule, strong opioids effective in the management of neuropathic and musculoskeletal pain, including osteoarthritis, are less effective for sympathetically maintained pain.

Agonist-antagonist and partial agonists

Most of the drugs in this category are either competitive antagonists at the μ opioid receptor, where they can bind to the site but exert no action, or they exert only limited actions; that is, they are partial agonists. Those that are antagonists at the μ opioid receptor can provoke a withdrawal syndrome in patients receiving concomitant opioid agonists such as morphine. These properties make it difficult to use these agents in the control of persistent pain, and the process of conversion from one group of drugs to another can be complex.

Buprenorphine

Buprenorphine is a semi-synthetic, highly lipophilic opioid that is a partial agonist at the μ opioid receptor and an antagonist at both the δ and κ receptors. It undergoes extensive metabolism when administered orally and to avoid this effect, it is given sublingually. It has high receptor affinity and, through this property, a duration of action of 6 h.

A long duration of action and high bioavailability would suggest a role for buprenorphine in the management of persistent pain. Relatively recently, buprenorphine has been marketed as a transdermal formulation and may be an effective alternative to other strong opioids for persistent non-cancer pain. There is limited evidence of efficacy in osteoarthri-

tis and low back pain. Following sublingual or intravenous administration the incidence of nausea and vomiting appears to be substantially higher than with morphine; however, respiratory depression and constipation are less frequent.

Pentazocine

Pentazocine, a benzomorphan derivative, is an agonist and at the same time a very weak antagonist at the μ opioid receptor. This drug became popular in the 1960s, when it was thought it would have little or no abuse potential. This is now known to be untrue, although its abuse potential is less than that of the conventional agonists such as morphine. It produces analgesia that is clearly different from morphine and is probably due to agonist actions at the κ-receptor. There are no detailed studies of its use in persistent pain, but its short duration of action (about 3 h) and the high incidence of psychomimetic side effects make it a totally unsuitable drug for such use.

Tramadol

Tramadol is a centrally acting analgesic that has opioid agonist activity and also has potent monoamine reuptake properties similar to many antidepressants. Indeed, tramadol appears to have intrinsic antidepressant activity. It is not as potent as morphine and efficacy is limited by side effects, including an unfavourably high risk of drowsiness and nausea and vomiting. Its monoaminergic activity appears to be valuable in the management of neuropathic pain and hence may be an acceptable alternative to a weak opioid.

Adverse effects of opioids

The adverse effects of opioids are nearly all dose related, and tolerance develops to the majority with long-term use.

Respiratory depression

Respiratory depression is potentially dangerous in patients with impaired respiratory function, but tolerance develops rapidly with regular dosing. It can be reversed by naloxone.

Sedation

Sedation is usually mild and self-limiting. Smaller doses, given more frequently, may counteract the problem. Rarely, dexamfetamine or methylphenidate has been used to counteract this effect.

Nausea and vomiting

Antiemetics should be co-prescribed routinely with opioids for the first 10 days. Choice of antiemetic will depend upon the cause, and a single drug will be sufficient in two-thirds of patients. Where nausea is persistent, additional causes should be sought and prescribing reviewed. If another antiemetic is used, it should have a different mode of action.

Constipation

Opioids reduce intestinal secretions and peristalsis, causing a dry stool and constipation. Unlike other adverse effects constipation tends not to improve with long-term use, and when opioids are used on a long-term basis most patients need a stool softener (e.g. docusate sodium) and a stimulant laxative (e.g. senna) regularly. Dosage should be titrated to give a comfortable stool. High-fibre diets and bulking agents do not work very well in preventing constipation in patients on opioids. Co-danthrusate (dantron + docusate sodium) and co-danthramer (dantron + poloxamer 188) are alternatives; however, because of the potential carcinogenicity and genotoxicity of dantron, they are only indicated for use in terminal care.

Tolerance, dependence and addition

Persistent treatment with opioids often causes tolerance to the analgesic effect, although the mechanism remains unclear (Holden et al., 2005). When this occurs the dosage should be increased or, alternatively, another opioid can be substituted, since cross-tolerance is not usually complete. Addiction is very rare when opioids are prescribed for pain relief.

Smooth muscle spasm

Opioids cause spasm of the sphincter of Oddi in the biliary tract and may cause biliary colic, as well as urinary sphincter spasm and urinary retention. Thus, in biliary or renal colic, it may be preferable to use another drug without these effects. Pethidine was believed to be the most effective in these circumstances but the evidence for this has been questioned (Thompson, 2001).

There is increasing evidence that long-term use of potent opioids may cause clinically significant adverse effects on the endocrine system, namely testosterone deficiency. Effects on the immune system are also under scrutiny.

Special techniques of opioid drug delivery

Patient-controlled analgesia (PCA)

PCA is a system which allows the patient to titrate the dose of opioid to suit their individual analgesic requirements. The drug is delivered using a syringe attached to an electronic or elastomeric pump, which delivers a preset dose when activated by the patient depressing a button. A lock-out period, during which the machine is programmed not to respond, ensures that a second dose is not delivered before the previous one has had an effect. Some devices allow an additional background infusion of drug to be delivered continuously. A maximum dose facility ensures that the machine does not deliver more than a preset dose over a given time. PCA is a useful technique for the management of pain after surgery. The system is convenient and enjoys a high degree of patient acceptability.

The traditional intermittent intramuscular injection of opioids can be effective but is less versatile than titrated intravenous administration. The subcutaneous route is subject to most of the problems associated with intramuscular administration but tends to be less painful.

Opioid use via any route is associated with nausea, and antiemetics should be prescribed routinely. Administration of compound preparations containing both opioids and antiemetics is not recommended as few preparations contain drugs with similar pharmacokinetic profiles and accumulation, usually of the antiemetic, may occur.

Epidural analgesia

Epidural injections and infusions may be effective in relieving pain arising from both malignant causes and non-cancer diseases and are very effective in postoperative and labour pain. Various combinations of local anaesthetics, opioids or steroids can be administered into the epidural space near to the spinal level of the pain.

Epidural opioids

Effective analgesia can be obtained by administering small doses of opioids to the epidural space. As there are opioid receptors in the spinal cord, smaller doses than administered by other parenteral routes are required and may be given with and without long acting local anaesthetic drugs. However, severe respiratory depression, nausea and vomiting, urinary retention and pruritus can occur after their use. Life threatening respiratory depression can occur when additional opioids are given by other routes to patients already receiving epidural opioids, and this practice should be actively discouraged. Respiratory depression which occurs soon after administration, due to intravascular absorption, is relatively common and simple to detect and treat. However, respiratory depression can also occur many hours after opioid administration. This is most common with morphine, probably because of its lower lipophilicity compared with fentanyl and diamorphine. Fentanyl has much greater stability than diamorphine and it can be prepared with bupivacaine in a terminally sterilised formulation which minimises the risk of adding the incorrect dose to an infusion fluid in a clinical environment and maintains sterility.

Local anaesthetics

Local anaesthetic drugs, such as lidocaine and bupivacaine, produce reversible blockade of neural transmission in automonic, sensory and motor nerve fibres by binding to sodium channels in the axon membrane from within, preventing sodium ion entry during depolarisation. The threshold potential is not reached, and consequently the action potential is not propagated. The concentration of local anaesthetic and dose used determine the onset, density and duration of the block. There are marked differences in the recommended maximum safe doses of different local anaesthetic agents. If the maximum dose is exceeded, serious cardiovascular (arrhythmias) and CNS effects (convulsions) may be observed.

Local anaesthetic drugs injected close to a sensory nerve or plexus will block the conduction of nerve impulses, including

pain from sensory fibres and provide excellent analgesia. Some local anaesthetics are given with adrenaline (epinephrine) to reduce systemic toxicity and increase the duration of action.

Local anaesthetics can be applied directly to wounds or by local infiltration to produce postoperative analgesia; however, these approaches will not normally block pain arising from deep internal organs. Local anaesthetic techniques are particularly useful in day-stay surgery and children. Continuous infusions via a catheter will allow prolonged analgesia. More permanent neural blockade for the control of cancer pain may be achieved by using a neurolytic agent such as absolute alcohol or phenol.

A topical formulation of lidocaine has been marketed for the management of neuropathic pain caused by post-herpetic neuralgia. Up to three plasters may be worn for a 12-h period each day.

Epidural local anaesthetics

Long acting local anaesthetic drugs such as bupivacaine are most effective in relieving pain after major surgery. They work by blocking nerves in the spinal canal serving both superficial and deep tissues, and thus analgesia can be obtained in deep internal organs. Sensory and sympathetic nerves that maintain smooth muscle tone in blood vessels are blocked. As a result, vasodilation can occur, which may result in significant hypotension. Epidural catheters allow continuous infusions and long-term therapy by this route. Adverse effects may include muscle weakness in the area supplied by the nerve and, rarely, infection and haematomas.

Non-opioid analgesics

The pharmacological actions and use of the conventional non-opioids such as paracetamol, aspirin and NSAIDs are well known and will not be discussed further here.

Nefopam is a drug which is chemically related to orphenadrine and diphenhydramine, however, it is neither an opioid, anti-inflammatory drug nor an antihistamine. The mechanism of analgesic action remains unclear. As a non-opioid, it is not associated with the problems of dependence and respiratory depression. The drug has a very high number of dose-related side effects in clinical use that may be linked to its anti-cholinergic actions. Nefopam may be useful in asthmatic patients and in those who are intolerant of NSAIDs.

Adjuvant medication

To be an analgesic, a drug must relieve pain in animal models and give demonstrable and reliable pain relief in patients. Drugs such as the opioids and the NSAIDs clearly are analgesics. In some types of pain, such as cancer pain or neuropathic pain, the addition of non-analgesic drugs to analgesic therapy can enhance pain relief. A list of some adjuvant drugs is given in Table 33.2. It should be remembered that some drugs such as tricyclic antidepressants (TCAs) have intrinsic analgesic

Table 33.2 Adjuvant drugs used in the treatment of pain

Drug class	Type of pain	Example
Anti-epileptics	Neuropathic pain Migraine Cluster headache	Carbamazepine Sodium valproate Gabapentin Pregabalin Lamotrigine
Antidepressants	Neuropathic pain Musculoskeletal pain	Amitriptyline Imipramine Venlafaxine Duloxetine
Intravenous anaesthetic agents	Neuropathic pain Burn pain Cancer pain	Ketamine
Skeletal muscle relaxants	Muscle spasm Spasticity	Baclofen Dantrolene Botulinum toxin (type A)
Steroids	Raised intracranial pressure Nerve compression	Dexamethasone Prednisolone
Antibiotics	Infection	As indicated by culture and sensitivity
Antispasmodics	Colic Smooth muscle spasm	Hyoscine butylbromide Loperamide
Hormones/hormonal analogues	Malignant bone pain Spinal stenosis Intestinal obstruction	Calcitonin Octreotide
Bisphosphonates	Bone pain (caused by cancer or osteoporosis)	Pamidronate (for cancer pain) Alendronate

activity, perhaps related to their ability to affect 5-HT and noradrenergic neurotransmission.

Antidepressants

Persistent pain is accompanied frequently by anxiety and depression. Thus, it is not surprising that the use of antidepressants and other psychoactive drugs is a routine component of pain management. There is evidence that some of these drugs have analgesic properties independent of their psychotropic effects.

The TCAs are frequently used for the treatment of persistent pain conditions with and without the anti-epileptics, and there is a substantial body of literature about their analgesic action (McQuay et al., 1996).

The biochemical activity of the TCAs suggests that their main effect is on serotonergic and noradrenergic neurones. The TCAs inhibit the reuptake of the monoamines, 5-HT and/or

noradrenaline in neurones found within in the brain and spinal cord. Through a rather complex mechanism, this causes an initial fall in the release of these transmitters followed by a sustained rise in the concentration of neurotransmitter at synapses in the pain neural pathways. This rise usually takes 2–3 weeks to develop. Tricyclic antidepressants are effective analgesics in headache, facial pain, low back pain, arthritis, and, to a lesser degree, cancer pain.

Clinical use of antidepressants in persistent pain

When used in pain management, it is usual to start with a very low TCA dose, for example, amitriptyline 10–25 mg at night and to titrate upwards according to response and adverse effects. Within clinical trials TCA doses have varied considerably but most are lower than used in psychiatry, in the order of amitriptyline 50–75 mg/day. Under specialist supervision higher doses, for example, amitriptyline 150–200 mg/day may be appropriate.

Tricyclic antidepressants have a wide range of adverse effects due to interaction with histamine and muscarinic acetylcholine receptors and these may cause a marked reduction in patient adherence. Newer antidepressant drugs have generally been disappointing from the analgesic perspective. However, much of the research has looked at the selective serotonin reuptake inhibitors (SSRIs). Scientific (Sindrup and Jensen, 1999) and clinical evidence (Sindrup et al., 2005) suggest that a combination of noradrenergic and serotonergic transmission both need to be enhanced for an analgesic effect to be seen. The serotonin/noradrenaline reuptake inhibitors (SNRIs) venlafaxine and duloxetine have effects on both monoamines and appear to possess analgesic activity in neuropathic pain models. A number of antidepressant compounds, including trazodone and mirtazepine, do not act via monoamine reuptake inhibition and do not appear to possess intrinsic analgesic activity. They are effective antidepressants and may have a place in the treatment of co-existing depression but analgesia should be treated separately.

Anti-epileptics

The usefulness of this group of drugs is well established for the treatment of neuropathic pain (McQuay et al., 1995). Conditions which may respond to anti-epileptics include trigeminal neuralgia, glossopharyngeal neuralgia, various neuropathies, lancinating pain arising from conditions such as postherpetic neuralgia and multiple sclerosis and similar pains that may follow amputation or surgery. Several classes of drugs show anti-epileptic activity and these can be broadly classed as sodium channel blockers (carbamazepine, phenytoin), glutamate inhibitors (lamotrigine), voltage gated calcium channel ligands (gabapentin, pregabalin), GABA potentiators (sodium valproate, tiagabine) or drugs showing a mixture of these effects (topiramate). Failure to respond to one particular drug does not indicate that anti-epileptics as a broad class will be ineffective. A drug with a different mechanism of action or combination therapy could be considered.

Anti-epileptics are surprisingly effective in the prophylaxis of migraine and cluster headache. Their mode of action is unclear but both of these conditions are associated with abnormal excitability of certain groups of neurones and the neuronal depression caused by anti-epileptics is probably important.

Ketamine

Ketamine is an intravenous anaesthetic agent with a variety of actions within the CNS. Many of its effects are related to its activity at central glutamate receptors, although it also has actions at certain voltage-gated ion channels and opioid receptors. Low doses of ketamine (0.1–0.3 mg/kg/h via the intravenous route) can produce profound analgesia, even in situations where opioids have been ineffective, such as neuropathic pain. Despite its variable oral availability, oral administration of ketamine can be surprisingly effective (Annetta et al., 2005; Mercadante, 1996). Its usefulness is limited by troublesome psychotropic side effects, although the simultaneous administration of benzodiazepines or antipsychotics can reduce these problems.

Anxiolytics

Benzodiazepines may be used for short-term pain relief in conditions associated with acute muscle spasm and are sometimes prescribed to reduce the anxiety and muscle tension associated with persistent pain conditions. Many authorities believe that they reduce pain tolerance and there is good evidence that they can reduce the effectiveness of opioid analgesics, although the mechanism by which this occurs is unclear. Clonazepam has been used in the management of neuropathic pain. Diazepam can be used to control painful spasticity, due to acute or spinal cord injury, but sedation may be troublesome and baclofen (see below) is probably a more suitable choice.

Antihistamines

These agents were introduced into the management of persistent pain because of their sedative muscle relaxant properties. These actions are non-specific and it is not clear whether the clinical effect is mediated centrally or peripherally. Most clinical studies have been carried out with hydroxyzine, which has shown benefit in acute pain, tension headache and cancer pain, but is not commonly used in current clinical practice.

Skeletal muscle relaxants

Drugs described in this section are used for the relief of muscle spasm or spasticity. It is essential that the underlying cause of the spasticity and any aggravating factors such as pressure sores or infections are treated. Skeletal muscle relaxants usually help spasticity but this may be at the cost of decreased muscle tone elsewhere, which may lead to a decrease in patient mobility, which may make matters worse.

The drug of first choice is probably baclofen, which has a peripheral site of action, working directly on skeletal muscle. Baclofen is a derivative of the inhibitory neurotransmitter GABA and appears to be an agonist at the $GABA_B$ receptor. It is used commonly in the treatment of spasticity caused by multiple sclerosis or other diseases of the spinal cord, especially traumatic lesions.

Dantrolene is an alternative that is effective orally and which may have fewer, but potentially more serious, adverse effects. Its effect is due to a direct action on skeletal muscle and takes several weeks to develop.

The α_2-adrenergic agonist tizanidine has potent muscle relaxant activity and is an alternative to baclofen. It may also have some direct analgesic effects.

Botulinum toxin

The bacterium *Clostridium botulinum* produces a potent toxin that interferes directly with neuromuscular transmission. Purified preparations of the type A toxin produce long-lasting relaxation of skeletal muscle. The effect often lasts in excess of 3 months and avoids the systemic side effects of agents such as baclofen. Great care must be taken in administering this drug as spread may occur to adjacent muscle groups, producing excessive weakness. Overdosage, with systemic absorption, may lead to generalised muscle weakness and even respiratory failure.

Clonidine

The α-adrenergic agonist clonidine has been shown to produce analgesia, and there is evidence that both morphine and clonidine produce a dose-dependent inhibition of spinal nociceptive transmission that is mediated through different receptors for each drug. This may explain why clonidine has been shown to work synergistically with morphine when given by the intrathecal or epidural routes. Clonidine also appears to be effective when given by other routes or even topically, but may cause severe hypotension by any route.

Cannabinoids

Cannabis has been used as an analgesic for hundreds of years. Problems concerning the legal status of cannabis in most countries have hindered scientific investigation of its analgesic properties. The active ingredient in preparations made from the hemp plant, *Cannabis sativa,* is δ-9 tetrahydrocannabinol. This compound has analgesic activity in animal models of experimental pain as well as in the clinical situation (Burns and Ineck, 2006). Overall, analgesic activity appears relatively weak and it has not been possible to separate the analgesic activity from the potent psychotropic effects characteristic of these drugs but a commercial preparation is now licensed for the management of spasticity in multiple sclerosis. There may be a clearer analgesic effect in neuropathic pain but the evidence for this remains anecdotal.

Stimulation-produced analgesia

Stimulation-produced analgesia can be used for trauma, postoperative pain, labour pain and various persistent pains.

TENS and acupuncture

TENS machines are portable battery-powered devices that generate a small current to electrodes applied to the skin. The electrodes are placed at the painful site or close to the course of the peripheral nerve innervating the painful area, and the current is increased until paraesthesia is felt at the site of the pain. The current stimulates the large, rapidly conducting (Aβ) fibres which close the gating mechanism in the dorsal horn cells, and this inhibits the small, slowly conducting (Aδ and C) fibres. TENS, in particular, offers the patient a simple, non-invasive, self-controlled method of pain relief with relatively few adverse effects.

Acupuncture also works using a similar manner, although additional mechanisms, including stimulation of endogenous opioid release, may be involved. Acupuncture has been recommended for the treatment of low back pain (National Institute for Health and Clinical Excellence, 2009).

Treatment of selected pain syndromes

Postoperative pain

The majority of patients experience pain following surgery. The site and nature of surgery influences the severity of pain, although individual variation between patients does not allow prediction of the severity of pain by the type of operation.

Apart from the obvious humanitarian benefit of relieving suffering, pain relief is desirable for a number of physiological reasons after surgery or any form of major tissue injury. For example, poor-quality analgesia reduces respiratory function, increases heart rate and blood pressure, and amplifies the stress response to surgery. The use of intermittent and patient-controlled intermittent intravenous opioids injections has been described earlier in this chapter. However, opioids themselves may delay recovery and are associated with adverse events in the postoperative period (Kehlet et al., 1996). It is now common to treat postoperative pain using a 'multimodal approach', consisting of paracetamol, NSAIDs, opioids and local anaesthetic blocks or wound infiltration. NSAIDs such as diclofenac and ketorolac are used frequently, but must be used with caution in the postoperative period where there is a possibility of renal stress, such as blood loss, and the normal protective effect of prostaglandins on the kidney will be lost, culminating in acute renal failure. There is no evidence to support the pre-emptive use of either NSAIDs or local anaesthetic techniques, although there is some theoretical and clinical evidence suggesting that opioids given prior to surgery may be more effective than when given postoperatively.

Cancer pain

Cancer and pain are not synonymous. One-third of patients with cancer do not experience severe pain. Of the remaining two-thirds that do, about 88% can be controlled using basic principles of pain management (Scottish Intercollegiate Guidelines Network, 2008). Pain associated with cancer may arise from many different sources, and may exhibit the characteristics of both acute and persistent pain. The mechanisms and sources of cancer pain may change with time and regular assessment is required. Cancer occurs more frequently in the elderly, who may have a larger proportion of painful conditions than the general population. Pain may be arising from these sources too, and these require treatment at the same time.

Cancer pain can be treated both with drugs and other interventional techniques, such as radiotherapy and nerve blocks. Usually, drug treatment is based on the WHO analgesic ladder together with the use of adjuvant analgesics. Opioids are the mainstay for the treatment of cancer pain, although increasingly some clinicians progress from non-opioid drugs to a strong opioid such as morphine, omitting the middle step of the analgesic ladder.

Although this chapter is concerned only with the management of pain, care of the patient with a terminal illness requires management of all aspects of the patient. The Liverpool Care Pathway (LCP) is a resource recommended to promote high-quality care in the last days of life (Ellershaw and Wilkinson, 2003). At a basic level, the LCP is a way of acknowledging that death is imminent and ensuring the patient's comfort by omitting long-term non-essential medication and anticipatory prescribing in case the patient experiences pain, delirium, vomiting or breathlessness.

Opioid use in cancer pain

Morphine is the first-line opioid used for the management of cancer pain and may be given in immediate or modified release oral formulations. If not tolerated, alternatives such as oxycodone or hydromorphone, both having relatively long half-lives, may be considered. Optimal dosage is determined on an individual basis for each patient by titration against the pain. Patients requiring long-term modified release opioids should have additional oral doses of rapidly acting opioid to act as an 'escape' medicine for incident or breakthrough pain. The British National Formulary recommends that the standard dose of a strong opioid for breakthrough pain is one-tenth to one-sixth of the regular 24 hour total daily dose. Methadone should not be used as first-line treatment of cancer pain, but may be useful when alternatives have failed or the patient has experienced intolerable adverse effects.

When the oral route is unavailable, other routes of administration such as the buccal, rectal, transdermal or parenteral (subcutaneous, intravenous) or spinal (epidural or intrathecal) routes may be considered. Syringe drivers or implanted pumps may be used to provide analgesia in cases where conventional opioid delivery is ineffective. Morphine and oxycodone are available for parenteral administration and in the UK, diamorphine is also suitable and readily available. Diamorphine hydrochloride has the advantage of being very water soluble, so a high dose may be given in a small volume, which reduces the frequency of changes of syringes and refills necessary to provide adequate pain relief. The proportion of patients who need an implanted pump for intrathecal drug delivery is extremely small and is confined largely to those who are persistently troubled with unacceptable adverse effects. Such patients may achieve pain relief with lower equivalent opioid doses and have few problems with side effects. Long-term maintenance of indwelling lines and catheters requires training for the patient and specialist expertise from physicians and nursing teams, but excellent long-term results are possible.

Use of adjuvant drugs and treatments for cancer pain

Neuropathic pain is common in cancer. As many as 40% of cancer patients may have a neuropathic component to their pain. Tricyclic antidepressants and anti-epileptic drugs should be introduced early but where these are ineffective, ketamine may have an important role.

Levomepromazine, a phenothiazine with analgesic activity, is a useful alternative when opioids cannot be tolerated. It causes neither constipation nor respiratory depression and has antiemetic and anxiolytic activity. It is sedative, which may be either a virtue or a problem in palliative care.

Corticosteroids are useful in managing certain aspects of acute and persistent cancer pain. They are particularly useful for raised intracranial pressure and for relieving pressure caused by tumours on the spinal cord or peripheral nerves. Dexamethasone is the most commonly used steroid to ameliorate raised intracranial pressure in patients with brain tumours. High steroid doses given for 1 or 2 weeks do not require a reducing-dosage regimen. Also, they may produce a feeling of well-being, increased appetite and weight gain, all beneficial for cancer patients, although these effects are usually transient.

It is essential that underlying causes of pain be treated; therefore, it is appropriate to use antibiotics to treat infections, radiotherapy to reduce tumour bulk or control bone pain, or surgery to achieve fracture fixation or to relieve bowel obstruction in conjunction with antispasmodics such as hyoscine butylbromide.

Specific cancer pain syndromes

Three types of malignant pain are briefly outlined below to indicate various therapeutic approaches.

Cancer of the pancreas. Pain is caused by infiltration of the tumour into the pancreas as well as by obstruction of the bowel and biliary tracts and metastases in the liver. Patients may experience anorexia, nausea, vomiting and diarrhoea, and also are often depressed. Surgery, radiotherapy and chemotherapy may relieve pain for long periods, as does neurolytic blockade of the coeliac plexus. Opioid analgesics

are useful and may be administered intravenously or epidurally by either bolus injection or continuous infusion.

Mesothelioma of the lung. Mesothelioma causes pain when the tumour penetrates surrounding tissues such as the pleura, chest wall and nerve plexuses. The WHO analgesic ladder should be used first, but it should be remembered that a NSAID may be beneficial as inflammation is often a component of the chest wall involvement. Adjuvants such as TCAs or steroids may be helpful. As the tumour progresses, nerve blocks or neurosurgery may be necessary, and invasion of the vertebrae can lead to nerve root or spinal cord compression. In the latter case, high dose steroids such as dexamethasone may be given intravenously, but radiotherapy is also useful in reducing the size of the tumour.

Metastatic bone pain. Metastatic bone pain is usually treated with courses of chemotherapy and radiotherapy, but analgesics may also be beneficial. A prostaglandin-like substance has been isolated from bone metastases and therefore NSAIDs and, more recently, bisphosphonates are often used in bone pain. Steroids also interfere with prostaglandin formation and dexamethasone, therefore, has a role, especially where there is nerve root or spinal cord compression.

Neuropathic pain

Neuropathic pain may be defined as 'pain arising as a direct consequence of a disease or lesion affecting the somatosensory system' and may occur as a result of pathological damage to nerve fibres in a peripheral nerve or in the CNS (see Table 33.3). Neuropathic pain may be spontaneous in nature

Table 33.3 Examples of causes of neuropathic pain

Cause of neuropathy	Examples
Trauma	Phantom limb Peripheral nerve injury Spinal cord injury Surgical
Infection/inflammation	Post-herpetic neuralgia HIV
Compression	Trigeminal neuralgia Sciatica
Cancer	Invasion/compression of nerve tissue by tumour
Ischaemia	Post-stroke pain Metabolic neuropathies (e.g. diabetic peripheral neuropathy)
Demyelination	Multiple sclerosis
Drugs	Vinca alkaloids Ethanol Taxols Anti-bacterials for TB and HIV

(continuous or paroxysmal) or evoked by sensory stimuli. As the underlying aetiology is different to inflammatory types of pain, patients typically present with disturbances in sensory function often describing their pain as tingling, shooting or electric shocks. It is possible for patients to present with pain in the context of sensory loss. Unlike inflammatory pain, neuropathic pain serves no biological advantage and can be described as an illness in its own right.

Typically, neuropathic pain does not respond as well to conventional analgesics, such as paracetamol and NSAIDs. Guidelines for the pharmacological management of neuropathic pain in the non-specialist setting have been published (National Institute for Health and Clinical Excellence, 2010).

Specific neuropathic pain syndromes

Postherpetic neuralgia. The pain associated with herpes zoster infection is severe, continuous and often described as burning and lancinating. Antiviral therapy, such as aciclovir, initiated at the first sign of the rash can reduce the duration of the pain, particularly postherpetic pain, which follows the disappearance of the rash. Tricyclic antidepressants such as amitriptyline are the mainstay of treatment, commencing with low doses (e.g. amitriptyline 10–25 mg at night) and gradually increased according to pain relief (usual dose amitriptyline 50–75 mg at night). This may be combined with anti-epileptic drugs if the response is poor or incomplete. Carbamazepine is historically important but newer anti-epileptic drugs, such as gabapentin and pregabalin, are considered first-line therapy and may be better tolerated. One study has demonstrated a significant difference in the incidence, and to a lesser extent the intensity, of pain in patients who received a single epidural methylprednisolone and bupivacaine injection, compared with those who received antiviral therapy and analgesia as 'standard care' (van Wijck et al., 2006). However, given the modest clinical effects on acute pain and no effect on the incidence of postherpetic neuralgia, the routine use of epidural local anaesthetic and steroid injection is not widely supported.

Diabetic peripheral polyneuropathy. Nerve damage and neuropathy is one of the long-term complications of diabetes mellitus (see Chapter 44) and is most prevalent in elderly patients with type II diabetes. Often patients describe numbness but also experience a burning sensation on their feet. The sensory loss can result in painless foot ulcers. Tricyclic antidepressants or serotonin noradrenaline reuptake inhibitors (duloxetine or venlafaxine), and anti-epileptics, such as gabapentin and pregabalin, have been demonstrated to be beneficial.

Trigeminal neuralgia. Trigeminal neuralgia presents as abrupt, intense bursts of severe, lancinating pain, provoked by touching sensitive trigger areas on one side of the face. The disorder may spontaneously remit for periods of several weeks or months. Anti-epileptic drugs, particularly carbamazepine, have been used successfully. If drug therapy is ineffective, neurosurgical techniques such as decompression of the fifth cranial nerve may be considered. If surgery is successful, anti-epileptics should be withdrawn gradually afterwards.

Peripheral nerve injury and neuropathy. Damage to, or entrapment of, nerves can cause pain, unpleasant sensations and paraesthesiae. Tricyclic antidepressants and anti-epileptic drugs, such as gabapentin, have been used with some success to treat neuropathic pain (Moore et al., 2011). A neuroma occurs when damaged or severed nerve fibres sprout new small fibres in an attempt to regenerate. Pain develops several weeks after the nerve injury, and is often due to the neuroma growing into scar tissue, causing pain as it is stretched or mobilised. Treatment of neuroma is very difficult and few treatments are successful. Options include surgery and injections of steroid and local anaesthetic agents.

Complex regional pain syndromes

These are an important group of painful conditions that may follow trauma or damage to nerves and are characterised by neuropathic pain, trophic changes and motor dysfunction. The key elements of successful treatment are effective multi-modal analgesia, including drugs with efficacy for neuropathic pain, and aggressive physiotherapy to facilitate a return to normal function. Sympathetic blockade using local anaesthetics may have a therapeutic role.

Back and neck pain

Back pain is one of the commonest reasons for presentation to a medical practitioner. Despite this, the problem is poorly understood. The most practical classification is based on the duration of symptoms (BenDebba et al., 1997). Acute low pain is generally defined as pain that lasts for a few days or weeks. The majority of these problems tend to be self-limiting and resolve spontaneously. Typical treatments include rest, adequate analgesia with paracetamol, combined with a NSAID and/or a weak opioid, and physiotherapy.

Persistent back pain lasts for much longer and progressively leads to a chronic state associated with pain, depression, anxiety and disability. Early intervention is necessary to ensure good functional and vocational outcomes. If a patient is off work for as much as 6 months, then there is a less than 50% chance of them ever returning to work. The likelihood of returning to work falls to less than 25% after 1 year and is almost zero after 2 years. Although pharmacological therapies may aid rehabilitation, other treatment strategies have a greater role to play in the management of persistent back pain. Guidelines for the management of non-specific persistent low back pain have been developed (National Institute for Health and Clinical Excellence, 2009). It is essential for the patient to develop self-management skills, and current recommendations emphasise the importance of using a biopsychosocial approach to manage this problem. Other treatment options include exercise programmes, manual therapy and acupuncture.

Osteoarthritis and rheumatoid arthritis

Pain often is a presenting symptom in osteoarthritis or the inflammatory arthritidies, which include rheumatoid arthritis. The pathophysiology and management of osteoarthritis and rheumatoid arthritis is covered in Chapter 53.

Myofascial pain

Myofascial pain is pain arising from muscles and is associated with stiffness and neuropathic symptoms such as tingling and paraesthesiae. It may occur spontaneously or following trauma, such as whiplash injury. Myofascial pain syndrome is sometimes also termed myositis, fibrositis, myalgia and myofasciitis. Acute muscle injury can be treated using first aid techniques with the application of a cooling spray or ice to reduce inflammation and spasm, followed by passive stretching of the muscle to restore its full range of motion. Injection therapy with local anaesthetic or saline may be used to disrupt sensitive muscle trigger points. Local injections of botulinum toxin have also been shown to be effective where muscle spasm is prolonged and severe. TENS and acupuncture have an important role to play in reducing pain and muscle spasm. Treatment of persistent myofascial syndromes should always include a programme of physical therapy.

Postamputation and phantom limb pain

The majority of amputees suffer significant stump or phantom limb pain for at least a few weeks each year. Pain will be present in the immediate postoperative period in the stump, and this may be caused by muscle spasm, nerve injury and sensitivity of the wound and surrounding skin. As the wound heals, the pain generally subsides. If it does not, the reason may be vascular insufficiency or infection. Pain occurring some number of years after amputation may be caused by changes in the structure of the bones or skin in the stump. Reduction in the thickness of overlying tissue with age may expose nerve endings to increased stimuli or ischaemia. Usually, conventional analgesics are beneficial for stump pain, although sometimes relatively high doses may be required. Tricyclic antidepressants may also be helpful for stump pain, and surgery may be necessary to restore the vascular supply or reduce trauma to nerve endings.

Phantom pain is a referred pain which produces a burning or throbbing sensation, felt in the absent limb. Cramping sensations are caused by muscular spasm in the stump. The patient with phantom limb pain is often anxious, depressed and frightened, all of which exacerbate the pain. Conventional analgesic drugs alone are generally not adequate for phantom pain, but TCAs and anti-epileptic drugs are useful adjuvants. Other therapy which can be effective includes TENS and sympathetic blockade. These patients frequently require management at specialist pain centres.

Headache

Everybody experiences the occasional tension headaches. They are caused by muscle contraction over the neck and scalp. Often they respond to simple analgesics available over-the-counter, such as paracetamol and NSAIDs. They may also respond to TCA drugs given as a single dose at night as well as non-pharmacological treatments, such as TENS. NSAIDs may be indicated if the headache is associated with cervical spondylosis or neck injury.

Migraine

Most migraine attacks respond to simple analgesics such as aspirin or paracetamol. Soluble preparations are best, as gut motility is reduced during a migraine attack and absorption of oral medication may be delayed. Migraine treatment has improved markedly with the development of the triptan drugs such as almotriptan, eletriptan, rizatriptan, sumatriptan, naratriptan and zolmitriptan (Goadsby, 2005). These are $5HT_{1B/1D}$-agonists that will often abort an attack, especially when given by the subcutaneous route. Their vaso-constrictor activity precludes their use in patients with angina or cerebrovascular disease but side effects are less serious than with the ergot derivatives they have replaced.

Prophylactic drug treatment of migraine includes α-adrenergic blockers, anti-epileptics and TCAs. Persistent treatment is undesirable.

Cluster headache

Cluster headache is a disabling condition characterised by severe unilateral head pain occurring in clusters of attacks varying from minutes to hours. It shares some pathologi-cal features with migraine and treatment is similar, although high-resolution MRI studies have shown specific anatomi-cal differences in the brains of people with cluster headache. Triptans are effective in acute attacks, as is inhalation of 100% oxygen. Prophylaxis is similar to that of migraine.

Dysmenorrhoea

Dysmenorrhoea is a common cause of pelvic pain in women. NSAIDs are effective as first-line therapy due to their effect on cyclo-oxygenase inhibition but it can be helped also by the prescription of oral contraceptives, since pain is absent in anovulatory cycles. Dysmenorrhoea due to endometriosis may require therapy with androgenic drugs such as danazol or regulators of the gonadotrophins such as norethisterone.

Burn pain

Patients with burns may require a series of painful proce-dures such as physiotherapy, debridement or skin grafting. Premedication with a strong opioid before the procedure and the use of Entonox® (premixed 50% nitrous oxide and 50% oxygen) may be necessary to control the pain. Regular opioid administration may be useful to prevent the pain induced by movement or touch in the affected area. The anaesthetic drug ketamine (see above) has potent analgesic activity when used in subhypnotic doses. Its short duration of action may be ben-eficial to reduce the pain of dressing changes or other forms of incident pain. Even with low doses, a significant propor-tion of patients will experience side effects of dysphoria or hallucinations. These can be treated with benzodiazepines or antipsychotic compounds, such as haloperidol.

A summary of medicine indications and common thera-peutic problems associated with analgesic use are presented in Table 33.4.

Table 33.4 Common therapeutic problems

Problem	Solution	Example
Neuropathic pain	Anti-epileptics	Carbamazepine Sodium valproate Gabapentin Lamotrigine
	Antidepressants	Amitriptyline Imipramine
	Intravenous anaesthetic agents	Ketamine
Malignant bone pain	Bisphosphonates	Pamidronate Calcitonin
Muscle spasm/ spasticity	Skeletal muscle relaxants	Baclofen Dantrolene Botulinum toxin (type A)
Raised intracranial pressure	Corticosteroids	Dexamethasone Prednisolone
Nausea with morphine	Antiemetic	Cyclizne Droperidol Ondansetron
	Use an alternative route of administration	Topical or subcutaneous
Constipation	Determine if drug induced, for example, opioids or tricyclic antidepressant	Co-prescribe laxatives (e.g. docusate sodium and senna)
Antidepressants in patients with ischaemic heart disease	Use a less cardiotoxic antidepressant	Duloxetine, venlafaxine
Drug interactions with carbamazepine	Use an anti-epileptic which does not affect hepatic enzymes	Gabapentin
Renal failure	Morphine accumulates; use lower dose Use a drug which is not eliminated by kidney	Fentanyl Buprenorphine
Sedation/ impaired cognition	Identify any drug-related causes and adjust dose or stop drug	

Case studies

Case 33.1

Mrs NP is a 55-year-old care home assistant who has type 2 diabetes. Her current prescription is for metformin 500 mg three times a day and amitriptyline 50 mg. When collecting her

repeat prescription she mentions that she 'Can't get on with the new tablets' because they make her very drowsy in the mornings. You invite Mrs NP to attend to review her medication. During the consultation Mrs NP explains that for some time she has suffered from constant tingling and occasional shooting pain in her legs and feet and 3 months ago amitriptyline 10 mg daily was prescribed. About 1 month ago the dose of amitriptyline was increased to 50 mg daily. She takes the dose at night, as advised by her primary care doctor. When she works an early shift (about three times a week) she usually omits the dose of amitriptyline to be sure that she wakes up in time to get to work. Mrs NP says that she takes the metformin regularly and has no associated problems. She is keen to be fit enough to work because she is supporting her youngest son who is studying to be a doctor.

Question

What advice should you give to this patient?

Answer

Mrs NP has developed diabetic peripheral neuropathy, a type of neuropathic pain. She is experiencing intolerable side effects from the increased dose of amitriptyline and therefore does not take it regularly. There are several options to improve tolerability. Firstly, Mrs NP should consider increasing the dose of amitriptyline more slowly. She may also benefit from taking her amitriptyline dose earlier in the evening, approximately 60–90 min before retiring to bed, so that it results in less hangover effect the following day. If neither of these strategies is beneficial, she should consult her primary care doctor about switching to an alternative drug to manage her neuropathic symptoms. Recent guidance (National Institute for Health and Clinical Excellence, 2010) recommends either pregabalin or duloxetine as alternatives to a tricyclic anti-depressant as first-line therapy for neuropathic pain in the non-specialist setting.

Case 33.2

A 55-year-old lady with metastatic abdominal cancer from a probable primary in the pelvis presents with an abdominal mass. Her pain is uncontrolled despite regular prescription of oral opioids, and she has been sick for a week. Subacute bowel obstruction is present.

Question

How should this lady be managed?

Answer

Management should begin with admission and rehydration. She may be dehydrated and have marked electrolyte abnormalities which would need to be corrected. The oral route is unavailable for the delivery of adequate analgesia, and thus consideration should be given to the use of parenteral administration, either by the subcutaneous route or using patient-controlled analgesia. The sickness should be treated, and an underlying cause sought. This may be subacute obstruction which, in turn, may be due to constipation caused by the opioids or by the disease process. Abdominal masses that indent on palpation are faeces (not tumour). Abdominal radiographs would show fluid levels if there was obstruction rather than constipation. Other possible causes of vomiting are recent anticancer therapy, anxiety, dyspepsia from NSAIDs, raised intracranial pressure and vertigo.

Surgery may be needed to relieve the obstruction, but the need may be avoided by use of hyoscine butylbromide, which may control colic with little additional sedation. If the problem is one of constipation, rectal measures may be necessary to re-establish function. These may include suppositories, enemas or digital disimpaction. Once control of pain has been achieved and bowel function has returned to normal, she must receive regular combination laxative therapy, ideally a stimulant laxative such as senna, and a faecal softener, such as docusate sodium. A high fluid intake and increased dietary fibre should be encouraged, as this will help prevent stool from becoming hard.

There has been interest in the use of peripheral opioid receptor antagonists to reduce opioid-induced constipation. As they have higher affinity for the opioid receptor than the agonist, they bind preferentially to opioid receptors in the gastro-intestinal tract, allowing the agonist to continue to have its desired effect in the CNS. A combination of prolonged-release oxycodone and prolonged release naloxone (Targinact®) may be an alternative if maximal laxative therapy does not help this patient.

Attention should be paid to Mrs NP's emotional and spiritual needs at all times.

Case 33.3

A 28-year-old man had a crush fracture of his ankle after falling from a roof. Fixation 9 months ago was described as satisfactory, but his leg is now very painful to even small stimuli and he cannot use it or bear weight. The lower leg has muscle wasting and is much colder than the opposite limb. The skin is very sensitive to touch, shiny and has a poor circulation.

Question

What is this condition and how should this pain be treated?

Answer

The patient presents with a complex regional pain syndrome. Management should be aggressive and directed towards functional restoration. Use of effective multi-modal analgesia using pharmacological and non-pharmacological treatments is required. The aim is to facilitate aggressive physiotherapy and occupational therapy. There may be a burning component to the pain, which may respond to low doses of TCAs such as amitriptyline (10–25 mg at night initially, increased in small increments to 50–75 mg at night).

Aggressive treatment early in the course of the disease can reduce the length of time that patients have this problem, and early referral to seek specialised help is recommended. A small percentage of patients continue to have problems whatever treatment is given.

Case 33.4

An 85-year-old man is admitted to hospital after falling down a flight of stairs and landing heavily on his right side. On admission, he is in severe pain and finds breathing, and especially coughing, unbearably painful. A chest X-ray reveals that he has fractures of the 5th to 8th ribs on the right side.

Question

How should his pain be managed and what are the risks of under treatment?

Answer

Multiple rib fractures are potentially very serious and good analgesia can prevent potentially dangerous complications. Initial analgesia should include both potent opioids and NSAIDs (unless contraindicated). Opioids should be administered parenterally in the first instance and subsequent use of patient-controlled analgesia would allow the patient to titrate their own analgesic requirements. The chest injury may well result in damage to the underlying lung and it is essential to administer unrestricted high-flow oxygen to the patient as the combination of lung injury and ventilatory suppression secondary to either pain or the effects of opioids could lead to dangerous hypoxia. TENS may also prove helpful.

Arterial oxygen saturation (and preferably arterial blood gases) should be monitored. If pain remains poorly controlled or the patient's oxygenation deteriorates, thoracic epidural analgesia using a mixture of local anaesthetic and opioid may be considered.

Failure to treat pain adequately in this situation may lead to a reduction in the patient's ability to cough and clear secretions from the chest. This can lead to respiratory failure and even death. Analgesia should be sufficient to allow regular physiotherapy in order to minimise the risk of such complications.

Case 33.5

A 45-year-old woman presents to her primary care doctor with a 2-day history of back pain following a lifting injury at work. The pain is constant and aching in character with radiation into the posterior aspect of both thighs as far as the knee. Physical examination shows her to be maintaining a very rigid posture with some spasm of the large muscles of the back. Her range of movement is very poor but there are no neurological signs in the legs.

Question

Which drugs may help this lady's pain? What other advice should be given?

Answer

Acute back pain is very common and is rarely associated with serious spinal pathology. The absence of neurological signs is reassuring and indicates that early activity, possibly aided by a short course of analgesics, is the best way forward. Regular paracetamol every 6h should be first-line treatment. This may be combined with NSAIDs, if tolerated. A muscle relaxant such as baclofen 20–40mg/day in divided doses may be beneficial for short-term use only. The role of opioids is less clear. Short-term (7–14 days) use of a weak opioid such as codeine or tramadol is probably safe. Longer term use is less satisfactory as

there is no clear evidence of their efficacy and sedative side effects may reduce the patient's capacity and motivation to remain active.

The patient should be advised to remain active and accept that some pain is likely during the recovery phase. Failure to remain active and, in particular, excessive bed rest are both associated with worse outcomes.

Case 33.6

A 50-year-old man is admitted to hospital with an acute onset of severe mid-thoracic spinal pain. He is found to be anaemic and investigations show that he has multiple myeloma with widespread bony lesions, including fresh spinal fractures.

Question

Which drugs may help this man's pain? What particular hazards may occur in this condition?

Answer

This patient is extremely ill and even with aggressive chemotherapy, he is unlikely to survive more than a few months. Most of his pain will be related to the destruction of bone and the aim should be to provide pain relief via a 'central' mechanism through the use of opioids as well as reducing the rate of bone destruction and associated inflammatory responses. A potent opioid will be required and oral morphine would usually be the drug of first choice. In this situation, a combination of a modified release preparation together with liberal 'as required' dosing would be appropriate. The correct dose is the dose required to produce adequate pain relief without producing excessive sedation. Inflammatory pain may be improved by the use of NSAIDs and these should be given regularly, although they may be contraindicated in this condition (see below). High dose corticosteroids may achieve a similar effect and may also reduce the hypercalcaemia that is often seen in myeloma. Bone destruction and its associated pain may be reduced by the use of bisphosphonate compounds. In this case, intravenous pamidronate should be given.

Renal failure is common in myeloma. This may be due to obstruction of renal tubules by myeloma proteins or the effects of some chemotherapeutic agents. If renal impairment occurs, opioids should be used with caution so as to avoid problems with accumulation. Transdermal fentanyl may be a more appropriate drug. NSAIDs can precipitate acute renal failure in the presence of reduced renal blood flow. Finally, platelet function is often poor in patients with myeloma. This can be due to direct effects of myeloma proteins on platelets, bone marrow replacement by myeloma or the effects of chemotherapy. Use of NSAIDs may be associated with increased risk of gastro-intestinal haemorrhage.

Nausea and vomiting 34

E. Mason and P. A. Routledge

Key points

- Patients must be assessed carefully, and often reassessed frequently, to identify the primary underlying cause of their nausea and/or vomiting.
- Antiemetics are symptomatic treatments only and do not treat the underlying cause.
- Drug choice is based on an understanding of the likely pathophysiology, the receptors involved, the available route of administration and drug side effects.
- In certain situations, prophylactic regimens are beneficial, for example, motion sickness, post-operative nausea and vomiting, chemotherapy-induced nausea and vomiting.
- Simple regimens are used where possible to prevent postoperative nausea and vomiting, such as parenteral cyclizine or prochlorperazine administered at induction. These and other antiemetics can be used for rescue therapy if vomiting occurs post-operatively.
- The choice of antiemetic to use in conjunction with cytotoxic chemotherapy depends on the emetogenicity of the cytotoxic drugs used. The $5HT_3$ antagonists such as ondansetron are very effective antiemetic drugs when highly emetogenic chemotherapy is used. The addition of dexametasone may provide further benefit.
- Anticipatory emesis associated with chemotherapy can be treated with benzodiazepine and dexametasone is useful in alleviating delayed emesis.

Nausea and vomiting are commonly (but not universally) associated symptoms. The word nausea is derived from the Greek *nautia*, meaning sea-sickness, while vomiting is derived from the Latin *vomere*, meaning to discharge. Nausea is a subjective sensation whereas vomiting is the reflex physical act of expulsion of gastric contents. Retching is defined as 'spasmodic respiratory movements' against a closed glottis with contractions of the abdominal musculature without expulsion of any gastric contents, that is, 'dry heaves' (American Gastroenterological Association, 2001). It is important to differentiate vomiting from regurgitation, rumination and bulimia. Regurgitation is the return of oesophageal or gastric contents into the hypopharynx with little effort. Rumination is the passive regurgitation of recently ingested food into the mouth followed by re-chewing, re-swallowing or spitting out. It is not preceded by nausea and does not include the various physical phenomena associated with vomiting. Bulimia involves over-eating followed by self-induced vomiting.

Epidemiology

Nausea and vomiting from all causes have significant associated social and economic costs in terms of loss of productivity and extra medical care. In the community, nausea (with or without vomiting) is most likely to be associated with infection, particularly gastro-intestinal infection. Vestibular disorders may cause vomiting as can motion sickness. Nausea and vomiting may be associated with pain, for example, migraine and severe cardiac pain. Many medicines also cause nausea and occasionally vomiting as a common dose-related (Type A) adverse effect. This is particularly common with opioid use in palliative care. Nausea and vomiting also occur post-operatively or in association with cytotoxic chemotherapy, or radiotherapy. These and other causes of nausea and vomiting are listed in Table 34.1.

Pathophysiology

Complex interactions between central and peripheral pathways occur in the production of the clinical features of nausea and vomiting. The most important areas involved peripherally are the gastric mucosa and smooth muscle (the enteric brain) and the afferent pathways of the vagus and sympathetic nerves. Centrally the significant areas involved are the area postrema, the chemoreceptor trigger zone (CTZ), the nucleus tractus solitarus (NTS) and the vomiting centre.

From a pharmacotherapeutic point of view, the most important aspect of this complex pathophysiology is the variety of receptors involved, including histaminergic (H_1), cholinergic (muscarinic M_1), dopaminergic (D2), serotonergic ($5HT_3$) and neurokinin-1 (NK_1) receptors. In the clinical situation, these become targets for various drugs directed at controlling the symptoms.

There are 10^8 neurons in the intestine and a complex interaction occurs between these, the mucosa, the smooth muscle in the intestine, the parasympathetic (vagus nerve) and sympathetic nerves and the higher centres in the spinal cord and brain to result in normal gastro-intestinal peristaltic activity. The enteric brain and the vagus nerve monitor stimuli from mucosal irritation and smooth muscle stretch which may result in nausea and/or vomiting.

The area postrema in the floor of the fourth ventricle contains the CTZ and is a special sensory organ rich in

Table 34.1 Selected causes of nausea and vomiting (adapted from Quigley et al., 2001)

Central	
i. Intracranial	Migraine Raised intracranial pressure (tumour, infection, haemorrhage, hydocephalus, etc.)
ii. Labyrinthine Iatrogenic	Labyrinthitis, motion sickness, Ménière's disease, otitis media Cancer chemotherapy Many other medicines (e.g. opioids) Radiotherapy Post-operative
Endocrine/metabolic	Pregnancy, uraemia, diabetic ketoacidosis, hyperthyroidism, hyperparathyroidism, hypoparathyroidism, Addison's disease, acute intermittent porphyria
Infectious	Gastroenteritis (viral or bacterial) Other infections elsewhere
Gastro-intestinal disorders	Mechanical obstruction (gastric outlet or small bowel) Organic gastro-intestinal disorders (e.g. cholecystitis, pancreatitis, hepatitis, etc.) Functional gastro-intestinal disorders (e.g. non-ulcer dyspepsia, irritable bowel syndrome, etc.)
Psychogenic disorders	Psychogenic vomiting, anxiety, depression
Pain related	Myocardial infarction

dopaminergic, serotonergic, histaminergic and muscarinic receptors. It is located outside the blood–brain barrier (BBB) and it is likely that chemicals, toxins, peptides, drugs and neurotransmitters in the cerebrospinal fluid (CSF) and bloodstream interact with this area to cause nausea and vomiting. However, the precise mechanism is not known.

The vomiting centre is situated in the dorsolateral reticular formation close to the respiratory centre and receives impulses from higher centres, visceral efferents, the eighth (auditory) nerve (the latter two through the nucleus tractus solitarius) and from the CTZ (Fig. 34.1). It includes a number of brainstem nuclei required to integrate the responses of the gastro-intestinal tract, pharyngeal muscles, respiratory muscles and somatic muscles to result in a vomiting episode. The vomiting centre may be stimulated in association with, or in isolation from, the nausea process.

The vomiting reflex can be elicited either directly via afferent neuronal connections, especially from the gastro-intestinal tract and is probably dependent on the integrity of the nucleus tractus solitarius, or from humoral factors dependent on the integrity of the area postrema. The sequence of muscle excitation and inhibition necessary for the act of vomiting is probably controlled by a central pattern generator located in the nucleus tractus solitarius, and information from the CTZ and vagus nerve converges at this point.

The central causes of nausea and vomiting include increased intracranial pressure, dilation of cerebral arteries during migraine and stimulation of the labyrinthine mechanism or of the senses of sight, smell and taste.

The peripheral causes of nausea and vomiting include motion sickness, delayed gastric emptying and gastric mucosal irritation (ulceration, NSAIDs). These mechanisms are all mediated through the vagal afferent neurons. The vomiting associated with distension or obstruction of the gastro-intestinal tract is mediated through both the sympathetic and vagal afferent neurons.

Patient management

Management of the patient with nausea and vomiting is approached in three steps.

1. Recognise and correct any complications. This includes correction of dehydration, hypokalaemia and metabolic alkalosis in the acute situation with symptoms of less than 4 weeks duration. Weight loss and malnutrition are features of chronic nausea/vomiting, that is, when symptoms have been present for 4 weeks or longer.
2. Where possible, identify the underlying cause (see Table 34.1) and institute appropriate treatment. Here it is important to be aware that metabolic or endocrine conditions such as hypercalcaemia, hyponatraemia and hyperthyroidism can result in vomiting.
3. Implement therapeutic strategies to suppress or eliminate symptoms (these depend on the severity and clinical context). Ideally, antiemetic drugs are prescribed only when the cause of the nausea and/or vomiting is known, since by suppressing symptoms, they may otherwise delay diagnosis. This is especially true in children. However, they may sometimes be necessary temporarily in situations when directly addressing the underlying cause will not bring symptom relief sufficiently rapidly.

Some scenarios illustrating common therapeutic problems in the management of nausea and vomiting are outlined in Table 34.2.

Antiemetic drugs

Several classes of antiemetic drugs are available that antagonise the neurotransmitter receptors involved in the pathophysiology of nausea and vomiting. These classes of drugs are generally distinguished from each other by the identity of their main target receptor, although some act at more than one receptor.

Antihistamines

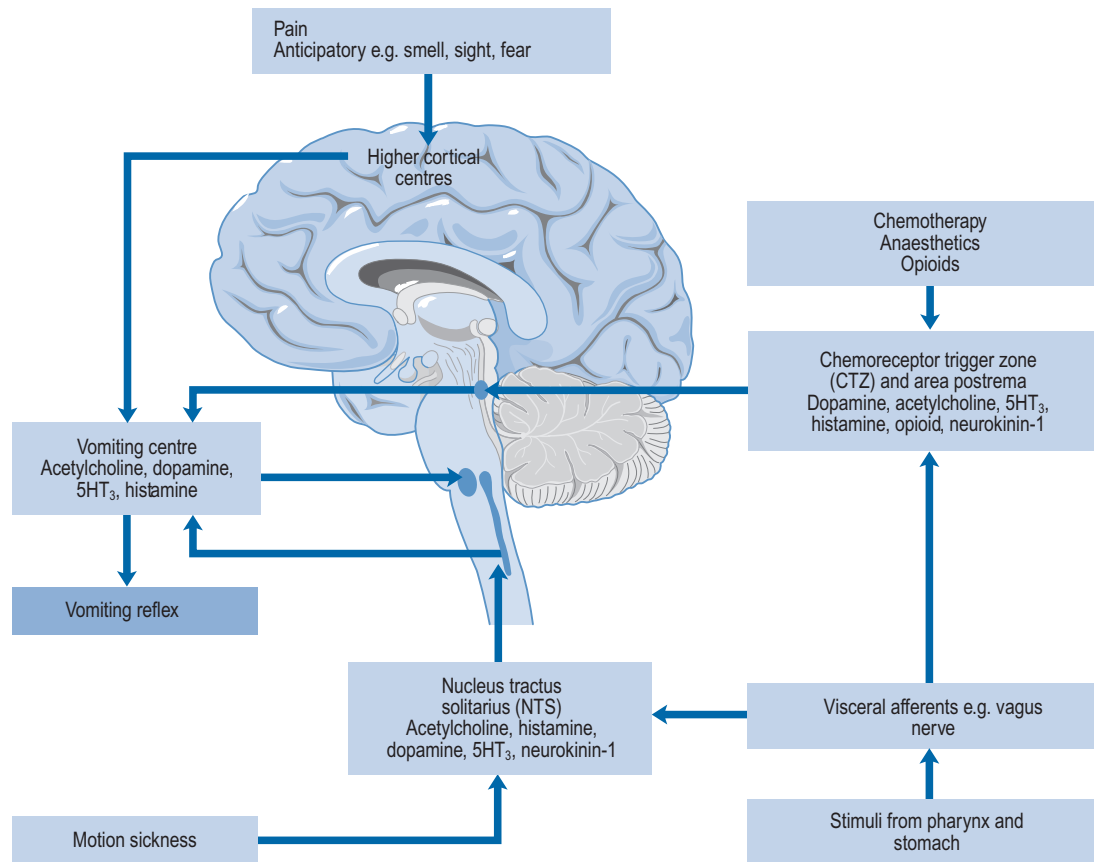
This group of medicines includes cinnarizine, cyclizine, diphenhydramine, diphenhydrinate and promethazine. They have some efficacy in nausea and vomiting caused by a wide


Fig. 34.1 Schematic representation of pathways involved in nausea and vomiting.

Table 34.2 Common therapeutic problems in managing patients with nausea and vomiting

Problem	Possible cause/solution
Persistent nausea and vomiting despite treatment	Is the cause correctly diagnosed? Review the antiemetic agent and the dose: if both correct, change to or add a second agent
Patient with PONV is vomiting despite suitable antiemetic regimen	Check analgesia: pain may be causing nausea and vomiting, or patient-controlled analgesia may require adjustment downwards to reduce analgesic dose
Patient with bowel obstruction is passing flatus	Prokinetic drug is first-choice antiemetic. $5HT_3$ antagonists may also be effective
Patient with bowel obstruction is not passing flatus	Spasmolytic drug is first choice. Prokinetic drugs are contraindicated. Similarly, bulk-forming, osmotic and stimulant laxatives are inappropriate; phosphate enemas and faecal softeners are better
A terminally ill patient receiving diamorphine is vomiting, despite use of haloperidol	Levomepromazine given as a 24-h subcutaneous infusion can be very effective
A patient with renal failure (uraemia) is vomiting	Consider a $5HT_3$ antagonist
A patient develops an acute dystonic reaction to metoclopramide	Give an intramuscular injection of an antihistamine. Such extrapyramidal reactions to metoclopramide are more common in young adults (especially females) and this agent is best avoided in this group

PONV, post-operative nausea and vomiting.

range of conditions, including motion sickness and post-operative nausea and vomiting (PONV). They are thought to block H_1 receptors in the CTZ and possibly elsewhere. However, several of these agents also have potent anticholinergic (M_1) receptor antagonist activity, which may contribute significantly to their efficacy as well as their adverse effect profile (see Section 'Anticholinergics'). The sedative effects of some antihistamines may also contribute to antiemetic activity, although this property appears not to be essential and it can be a particular problem when skilled tasks, such as driving, need to be performed. Nevertheless, the newer non-sedating antihistamines, for example, fexofenadine, are of limited value in nausea and vomiting.

Anticholinergics

This is one of the oldest classes of antiemetics, of which many members are potent inhibitors of muscarinic receptor (M_1) activity both peripherally and centrally. Anticholinergic drugs such as atropine, hyoscine and glycopyrronium have been used preoperatively to inhibit salivation and excessive respiratory secretions during anaesthesia. Anticholinergics act by inhibiting cholinergic transmission from the vestibular nuclei to higher centres within the cerebral cortex, thereby explaining their predominant use in the treatment of motion sickness. Hyoscine hydrobromide (scopolamine hydrobromide) is the most widely used agent and it can be given orally, by subcutaneous or intramuscular injection, or transdermally for motion sickness. Inhibition of peripheral muscarinic receptors can cause drowsiness, dry mouth, dilated pupils and blurred vision, decreased sweating, gastro-intestinal motility and gastro-intestinal secretions and difficulty with micturition. Anticholinergic agents may also precipitate closed-angle glaucoma in susceptible individuals.

Antidopaminergics

Phenothiazines and butyrophenones

Phenothiazines (e.g. prochlorperazine, perphenazine, and trifluoperazine) and butyrophenones (e.g. haloperidol and droperidol) act as antagonists at dopamine (D2) receptors in the CTZ, but may also have cholinergic (M_1) and histaminergic (H_1) receptor antagonist activity. As a consequence they share several adverse effects with antihistamines and anticholinergics, including drowsiness. In addition, the dopamine-blocking effects may be associated with acute dystonia (especially in children), and tardive dyskinesias or parkinsonism when used for prolonged periods. Prochlorperazine is less sedating and available as a buccal tablet and suppository for use when vomiting precludes oral administration. Phenothiazines are sometimes used for drug-associated emesis, including chemotherapy-induced nausea and vomiting (CINV), but like the butyrophenones, have in many situations been superseded by more specific agents such as metoclopramide and the selective $5HT_3$ antagonists. Levomepromazine is sometimes used to relieve nausea and vomiting in terminal care.

Metoclopramide

At lower doses, metoclopramide acts as a selective D2 antagonist at the CTZ and its effects mirror those of the phenothiazines and butyrophenones. However, it also exerts peripheral D2 antagonism at these doses, and stimulates cholinergic receptors in gastric smooth muscle, thus stimulating gastric emptying. It may, therefore, be more effective than phenothiazines and butyrophenones when nausea is related to gastro-intestinal or biliary disease. At higher doses, it may exert some $5HT_3$-receptor antagonism but at these doses, the incidence of acute dystonic reactions, particularly in young women and the elderly, may limit its usefulness in CINV.

Domperidone

Although domperidone does not readily cross the BBB, it is a selective antagonist of D2 receptors at the CTZ, which lies outside the BBB in the area postrema. It may also have peripheral effects that result in increased gastro-intestinal motility and faster gastric emptying. It is used in drug-associated vomiting, including CINV, and is relatively non-sedating. It can be given orally or by suppository. Acute dystonic reactions occur less frequently than with metoclopramide. It prevents nausea and vomiting during treatment with apomorphine and other dopamine agonists in Parkinson's disease and is also used to treat vomiting associated with emergency hormonal contraception.

Selective $5HT_3$-receptor antagonists

Serotonin or 5-hydroxytryptamine (5HT) plays an important role in nausea and vomiting. The subtype $5HT_3$-receptors, which mediate the vomiting pathway, are located peripherally on vagal nerve endings in the gastro-intestinal tract and centrally in the brain, with high concentrations found in the area postrema and nucleus tractus solitarius. Highly emetogenic agents such as cisplastin are thought to disrupt gastric mucosa and initiate the release of 5HT from enterochromaffin cells, which stimulate the $5HT_3$-receptors on afferent vagal nerve endings and thus trigger the emetic reflex. Selective $5HT_3$-receptor antagonists that act centrally and peripherally are now commonly used to treat or prevent CINV (with drugs of moderate to high emetogenic potential) and PONV. They are also effective in radiotherapy-induced nausea and vomiting. Selective $5HT_3$ antagonists are generally well tolerated, with the most common adverse effects being constipation, headache, dizziness and sensation of warmth or flushing. Some available agents include granisetron, ondansetron and palonosetron. They are all more expensive than antihistamines, phenothiazines, anticholinergics or dopamine antagonists.

Neurokinin-1 (NK_1) receptor antagonists

Substance P is a bioactive peptide that shares a common amino acid sequence with other bioactive peptides known as tachykinins. It appears to play an important role as a neurotransmitter in emesis as well as in pain and a number of

other inflammatory processes. Substance P binds to the sub-type neurokinin-1, or NK_1 receptors, which are found in the area postrema and nucleus tractus solitarius. Selective NK_1 receptor antagonists, aprepitant and fosaprepitant (a prodrug of aprepitant), are now available for use as an adjunct to dexametasone and a $5HT_3$ antagonist in preventing, but not treating, nausea and vomiting associated with moderately and highly emetogenic chemotherapy. They appear to be well tolerated but it is an inhibitor (and sometimes inducer) of cytochrome P450 (CYP3A4) and inducer of CYP2C9 and glucuronidation, so potential drug interactions with chemotherapeutic agents as well as other concomitantly administered agents, for example, possibly warfarin, may occur.

Cannabinoids

It is likely that the antiemetic activity of cannabinoids is related to stimulation of central and peripheral cannabinoid (CB1) receptors. Cannabinoids have modest antiemetic activity that is of similar magnitude to prochlorperazine in CINV, but they can cause a range of central nervous adverse effects, including drowsiness and sometimes behavioural disturbances, which may at times be severe. Thus, while the synthetic cannabinoid nabilone is indicated for nausea and vomiting caused by cytotoxic chemotherapy unresponsive to conventional antiemetics, it is recommended that patients are made aware of possible changes in their mood and other unwanted effects on their behaviour. In addition, nabilone should be used under close supervision, preferably in a hospital setting.

Corticosteroids

Corticosteroids are known to have antiemetic effects. Their mechanism of action is unclear but steroid receptors are thought to exist in the area postrema. As single agents, they appear to be at least as effective as prochlorperazine in preventing nausea and vomiting associated with mild to moderately emetogenic cytotoxic chemotherapy. Dexamethasone, the most widely used corticosteroid in this context, improves the antiemetic activity of prochlorperazine and metoclopramide and may reduce some of the side effects associated with the latter. When combined with $5HT_3$ antagonists, corticosteroids are particularly effective in CINV associated with moderately emetogenic chemotherapy, or when used in delayed emesis. The same combination of dexamethasone and a $5HT_3$ antagonist, and sometimes with aprepitant, may also be effective in CINV associated with highly emetogenic chemotherapy regimens.

Complementary and alternative medicines

Systematic reviews support the use of stimulating wrist acupuncture point P6 for preventing PONV in combination with, or as an alternative to, conventional antiemetics (Lee and Done, 2004). A systematic review of randomised trials has also demonstrated the efficacy of ginger (at least 1 g preoperatively) in PONV. Ginger has also been claimed to be beneficial

in motion sickness and pregnancy-associated nausea, but the evidence for each is limited to single randomised trials (Ernst and Pittler, 2000).

Drug treatment in selected circumstances

Post-operative nausea and vomiting

Around 25% of patients experience PONV within 24 h of surgery (Gan et al., 2003). The aetiology is complex and multifactorial and includes patient-, medical-, surgical- and anaesthetic-related factors. Management is multimodal and involves strategies to reduce baseline risk such as using less emetogenic induction agents, anaesthetic agents and analgesics, consideration of the use of regional rather than general anaesthesia, adequate hydration and intraoperative supplemental oxygen use and avoidance of high-dose neostigmine.

Many antiemetic agents have some efficacy in post-operative nausea and vomiting but combination therapy with drugs from different classes may be needed in patients at high risk, such as those with a previous history of post-operative nausea and vomiting or motion sickness, or after high-risk procedures, for example, prolonged operations. Prophylactic treatments include dexametasone before induction or $5HT_3$ antagonists, antihistamines or phenothiazines at the end of surgery. Metoclopramide and cannabinoids appear to be of limited value in the management of post-operative nausea and vomiting.

Premedication with opioids increases the incidence of post-operative nausea and vomiting and this may be reduced by concurrent administration of either atropine or hyoscine, which are primarily used as anti-secretory drugs at premedication.

Risk scores

Prophylaxis is preferable to treatment and this can often be achieved not only by use of antiemetic drugs but also by suitable planning. For example, not all patients undergoing surgery will experience post-operative nausea and vomiting and universal prophylaxis is not cost-effective (Habib and Gan, 2004). A simple risk scoring system has been devised in which the score increases relative to the presence or absence of four factors:

- female gender
- history of motion sickness or PONV
- non-smoker
- opioid use during operation.

The incidence of post-operative nausea and vomiting with the presence of none, one, two, three or all four of these risk factors has been shown to be 10%, 20%, 40%, 60% and 80%, respectively (Apfel et al., 1999). Use of risk scores based on these criteria helps to appropriately tailor antiemetic use and can significantly reduce the incidence of nausea and vomiting in clinical practice (Apfel et al., 2002; Pierre et al., 2004).

Chemotherapy-induced nausea and vomiting

Three different types of CINV have been identified: acute, delayed and anticipatory. Acute emesis begins within 1 or 2h of treatment and peaks in the first 4–6h. Delayed emesis occurs more than 24h after treatment, peaks at 48–72h and then subsides over 2–3 days. It occurs characteristically after high-dose cisplatin but may also occur after the related agent carboplatin, as well as cyclophosphamide or an anthracycline. Anticipatory emesis occurs in patients who have developed significant CINV during previous cycles of therapy. Acute CINV is often associated with an increase in plasma serotonin concentrations for the most emetogenic agents, while delayed and anticipatory vomiting seem to be mediated by serotonin-independent pathways.

Management of CINV depends on the emetogenicity of the chemotherapy regimen and the use of combinations of antiemetic drugs based on their varying target receptors. Chemotherapy agents are divided into four emetogenic levels (Table 34.3) defined by expected frequency of emesis (Kris et al., 2006).

In high-level acute emesis, a single dose of a $5HT_3$ antagonist given before chemotherapy is therapeutically equivalent to a multidose regimen with these agents. Odansetron and granisetron appear to be equally effective in CINV and only one study suggests palonosetron is superior to granisetron when given in combination with dexametasone (Billio et al., 2010). Oral formulations of antiemetics are often as effective as intravenous ones. In lower level acute emesis, the cost of the $5HT_3$ antagonists is prohibitive and metoclopramide or prochlorperazine are commonly used and are sufficiently effective.

Dexametasone is the most extensively evaluated steroid in the management of CINV. Used alone, it is not sufficiently potent in CINV. However, it enhances the effect of other agents such as $5HT_3$ antagonists in high-risk situations and, together with metoclopramide, it also appears to be useful in treating delayed emesis.

The best management for anticipatory emesis is the avoidance of acute and delayed emesis during previous cycles. However, when anticipatory nausea and vomiting are a problem, a low dose of a benzodiazepine such as lorazepam is often effective.

When apparently appropriate antiemesis regimens fail, consideration should be given to the possibility of other underlying disease- and medication-related issues (Box 34.1).

Pregnancy-associated nausea and vomiting

Pregnancy-associated nausea and/or vomiting occurs in about 70% of women during the first trimester. Risk factors for vomiting include a personal history of previous pregnancy-associated nausea/vomiting or motion sickness or migraine-associated nausea/vomiting, a family history of hyperemesis gravidarum or a large placental mass, for example, due to multiple pregnancy. Symptoms usually begin 4 weeks after the last menses and in 80% of cases end at 12 weeks, having peaked at 9 weeks. In some women, the problem may persist

Table 34.3 Relative emetogenicity of chemotherapy drugs (from Kris et al., 2006)

Emetic risk (incidence of emesis without antiemetics)	Agent
High (>90%)	Cisplatin Mechlorethamine Streptozotocin Cyclophosphamide ≥1500 mg/m² Carmustine Dacarbazine Dactinomycin
Moderate (30–90%)	Oxaliplatin Cytarabine >1000 mg/m² Carboplatin Ifosfamide Cyclophosphamide <1500 mg/m² Doxorubicin Daunorubicin Epirubicin Idarubicin Irinotecan
Low (10–30%)	Paclitaxel Docetaxel Mitoxantrone Topotecan Etoposide Pemetrexed Methotrexate Mitomycin Gemcitabine Cytarabine ≤1000 mg/m² Flurouracil Bortezomib Cetuximab Trastuzumab
Minimal (<10%)	Bevacizumab Bleomycin Busulfan 2-Chlorodeoxyadenosine Fludarabine Rituximab Vinblastine Vincristine Vinrelbine

Box 34.1 Factors that cause nausea and vomiting in their own right and may contribute to the failure of apparently appropriate prophylactic regimens for chemotherapy-induced nausea and vomiting (CINV)

Hypercalcaemia or other metabolic or endocrine disturbance
CNS metastases
Antibiotics such as erythromycin/clarithromycin
Gastro-intestinal obstruction
Radiotherapy enteropathy

until 16–20 weeks. First-trimester nausea and vomiting are not usually harmful to either the fetus or the mother and is not generally associated with a poor pregnancy outcome.

In contrast, hyperemesis gravidarum is a condition of intractable vomiting complicating between 1% and 5% of pregnancies and sometimes resulting in serious fluid and electrolyte disturbance and nutritional deficits.

In first-trimester nausea and vomiting, simple measures such as small frequent carbohydrate-rich meals and reassurance are sufficient to control symptoms. Ginger and P6 acupressure have also been advocated, although the evidence base is equivocal in early pregnancy (Jewell and Young, 2003). More recent studies on the use of acupuncture in pregnancy-associated nausea and vomiting remain unclear (King and Murphy, 2009). It is important to avoid antiemetic drugs when possible, but promethazine has been recommended in severe vomiting, with prochorperazine or metoclopramide as second line agents. In Canada and the USA, a combination of pyridoxine (vitamin B_6) and an antihistamine (doxylamine) is approved for the treatment of nausea in pregnancy but this combination treatment appears to be less effective for controlling vomiting.

In the serious condition of hyperemesis gravidarum, drug therapy may be used, although no trials have shown clear benefit (Jewell and Young, 2003). Fluid and electrolyte replacement, rest and if necessary postpyloric or parenteral feeding to provide nutritional support and vitamins (e.g. thiamine to reduce the risk of Wernicke's encephalopathy) supplementation should be considered. There are few safety or efficacy data on which to select the most appropriate treatments so the agents recommended for vomiting of pregnancy mentioned above are generally used in the first instance in the UK.

Migraine

Migraine is a paroxysmal disorder with attacks of headaches, nausea, vomiting, photophobia and malaise. Treatment is directed at:

- prophylaxis: avoid triggers, try β-blockers, pizotifen and in severe cases a $5HT_{1B/D}$-receptor agonist such as sumatriptan
- analgesia, including aspirin, paracetamol, opioids, NSAIDs
- antiemetics.

Nausea and vomiting in migraine are associated with headache intensity, and the concomitant gastric stasis aggravates the nausea and vomiting and may also delay absorption of oral analgesics. Metoclopramide and domperidone attenuate the autonomic dysfunction and promote gastric emptying but the risk of acute dystonic crisis, especially with metoclopramide therapy should be borne in mind, especially in young women and children, but also in the elderly.

Labyrinthitis

Labyrinthine dysfunction results in vertigo, nausea and vomiting. Episodes may last a few hours or days. Causes include labyrinth viral infections, tumours and Ménière's disease. The onset of episodes is often unpredictable and disabling.

Betahistine sometimes has some benefit. The anticholinergics, antihistamines, phenothiazines or benzodiazepines can be used to suppress the vestibular system. Usually hyoscine is sufficient but if there is severe vomiting, prochlorperazine or metoclopramide may be of value.

Motion sickness

Motion sickness is a syndrome, a collection of symptoms without an identifiable cause. It is brought on by chronic repetitive movements which stimulate afferent pathways to the vestibular nuclei and lead to activation of the brainstem nuclei. Histaminergic and muscarinic pathways are involved. The symptoms include vague epigastric discomfort, headache, cold sweating and nausea which may culminate in vomiting. This is often followed by marked fatigue which can last hours or days. Onset of symptoms may be abrupt or gradual.

The anticholinergic agent hyoscine is the prophylactic drug of choice, although there is no evidence of its benefit once motion sickness is established (Spinks et al., 2004). Antihistamine drugs may also be effective. The less sedating antihistamines cinnarizine or cyclizine are used. Promethazine, an antihistamine with sedative effects, is also effective but phenothiazines, domperidone, metoclopramide and $5HT_3$-receptor antagonists appear to be ineffective in this situation. Treatment should be started before travel; for long journeys, promethazine or transdermal hyoscine may be preferred for their longer duration (24 h and 3 days, respectively). Otherwise, repeated doses will be needed.

The most important adverse effect of many drugs used is sedation, whilst for anticholinergic drugs it is blurred vision, urinary retention and constipation. In laboratory studies, the degree to which these effects impair performance, for example, driving a car, is highly variable but subjects who take anti-motion sickness drugs should normally be deemed unfit for such tasks. These drugs also potentiate the effects of alcohol.

Many non-drug treatments have been advocated for alleviation of motion sickness, including wristbands, which act on acupuncture points, variously positioned pieces of coloured paper or card, as well as plant extracts such as ginger. The evidence base for these interventions remains very limited.

Drug-associated nausea and vomiting

As well as chemotherapeutic agents, many commonly used medications for other disorders can cause nausea and vomiting (Quigley et al., 2001). Opioids are perhaps the most important group clinically, but dopamine agonists (used in Parkinson's disease), theophylline, digoxin and macrolide antibiotics such as erythromycin can all cause nausea and/or vomiting, often in a dose-related manner (Type A toxicity). High-dose oestrogen, used in postcoital contraception, can produce these symptoms. Consideration should be given to altering the dose of the offending agent when possible, and administering the medication with food. With some agents, tolerance may develop. Thus, tolerance to the emetic effects of opioids often develops within 5–10 days and, therefore, antiemetic therapy is not generally needed for long-term opioid use.

Palliative care-associated nausea and vomiting

Nausea and vomiting are common and distressing symptoms in cancer patients. In most cases, the causes of nausea and vomiting are due to multiple factors such as the tumour itself, concurrent infection, drugs and metabolic disturbances such as renal failure.

It is important to determine the predominant underlying cause for patients' symptoms by taking a careful history, examination and appropriate investigations so that potentially reversible causes of nausea and vomiting can be treated (Box 34.2) and the most suitable antiemetic prescribed.

Oral antiemetic therapy is effective for treatment of nausea in patients with advanced cancer but the subcutaneous route is preferred for those with severe persistent vomiting, either as a single dose injection or a continuous infusion via a syringe driver. When patients' symptoms improve, switching from subcutaneous injection to oral route might be preferable. Non-pharmacological interventions such as avoidance of certain food smells or unpleasant odours, relaxation techniques and use of acupuncture should be considered.

CINV is described in detail elsewhere in the chapter. Strong opioids such as morphine, diamorphine, oxycodone and fentanyl cause nausea and/or vomiting in up to one-third of patients following initiation of treatment but the incidence is lower for weaker opioids such as codeine. Metoclopramide, cyclizine or haloperidol are often given for the relief of the nausea and vomiting induced by opioids.

Gastroduodenal or intestinal obstructions in advanced malignancy are usually caused by occlusion to the lumen (intrinsically and/or extrinsically) or by absence of normal peristaltic propulsion. Surgery remains the definitive treatment for luminal occlusion due to cancer but this is often inappropriate for patients who are frail or with advanced malignancy. The main aim of pharmacological interventions is symptom control. A prokinetic dopamine (D2) antagonist such as metoclopramide or domperidone should be used for patients with nausea and vomiting associated with functional gastric or intestinal stasis. Prokinetics are also used in patients with partial gastric outlet obstruction but can worsen patients' symptoms of abdominal pain in complete gastric outlet obstruction. As prokinetics can exacerbate abdominal colicky pain associated with intestinal obstruction, their use should be avoided in that situation and antiemetics such as cyclizine or haloperidol should be used for symptom control.

Dexametasone has also been used for control of symptoms in malignant intestinal obstruction, not only for any antiemetic effect but also to reduce inflammatory tumour oedema around the obstructive lesion. Anticholinergics such as hyoscine butylbromide and somatostatin analogues such as octreotide have been used for symptom relief in intestinal obstruction by reducing gastro-intestinal secretion and motility and thus reducing the frequency and volume of vomitus.

Biochemical disturbances such as hypercalcaemia and renal failure can be a cause of nausea and vomiting in patients with advanced malignancy. However, aggressive treatment with bisphosphonates or insertion of nephrostomy tubes, respectively, would not be appropriate for those who are in the terminal stages of their disease. Haloperidol and cyclizine appear to be effective for biochemical causes of nausea and vomiting. Levomepromazine has antidopaminergic, antihistaminergic, antimuscarinic and antiserotonergic activity. It is effective for most causes of nausea and vomiting and may help alleviate restlessness. It can also be given intramuscularly, intravenously or subcutaneously, including by continuous subcutaneous infusion. It may be considered if first line antiemetics are insufficiently effective. Unfortunately, sedation and postural hypotension can be a problem in association with this agent.

Conclusion

Nausea and vomiting are symptoms caused by a variety of underlying causes. Thorough clinical assessment and appropriate investigations should be undertaken when prescribing a therapeutic trial of an antiemetic. The choice of agent(s) should be based upon the likely cause and severity of the symptoms, the possible underlying pathophysiology, and the recommendations of evidence-based guidelines which take into account clinical effectiveness and cost-effectiveness.

Case studies

Case 34.1

A 30-year-old man presents seeking a remedy for vomiting which had an acute onset, 12 h previously.

Question

What questions should be asked to determine the nature, cause and seriousness of these symptoms?

Answer

The cause of vomiting needs to be determined where possible to allow appropriate treatment to be initiated. The following questions should be asked.

- Are there symptoms or signs of infection, such as diarrhoea, sore throat, dysuria, photophobia, fever? (Infection, often of the gastro-intestinal tract, is one of the commonest causes of vomiting.)

Box 34.2 Potentially treatable causes of nausea and vomiting in palliative care

Hypercalcaemia
Constipation
Renal failure
Raised intracranial pressure
Infection
Bowel obstruction
Peptic ulcer disease
Drugs
Anxiety

- Is there headache? (Raised intracranial pressure and meningitis can present with vomiting as an early symptom, usually without any nausea.)
- Is there abdominal pain? (Abdominal pain before vomiting usually means an organic gastro-intestinal cause. Pain after vomiting may be due to muscle tenderness.)
- Has the patient started any new drugs (opioids, chemotherapeutic agents, digoxin, nicotine, NSAIDs, oral hypoglycaemics and some antibiotics are common causes) or drunk excess alcohol?
- Is there vertigo? (If present, this is suggestive of a labyrinthine cause.)

Case 34.2

A 19-year-old girl who is 12 weeks pregnant presents to hospital with intractable nausea and vomiting which has not responded to home therapy and which has resulted in hypotension and dehydration.

Question

List, in order of importance, the therapeutic strategies for this problem.

Answer

Treatment would normally involve:

- intravenous rehydration and electrolyte replacement
- bed rest
- antiemetics, such as promethazine; these are likely to be effective and there is little evidence to suggest that they have teratogenic effects
- postpyloric feeding
- steroids
- parenteral nutrition.

Case 34.3

A 45-year-old woman presents with ovarian carcinoma for which she is due to receive a course of cancer chemotherapy.

Question

What drugs might be appropriate, when should they be given, and what advice should be given to the patient regarding monitoring of symptoms after treatment with the chemotherapy?

Answer

This woman is likely to receive repeated cycles of emetic chemotherapy with carboplatin (moderate emetic risk) or cisplatin (high emetic risk) and, therefore, should be given prophylactic antiemetics before the start of chemotherapy. The choice of drug lies between metoclopramide combined with dexametasone for some moderate emetic risk situations, and one of the $5HT_3$-receptor antagonists (granisetron, ondansetron, or palonosetron) for high-risk situations, with dexametasone to provide additional benefit. The monitoring of emesis and nausea both within and outside hospital for up to 5 days after treatment is a useful exercise in deciding which patients may need other therapies. It is also important to remember that patients should be given appropriate doses of antiemetics as rescue therapy to cover delayed-onset nausea.

Case 34.4

A hospital with a large number of surgical specialties, including major inpatient thoraco-abdominal and day care procedures, wishes to update its PONV programme.

Question

What principles for a PONV programme should be taken into account?

Answer

The programme should contain a PONV risk score which can be used in preoperation assessment. A simplified score has been devised, adding one point for each of the following: female gender, non-smoking status, history of PONV, and opioid use. In low-risk individuals scoring 0 or 1 (<10% risk), prophylactic antiemetic therapy is unnecessary. Moderate-risk subjects (score 1, risk 10–30%) may require single-agent antiemetic prophylaxis, while in high-risk subjects (score 3, risk 30–60%) two agents (one of them often dexametasone) may be needed if intravenous anaesthesia is not possible. In very high-risk subjects (score 4, risk > 60%), intravenous anaesthesia should be considered when possible and dexametasone and another antiemetic agent administered. PONV rescue therapy should be chosen depending on the post-operative clinical situation.

Respiratory infections 35

A. Robb and A. W. Berrington

Key points

- Oral cephalosporins have better clinical efficacy than penicillins in the treatment of streptococcal pharyngitis.
- There is controversy about whether otitis media should be treated with antibiotics or allowed to run its course.
- Viral respiratory tract infections are usually mild and self-limiting, but influenza and severe acute respiratory syndrome (SARS) can have severe consequences for individuals, for public health and for economic activity.
- Exacerbations of chronic bronchitis are not always infective in origin; antibiotics are used where appropriate but other therapeutic modalities are also valuable.
- *Streptococcus pneumoniae* remains the single most common cause of community-acquired pneumonia (CAP). Reduced susceptibility to penicillin can complicate the management of serious pneumococcal infections, but more significant degrees of resistance are currently not widespread among UK strains.
- CAP can be caused by a variety of pathogens, and this is reflected in the antimicrobial regimens recommended for initial treatment.
- There are many potential causes of hospital-acquired (nosocomial) pneumonia and each unit with patients at risk will have its own resident bacterial flora. This will strongly influence the choice of antibiotics for empiric therapy.
- *Pseudomonas aeruginosa* remains the most important respiratory pathogen in infections complicating cystic fibrosis; antibiotic treatment is targeted at this organism.
- Immunocompromised patients are at risk from a variety of opportunistic respiratory infections, for example, pneumocystis pneumonia in AIDS and invasive aspergillosis in neutropenic states.
- Health care-associated infections such as meticillin-resistant *Staphylococcus aureus* (MRSA) infection and *Clostridium difficile* infection (CDI) remain prevalent and should always be considered when choosing antibiotics.

Respiratory tract infections are the most common group of infections seen in the UK. Most are viral, for which (with some exceptions) only symptomatic therapy is available. In contrast, bacterial infections are a major cause of treatable respiratory illness.

The respiratory tract is divided into upper and lower parts: the upper respiratory tract consists of the sinuses, middle ear, pharynx, epiglottis and larynx, while the lower respiratory tract consists of the structures below the larynx, the bronchi, bronchioles and alveoli. Although there are anatomical and functional divisions both within and between these regions, infections do not always respect such boundaries. Nevertheless, it is clinically and bacteriologically convenient to retain a distinction between upper respiratory tract infections (URTIs) and lower respiratory tract infections (LRTIs).

Upper respiratory tract infections

Colds and flu

Viral URTIs causing coryzal symptoms, rhinitis, pharyngitis and laryngitis, and associated with varying degrees of systemic symptoms, are extremely common. These infections are usually caused by viruses from the rhinovirus, coronavirus, parainfluenza virus, respiratory syncytial virus, influenza virus and adenovirus families, although new viruses continue to be identified. For instance, in 2001, a novel respiratory pathogen was described that has become known as human *metapneumovirus* (hMPV). This causes a spectrum of respiratory illnesses particularly in young children, the elderly and the immunocompromised (Van Den Hoogen et al., 2001).

Colloquially, milder infections are called 'colds', while more severe infections may be known as 'flu'. This term should be distinguished from true influenza, reserved for infection caused by the influenza virus. In general, the management of these infections is symptomatic and consists of rest, adequate hydration, simple analgesics and antipyretics. Apart from one or two exceptional situations, antiviral drugs are not indicated and in most cases are not active. Antibacterial drugs have no activity against viral infections, although in the past they were widely prescribed, sometimes with spurious rationale such as prophylaxis against bacterial superinfection, sometimes simply because patients demanded them. In recent years, heightened awareness of the adverse consequences of antibiotic overuse has led to national campaigns aimed at discouraging the public from seeking antibiotic treatment for viral infections.

Influenza

True influenza is caused by one of the influenza viruses (influenza A, B or rarely C). It can be a serious condition characterised by severe malaise and myalgia and potentially complicated by life-threatening secondary bacterial infections such as staphylococcal pneumonia. Coryzal symptoms are not usually a feature of influenza, but the patient may have

545

a cough. Influenza tends to occur during the winter months, providing an opportunity to offer preventive vaccination in the autumn. In the UK, influenza vaccine is normally targeted at three groups:

- those at risk of severe infection, for example, people aged 65 years and over, and younger patients in special disease risk groups
- those living in long-stay care facilities in which the infection might spread particularly rapidly, and
- those in whom infection would be problematic for other reasons, such as carers and health care workers.

Unfortunately, the virus mutates so rapidly that the circulating strains tend to change from season to season, necessitating annual revaccination against the prevailing virus.

Influenza A and B infections are amenable to both prevention and treatment with neuraminidase inhibitors (NAIs) and include agents such as zanamivir and oseltamivir, although there is controversy about whether the benefits justify the costs involved. Zanamivir is administered by dry powder inhalation, whereas oseltamivir is given orally. Clinical trials on parenteral administration for use in individuals with life-threatening infections are underway.

National guidelines for the UK recommend NAIs should only be used when influenza is circulating in the community (which is carefully defined), and in patients who are both at risk of developing complications and can commence treatment within a defined time window of onset or exposure (NICE, 2008, 2009). Individuals at risk and eligible for treatment include those:

- with chronic lung disease including asthma and chronic obstructive pulmonary disease (COPD)
- with heart disease (excluding uncomplicated hypertension)
- with chronic kidney disease
- with diabetes mellitus
- with chronic liver disease
- with chronic neurological disease
- who might be immunosuppressed
- aged 65 years or older
- in long-term residential or nursing homes during local outbreaks.

The anti-Parkinsonian drug amantadine, which has activity against influenza A virus, is not recommended for the treatment or prophylaxis of influenza due to emergence of resistance and the high incidence of adverse effects.

Pandemics (or global epidemics) of influenza A occur around every 25 years and affect huge numbers of people. The 1918 'Spanish flu' pandemic is estimated to have killed 20 million people. Further pandemics have taken place in 1957–1958 (Asian flu), 1968–1969 (Hong Kong flu) and 1977 (Russian flu). An avian strain, H5N1, emerged in South East Asia in 2003 and is now considered endemic in many parts of South East Asia and remains a concern for public health (WHO, 2010).

The World Health Organisation declared a worldwide influenza pandemic in June 2009 following the emergence of a novel H1N1 strain of swine lineage. In the UK, NICE guidance was superseded during the pandemic and NAIs were given to all individuals with flu-like illness. A vaccine was also developed. Pandemic planning had been in operation for many years with plans for rapid vaccine development and stockpiling of antivirals. However, in retrospect, infections caused by the pandemic strain were generally associated with much milder disease than seen in previous pandemics, and some authorities have been accused of over-reaction.

The widespread use of NAIs during the 2009 pandemic brought its own problems. Resistance to oseltamivir emerged (Gulland, 2009), and some argued that the cure was worse than the disease (Strong et al., 2009). Further, a Cochrane review (Jefferson et al., 2009) found no good evidence that oseltamivir prevents secondary complications such as pneumonia, one of the main justifications for its widespread use in pandemic influenza. However, the relatively benign course of the 2009 pandemic should not provide false reassurance as to the risks associated with future pandemics.

Sore throat (pharyngitis)

Causative organisms

Pharyngitis is a common condition. In most cases, it never comes to medical attention and is treated with simple therapy directed at symptom relief. Many cases are not due to infection at all but are caused by other factors such as smoking. Where infection is the cause, most cases are viral and form part of the cold-and-flu spectrum. Epstein–Barr virus (EBV), which causes glandular fever (infectious mononucleosis), is a less common but important cause of sore throat since it may be confused with streptococcal infection.

The only common bacterial cause of sore throat is *Streptococcus pyogenes*, the Lancefield group A β-haemolytic streptococcus. Infrequent causes include β-haemolytic streptococci of groups C and G, *Arcanobacterium haemolyticum, Neisseria gonorrhoeae* and mycoplasmas. *Corynebacterium diphtheriae*, the cause of diphtheria, is rare in the UK but should be borne in mind when investigating travellers returning from parts of the world where diphtheria is common. *C. ulcerans* is as common a cause of clinical diphtheria in the UK as *C. diphtheriae* but usually runs a more benign course.

Clinical features

The presenting complaint is sore throat, often associated with fever and the usual symptoms of the common cold. It is standard teaching that sore throats of different aetiology cannot be distinguished clinically. Nevertheless, more severe cases are more likely to be caused by EBV or *S. pyogenes,* and in these patients, there may be marked inflammation of the pharynx with a whitish exudate on the tonsils, plus enlarged and tender cervical lymph nodes.

Group A streptococcal infection has a number of potential complications. Pharyngeal infection may occasionally give rise to disseminated infection elsewhere, but this is rare. More frequent accompaniments are otitis media, peritonsillar abscess and sinusitis. These should be distinguished from the non-suppurative complications of streptococcal infection,

rheumatic fever and glomerulonephritis, which are mediated immunologically. Occasional cases are still seen in the UK and remain important causes of renal and cardiac disease in developing countries. Scarlet fever, a toxin-mediated manifestation of streptococcal infection, is associated with a macular rash and sometimes considerable systemic illness.

In the UK, there has been a recent increase in rates of group A streptococcal infection. This includes invasive group A streptococcal infection (iGAS), associated with infection in normally sterile sites such as blood or tissue. The most common serotypes seen in England and Wales are *emm* 1, 3, and 89; *emm* 3 infections are associated with higher case fatality rates. The cause of the upsurge is unknown but may represent a natural periodic increase or alternatively excess transmission associated with high rates of influenza in 2008 (Lamagni et al., 2009).

Diagnosis

In most cases of pharyngitis, a bacteriological diagnosis cannot be made and thereby these are presumed to be viral in origin. The aim of any diagnostic procedure is to distinguish the streptococcal sore throat, which is amenable to antibiotic treatment, from viral infections, which are not. If a definite bacterial diagnosis is required, a throat swab should be taken for culture and, unless the details of a particular case prompt a search for more unusual organisms, culture techniques are directed towards detecting β-haemolytic streptococci. If bacterial culture is negative and glandular fever is suspected, blood should be taken for serological confirmation using either the non-specific 'monospot test' for atypical lymphocytes or specific tests for antibodies to EBV. Other viruses may be diagnosed by viral culture or serology, but this does not usually contribute to management. Rapid bedside tests are available that detect group A streptococcal antigens in the throat, but there are concerns about their sensitivity and specificity and they have not been widely introduced in the UK.

Treatment

Treatment of viral sore throat is directed at symptomatic relief, for example with rest, antipyretics and aspirin gargles. Streptococcal sore throat is usually treated with antibiotics although the extent to which they shorten the duration of symptoms and reduce the incidence of suppurative complications is modest (Del Mar et al., 2004). Antibiotic treatment also reduces the incidence of non-suppurative complications so is likely to be of greater benefit where these are common. There is also an argument that treating to eradicate streptococcal carriage might reduce the risk of relapse or later streptococcal infection at other sites.

Broadly, there are three treatment strategies:

1. give antibiotics to all patients with suspected streptococcal infection and do not investigate unless symptoms persist
2. give antibiotics to all patients with suspected streptococcal infection but stop them if a throat swab is negative, or
3. wait for throat swab culture results before starting antibiotics.

There is no correct approach and each has its advocates, although the problem of resistance has led to increasing pressure on prescribers to restrict empirical antibiotic use particularly for conditions such as pharyngitis that are frequently viral. The prevailing view is that antibiotics should not be routinely prescribed except where there is a high risk of severe infection, for instance, in immunocompromised patients (NICE, 2010).

Antibiotics effective against *S. pyogenes* include penicillins, cephalosporins and macrolides. Resistance to penicillins and cephalosporins has not (yet) been described in group A streptococci, although about 4% of isolates are resistant to erythromycin. Even against sensitive strains, macrolides such as erythromycin are demonstrably less effective than β-lactams.

Penicillins such as benzylpenicillin (penicillin G) or phenoxymethylpenicillin (penicillin V) have traditionally been regarded as the treatment of choice for streptococcal sore throat, but there is now convincing evidence that cephalosporins are more effective in terms of both clinical response and eradication of the organism from the oropharynx. This was summarised in a large meta-analysis of 40 studies in which 10-day courses of oral cephalosporins and penicillins were compared in the management of children with streptococcal pharyngitis (Casey and Pichichero, 2004). Bacteriological and clinical cure significantly favoured cephalosporins over penicillins, perhaps because penicillins are hydrolysed by β-lactamases produced by organisms such as anaerobes naturally resident in the oropharynx, whereas cephalosporins are not. The 10-day course length became accepted following earlier studies that compared the effect of different durations of penicillin treatment on bacteriological colonisation, but a recent systematic review (Atamimi et al., 2009) found comparable efficacy with shorter courses of newer antibiotics such as azithromycin.

However, despite the therapeutic superiority, it remains debatable whether the extra expense of cephalosporins is justified. Cefalexin is the preferred cephalosporin. Penicillin or amoxicillin is the preferred penicillin, with the proviso that amoxicillin and other aminopenicillins should not be used unless EBV infection is unlikely, since for reasons that are not understood, these drugs often cause skin rashes if used in this condition.

Acute epiglottitis

Acute epiglottitis is a rapidly progressive cellulitis of the epiglottis and adjacent structures. Local swelling has the potential to cause rapid-onset airway obstruction, so the condition is a medical emergency. Previously, almost all childhood cases and a high proportion of adult cases were caused by *Haemophilus influenzae* type b (Hib), with the rest being caused by other organisms such as pneumococci, streptococci and staphylococci. With the advent of routine vaccination against *H. influenzae* type b in October 1992, this disease has become uncommon.

The typical patient is a child between 2 and 4 years old with fever and difficulty speaking and breathing. The patient may

drool because of impaired swallowing. The diagnosis is made clinically and the initial management is concentrated upon establishing or maintaining an airway. This takes priority over all other diagnostic and therapeutic manoeuvres. Thereafter, the diagnosis may be confirmed by visualisation of the epiglottis, typically described as 'cherry-red'. Microbiological confirmation may be obtained by culturing the epiglottis and the blood, but not until the airway is secure.

In view of the high prevalence of amoxicillin resistance among encapsulated *H. influenzae*, the treatment of choice is a cephalosporin. It is customary to use a third-generation cephalosporin such as cefotaxime or ceftriaxone, but there is no reason why the infection should not respond to a second-generation agent such as cefuroxime. If a sensitive organism is recovered, high-dose parenteral amoxicillin may be substituted.

Otitis media

Causative organisms

Inflammation of the middle ear (otitis media) is a common condition seen most frequently in children under 3 years of age. Most cases are due to bacteria, although viruses such as influenza virus and rhinoviruses have been implicated in a sizeable minority. *S. pneumoniae* and *H. influenzae* are the two most commonly encountered bacterial pathogens. *Moraxella catarrhalis* and *S. pyogenes* account for a smaller proportion of cases, perhaps 10%, and other bacteria are seen only rarely.

Clinical features

Classically, otitis media presents with ear pain, which may be severe. If the drum perforates, the pain is relieved and a purulent discharge may follow. There may be a degree of hearing impairment plus non-specific symptoms such as fever or vomiting. Complications include mastoiditis (which is now rare), meningitis and, particularly in the case of *H. influenzae* infection, septicaemia and disseminated infection. With the advent of routine vaccination against *H. influenzae* type b, these complications have become uncommon.

Diagnosis

The diagnosis of otitis media is essentially made clinically and laboratory investigations have little role to play. Unless the drum is perforated, there is little sense in sending a swab of the external auditory canal, the results of which are likely to be unhelpful or misleading. For this reason, a causative organism is rarely isolated and treatment has to be given empirically.

Treatment

There has been much debate about whether or not antibiotics should be used for the initial treatment of acute otitis media. A meta-analysis combined seven clinical trials involving 2202 children and concluded that, although antibiotics confer a modest reduction in pain at 2–7 days, they do not reduce the incidence of short-term complications such as hearing problems and they do cause side effects (Glasziou et al., 2004). The benefit of antibiotic treatment may be greater in children under two than in older children (Damoiseaux et al., 2000), but in any case about 80% of cases treated without antibiotics will resolve spontaneously within 3 days. If antibiotic treatment is to be given, it should be effective against the three main bacterial pathogens: *S. pneumoniae*, *H. influenzae* and *S. pyogenes*. The streptococci are usually sensitive to penicillins, but these are much less active against *H. influenzae*, so the broader spectrum agents amoxicillin or ampicillin are preferred. These drugs have identical antibacterial activity, but amoxicillin is recommended for oral treatment since it is better absorbed from the gastro-intestinal tract. Patients with penicillin allergy may be treated with a later-generation cephalosporin (see later).

About 20% of *H. influenzae* strains are resistant to amoxicillin due to production of β-lactamase, so if there is no response to amoxicillin, an alternative agent should be chosen. Both erythromycin and the earlier oral cephalosporins such as cefalexin are insufficiently active against *H. influenzae* and should not be used. Alternatives include co-amoxiclav (a combination of amoxicillin and the β-lactamase inhibitor clavulanic acid) or an orally active later-generation cephalosporin such as cefixime. Cefuroxime axetil, while active *in vitro*, is poorly absorbed and often causes diarrhoea.

Pneumococcal conjugate vaccines, which are currently given routinely in the childhood vaccination schedule, may reduce the incidence of acute otitis media, although a recent review (Jansen et al., 2009) found only modest benefit. No benefit was found for influenza vaccination (Hoberman et al., 2003). Long-term antibiotic prophylaxis might have a role in some children (Leach and Morris, 2006), but any benefit has to be balanced against the risks.

Acute sinusitis

Causative organisms

Normally, the paranasal sinuses are sterile but they can become infected following damage to the mucous membrane which lines them. This usually occurs following a viral URTI but is sometimes associated with the presence of dental disease. Acute sinusitis is usually caused by the same organisms which cause otitis media, but occasionally other organisms such as *S. aureus*, viridans streptococci (a term used to describe α-haemolytic streptococci other than *S. pneumoniae*) and anaerobes may be found. Viruses are occasionally found in conjunction with the bacteria.

Clinical features

The main feature of acute sinusitis is facial pain and tenderness, often accompanied by headache and a purulent nasal discharge. Complications include frontal bone osteomyelitis, meningitis and brain abscess. The condition may become chronic with persistent low-grade pain and nasal discharge, sometimes with acute exacerbations.

Diagnosis

As with otitis media, this is a clinical diagnosis and obtaining specimens for bacteriological examination is not usually practicable. In patients with chronic sinusitis, therapeutic sinus washouts may yield specimens for microbiological culture.

Treatment

Since the causative organisms are the same as those found in otitis media, the same recommendations for treatment apply. Proximity to the mouth means that anaerobes are implicated quite frequently in acute sinusitis, particularly if associated with dental disease, and in such cases, the addition of metronidazole may be worthwhile. Amoxicillin/clavulanate (co-amoxiclav) has also demonstrated effectiveness. Doxycycline has proved popular due to its broad spectrum of activity and once-daily dosage.

Lower respiratory infections

Acute bronchitis and acute exacerbations of COPD

Bronchitis means inflammation of the bronchi. It is important to distinguish between acute bronchitis, which is usually, if not always, infective, and chronic bronchitis, which is a chronic inflammatory condition characterised by thickened, oedematous bronchial mucosa with mucus gland hypertrophy and usually caused by smoking. Chronic bronchitis often co-exists with emphysema, both of which lead to airflow limitation and the clinical syndrome of COPD.

The importance of chronic bronchitis is that it renders the patient more susceptible to acute infections and more likely to suffer respiratory compromise as a result. These acute exacerbations of COPD are a frequent cause of morbidity and admission to hospital. An exacerbation is defined as 'a sustained worsening of the patient's symptoms from his or her usual stable state that is beyond normal day-to-day variations, and is acute in onset' (NICE, 2004). Common symptoms include worsening breathlessness, cough, increased sputum production and change in sputum colour. It is important to remember that not all acute exacerbations of COPD have an infective aetiology since atmospheric pollutants are sometimes implicated.

Causative organisms

In otherwise healthy patients, the causes of acute bronchitis include viruses such as rhinovirus, coronavirus, adenovirus and influenza virus, and bacteria such as *Bordetella pertussis*, *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae* (formerly *Chlamydia pneumoniae*). The role of bacteria such as *S. pneumoniae* and *H. influenzae* is uncertain because these organisms are nasopharyngeal commensals and their isolation can be misleading, but there is a presumption that they account for at least a proportion of infections.

In patients with acute exacerbations of chronic bronchitis, sputum culture frequently yields potential pathogens such as *S. pneumoniae*, *H. influenzae* and *M. catarrhalis*. However, these organisms are also found in the sputum at much the same frequencies between exacerbations, so it is unclear to what extent (if at all) they play a pathogenic role. A considerable proportion of acute exacerbations is associated with viral infections such as colds or influenza, or might even be non-infective.

Clinical features

The characteristic feature of acute bronchitis is a cough productive of purulent sputum, that is, phlegm that is yellow or green, the colour reflecting the presence of pus cells, sometimes with wheezing and breathlessness. In patients with pre-existing lung disease, the lack of reserve may lead to respiratory compromise, which in turn may exacerbate, or be exacerbated by, cardiac failure. Sometimes, the condition progresses to frank bronchopneumonia (see later), although the dividing line between a severe exacerbation of COPD and bronchopneumonia is often unclear.

Diagnosis

The diagnosis of acute bronchitis or acute exacerbation of COPD is made clinically and does not depend on the results of investigations. If antibiotics are to be given, a sputum sample should be sent for bacteriology, as this will allow antibiotic sensitivity tests to be performed on potential pathogens. However, the decision to treat should not be based on the results of sputum culture alone.

Treatment

Younger patients without pre-existing respiratory disease are likely to recover rapidly and might not require specific treatment. For more severe cases, including exacerbations of COPD, the two main arms of treatment are airflow optimisation and antibiotic therapy. Airflow optimisation consists of physiotherapy to aid expectoration of secretions, adjunctive oxygen if appropriate, bronchodilators and sometimes short-course corticosteroids. In severe cases, a period of artificial ventilation may be required, an intervention which has become more common with the advent of non-invasive ventilation techniques.

Despite the reservation that many cases are non-infective, current guidelines recommend that antibiotics are prescribed when an exacerbation is associated with more purulent sputum (NICE, 2004). There is no unequivocal evidence that one antibiotic is better than another, so recommendations for empiric treatment are based generally upon spectrum, side effects and cost. Most authorities favour either a tetracycline such as doxycycline or an aminopenicillin such as amoxicillin, since these agents cover most strains of *S. pneumoniae* and *H. influenzae*. Some people argue in favour of co-amoxiclav, which covers β-lactamase producing strains of *H. influenzae*

and *M. catarrhalis* that are therefore resistant to amoxicillin, but this agent is more expensive and has a greater incidence of side effects. For penicillin-allergic patients for whom tetracyclines are contraindicated, neither the macrolide erythromycin nor the earlier oral cephalosporins such as cefalexin or cefradine are sufficiently active against *H. influenzae* for empiric use. However, both clarithromycin and newer oral cephalosporins such as cefixime are active against haemophili while retaining activity against pneumococci.

The following recommendations can be made for the empiric antibiotic treatment of acute bronchitis and exacerbations of COPD. If a plausible pathogen is isolated, treatment can be modified accordingly.

First-line agents

- Doxycycline
- Amoxicillin

Second-line agents

- Co-amoxiclav
- Clarithromycin
- Cefixime

A number of other drugs are promoted for the treatment of COPD exacerbations. Of these, azithromycin is not recommended, as it is less active than clarithromycin against *S. pneumoniae*. The activity of ciprofloxacin against *S. pneumoniae* is insufficient to justify its use as monotherapy against pneumococcal infections (although it has useful activity against *H. influenzae* and *M. catarrhalis*), and levofloxacin (which is the active isomer of ofloxacin) does not seem to offer any great microbiological advantage. Moxifloxacin is a quinolone that retains activity against Gram-negative organisms such as *Haemophilus* and *Moraxella* but has greater activity against Gram-positives such as *S. pneumoniae*. It has been favourably compared to standard treatment in exacerbations of COPD (Wilson et al., 2004). However, its use has been limited by the high incidence of *Clostridium difficile* infection (CDI) associated with quinolone use, and rarely the development of life-threatening hepatic toxicity.

Bronchiolitis

Bronchiolitis is characterised by inflammatory changes in the small bronchi and bronchioles, but not by consolidation. It is particularly recognised as a disease of infants in the first year of life, in whom a small degree of airway narrowing can have a dramatic effect on airflow, but the causal organisms are equally capable of infecting adults, who may then act as reservoirs of infection. Most cases are caused by respiratory syncytial virus (RSV), which occurs in annual winter epidemics, but hMPV, parainfluenzaviruses, rhinoviruses, adenoviruses and occasionally *M. pneumoniae* have also been implicated.

Bronchiolitis is characterised by a prodrome of fever and coryzal symptoms which progresses to wheezing, respiratory distress and hypoxia of varying degrees. Aetiological confirmation may be made by immunofluorescence and/or viral culture of respiratory secretions, although increasingly the diagnosis of respiratory syncytial virus is made using rapid antigen detection tests.

The treatment of bronchiolitis is mainly supportive and consists of oxygen, adequate hydration and ventilatory assistance if required. Severe cases of respiratory syncytial virus disease may be treated with ribavirin, a synthetic nucleoside administered by nebuliser. There is limited evidence for its efficacy and it is currently only recommended for use in immunocompromised patients to reduce the duration of viral shedding (Yanney and Vyas, 2008).

Babies born earlier than 35 weeks of gestation or those less than 6 months of age at the onset of the respiratory syncytial virus season are at high risk of the disease. Likewise, infants under two years of age with chronic lung disease or severe immunodeficiency, or under 6 months of age with congenital heart disease are similarly at high risk, and all are candidates for prophylactic treatment with palivizumab. This is a humanised monoclonal antibody used for passive immunisation against respiratory syncytial virus (JCVI, 2005). There is currently no vaccine against RSV.

Pneumonia

Pneumonia is defined as inflammation of the lung parenchyma, that is, of the alveoli rather than the bronchi or bronchioles, of infective origin and characterised by consolidation. Consolidation is a pathological process in which the alveoli are filled with a mixture of inflammatory exudate, bacteria and white blood cells that on chest X-ray appear as an opaque shadow in the normally clear lungs.

A wide range of organisms can cause pneumonia, so it is useful to apply some kind of classification system, at least until the aetiology of a particular case has been determined. Pneumonia is often classified clinically into lobar pneumonia, bronchopneumonia or atypical pneumonia, but this does not correlate entirely with the bacteriological cause and in any case the distinctions are often blurred. It is more practical to classify pneumonia according to the nature of its acquisition, the usual terms being community-acquired pneumonia (CAP) and hospital-acquired pneumonia (HAP).

Community-acquired pneumonia

Causative organisms. The causes of CAP are summarised in Table 35.1. The most common vegetative bacterial causes are *S. pneumoniae*, the pneumococcus, which can cause both lobar and bronchopneumonia, and non-capsulate strains of *H. influenzae* which usually give rise to bronchopneumonia.

The so-called atypical pneumonias are a heterogeneous group of diseases which nevertheless have several clinical features in common and which are clinically distinct from the classic picture of pneumococcal pneumonia. Aetiological agents include *Legionella pneumophila, M. pneumoniae, C. pneumoniae, Chlamydophila psittaci, Coxiella burnetii* and viruses. *L. pneumophila* is the cause of Legionnaire's disease which occurs sporadically and in outbreaks often associated with contaminated air-conditioning or water systems. From 2002 to 2008, there were 300–600 new cases a year reported in England and Wales.

Table 35.1 Causes of community-acquired pneumonia

Organism	Comments
Streptococcus pneumoniae	Classically causes lobar pneumonia, bronchopneumonia now common
Haemophilus influenzae	Cause of bronchopneumonia, usually non-capsulate strains
Staphylococcus aureus	Severe pneumonia with abscess formation, typically following influenza
Klebsiella pneumoniae	Friedlander's bacillus, causing an uncommon but severe necrotising pneumonia
Legionella pneumophila	Particularly serogroup 1; causes Legionnaire's disease, usually acquired from aquatic environmental sources
Mycoplasma pneumoniae	Cause of acute pneumonia in young people, respiratory symptoms often overshadowed by systemic upset
Chlamydophila pneumoniae	Mild but prolonged illness usually seen in older people, respiratory symptoms often overshadowed by systemic upset
Chlamydophila psittaci	Causes psittacosis, a respiratory and multisystem disease acquired from infected birds
Coxiella burnetii	Causes Q fever, a respiratory and multisystem disease acquired from animals such as sheep
Viruses	Several viruses can cause pneumonia in adults, including influenza, parainfluenza and varicella zoster viruses

Legionnaire's disease may be rapidly progressive with very extensive consolidation and consequent respiratory failure.

Viral infections should not be forgotten as causes of pneumonia, although in practice it is unusual to make a definitive early diagnosis, so most cases are treated with antibacterials. Influenza can cause a primary viral pneumonia as well as be complicated by secondary bacterial (particularly staphylococcal) pneumonia, chickenpox can be complicated by primary varicella pneumonia particularly in adults, and cytomegalovirus is capable of causing a variety of infections, including pneumonia, in patients with compromised cell-mediated immunity.

Clinical features. Pneumococcal lobar pneumonia presents with a cough, initially dry but later producing purulent or blood-stained, rust-coloured sputum, together with dyspnoea, fever and pleuritic chest pain. The peripheral white blood cell count is usually raised and the patient may be bacteraemic. The chest X-ray shows consolidation confined to one or more lobes (or segments of lobes) of the lungs. This classic picture is now quite rare perhaps because the early use of antibiotics modifies the natural history of the disease.

Bronchopneumonia presents more non-specifically with productive cough and breathlessness, and patchy consolidation on the chest X-ray usually in the bases of both lungs. This disease is very common and is typically seen in patients with severe COPD or in those who are frail and terminally ill. In fact, pneumonia has been described as the old man's friend because it is a relatively painless cause of death.

The atypical pneumonias are characterised clinically by fever, systemic symptoms and a dry cough, radiologically by widespread patchy consolidation in both lungs and biochemically by abnormalities in liver enzymes and perhaps evidence of inappropriate antidiuretic hormone secretion, evident as a low plasma sodium.

Despite the differences described, clinical features alone are not usually sufficient to make a confident bacteriological diagnosis, a fact that has major implications for the empirical treatment of pneumonia.

Diagnosis. Sputum culture is the mainstay of diagnosis for pneumonia caused by pneumococci and *H. influenzae*. Sputum microscopy is unreliable because oropharyngeal contaminants are often indistinguishable from pathogens. The success of sputum culture is very dependent upon the quality of the specimen, which may be inadequate either because the patient is unable to expectorate or because the nature of the disease is such that sputum production is not a major feature. A more sensitive (although more invasive) technique is to perform bronchoscopy and bronchoalveolar lavage. Lavage fluid, being uncontaminated by mouth flora, is suitable for microscopy as well as culture.

In pneumococcal disease, blood cultures are frequently positive and national guidance (Lim et al., 2009) suggests that laboratories should also offer plasma and urine testing for pneumococcal antigen. *Legionella* infection may be diagnosed by culture (if appropriate media are used) or by urinary antigen testing, but culture of *Mycoplasma* and *Chlamydophila* species is beyond the scope of most routine diagnostic laboratories. Viruses may be detected by immunofluorescence, by viral culture or by polymerase chain reaction (PCR), but timely diagnosis requires a good specimen such as bronchoalveolar lavage fluid. In practice, the aetiology of atypical pneumonia is usually determined serologically (for instance, by acute and convalescent antibody testing), if at all.

Targeted treatment. The treatment of choice for pneumococcal pneumonia is benzylpenicillin or amoxicillin. Erythromycin monotherapy may be used in penicillin-allergic patients, but resistance rates are rising, macrolides are bacteriostatic rather than bactericidal and the comparative efficacy of this approach is not known. There is retrospective evidence that combination therapy using both a β-lactam and a macrolide can reduce mortality in patients whose pneumonia is complicated by pneumococcal bacteraemia (Martinez et al., 2003).

Pneumococci with reduced susceptibility to penicillin are becoming increasingly common, particularly in continental Europe and the USA. In the UK, about 5–10% of strains express 'intermediate susceptibility' (minimum inhibitory concentration; MIC 0.1–1 mg/L), but high-level resistance (MIC >1 mg/L) remains uncommon. Intermediate susceptibility may result in treatment failure in conditions such as

otitis media or meningitis, infections at sites where antibiotic penetration is reduced, but antibiotic penetration into the lungs is sufficiently good that penicillin and amoxicillin remain effective for pneumonia. Strains expressing high-level resistance are unlikely to respond to penicillins, however. Such strains are often co-resistant to macrolides and other first-line agents, and may require treatment with a later-generation cephalosporin or a glycopeptide.

The sensitivity of *H. influenzae* to antibiotics has been discussed above. Amoxicillin is the agent of choice, with co-amoxiclav, parenteral cefuroxime, cefixime or ciprofloxacin as alternatives. Erythromycin is poorly active, but the newer macrolide clarithromycin and the azalide azithromycin possess more activity.

M. pneumoniae does not possess a cell wall and is therefore not susceptible to β-lactam agents. A tetracycline or a macrolide are suitable alternatives. Tetracyclines are also effective against *C. pneumoniae, C. psittaci* and *C. burnetii*, but erythromycin is probably less effective. Quinolones are also highly active against these organisms.

Staphylococcal pneumonia is usually treated with flucloxacillin plus a second agent such as rifampicin or fusidic acid, although there is no good clinical evidence that combination treatment is better than a single agent. MRSA (meticillin-resistant *S. aureus*) pneumonia is being seen more commonly in the community as well as in hospital. Strains of *S. aureus* expressing Panton-Valentine Leukocidin, an exotoxin, are capable of causing a severe necrotising pneumonia and if clinically suspected should warrant urgent critical care and specialist microbiological input.

Treatment recommendations for Legionnaire's disease are based on a retrospective review of the famous Philadelphia outbreak of 1976 (Fraser et al., 1977), in which two deaths occurred among the 18 patients who were given erythromycin, compared to 16 deaths in 71 patients treated with penicillin or amoxicillin. This observation accords with the facts that *Legionella* is an intracellular pathogen and that macrolides penetrate more efficiently than β-lactams into cells. Azithromycin is probably the most effective of the macrolide/azalide derivatives, but clinical evidence to confirm this is lacking. Other agents with proven clinical efficacy and good intracellular activity against *Legionella* include rifampicin and quinolones. There have been no randomised controlled clinical trials, nor are there likely to be. Guidance, based on observation studies, suggests non-severe cases should be treated with an oral fluoroquinolone (with a macrolide as an alternative), and severe cases treated with a combination of a fluoroquinolone plus either a macrolide or rifampicin, de-escalating to a fluoroquinolone as the sole agent after the first few days (Lim et al., 2009). Treatment is not recommended for the non-pneumonic form of legionellosis (Pontiac fever) which presents as a self-limiting flu-like illness.

Empiric treatment. All of the foregoing recommendations presuppose that the infecting organism is known before treatment is commenced. In practice, this is rarely the case and therapy will initially be empirical or best-guess in nature (Table 35.2). The most authoritative recommendations for the initial treatment of CAP are those produced by the British

Thoracic Society (Lim et al., 2009). For mild disease, these recommend treatment with amoxicillin, providing activity against pneumococci and most strains of *H. influenzae*, with doxycycline or clarithromycin being the preferred alternatives in penicillin-allergic patients. However, for moderate or severe disease requiring admission to hospital, they take the view that, until the aetiology is known, treatment should cover both 'typical' causes (such as *S. pneumoniae* and *H. influenza*) and atypical causes (such as *M. pneumoniae*, *Chlamydophila* species and *Legionella*). For patients with moderate or severe CAP, the guidelines therefore recommend a combination of a β-lactam drug plus a macrolide, the exact choice of agent and route being decided according to the clinical severity of the infection. In practice, this is usually interpreted as amoxicillin plus a macrolide for less severe disease, and co-amoxiclav plus a macrolide (or cefuroxime plus a macrolide) for more severe disease. Severity is assessed according to clinical parameters and outcome predicted by use of one of a number of assessment tools such as CURB-65, based on the onset of *C*onfusion, the serum *U*rea, the *R*espiratory rate, the *B*lood pressure and age >65 years.

Moxifloxacin, a newer fluoroquinolone, is licensed in the UK for treatment of non-severe pneumonia where other antibiotics cannot be used. Currently, it is licensed only in oral form.

Pressure to treat pneumonia (much of which is pneumococcal and would respond to penicillin) with broad-spectrum empiric regimens, in particular, with cephalosporins and fluoroquinolones, has been cited as a factor in the rising incidence of *Clostridium difficile* and MRSA infections. The treatment of pneumonia illustrates many of the dilemmas and conflicting priorities of modern antimicrobial prescribing.

Prevention. Pneumococcal 23-valent polysaccharide vaccine and influenza vaccine should be offered to all those at risk of infection. For pneumococcal infection, this includes patients who fulfil the following criteria:

- asplenia or dysfunction of the spleen
- chronic respiratory disease
- chronic heart disease
- chronic renal disease
- chronic liver disease
- diabetes
- immunosuppressed
- aged 65 years or older
- cochlear implants
- cerebrospinal fluid leaks.

Hospital-acquired (nosocomial) pneumonia

Causative organisms. The most frequent causes of HAP are Gram-negative bacilli (Enterobacteriaceae, *Pseudomonas* spp. and *Acinetobacter* spp.) and *S. aureus*, including MRSA (Box 35.1). However, it is important to remember that pneumococcal pneumonia may develop in hospitalised patients and also that hospital water supplies have been implicated in outbreaks and sporadic cases of *Legionella* infection. Further, it must be recognised that the common Gram-negative causes of nosocomial pneumonia will vary between

Table 35.2 Treatment of community-acquired pneumonia

Scenario	Typical regimen	Comments
Mild to moderate pneumonia, organism unknown	Amoxicillin plus a macrolide	Amoxicillin covers *S. pneumoniae* and most *H. influenzae* while macrolide provides cover against atypical pathogens. It is debatable whether clinical outcomes are improved by using antibiotics active against atypical pathogens in all-cause non-severe community-acquired pneumonia
Severe pneumonia, organism unknown	Co-amoxiclav plus a macrolide Cefuroxime plus a macrolide in penicillin allergy	Co-amoxiclav and cefuroxime provide cover against *S. aureus*, coliforms and β-lactamase producing haemophili while retaining the pneumococcal cover of amoxicillin
Pneumococcal pneumonia	Penicillin or amoxicillin or a macrolide	High-level penicillin resistance remains uncommon in the UK.
H. influenzae	Non-β-lactamase producing: amoxicillin β-lactamase producing: cefuroxime or co-amoxiclav	Also sensitive to quinolones
Staphylococcal pneumonia	Non-MRSA: flucloxacillin +/– a second agent such as rifampicin or fusidic acid MRSA: requires microbiology input, options include linezolid or glycopeptides	Isolation of *S. aureus* from sputum may reflect contamination with oropharyngeal commensals and should be interpreted cautiously. MRSA pneumonia may also be treated with linezolid
Mycoplasma pneumoniae	Macrolide or tetracycline	Treat for 14 days
Chlamydophila spp.	Tetracycline preferred	Treat for 14 days
Legionella spp.	A fluoroquinolone such as ciprofloxacin. A macrolide such as clarithromycin is an alternative if intolerant.	Addition of a macrolide or rifampicin in severe cases

Box 35.1 Causes of hospital-acquired pneumonia

Common organisms
1. Gram-negative bacteria:
   Pseudomonas aeruginosa
   E. coli
   Klebsiella spp.
2. Gram-positive bacteria:
   S. pneumoniae
   S. aureus including MRSA

Less common organisms
1. Other 'coliforms' such as *Enterobacter* spp., *Serratia marcescens*, *Citrobacter* spp., etc.
   Acinetobacter spp.
   Other *Pseudomonas* and related species, such as
   S. maltophilia
   L. pneumophila (and other species)
2. Anaerobic bacteria
3. Fungi:
   Candida albicans (and other species)
   Aspergillus fumigatus (particularly following prolonged episodes of neutropenia)
4. Viruses:
   Cytomegalovirus
   Herpes simplex virus

hospitals and even between different units within the same hospital. This is especially true of ventilator-associated pneumonia, which for obvious reasons is usually acquired on intensive care units where broad-spectrum antibiotics are frequently used, and where there may be a particular 'resident flora' with an established antibiotic resistance pattern.

Clinical features. Nosocomial pneumonia accounts for 10–15% of all hospital-acquired infections, usually presenting with sepsis and/or respiratory failure. Up to 50% of cases are acquired on intensive care units. Predisposing features include stroke, mechanical ventilation, chronic lung disease, recent surgery and previous antibiotic exposure.

Diagnosis. Sputum is commonly sent for culture but is sometimes unhelpful as it may be contaminated by mouth flora. If the patient has received antibiotics, the normal mouth flora is often replaced by resistant organisms such as staphylococci or Gram-negative bacilli, making the interpretation of culture results difficult. Bronchoalveolar lavage is often more helpful. Blood cultures may be positive.

Treatment. The range of organisms causing nosocomial pneumonia is very large, so broad-spectrum empiric therapy is indicated. The choice of antibiotics will be influenced by preceding antibiotic therapy, the duration of hospital admission and above all by the individual unit's

Table 35.3 Treatment regimens for hospital-acquired pneumonia (HAP)

Regimen	Comments
Co-amoxiclav	Good activity against community-associated pathogens, many Enterobacteriaceae and *S. aureus*. Recommended for early-onset HAP (within 5 days of admission) in antibiotic naïve patients without other risk factors
Ureidopenicillin plus aminoglycoside (e.g. piperacillin plus gentamicin)	Good activity against Gram-negative bacilli such as *P. aeruginosa* and also against pneumococci. Combination of piperacillin with the β-lactamase inhibitor tazobactam, currently the only ureidopenicillin product marketed in the UK, extends the spectrum to include *S. aureus* (not MRSA), anaerobes and some strains of *E. coli, Klebsiella*, etc. that are resistant to piperacillin alone. Piperacillin-tazobactam can also be used reliably as monotherapy
Cephalosporin plus an aminoglycoside (e.g. cefuroxime plus gentamicin)	Good activity against Gram-negative bacilli such as *E. coli, Klebsiella*, and Gram-positive organisms, but poor against *P. aeruginosa* and anaerobes
Clindamycin plus aminoglycoside	Good activity against Gram-positive organisms and anaerobes but much less so against Gram-negatives. Favoured in the USA where metronidazole is unpopular for the treatment of anaerobic infections
Ciprofloxacin plus glycopeptide (vancomycin or teicoplanin)	Ciprofloxacin provides good activity against most Gram-negative bacilli including *P. aeruginosa*. Glycopeptide provides activity against *S. aureus* (including MRSA) and pneumococci, although its penetration into the respiratory tract is relatively poor
Meropenem (monotherapy)	Broad-spectrum agent including activity against Extended Spectrum Beta Lactamase (ESBL) producing Enterobacteriaceae. Not active against MRSA. Ertapenem does not cover *Pseudomonas* spp. or *Acinetobacter* spp. so is unsuitable
Linezolid combinations	It is increasingly necessary to cover MRSA in empiric or targeted treatment of hospital-acquired pneumonia. Traditional options include glycopeptides and, where the prevailing strains are sensitive, aminoglycosides, but there are concerns about penetration into the lung. Linezolid, an oxazolidinone, provides reliable activity
Aztreonam combinations	Good activity against gram-negative bacilli Including *Pseudomonas* but offers no activity against anaerobic or Gram-positive organisms. Expensive. A β-lactam agent that can be used safely in patients with history of severe penicillin allergy
Temocillin	Excellent activity against Gram-negative organisms including ESBL-producing Enterobacteriaceae. No activity against Gram-positive organisms and *Pseudomonas*
Ceftazidime (monotherapy)	Very active against Gram-negative bacilli including *Pseudomonas* but less so against Gram-positive organisms and anaerobes. Due to the high incidence of *Clostridium difficile* infection and selection of multi-resistant organisms associated with its use, this agent has largely been superseded by other newer agents

experience with hospital bacteria. The combinations shown in Table 35.3 have all been used at some time and all have advantages and disadvantages. Several of the combinations include an aminoglycoside, and this may not be desirable in all patients. Single-agent therapy is attractive for ease of administration, and agents such as piperacillin-tazobactam and meropenem have suitably broad spectra that include activity against *P. aeruginosa*. Currently licensed β-lactam agents are inactive against MRSA infections; in such cases specialist management advice is required.

In all cases, a macrolide would be added if Legionnaire's disease was suspected and, if not already covered by the regimen, metronidazole would be required for suspected anaerobic infection.

Prevention. General strategies for minimising the incidence of HAP include early postoperative mobilisation, analgesia, phys-iotherapy and promotion of rational antibiotic prescribing. The Department of Health's Saving Lives programme makes specific recommendations for the prevention of ventilator-associated pneumonia (DoH, 2007), including head of bed elevation, sedation holding to reduce the duration of mechanical ventilation and good general hygiene of tubing management and suction.

Another strategy proposed for the prevention of ventilator-associated pneumonia is selective decontamination of the digestive tract (SDD), based on the premise that the infecting organisms initially colonise the patient's oropharynx or intestinal tract (Kallett and Quinn, 2005). By administering non-absorbable antibiotics such as an aminoglycoside or colistin to the gut, and applying a paste containing these agents to the oropharynx, it is proposed that the potential causative organisms will be eradicated and the incidence of pneumonia

thereby reduced. In some centres, an antifungal agent such as amphotericin B is added; others also advocate addition of a systemic broad-spectrum agent such as cefotaxime.

The role of selective decontamination of the digestive tract remains controversial. Recent guidelines (Masterton et al., 2008) recommend its consideration in patients in whom mechanical ventilation is anticipated for more than 48 h. Whether any benefits really outweigh the risks is unclear.

Another suggestion is prophylactic administration of aerosolised antibiotics to ventilated patients (and perhaps other patients at risk). Agents suitable for aerosolised delivery and with the appropriate antimicrobial spectrum include aminoglycosides (particularly tobramycin) and the polymyxin drug colistin. There are no published data available at present and therefore this approach cannot be universally recommended.

Aspiration pneumonia

One further condition which may be seen either in hospital or in the community is aspiration pneumonia, initiated by inhalation of stomach contents contaminated by bacteria from the mouth. Risk factors include alcohol, hypnotic drugs and general anaesthesia, all of these being factors that may make a patient vomit while unconscious. Gastric acid is very destructive to lung tissue and leads to severe tissue necrosis. Damaged tissue is then prone to secondary infection often with abscess formation. Anaerobic bacteria are particularly implicated, but these are often accompanied by aerobic organisms such as viridans streptococci. Treatment with metronidazole plus amoxicillin is usually adequate, but broader spectrum drugs may be used if there are reasons to suspect Gram-negative involvement, for instance, if the patient has been in hospital or previously exposed to antibiotics.

Severe acute respiratory syndrome

Severe acute respiratory syndrome (SARS) is caused by a coronavirus (SARS-associated coronavirus or SARS CoV). Clinically it causes pneumonitis, presenting with a flu-like prodrome and progressing to dyspnoea, dry cough and often adult respiratory distress syndrome, requiring ventilatory support. Treatment is largely supportive. It was first described in 2003 (Drosten et al., 2003) after a large outbreak originating in China spread throughout the Americas, Europe and Asia. The outbreak terminated in that year, with only small numbers of cases occurring since. Many experts predict that SARS will re-emerge.

Cystic fibrosis

Cystic fibrosis (CF) is an inherited, autosomal recessive disease which at the cellular level is due to a defect in the transport of ions in and out of cells. This leads to changes in the consistency and chemical composition of exocrine secretions, which in the lungs is manifest by the production of very sticky, tenacious mucus which is difficult to clear by mucociliary action. The production of such mucus leads to airway obstruction with resulting infection. Repeated episodes of infection lead eventually to bronchiectasis and permanent lung damage, which in turn predisposes the patient to further infection.

Infecting organisms

In infants and young children, *S. aureus* is the most common pathogen. *H. influenzae* is sometimes encountered, but from the age of about 5 years onwards *P. aeruginosa* is seen with increasing frequency until, by the age of 18, most patients are chronically infected with this organism, which once present is never completely eradicated. An important feature of those *P. aeruginosa* strains which infect patients with cystic fibrosis is their production of large amounts of alginate, a polymer of mannuronic and glucuronic acid. This seems to be a virulence factor for the organism in that it inhibits opsonisation and phagocytosis and enables the bacteria to adhere to the bronchial epithelium, thus inhibiting clearance. It does not confer additional antibiotic resistance. Strains which produce large amounts of alginate have a wet, slimy appearance on laboratory culture media and are termed 'mucoid' strains.

Occasionally, other Gram-negative bacteria are seen, such as *Escherichia coli*, which interestingly may also produce alginate in these patients, a characteristic which is otherwise very rare, or *Stenotrophomonas maltophilia*. Many centres worldwide have also experienced problems with members of the *Burkholderia cepacia* complex, which previously were known as plant pathogens. The most frequent culprits are *B. cenocepacia* (formerly *B. cepacia* genomovar III) and *B. multivorans* (formerly *B. cepacia* genomovar II). These organisms are often exceptionally resistant to antibiotics, and their acquisition may be associated with rapidly progressive respiratory failure. Patients colonised with *P. aeruginosa* and *B. cepacia* complex should be isolated to prevent transmission to other CF patients.

Clinical features

CF is characterised by persistent cough and copious sputum production. Many patients are chronically breathless. At times, acute exacerbations occur in which there is fever, increased cough with purulent sputum and increased dyspnoea. Systemic sepsis, however, is very rare. Eventually, chronic pulmonary infection leads to respiratory insufficiency, cardiac failure and death.

Treatment

Although this section will concentrate on antibiotic therapy, it should not be forgotten that other means of treatment such as physiotherapy play a vital part, while lung transplantation can be life saving. Even regarding antibiotics, there are fundamental questions that remain to be addressed; for instance, it is not known whether it is best to give antibiotics according to a planned, regular schedule or in response to exacerbations, and practice varies.

The treatment of infection in a child with cystic fibrosis will probably be directed against staphylococci, for which the usual anti-staphylococcal antibiotics such as flucloxacillin or erythromycin can be used. Once the patient is colonised by *P. aeruginosa*, treatment depends on early and vigorous therapy with antipseudomonal antibiotics (see Table 35.4). At first isolation of *P. aeruginosa*, eradication is attempted with oral ciprofloxacin and a nebulised antibiotic such as colistin.

Table 35.4 Antipseudomonal antibiotics

Antibiotic	Comment
Ticarcillin	One of the first β-lactam agents effective against *Pseudomonas* but now considered insufficiently active. In combination with the β-lactamase inhibitor clavulanic acid, it may be active against some otherwise resistant strains
Ureidopenicillins	Piperacillin, formulated in combination with the β-lactamase inhibitor tazobactam, is the only one of these agents now available in the UK
Monobactams	Aztreonam offers good activity against Gram-negative organisms but no activity against Gram-positive organisms
Cephalosporins	Ceftazidime is the most active antipseudomonal cephalosporin and is very active against other Gram-negative bacilli. It has rather lower activity against Gram-positive bacteria. *Pseudomonas* may develop resistance during treatment
Aminoglycosides	Gentamicin and tobramycin have very similar activity against *Pseudomonas*; tobramycin is perhaps slightly more active. Netilmicin is less active, while amikacin may be active against some gentamicin-resistant strains
Quinolones	Ciprofloxacin can be given orally and parenterally but as with ceftazidime, resistance can develop while the patient is on treatment. Other quinolones such as ofloxacin, its L-isomer levofloxacin, and moxifloxacin have better Gram-positive spectrum but concomitantly less activity against *Pseudomonas*
Polymyxins	These peptide antibiotics are considered too toxic for systemic use in all but the most desperate cases, but colistin (polymyxin E) can be given by inhalation
Carbapenems	Broad-spectrum agents with good Gram-negative activity. Imipenem was the first of these drugs, but CNS toxicity and its requirement for combination with the renal dipeptidase inhibitor cilastatin have largely led to its replacement by meropenem. Doripenem is a newer carbapenem with similar activity to meropenem. Ertapenem has poor activity against *P. aeruginosa*

For chronically colonised patients, regular prophylactic intravenous treatment is given with a β-lactam/aminoglycoside combination such as ceftazidime plus tobramycin. Agents such as meropenem or a quinolone are usually reserved for treatment failures or when resistant organisms are encountered. The prolonged use of ceftazidime or ciprofloxacin alone should be avoided if possible since strains of *P. aeruginosa* and some other Gram-negative bacilli may become resistant to these agents while the patient is receiving treatment. Other treatment modalities are emerging: in a multi-centre, randomised controlled trial, long-term low-dose azithromycin was associated with improvements in lung function in patients chronically infected with *P. aeruginosa* (Saiman et al., 2003).

Interestingly, patients with cystic fibrosis have a more rapid clearance of some antibiotics than other patients. This is particularly noticeable with the aminoglycosides and larger doses are often required to achieve satisfactory plasma levels.

Children with cystic fibrosis are admitted to hospital very frequently, sometimes for long periods of time, and it is not surprising that some of these children develop an intense dislike of hospitals. This has encouraged the use of long-term indwelling central venous cannulae to allow administration of intravenous antibiotics at home by the parents. Ciprofloxacin can be given orally and offers the possibility of treatment for less severe exacerbations at home, perhaps after a brief time in hospital for parenteral therapy.

B. cepacia is often very difficult to treat and strains may be resistant to all available antibiotics. Under these circumstances, combination therapy is often used.

There is some evidence that *in vitro* resistance in some Gram-negative organisms such as *P. aeruginosa* and *B. cepacia* complex does not correlate with treatment failure in the patient.

The use of inhaled (usually nebulised) antibiotics as an adjunct to parenteral therapy has attracted attention, both for treatment of acute exacerbations and for longer-term use in an attempt to reduce the *Pseudomonas* load. Agents which have been administered in this way include colistin, tobramycin and other aminoglycosides, carbenicillin and ceftazidime. The best evidence that long-term administration can be beneficial comes from a large multi-centre trial of nebulised tobramycin (Moss, 2001) in which 520 patients were randomised to receive once-daily nebulised tobramycin or placebo in on–off cycles for 24 weeks, followed by open-label tobramycin to complete 2 years of study. Nebulised tobramycin was safe and well tolerated and was associated with a reduction in hospitalisation and improvements in lung function. This was at the expense of a degree of tobramycin resistance, although this did not seem to be clinically significant.

Respiratory infection in the immunocompromised

The increased use of immunosuppressive agents, and to a lesser extent, the spread of HIV infection, has led to increasing numbers of immunocompromised individuals. Respiratory tract infections, in general, and pneumonia, in particular, are

Table 35.5 Basic causes, defects and infections in immunocompromised individuals

Principal defect	Causative illnesses, diseases or agents	Pathogens causing chest problem (defect related)			
		Bacteria	Viruses	Fungi	Others
Phagocytes	Acute leukaemia, bone marrow failure and chronic granulomatous disease	Staphylococci, aerobic Gram-negative bacilli, *Nocardia asteroides*		*Candida* and *Aspergillus* species	
Antibody (B-cell) immunity	X-linked agammaglobulinaemia, multiple myeloma, Waldenstrom's macroglobulinaemia and chronic lymphocytic leukaemia	Encapsulated bacteria such as *S. pneumoniae, H. influenzae, S. aureus*		*Pneumocystis jiroveci*	
Complement system		Encapsulated bacteria, and *N. meningitidis*			
Cell-mediated (T-cell) immunity	Di George syndrome, lymphoma, hairy cell leukaemia, medications (ciclosporin, steroids), AIDS, CMV and EBV infection	Intracellular micro-organisms, for example, mycobacteria, *Nocardia asteroides*	Varicella zoster virus, herpes simplex virus, cytomegalovirus, EBV	*Cryptococcus neoformans, Histoplasma capsulatum, Pneumocystis jiroveci*	*Toxoplasma gondii*
Defects caused by splenectomy or hyposplenism		Encapsulated bacteria such as *S. pneumoniae, H. influenzae, N. meningitidis* and *Capnocytophaga canimorsus*			

Most agents currently used in mainstay immunosuppression regimens to prevent graft rejection, in organ transplantation, interfere with discrete sites in the T- and B-cell activation cascades.

frequent complications. Morbidity and mortality are high; so rapid recognition, accurate diagnosis and correct treatment are of prime importance. Diagnosis may be complicated by the sheer number of potential pathogens, the problem of distinguishing infection from non-infective conditions such as malignant infiltration or radiation pneumonitis, and non-specific or delayed presentation. The nature, duration and severity of the underlying immune defect, together with specific epidemiologic or environmental factors, influence the risk of infection by different organisms. These are summarised briefly in Table 35.5. Common therapeutic problems are summarised in Table 35.6.

Table 35.6 Common therapeutic problems

Problem	Comments
No pathogens isolated on sputum culture	Possibilities include an inadequate specimen such as saliva, non-infected or sterilised sputum, or a pathogen that cannot be cultured on routine media such as *Chlamydophila pneumoniae* or *Mycobacterium tuberculosis*. Pneumococci are susceptible to autolysis and may fail to grow even from a well-taken specimen, particularly if transport to the laboratory is delayed
Staphylococcus aureus isolated (including MRSA)	*S. aureus* pneumonia is a severe disease with characteristic clinical features, often associated with bacteraemia. However, the organism is frequently isolated from the sputum of patients with bronchitis or bronchopneumonia. In these instances, it usually reflects contamination of the specimen with oropharyngeal commensals although some patients undoubtedly have a clinical infection requiring anti-staphylococcal antibiotics
Candida spp. isolated	Unless there are reasons to suspect *Candida* pneumonia (as a consequence of neutropenia, for example), the isolation of yeasts is likely to reflect oropharyngeal contamination of the specimen. Yeasts can be carried commensally in the mouth, particularly in the presence of dentures, but a search for clinically apparent mucocutaneous candidiasis should be made
Aspergillus spp. isolated	Invasive aspergillosis, allergic bronchopulmonary aspergillosis and aspergilloma should be considered. Alternatively, the finding might reflect inconsequential oropharyngeal carriage

Table 35.6 Common therapeutic problems—cont'd

Problem	Comments
Penicillin-resistant pneumococci isolated	Respiratory infections caused by strains with low-level resistance (MIC 0.1–1 mg/L) may be treated with penicillins. Strains with high-level resistance should be treated according to their sensitivity profile, for example, using a later-generation cephalosporin or a macrolide
Coliforms isolated	Significance depends on the clinical context: unlikely to be responsible for community-acquired infection unless there is bronchiectasis, but may be relevant to hospital-acquired infections particularly if present in pure culture
Failure of a chest infection to respond to antibiotics	Consider poor compliance, inadequate dosage, viral or otherwise insensitive aetiology. Remember that β-lactam drugs are ineffective against *Chlamydophila*, *Mycoplasma* and *Legionella* infections
Sore throat, no pathogens isolated	Consider viral aetiology, particularly glandular fever in teenagers and young adults
Persistent illness following treatment for pneumococcal pneumonia	Consider the possibility of an empyema (pus in the pleural space), a condition which usually requires surgical drainage

Case studies

Case 35.1

A 40-year-old woman presents to her GP with a 1-week history of sore throat. She is normally fit and well and has had no other symptoms other than some lethargy.

Questions

1. What are the likely causes of the sore throat?
2. Should antibiotics be prescribed?

   The GP decides to prescribe a 10-day course of penicillin V to cover possible streptococcal infection. Two weeks later the patient returns. She is feeling worse and now experiencing difficulty in swallowing. Examination of the throat reveals widespread white plaques.
3. What is the likely diagnosis?
4. What other investigations might be indicated?

Answers

1. A viral aetiology is the most likely cause. These are usually the same viruses that cause colds. Bacterial infection with group A streptococci usually presents with a more severe infection, but where there is doubt a throat swab can establish if bacteria are responsible.
2. Antibiotics are not recommended for routine use. Treatment is directed at symptomatic relief.
3. The likely cause is oral candidiasis. The presence of dysphagia raises the question of oesophageal involvement and hospital admission may be indicated.
4. Underlying immunocompromise must be considered. All patients with oral candidiasis should be offered HIV testing.

Case 35.2

A 61-year-old man is found collapsed at home and taken to hospital. His family report him complaining of a sore throat a few days before admission. On examination, he is pyrexial, hypoxic

and tachycardic with reduced air entry to auscultation at the right base. Chest X-ray reveals a right basal pneumonia.

Questions

1. What is the likely diagnosis?
2. What are the possible infecting organisms?
3. What empirical antibiotics would you choose?

   The next day, his sputum yields a growth of beta haemolytic streptococci group A.
4. How should the patient be treated now?

Answers

1. Community-acquired pneumonia.
2. *S. pneumoniae*, *H. influenzae*; sore throat should alert to the possibility of iGAS.
3. Treatment should be guided by the CURB65 score, which assesses severity. Generally, a beta lactam antibiotic and a macrolide are used in combination.
4. There has been no reported resistance of group A streptococci to penicillins, so beta lactam agents should be appropriate. Patients should be isolated until they have received 24 h of treatment. However, this period has often elapsed by the time the diagnosis is made. Blood culture samples should also have been received as invasive infection may often cause an associated bacteraemia.

Case 35.3

A 72-year-old man with a known history of COPD presents to the hospital accident and emergency department with increasing breathlessness. He has a cough productive of cream coloured sputum which is normal for him. He has not noticed an increase in purulence or volume. Chest X-ray showed hyperinflated lungs but no focal consolidation, and a diagnosis of acute exacerbation of COPD was made.

Questions

1. How should this patient be managed?
2. What investigations would inform the diagnosis?

Answers

1. Many exacerbations of COPD are non-infective. Antibiotics should be reserved for where sputum has become more purulent.
2. The diagnosis of exacerbation of COPD is clinical. Sputum cultures should only be performed where antibiotics are being prescribed.

Case 35.4

A 7-year-old girl is seen in the hospital paediatric outpatient clinic. She is known to have cystic fibrosis and has had several exacerbations in the past which have been treated with flucloxacillin. On this visit she is stable, but a report of sputum culture received two days after the clinic shows a growth of *P. aeruginosa*.

Questions

1. What treatment should be started?
2. What other options are available?

   One week later, you receive a telephone call from the parents that she has become unwell and they suspect she has another chest infection.
3. What agents might be appropriate in treating the infection?

Answers

1. Eradication treatment should be commenced, with oral ciprofloxacin plus a nebulised antibiotic such as colistin.
2. In patients with chronic *Pseudomonas* carriage, there are other options to help reduce the frequency of infections. These include regular low-dose azithromycin and nebulised antibiotics such as tobramycin. Non-pharmacological measures such as physiotherapy should also be included.

3. Combination treatment is usually favoured, depending on individual susceptibility results, but might include a beta lactam antibiotic such as ceftazidime or piperacillin-tazobactam in combination with an aminoglycoside such as tobramycin.

Case 35.5

A 70-year-old man who is a lifelong non-smoker presents to his GP with recurrent chest infections. He has been experiencing a cough productive of sputum which is occasionally blood-stained for several months. He also complains of increasing breathlessness. He has had no relief from several courses of antibiotics. Chest examination is unremarkable. The following day the local microbiology laboratory reports the presence of acid-fast bacilli in the sputum.

Questions

1. What is the likely diagnosis?
2. What are the next steps in the management of this patient?

Answers

1. Acid-fast bacilli are consistent with the presence of *Mycobacterium* species in the sputum. This may indicate TB but does not confirm this, as other non-tuberculous mycobacteria may be present. The culture result will confirm the identity.
2. TB is best managed by a specialist in respiratory medicine and this patient should be referred for further investigation. Community infection control teams should be made aware of this result as this patient might have infective TB and may have come into contact with at risk individuals.

Urinary tract infections 36

N. J. B. Carbarns

Key points

- Urinary tract infection (UTI) is one of the most common complaints seen in general practice and accounts for about one-third of hospital-acquired infections.
- UTI is one of the commonest reasons for prescribing antibiotics.
- *Escherichia coli* is the most frequent pathogen, accounting for more than three-quarters of community-acquired urinary tract infections.
- Symptoms are variable; many UTIs are asymptomatic and some present atypically, particularly in children and the elderly.
- The concept of significant bacteriuria (at least 100,000 organisms/mL of urine) is generally used to distinguish between contamination and infection, but lower counts than this can cause symptoms and disease.
- Asymptomatic UTI should be treated in children and pregnant women.
- Catheter-related UTI should be treated only when the patient has systemic evidence of infection.
- Antimicrobial sensitivity patterns are changing. *E. coli* is becoming increasingly resistant to amoxicillin, cephalosporins, trimethoprim and the quinolones.
- A 3-day treatment course is usually sufficient in uncomplicated lower UTI in women. Longer, 7–14-day courses are recommended for men, children and pregnant women.
- While it is not always necessary to send urine samples for laboratory analysis unless empirical treatment fails, they provide local epidemiology and antibiotic resistance data.
- Antibiotic prophylaxis may be beneficial in women with recurrent UTIs and in children with structural or functional abnormalities.

The term urinary tract infection (UTI) usually refers to the presence of organisms in the urinary tract together with symptoms, and sometimes signs, of inflammation. However, it is more precise to use one of the following terms.

- *Significant bacteriuria:* defined as the presence of at least 100,000 bacteria/mL of urine. A quantitative definition such as this is needed because small numbers of bacteria are normally found in the anterior urethra and may be washed out into urine samples. Counts of fewer than 1000 bacteria/mL are normally considered to be urethral contaminants unless there are exceptional clinical circumstances, such as a sick immunosuppressed patient.

- *Asymptomatic bacteriuria:* significant bacteriuria in the absence of symptoms in the patient.
- *Cystitis:* a syndrome of frequency, dysuria and urgency, which usually suggests infection restricted to the lower urinary tract, that is, the bladder and urethra.
- *Urethral syndrome:* a syndrome of frequency and dysuria in the absence of significant bacteriuria with a conventional pathogen.
- *Acute pyelonephritis:* an acute infection of one or both kidneys. Usually, the lower urinary tract is also involved.
- *Chronic pyelonephritis:* a potentially confusing term used in different ways. It can refer to continuous excretion of bacteria from the kidney, to frequent recurring infection of the renal tissue or to a particular type of pathology of the kidney seen microscopically or by radiographic imaging, which may or may not be due to infection. Although chronic infections of renal tissue are relatively rare, they do occur in the presence of kidney stones and in tuberculosis.
- *Relapse and reinfection:* recurrence of urinary infection may be due to either relapse or reinfection. Relapse is recurrence caused by the same organism that caused the original infection. Reinfection is recurrence caused by a different organism, and is therefore a new infection.

Epidemiology

UTIs are among the most common infectious diseases occurring in either the community or health care setting. Uncomplicated UTIs typically occur in healthy adult non-pregnant women, whereas complicated UTIs are found in either sex and at any age, frequently associated with structural or functional urinary tract abnormalities.

Babies and infants

UTI is a problem in all age groups, although its prevalence varies markedly. In infants up to the age of 6 months, symptomatic UTI has a prevalence of about two cases per 1000 and is much more common in boys than in girls. In addition to these cases, asymptomatic UTI is much more common than this, occurring in around 2% of boys in their first few months of life.

Children

In preschool children, UTIs become more common and the sex ratio reverses, such that the prevalence of bacteriuria is 4.5% in girls and 0.5% in boys. In older children, the prevalence of bacteriuria falls to 1.2% among girls and 0.03% among boys. Overall, about 3–5% of girls and 1–2% of boys will experience a symptomatic UTI during childhood. However, in girls, about two-thirds of UTIs are asymptomatic. The occurrence of bacteriuria during childhood appears to correlate with a higher incidence of bacteriuria in adulthood.

Adults

When women reach adulthood, the prevalence of bacteriuria rises to between 3% and 5%. Each year, about a quarter of these bacteriuric women clear their infections spontaneously and are replaced by an equal number of newly infected women, who are often those with a history of previous infections. On average, about one in eight adult women has a symptomatic UTI each year and over half of adult women report that they have had a symptomatic UTI at some time, 20% recurrently, with the peak age incidence in their early 20s. UTI is uncommon in young healthy men, with 0.5% of adult men having bacteriuria. The rate of symptomatic UTI in men rises progressively with age, from 1% annually at age 18 to 4% at age 60.

Elderly

In the elderly of both sexes, the prevalence of bacteriuria rises dramatically, reaching 20% among women and 10% among men. In hospitals, a major predisposing cause of UTI is urinary catheterisation. With time, even with closed drainage systems and scrupulous hygiene, bacteria can be found in almost all catheters and this is a risk for the development of symptomatic infection.

Aetiology and risk factors

In acute uncomplicated UTI acquired in the community, *Escherichia coli* is by far the most common causative bacterium, being responsible for about 80% of infections. The remaining 20% are caused by other Gram-negative enteric bacteria such as *Klebsiella* and *Proteus* species, and by Gram-positive cocci, particularly enterococci and *Staphylococcus saprophyticus*. The latter organism is almost entirely restricted to infections in young, sexually active women.

UTI associated with underlying structural abnormalities, such as congenital anomalies, neurogenic bladder and obstructive uropathy, is often caused by more resistant organisms such as *Pseudomonas aeruginosa*, *Enterobacter* and *Serratia* species. Organisms such as these are also more commonly implicated in hospital-acquired urinary infections, including those in patients with urinary catheters.

Rare causes of urinary infection, nearly always in association with structural abnormalities or catheterisation, include anaerobic bacteria and fungi. Urinary tract tuberculosis is an infrequent but important diagnosis that may be missed through lack of clinical suspicion. A number of viruses are excreted in urine and may be detected by culture or nucleic acid amplification methods, but symptomatic infection is confined to immunocompromised patients, particularly children following bone marrow transplantation, in whom adenoviruses and polyomaviruses such as BK virus are associated with haemorrhagic cystitis.

Pathogenesis

There are three possible routes by which organisms might reach the urinary tract: the ascending, blood-borne and lymphatic routes. There is little evidence for the last route in humans. Blood-borne spread to the kidney can occur in bacteraemic illnesses, most notably *Staphylococcus aureus* septicaemia, but by far the most frequent route is the ascending route.

In women, UTI is preceded by colonisation of the vagina, perineum and periurethral area by the pathogen, which then ascends into the bladder via the urethra. Uropathogens colonise the urethral opening of men and women. That the urethra in women is shorter than in men and the urethral meatus is closer to the anus are probably important factors in explaining the preponderance of UTI in females. Further, sexual intercourse appears to be important in forcing bacteria into the female bladder, and this risk is increased by the use of diaphragms and spermicides, which have both been shown to increase *E. coli* growth in the vagina. Whether circumcision reduces the risk of infection in adult men is not known, but it markedly reduces the risk of UTI in male infants.

Organism

E. coli causes most UTIs and although there are many serotypes of this organism, only a few of these are responsible for a disproportionate number of infections. While there are as yet no molecular markers that uniquely identify uropathogenic *E. coli*, some strains possess certain virulence factors that enhance their ability to cause infection, particularly infections of the upper urinary tract. Recognised factors include bacterial surface structures called P-fimbriae, which mediate adherence to glycolipid receptors on renal epithelial cells, possession of the iron-scavenging aerobactin system, and increased amounts of capsular K antigen, which mediates resistance to phagocytosis.

Host

Although many bacteria can readily grow in urine, and Louis Pasteur used urine as a bacterial culture medium in his early experiments, the high urea concentration and extremes of osmolality and pH inhibit growth. Other defence mechanisms include the flushing mechanism of bladder emptying, since small numbers of bacteria finding their way into the bladder are likely to be eliminated when the bladder is emptied. Moreover, the bladder mucosa, by virtue of a surface

glycosaminoglycan, is intrinsically resistant to bacterial adherence. Presumably, in sufficient numbers, bacteria with strong adhesive properties can overcome this defence. Finally, when the bladder is infected, white blood cells are mobilised to the bladder surface to ingest and destroy invading bacteria. The role of humoral antibody-mediated immunity in defence against infection of the urinary tract remains unclear. Genetic susceptibility of individual patients to UTI has been reviewed (Lichtenberger and Hooton, 2008).

Abnormalities of the urinary tract

Any structural abnormality leading to the obstruction of urinary flow increases the likelihood of infection. Such abnormalities include congenital anomalies of the ureter or urethra, renal stones and, in men, enlargement of the prostate. Renal stones can become infected with bacteria, particularly *Proteus* and *Klebsiella* species, and thereby become a source of 'relapsing' infection. Vesicoureteric reflux (VUR) is a condition caused by failure of physiological valves at the junction of the ureters and the bladder which allows urine to reflux towards the kidneys when the bladder contracts. It is probable that VUR plays an important role in childhood UTIs that lead to chronic renal damage (scarring) and persistence of infection. If there is a diminished ability to empty the bladder such as that due to spinal cord injury, there is an increased risk of bacteriuria.

Clinical manifestations

Most UTIs are asymptomatic. Symptoms, when they do occur, are principally the result of irritation of the bladder and urethral mucosa. However, the clinical features of UTI are extremely variable and to some extent depend on the age of the patient.

Babies and infants

Infections in newborn babies and infants are often overlooked or misdiagnosed because the signs may not be referable to the urinary tract. Common but non-specific presenting symptoms include failure to thrive, vomiting, fever, diarrhoea and apathy. Further, confirmation may be difficult because of problems in obtaining adequate specimens. UTI in infancy and childhood is a major risk factor for the development of renal scarring, which in turn is associated with future complications such as chronic pyelonephritis in adulthood, hypertension and renal failure. It is therefore vital to make the diagnosis early, and any child with a suspected UTI should receive urgent expert assessment.

Children

Above the age of 2, children with UTI are more likely to present with some of the classic symptoms such as frequency, dysuria and haematuria. However, some children present with acute abdominal pain and vomiting, and this may be so marked as to raise suspicions of appendicitis or other intra-abdominal

pathology. Again, however, it is extremely important that the diagnosis of UTI is made promptly to pre-empt the potential long-term consequences. National guidance has been published in the UK on paediatric UTIs to promote a more consistent clinical practice by ensuring prompt, accurate diagnosis and appropriate management (NICE, 2007). A key feature of the guidance is that children with unexplained fever should have their urine tested within 24 h and attention is given to avoiding over- or underdiagnosis, appropriate investigation and the prompt start of antibiotic treatment.

Adults

In adults, the typical symptoms of lower UTI include frequency, dysuria, urgency and haematuria. Acute pyelonephritis (upper UTI) usually causes fever, rigors and loin pain in addition to lower tract symptoms. Systemic symptoms may vary from insignificant to extreme malaise. Importantly, untreated cystitis in adults rarely progresses to pyelonephritis, and bacteriuria does not seem to carry the adverse long-term consequences that it does in children.

In about 40% of women with dysuria, urgency and frequency, the urine sample contains fewer than 100,000 bacteria/mL. These patients are said to have the urethral syndrome. Some have a true bacterial infection but with relatively low counts (100–1000 bacteria/mL). Some have urethral infection with *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, mycoplasmas or other 'fastidious' organisms, any of which might give rise to symptoms indistinguishable from those of cystitis. In others, no known cause can be found by conventional laboratory techniques. It is important to consider the possibility of urinary tract tuberculosis, as special methods are necessary for its detection. Sometimes, the symptoms are of non-infectious origin, such as menopausal oestrogen deficiency or allergy. However, most cases of urethral syndrome will respond to standard antibiotic regimens as used for treating confirmed UTI.

Elderly

Although UTI is frequent in the elderly, the great majority of cases are asymptomatic, and even when present, symptoms are not diagnostic because frequency, dysuria, hesitancy and incontinence are fairly common in elderly people without infection. Further, there may be non-specific systemic manifestations such as confusion and falls, or alternatively the infection may be the cause of deterioration in pre-existing conditions such as diabetes mellitus or congestive cardiac failure, whose clinical features might predominate. UTI is one of the most frequent causes of admission to hospital among the elderly.

Investigations

The key to successful laboratory diagnosis of UTI lies in obtaining an uncontaminated urine sample for microscopy and culture. Contaminating bacteria can arise from skin, vaginal flora in women and penile flora in men. Patients therefore

need to be instructed in how to produce a midstream urine sample (MSU). For women, this requires careful cleansing of the perineum and external genitalia with soap and water. Uncircumcised men should retract the foreskin. This is followed by a controlled micturition in which about 20 mL of urine from only the middle portion of the stream is collected, the initial and final components being voided into the toilet or bedpan. Understandably, this is not always possible and many so-called MSUs are in fact clean-catch specimens in which the whole urine volume is collected into a sterile receptacle and an aliquot transferred into a specimen pot for submission to the laboratory. These are more likely to contain urethral contaminants. In very young children, special collection pads for use inside nappies or stick-on bags are useful ways of obtaining a urine sample. Occasionally, in-and-out diagnostic catheterisation or even suprapubic aspiration directly from the bladder is necessary.

For primary care doctors located some distance from a laboratory, transport of specimens is a problem. Specimens must reach the laboratory within 1–2 h or should be refrigerated; otherwise, any bacteria in the specimen will multiply and might give rise to a false-positive result. Methods of overcoming bacterial multiplication in urine include the addition of boric acid to the container and the use of dipslides, in which an agar-coated paddle is dipped into the urine and submitted directly to the laboratory for incubation. Both of these alternatives have difficulties. For the boric acid technique, it is important that the correct amount of urine is added to the container to achieve the appropriate concentration of boric acid (1.8%, w/v), as the chemical has significant antibacterial activity when more concentrated. When the dip-slide is used, no specimen is available on which to do cell counts.

Concerns about the relative expense and slow turn-around time of urine microscopy and culture have stimulated interest in alternative diagnostic strategies. Some advocate a policy of empirical antimicrobial treatment in the first instance, and reserve investigation only for those cases that do not respond. Others are in favour of using cheaper, more convenient screening tests, for example, urine dipsticks. It is important to be aware that there is no rapid screening test that will reliably detect all UTIs. Urine microscopy and culture remain the standard by which other investigations are measured.

Dipsticks

Dipsticks for rapid near-patient testing for urinary blood, protein, nitrites and leucocyte esterase are usually used, although there are concerns that these are reliable only when applied to fresh urine samples tested at the point of care. Assessment of colour changes on dipsticks can be subjective and automated reading systems have been developed to assist interpretation. Generally, the negative predictive value is better than the positive predictive value, so their preferred use is as screening tests to identify those specimens which are least likely to be infected and which therefore do not require culture. A perfectly valid alternative is just to hold the specimen up to the light: specimens that are visibly clear are very likely to be sterile.

The leucocyte esterase test detects enzyme released from leucocytes in urine and is ~90% sensitive at detecting white blood cell counts of >10 mm^{-3}. It will be positive even if the cells have been destroyed due to delays in transport to a laboratory. However, vitamin C and antibiotics in the urine such as cephalosporins, gentamicin and nitrofurantoin may interfere with the reaction. Although the presence of leucocytes is common in UTIs, it may also occur in other conditions. Particularly in children, white blood cells can be present for many reasons, including fever alone.

The nitrite test (also called the Griess test) detects urinary nitrite made by bacteria that can convert excreted dietary nitrate used as a food preservative to nitrite. Although the coliform bacteria that commonly cause UTI can be detected in this way, some organisms cannot, for example, enterococci, group B streptococci, *Pseudomonas*, because they do not contain the converting enzyme. In addition, the test depends on sufficient nitrate in the diet and on allowing enough time, at least 4 h, for the chemical conversion to occur in the urine. Performance of the dipstick test is generally less diagnostic in infants and younger children than in the older age groups, and this may relate in part to the small capacity and frequent emptying of the infant bladder, resulting in lower numbers of organisms and less pyuria. The use of dipsticks alone for the diagnosis of UTI is not recommended for children under 3 years of age (NICE, 2007). The inability of the test to detect group B streptococci also makes it a relatively inappropriate test for screening for asymptomatic bacteriuria in pregnancy, in which this organism assumes particular importance as a cause of neonatal sepsis.

Although a negative dipstick test for leucocytes and nitrites can quite accurately predict absence of infection, their absence does not necessarily predict non-response to antibiotic treatment and further research is needed on this (Richards et al., 2005). Some experts consider that detection of nitrites in a symptomatic patient should prompt initiation of treatment (Gopal Rao and Patel, 2009). An algorithm for the use of dipstick testing in uncomplicated UTI in adult women is set out in Fig. 36.1.

There are other rapid methods for detecting bacteriuria, such as tests for interleukin-8, and no shortage of data concerning their sensitivity and specificity, but the optimal strategy will always be a compromise between accuracy, speed, convenience and cost, and is likely to be very different for different settings and populations.

Microscopy

Microscopy is the first step in the laboratory diagnosis of UTI and can be readily performed in practice. A drop of uncentrifuged urine is placed on a slide, covered with a coverslip and examined under a 40× objective. Excess white cells are usually seen in the urine of patients with symptomatic UTI, and more than 10 per high-power field is abnormal. It should be noted that there are other methods in common use, and laboratories may report white cell counts per microlitre (cubic millimetre) of urine or per millilitre. Automated machinery for microscopy of urine is increasingly used and

offers increased precision and handling capacities of over 100 specimens/h. Although there is a substantial capital cost to such equipment, it is offset by savings in labour and bacterial culture materials. One feature of this equipment is that it is generally much more sensitive in detecting cells, so much so that laboratories using such systems will have a much higher number for significant results (e.g. >50 rather than >10 white cells/mm³).

It is important not to be too rigid in the interpretation of the white cell count. UTI may occur in the absence of pyuria, particularly at the extremes of age, in pregnancy and in pyelonephritis. Red blood cells may be seen, as may white cell casts, which are suggestive of pyelonephritis. As a rule of thumb, the presence of at least one bacterium per field correlates with 100,000 bacteria/mL.

Culture

Bladder urine is normally sterile, but when passed via the urethra, it is inevitable that some contamination with the urethral bacterial flora will occur. This is why it is important that laboratories quantify the number of bacteria in urine specimens. In work carried out over 40 years ago, it was demonstrated that patients with UTI usually have at least 100,000 bacteria/mL, while in patients without infection, the count is usually below 1000 bacteria/mL. Between these figures lies a grey area, and it should be appreciated that the MSU is not an infallible guide to the presence or absence of urinary infection. True infections may be associated with low counts, particularly when the urine is very dilute because of excessive fluid intake or where the pathogen is slow growing. While the

quantitative criterion for 'significant' bacteriuria is generally taken as >100,000/mL, in some specific groups, it is less: for men, >1000/mL and for women with symptoms of UTI, it is >100/mL (SIGN, 2006).

Most genuine infections are caused by one single bacterial species; mixed cultures usually suggest contamination. If a patient is taking an antibiotic when a urine specimen is obtained for culture, growth of bacteria may be inhibited. The laboratory may perform a test to detect antimicrobial substances in the urine, and this may be useful information to clarify circumstances in which the culture is negative but a significant pyuria is present.

Treatment

Although many, and perhaps most, cases clear spontaneously given time, symptomatic UTI usually merits antibiotic treatment to eradicate both symptoms and pathogen. Asymptomatic bacteriuria may or may not need treatment depending upon the circumstances of the individual case. Bacteriuria in children and in pregnant women requires treatment, as does bacteriuria present when surgical manipulation of the urinary tract is to be undertaken, because of the potential complications. On the other hand, in non-pregnant, asymptomatic bacteriuric adults without any obstructive lesion, screening and treatment are probably unwarranted in most circumstances (Nicolle et al., 2005). Unnecessary treatment will lead to selection of resistant organisms and puts patients at risk of adverse drug effects including bowel infection with *Clostridium difficile*, which has been particularly associated with the use of cephalosporins and quinolones. A number of common management problems are summarised in Table 36.1.

Non-specific treatments

Advising patients with UTI to drink a lot of fluids is common practice on the theoretical basis that more infected urine is removed by frequent bladder emptying. This is plausible, although not evidence based. Some clinicians recommend urinary analgesics such as potassium or sodium citrate, which alkalinise the urine, but these should be used as an adjunct to antibiotics. They should not be used in conjunction with nitrofurantoin, which is active only at acidic pH.

Antimicrobial chemotherapy

The principles of antimicrobial treatment of UTI are the same as those of the treatment of any other infection: from a group of suitable drugs chosen on the basis of efficacy, safety and cost, select the agent with the narrowest possible spectrum and administer it for the shortest possible time. In general, there is no evidence that bactericidal antibiotics are superior to bacteriostatic agents in treating UTI, except perhaps in relapsing infections. Blood levels of antibiotics appear to be unimportant in the treatment of lower UTI; what matters is the concentration in the urine. However, blood levels probably

are important in treating pyelonephritis, which may progress to bacteraemia. Drugs suitable for the oral treatment of cystitis include trimethoprim, the β-lactams, particularly amoxicillin, co-amoxiclav and cefalexin, fluoroquinolones such as ciprofloxacin, norfloxacin and ofloxacin, and nitrofurantoin. Where intravenous administration is required, suitable agents include β-lactams such as amoxicillin and cefuroxime, quinolones, and aminoglycosides such as gentamicin.

In renal failure, it may be difficult to achieve adequate therapeutic concentrations of some drugs in the urine, particularly nitrofurantoin and quinolones. Further, accumulation and toxicity may complicate the use of aminoglycosides. Penicillins and cephalosporins attain satisfactory concentrations and are relatively non-toxic, and are therefore the agents of choice for treating UTI in the presence of renal failure.

Antibiotic resistance

Antimicrobial resistance is a major concern worldwide. The susceptibility profile of commonly isolated uropathogens has been constantly changing. Coliform bacteria of many species that produce extended-spectrum β-lactamase (ESBL) enzymes have emerged in recent years, particularly as a cause of UTI in community-based patients. Before 2003, most ESBL-producing bacteria were hospital acquired and occurred in specialist units.

ESBL-producing bacteria are clinically important as they produce enzymes that destroy almost all commonly used β-lactams except the carbapenem class, rendering most penicillins and cephalosporins largely useless in clinical practice. Some ESBL enzymes can be inhibited by clavulanic acid, and combinations of an agent containing it, for example, co-amoxiclav, with other oral broad-spectrum β-lactams, for example, cefixime or cefpodoxime, have been used to treat UTIs caused by ESBL-producing *E. coli* (Livermore et al., 2008). These combinations are unlicensed and their effectiveness is variable.

In addition, many ESBL-producing bacteria are multiresistant to non-β-lactam antibiotics too, such as quinolones, aminoglycosides and trimethoprim, narrowing treatment options. ESBL-*E. coli* is often pathogenic and a high proportion of infections result in bacteraemia with resultant mortality (Tumbarello et al., 2007). Some strains cause outbreaks both in hospitals and in the community. Empirical treatment strategies may need to be reviewed in settings where ESBL-producing strains are prevalent, and it may be considered appropriate to use a carbapenem in seriously ill patients until an infection has been proved not to involve an ESBL producer.

Recently, even more resistant strains have emerged in India and Pakistan, with subsequent transfer to the UK, that carry a gene for a novel New Delhi metallo-β-lactamase-1 that also confers resistance to carbapenems. This bla_{NDM-1} gene was mostly found among *E. coli* and *Klebsiella*, which were highly resistant to all antibiotics except to colistin and tigecycline, which is not effective for UTI as it is chemically unstable in the urinary tract (Kumarasamy et al., 2010).

Table 36.1 Common management problems with urinary tract infections (UTI)

Problem	Comments
Asymptomatic infection	Asymptomatic bacteriuria should be treated where there is a risk of serious consequences (e.g. in childhood), where there is renal scarring, and in pregnancy. Otherwise, treatment is not usually required
Catheter *in situ*, patient unwell	Systemic symptoms may result from catheter-associated UTI, and should respond to antibiotics although the catheter is likely to remain colonised. Local symptoms such as urgency are more likely to reflect urethral irritation than infection
Catheter *in situ*, urine cloudy or smelly	Unless the patient is systemically unwell, antibiotics are unlikely to achieve much and may give rise to resistance. Interventions of uncertain benefit include bladder wash-outs or a change of catheter
Penicillin allergy	Clarify 'allergy': vomiting or diarrhoea are not allergic phenomena and do not contraindicate penicillins. Penicillin-induced rash is a contraindication to amoxicillin, but cephalosporins are likely to be tolerated. Penicillin-induced anaphylaxis suggests that all β-lactams should be avoided
Symptoms of UTI but no bacteriuria	Exclude urethritis, candidosis, etc. Otherwise likely to be urethral syndrome, which usually responds to conventional antibiotics
Bacteriuria but no pyuria	May suggest contamination. However, pyuria is not invariable in UTI and may be absent particularly in pyelonephritis, pregnancy, neonates, the elderly, and *Proteus* infections
Pyuria but no bacteriuria	Usually, the patient has started antibiotics before taking the specimen. Rarely, a feature of unusual infections (e.g. anaerobes, tuberculosis, etc.)
Urine grows *Candida*	Usually reflects perineal candidosis and contamination. True candiduria is rare, and may reflect renal candidosis or systemic infection with candidaemia
Urine grows two or more organisms	Mixed UTI is unusual – mixed cultures are likely to reflect perineal contamination. A repeat should be sent unless this is impractical (e.g. frail elderly patients), in which case best-guess treatment should be instituted if clinically indicated
Symptoms recur	May represent relapse or reinfection. A repeat urine culture should be performed shortly after treatment

Uncomplicated lower UTI

The problem with empirical treatment is that over 10% of the healthy adult female population would receive an antibiotic each year. The use of antibiotics to this extent in the population has implications for antibiotic resistance, a major focus of public health policy worldwide. This highlights the tension between maximising the benefit for individuals and minimising antibiotic resistance at a population level. Strategies have included diagnostic algorithms to predict more precisely who has a UTI, as well as issuing delayed prescriptions (Mangin, 2010).

Therapeutic decisions should be based on accurate, up-to-date antimicrobial susceptibility patterns. Data have been published from a European multicentre survey that examined the prevalence and antimicrobial susceptibility of community-acquired pathogens causing uncomplicated UTI in women (Kahlmeter, 2003). Among almost 2500 *E. coli* isolates, the resistance rates were 30% for amoxicillin, 15% for trimethoprim, 3.4% for co-amoxiclav, 2.3% for ciprofloxacin, 2.1% for cefadroxil and 1.2% for nitrofurantoin. These figures are lower than most routine laboratory data would suggest, but it should be remembered that the experience of diagnostic laboratories is likely to be biased by the overrepresentation of specimens from patients in whom empirical treatment has already failed. It is important to be aware of local variations in sensitivity pattern and to balance the risk of therapeutic failure against the cost of therapy.

Adults

The preference for best-guess therapy would seem to be a choice between trimethoprim, an oral cephalosporin such as cefalexin, co-amoxiclav or nitrofurantoin, with the proviso that therapy can be refined once sensitivities are available. The quinolones are best reserved for treatment failures and more difficult infections, since overuse of these important agents is likely to lead to an increase in resistance, as has been seen in countries such as Spain and Portugal. These recommendations are summarised in Table 36.2.

Other drugs that have been used for the treatment of UTI include co-trimoxazole, pivmecillinam, fosfomycin and earlier quinolones such as nalidixic acid. Co-trimoxazole is now recognised as a cause of bone marrow suppression and other haematological side effects, and in the UK, its use is greatly restricted. Further, despite superior activity *in vitro*, there is no convincing evidence that it is clinically superior to trimethoprim alone in the treatment of UTI caused by strains susceptible to both. Pivmecillinam is an oral pro-drug that is metabolised

Table 36.2 Oral antibiotics used for lower urinary tract infections

Antibiotic	Dose (adult)	Side effects	Contraindications	Comments
Amoxicillin	250–500 mg three times a day	Nausea, diarrhoea, allergy	Penicillin hypersensitivity	High levels of resistance (>50%) in *E. coli*. Not used empirically
Co-amoxiclav	375–625 mg three times a day	See amoxicillin	See amoxicillin	Amoxicillin and clavulanic acid
Cefalexin	250–500 mg four times a day	Nausea, diarrhoea, allergy	Cephalosporin hypersensitivity, porphyria	
Trimethoprim	200 mg twice a day	Nausea, pruritus, allergy	Pregnancy, neonates, folate deficiency, porphyria	
Nitrofurantoin	50 mg four times a day	Nausea, allergy, rarely pneumonitis, pulmonary fibrosis, neuropathy	Renal failure, neonates, porphyria, G6PD deficiency	Modified-release form may be given twice daily. Inactive against *Proteus*
Ciprofloxacin	100–500 mg twice a day	Rash, pruritus, tendinitis	Pregnancy, children	Reserve for difficult cases

G6PD, glucose-6-phosphate dehydrogenase.

to mecillinam, a β-lactam agent with a particularly high affinity for Gram-negative penicillin-binding protein 2 and a low affinity for commonly encountered β-lactamases, and which therefore has theoretical advantages in the treatment of UTI. Pivmecillinam has been extensively used for cystitis in Scandinavian countries, where it does not seem to have led to the development of resistance, and for this reason, there have been calls for wider recognition of its usefulness, particularly for UTI caused by ESBL-producing strains. Fosfomycin is a broad-spectrum antibiotic with pharmacokinetic and pharmacodynamic properties that favour its use for treatment of cystitis with a single oral dose (Falagas et al., 2010). Finally, older quinolones such as nalidixic acid and cinoxacin were once widely used, but generally these agents have given ground to the more active fluorinated quinolones.

Duration of treatment

The question of duration of treatment has received much attention. Traditionally, a course of 7–10 days has been advocated, and this is still the recommendation for treating men, in whom the possibility of occult prostatitis should be borne in mind. For women, though, there has been particular emphasis on the suitability of short-course regimens such as 3-day or even single-dose therapy. The consensus of an international expert working group was that 3-day regimens are as effective as longer regimens in the cases of trimethoprim and quinolones. β-Lactams have been inadequately investigated on this point but short courses are generally less effective than trimethoprim and quinolones, and nitrofurantoin requires further study before definite conclusions can be drawn. Single-dose therapy, with its advantages of cost, adherence and the minimisation of side effects, has been used successfully in many studies but in general is less effective than when the same agent is used for longer.

In the urethral syndrome, it is worth trying a 3-day course of one of the agents mentioned earlier. If this fails, a 7-day course of tetracycline could be tried to deal with possible chlamydia or mycoplasma infection.

Children

In children, the risk of renal scarring is such that UTI should be diagnosed and treated promptly, even if asymptomatic. The drugs of choice include β-lactams, trimethoprim and nitrofurantoin. Quinolones are relatively contraindicated in children because of the theoretical risk of causing cartilage and joint problems. Children should be treated for 7–10 days.

Renal scarring occurs in 5–15% of children with UTI, who should be identified so that appropriate treatment can be instituted. Unfortunately, the subgroup at high risk cannot be predicted, and for this reason, many clinicians choose to investigate all children with UTI, for example, using ultrasound and radioisotope scanning.

Acute pyelonephritis

Patients with pyelonephritis may be severely ill and, if so, will require admission to hospital and initial treatment with a parenteral antibiotic. Suitable agents with good activity against *E. coli* and other Gram-negative bacilli include cephalosporins such as cefuroxime and ceftazidime, some penicillins such as co-amoxiclav, quinolones, and aminoglycosides such as gentamicin (Table 36.3). A first-choice agent would be parenteral cefuroxime, gentamicin or ciprofloxacin. When the patient is improving, the route of administration may be switched to oral therapy, typically using a quinolone. Conventionally, treatment is continued for 10–14 days.

Patients who are less severely ill at the outset may be treated with an oral antibiotic, and possibly with a shorter course of

Table 36.3 Parenteral antibiotics used for pyelonephritis

Antibiotic	Dose (adult)	Side effects	Contraindications	Comments
Cefuroxime	750 mg three times a day	Nausea, diarrhoea, allergy	Cephalosporin hypersensitivity, porphyria	Implicated in *Clostridium difficile*
Ceftazidime	1 g three times a day	See cefuroxime	See cefuroxime	See cefuroxime
Co-amoxiclav	1.2 g three times a day	Nausea, diarrhoea, allergy	Penicillin hypersensitivity	
Gentamicin	80–120 mg three times a day or 5 mg/kg once daily	Nephrotoxicity, ototoxicity	Pregnancy, myasthenia gravis	Monitor levels
Ciprofloxacin	200–400 mg twice a day	Rash, pruritus, tendinitis	Pregnancy, children	Implicated in *Clostridium difficile*
Piperacillin with tazobactam	4.5 g three times a day	Nausea, allergy	Penicillin hypersensitivity	
Meropenem	500 mg three times a day	Nausea, rash, convulsions		Reserve for multiresistant cases

treatment. The safety of this approach has been demonstrated in a study of adult women with acute uncomplicated pyelonephritis (Talan et al., 2000). Among 113 patients treated with oral ciprofloxacin 500 mg twice daily for 7 days (± an initial intravenous dose), the cure rate was 96%.

In hospital-acquired pyelonephritis, there is a risk that the infecting organism may be resistant to the usual first-line drugs. In such cases, it may be advisable to start a broad-spectrum agent such as ceftazidime, ciprofloxacin or meropenem.

Relapsing UTI

The main causes of persistent relapsing UTI are renal infection, structural abnormalities of the urinary tract and, in men, chronic prostatitis. Patients who fail on a 7–10-day course should be given a 2-week course, and if that fails, a 6-week course can be considered. Structural abnormalities may need surgical correction before cure can be maintained. It is essential that prolonged courses (i.e. more than 4 weeks) are managed under bacteriological control, for example, with monthly cultures. In men with prostate gland infection, it is appropriate to select antibiotics with good tissue penetration such as trimethoprim and the fluoroquinolones.

Catheter-associated infections

In most large hospitals, 10–15% of patients have an indwelling urinary catheter. Even with the very best catheter care, most will have infected urine after 10–14 days of catheterisation, although most of these infections will be asymptomatic. Antibiotic treatment will often appear to eradicate the infecting organism, but as long as the catheter remains in place, the organism, or another more resistant one, will quickly return. The principles of antibiotic therapy for catheter-associated UTI are therefore as follows:

- Do not treat asymptomatic infection.
- If possible, remove the catheter before treating symptomatic infection.

Although it often prompts investigation, cloudy or strong-smelling urine is not *per se* an indication for antimicrobial therapy. In these situations, saline or antiseptic bladder wash-outs are often performed, but there is little evidence that they make a difference. Similarly, encrusted catheters are often changed on aesthetic grounds, but it is not known whether this reduces the likelihood of future symptoms.

Following catheter removal, bacteriuria may resolve spontaneously but more often it persists (typically for over 2 weeks in over half of patients) and may become symptomatic, though usually it will respond well to short-course treatment.

Antimicrobial catheters

Several different types of novel catheters with anti-infective properties have been developed with the aim of reducing the ability of bacteria to adhere to the material, which should lead to a decreased incidence of bacteriuria and symptomatic infection. Several studies of the effect of incorporating antibiotics such as rifampicin and minocycline or silver-based alloys into the catheter have shown benefit. Although clearly more costly than standard catheters, economic evaluation shows silver alloy catheters to be cost efficient when used in patients needing catheterisation for several days. The effect of these catheters on clinical outcomes such as bacteraemia remains to be determined.

Bacteriuria of pregnancy

The prevalence of asymptomatic bacteriuria of pregnancy is about 5%, and about a third of these women proceed to develop acute pyelonephritis, with its attendant consequences

for the health of both mother and pregnancy. Further, there is evidence that asymptomatic bacteriuria is associated with low birth weight, prematurity, hypertension and pre-eclampsia. For these reasons, it is recommended that screening be carried out, preferably by culture of a properly taken MSU, which should be repeated if positive for confirmation (National Collaborating Centre for Women's and Children's Health, 2003).

Rigorous meta-analysis of published trials has shown that antibiotic treatment of bacteriuria in pregnancy is effective at clearing bacteriuria, reducing the incidence of pyelonephritis and reducing the risk of preterm delivery. The drugs of choice are amoxicillin or cefalexin or nitrofurantoin, depending on the sensitivity profile of the infecting organism. Co-amoxiclav is cautioned in pregnancy because of lack of clinical experience in pregnant women. Trimethoprim is contraindicated (particularly in the first trimester) because of its theoretical risk of causing neural tube defects through folate antagonism. Nitrofurantoin should be avoided close to the time of expected delivery because of a risk of haemolysis in the baby. Ciprofloxacin is contraindicated because it may affect the growing joints. There are insufficient data concerning short-course therapy in pregnancy, and 7 days of treatment remains the standard. Patients should be followed up for the duration of the pregnancy to confirm cure and to ensure that any reinfection is promptly addressed.

Prevention and prophylaxis

There are a number of folklore and naturopathic recommendations for the prevention of UTI. Most of these have not been put to statistical study, but at least are unlikely to cause harm.

Cranberry juice

Cranberry juice (*Vaccinium macrocarpon*) has long been thought to be beneficial in preventing UTI, and this has been studied in a number of clinical trials. Cranberry is thought to inhibit adhesion of bacteria to urinary tract cells on the surface of the bladder. In sexually active women, a daily intake of 750 mL cranberry juice was associated with a 40% reduction in the risk of symptomatic UTI in a double-blinded 12-month trial. Many studies have been criticised for methodological flaws, and currently there is only limited evidence that cranberry juice is effective at preventing recurrent UTI (McMurdo et al., 2009). There have been no randomised controlled trials of the use of cranberry products (juice, tablets or capsules) in the treatment of established infection, or comparing it with established therapies such as antibiotics for preventing infection.

A hypothetical benefit in using cranberry instead of antibiotics for this purpose is a reduced risk of the development of antibiotic-resistant bacteria. A significant hazard is an interaction of cranberry with warfarin, with a risk of bleeding episodes, and available products are not available in standardised formulations. Further, cranberry juice is unpalatable unless sweetened with sugar and therefore carries a risk of tooth decay, although ironically it is reported to prevent dental caries by blocking adherence of plaque bacteria to teeth.

Antibiotic prophylaxis

In some patients, mainly women, reinfections are so frequent that long-term antimicrobial prophylaxis with specific antibiotics is indicated. If the reinfections are clearly related to sexual intercourse, then a single dose of an antibiotic after intercourse is appropriate. In other cases, long-term, low-dose prophylaxis may be beneficial. One dose of trimethoprim (100 mg) or nitrofurantoin (50 mg) at night will suffice. These drugs are unlikely to lead to the emergence of resistant bacteria, although breakthrough infection with strains intrinsically resistant to the chosen prophylactic antibiotic is possible.

Children

In children, recurrence of UTI is common and the complications potentially hazardous, so many clinicians recommend antimicrobial prophylaxis following documented infection. The evidence in favour of this practice is not strong (Le Saux et al., 2000), and although it has been shown to reduce the incidence of bacteriuria, there is no good-quality evidence that prophylactic antibiotics are effective in preventing further symptomatic UTIs and they have not been shown to reduce the incidence of renal scarring complications, which are the most important outcomes for the patient (Mori et al., 2009). Further, important variables remain to be clarified, such as when to begin prophylaxis, which agent to use and when to stop. Recent guidelines have abandoned the time-honoured recommendation for routine antibiotic prophylaxis following a first infection, although it may be considered when there is recurrent UTI (NICE, 2007).

Although evidence is limited for some recommendations, there are many common-sense general measures aimed at reducing the risk of recurrence of infection, particularly in girls. They include advice on regular bladder emptying, cleaning the perineal/anal area from front to back after toilet, treating constipation adequately and avoiding both bubble baths and washing the hair in the bath.

Case studies

Case 36.1

A 70-year-old man has consulted his primary care doctor three times in the past 3 months and seems to have the same *E. coli* infection on each occasion. A short course of antibiotics clears up the symptoms, but a clinical relapse is soon apparent. He is admitted to hospital for transurethral resection of the prostate and 2 days after the operation he becomes unwell with rigors, fever and loin pain. Microscopy of his urine shows over 200 white cells/mm³. Blood cultures are taken and rapidly become positive, with Gram-negative bacilli seen on microscopy.

Question

Is there any way of predicting which UTIs are likely to go on to cause further problems such as pyelonephritis or prostatitis? What antibiotic therapy is indicated now?

Answer

Progression of a simple UTI is much more common in patients other than young women. Foreign bodies such as catheters and stents, or physiological problems such as neurogenic bladder, increase the risk of a complicated UTI. In men, persistent or recurrent infection with the same organism is highly suggestive of prostatitis and should prompt an extended course of treatment. Pyelonephritis is more difficult to predict. Frequency, dysuria and haematuria indicate lower tract infection. Fever, vomiting, rigors and flank pain are more suggestive of upper renal tract involvement.

The patient should be started on intravenous antibiotic therapy for presumed prostatitis or pyelonephritis and consequent bacteraemia. The antibiotic should cover Gram-negative organisms found in the hospital environment such as *Klebsiella*, *Enterobacter* and *Pseudomonas*. Appropriate agents would be piperacillin-tazobactam, ceftazidime, ciprofloxacin or meropenem. An alternative would be an aminoglycoside such as gentamicin, provided the patient has satisfactory renal function.

Case 36.2

A pregnant woman aged 26 years is found to have bacteriuria at her first antenatal visit. There are no white or red cells seen in her urine. Urine culture demonstrates *E. coli* at a count of more than 100,000 bacteria/mL, sensitive to trimethoprim, nitrofurantoin and cefalexin but resistant to amoxicillin. Other than a degree of urinary frequency, which she ascribes to the pregnancy itself, the patient does not complain of any urinary symptoms.

Question

Does this patient need antibiotic treatment, and if so, which drugs could be safely used?

Answer

The patient may be correct that her urinary frequency is a consequence of pregnancy. However, because of the consequences of untreated infection during pregnancy, even asymptomatic bacteriuria should be treated. A repeat urine specimen should be obtained to confirm the finding, and treatment started with either cefalexin or co-amoxiclav for 7 days. Trimethoprim should be avoided during early pregnancy because of its theoretical risk of teratogenicity, and nitrofurantoin should be avoided in late pregnancy as it may cause neonatal haemolysis. Following treatment, she should be reviewed throughout the pregnancy to ensure eradication of the bacteriuria, and to permit early treatment of any relapse or reinfection.

Case 36.3

A 2-year-old boy is admitted to hospital with vomiting and abdominal pain. His mother reports that he was treated for UTI 6 months previously, but was not investigated further at the time. A clean catch urine sample shows over 50 white cells/mm³ and bacteria are seen on microscopy.

Question

What action should be taken?

Answer

It seems that this child is suffering from a recurrent UTI. An intravenous antibiotic such as cefuroxime should be started, since the child will not tolerate oral antibiotics at present. If the organism proves to be sensitive to amoxicillin, the treatment could be changed accordingly. Further investigations, for example, ultrasonography and radioisotope scan, may be carried out to determine any underlying cause of the infection and to look for already established renal scarring. The child may require long-term prophylaxis to prevent a further recurrence.

Case 36.4

A 62-year-old lady has been troubled by recurrent symptoms of UTI. She has been taking an oral oestrogen preparation for menopausal symptoms for some years. She is currently on an orthopaedic ward and catheterised because of incontinence. She is afebrile but has been confused since her hip replacement 5 days earlier, and remains on cefuroxime, which was started as prophylaxis at the time of the operation. The urine in her catheter bag is cloudy, has a high white cell count, and grows *Enterococcus faecalis* sensitive to amoxicillin but resistant to cephalosporins.

Question

How should this patient be managed? In older women, is there any association with the use of different types of oestrogen delivery systems and UTIs?

Answer

The patient's confusion may have a number of causes, including her recent surgery, sleep disturbance, drug toxicity, deep venous thrombosis or infection. If, following clinical examination and investigation, which should include blood cultures, her catheter-associated infection is thought to be contributing to her systemic problems, it should be treated with amoxicillin. If possible, the catheter should be removed, even if this is inconvenient for the nursing staff. Unless it has been prescribed for another indication, the cefuroxime is achieving nothing and may be stopped.

In post-menopausal women, there have been trials assessing the merits of topical oestrogen creams. Topical intravaginal oestriol cream has significant benefits in reducing the number of UTIs in those suffering recurrent infections. In a placebo-controlled trial, the rate of UTI was 12-fold less in the group receiving active oestrogen cream. This effect is not seen with oral oestrogens (Perrotta et al., 2008).

Case 36.5

A 45-year-old woman suffers from recurrent episodes of cystitis. Examination is unremarkable. On the occasions when a specimen has been sent, the urine has contained few white cells and no significant growth of organisms.

Question

How should the patient be managed?

Answer

This patient is suffering from the urethral syndrome, in which symptoms of infection are not associated with objective evidence of UTI. It may be felt necessary to investigate her to exclude less common causes of UTI such as herpes simplex virus, *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Gardnerella vaginalis*, *Mycoplasma hominis* and *Lactobacilli*. Otherwise, her symptoms are likely to respond to conventional courses of antibiotics. Consider non-infective causes, for example, psychological factors, trauma from intercourse.

Case 36.6

A 23-year-old woman has recurrent symptoms of UTI temporally related to sexual intercourse, despite following advice to empty her bladder as soon as possible after sex.

Question

What do you think of the use of antibiotics such as trimethoprim for women who get recurrent problems after sexual intercourse?

Answer

Post-coital voiding does not have any prospective data to support it, but it is a simple, harmless intervention. Long-term continuous antimicrobial prophylaxis is unquestionably an effective treatment but may be overtreating those in whom UTIs follow intercourse. Post-coital prophylaxis, a single dose within 2 h of intercourse, has the advantage of using less antibiotic overall. One small placebo-controlled double-blind trial assessed the efficacy of post-coital co-trimoxazole in preventing recurrent UTI and found that 12% of the active-treatment patients developed a UTI in 6 months, compared to 82% of the control group. Other studies have shown nitrofurantoin, cefalexin and ciprofloxacin also to be effective.

Gastro-intestinal infections 37

J.W. Gray

Key points

- There are many different microbial causes of gastro-intestinal infections.
- Gastroenteritis is the most common syndrome of gastro-intestinal infection, but some gastro-intestinal pathogens can cause systemic infections.
- Fluid and electrolyte replacement is the mainstay of management of gastroenteritis.
- Most cases of gastroenteritis that occur in developed countries are mild and self-limiting, and do not require antibiotic therapy.
- Antibiotic therapy should be considered for patients with underlying conditions that predispose to serious or complicated gastroenteritis, or where termination of faecal excretion of pathogens is desirable to prevent further spread of the infection.
- *Clostridium difficile* is a very important cause of diarrhoea in hospitals. Strict control measures are required, and cases should be treated with oral metronidazole or vancomycin.
- Antibiotic therapy is also essential for life-threatening systemic infections, such as enteric fever.
- Where possible, antibiotic therapy should be delayed until a microbiological diagnosis has been established.
- The fluoroquinolones, for example, ciprofloxacin, are currently the most useful antibiotics for treating most bacterial gastro-intestinal infections, but resistance rates are increasing in many pathogens.
- Antibiotic resistance in gastro-intestinal pathogens is an escalating problem.

Gastro-intestinal infections represent a major public health and clinical problem worldwide. Many species of bacteria, viruses and protozoa cause gastro-intestinal infection, resulting in two main clinical syndromes. Gastroenteritis is a non-invasive infection of the small or large bowel that manifests clinically as diarrhoea and vomiting. Other infections are invasive, causing systemic illness, often with few gastro-intestinal symptoms. *Helicobacter pylori*, and its association with gastritis, peptic ulceration and gastric carcinoma, is discussed in Chapter 12.

Epidemiology and aetiology

In Western countries, the average person probably experiences one or two episodes of gastro-intestinal infection each year. Infections are rarely severe and the vast majority of cases never reach medical attention. Nevertheless, they are of considerable economic importance. In the UK, viruses such as rotaviruses, adenoviruses and noroviruses are probably the most common causes of gastroenteritis. *Campylobacter*, followed by non-typhoidal serovars of *Salmonella enterica*, are the most common reported causes of bacterial gastroenteritis. Cryptosporidiosis is the most commonly reported parasitic infection. In developing countries, the incidence of gastro-intestinal infection is at least twice as high and the range of common pathogens is much wider. Infections are more often severe and represent a major cause of mortality, especially in children.

Gastro-intestinal infections can be transmitted by consumption of contaminated food or water or by direct faecal–oral spread. Air-borne spread of viruses that cause gastroenteritis also occurs. The most important causes of gastro-intestinal infection, and their usual modes of spread, are shown in Table 37.1. In developed countries, the majority of gastro-intestinal infections are food borne. Farm animals are often colonised by gastro-intestinal pathogens, especially *Salmonella* and *Campylobacter*. Therefore, raw foods such as poultry, meat, eggs and unpasteurised dairy products are commonly contaminated and must be thoroughly cooked to kill such organisms. Raw foods also represent a potential source of cross-contamination of other foods, through hands, surfaces or utensils that have been inadequately cleaned. Food handlers who are excreting pathogens in their faeces can also contaminate food. This is most likely when diarrhoea is present, but continued excretion of pathogens during convalescence also represents a risk. Food handlers are the usual source of *Staphylococcus aureus* food poisoning, where toxin-producing strains of *S. aureus* carried in the nose or on skin are transferred to foods. Bacterial food poisoning is often associated with inadequate cooking and/or prolonged storage of food at ambient temperature before consumption. Water-borne gastro-intestinal infection is primarily a problem in countries without a sanitary water supply or sewerage system, although outbreaks of water-borne cryptosporidiosis occur from time to time in the UK. Spread of pathogens such as *Shigella* or enteropathogenic *Escherichia coli* by the faecal–oral route is favoured by overcrowding and poor standards of personal hygiene. Such infections in developed countries are most common in children and can cause troublesome outbreaks in paediatric wards, nurseries and residential children's homes.

Treatment with broad-spectrum antibiotics alters the bowel flora, creating conditions that favour superinfection with micro-organisms (principally *Clostridium difficile*) that can cause diarrhoea. *C. difficile* infection (CDI) may be associated

Table 37.1 Important causes of gastro-intestinal infection, their modes of spread and pathogenic mechanisms

Causative agent	Chief mode(s) of spread	Pathogenic mechanisms
Bacteria		
Campylobacter	Food, especially poultry, milk	Mucosal invasion Enterotoxin
Salmonella enterica, non-typhoidal serovars	Food, especially poultry, eggs, meat	Mucosal invasion Enterotoxin
Salmonella enterica serovars Typhi and Paratyphi	Food, water	Systemic invasion
Shigella	Faecal–oral	Mucosal invasion Enterotoxin
Escherichia coli		
Enteropathogenic	Faecal–oral	Mucosal adhesion
Enterotoxigenic	Faecal–oral, water	Enterotoxin
Enteroinvasive	Faecal–oral, food	Mucosal invasion
Verotoxin-producing	Food, especially beef	Verotoxin
Staphylococcus aureus	Food, especially meat, dairy produce	Emetic toxin
Clostridium perfringens	Food, especially meat	Enterotoxin
Bacillus cereus		
Short incubation period	Food, especially rice	Emetic toxin
Long incubation period	Food, especially meat and vegetable dishes	Enterotoxin
Vibrio cholerae O1, O139	Water	Enterotoxin
Vibrio parahaemolyticus	Seafoods	Mucosal invasion Enterotoxin
Clostridium difficile	Faecal–oral (nosocomial)	Cytotoxin Enterotoxin
Clostridium botulinum	Inadequately heat-treated canned/preserved foods	Neurotoxin
Protozoa		
Giardia lamblia	Water	Mucosal invasion
Cryptosporidium	Water, animal contact	Mucosal invasion
Entamoeba histolytica	Food, water	Mucosal invasion
Viruses	Food, faecal–oral, respiratory secretions	Small intestinal mucosal damage

with any antibiotic but clindamycin, the cephalosporins and the fluoroquinolones are most commonly implicated. CDI is most common in patients with serious underlying disease and in the elderly. Although some sporadic cases are probably due to overgrowth of endogenous organisms, person-to-person transmission also occurs in hospitals and care homes, sometimes resulting in large outbreaks.

Pathophysiology

Development of symptoms after ingestion of gastro-intestinal pathogens depends on two factors. First, sufficient organisms must be ingested and then survive host defence mechanisms,

and second, the pathogens must possess one or more virulence mechanisms to cause disease.

Host factors

Healthy individuals possess a number of defence mechanisms that protect against infection by enteropathogens. Therefore, large numbers of many pathogens must be ingested for infection to ensue; for example, the infective dose for *Salmonella* is typically around 10^5 organisms. Other species, however, are better able to survive host defence mechanisms; for example, infection with *Shigella* or verotoxin-producing *E. coli* (VTEC) can result from ingestion of fewer than 100 organisms. VTEC (principally *E. coli* O157) are especially important because

of the risk of a life-threatening complication, haemolytic uraemic syndrome (HUS).

Gastric acidity

Most micro-organisms are rapidly killed at normal gastric pH. Patients whose gastric pH is less acidic, as for example, following treatment with antacids or ulcer-healing drugs, are more susceptible to gastro-intestinal infections. There is a particularly strong association between proton pump inhibitor use and CDI.

Intestinal motility

It is widely held that intestinal motility helps to rid the host of enteric pathogens, and that anti-motility agents are therefore potentially hazardous in patients with infective gastroenteritis. Despite this, self-medication with antidiarrhoeals is commonly practised, and in otherwise healthy individuals is probably safe.

Resident microflora

The resident microflora of the lower gastro-intestinal tract, largely composed of anaerobic bacteria, help to resist colonisation by enteropathogens.

Immune system

Phagocytic, humoral and cell-mediated elements are important in resistance to different pathogens. Individuals with inherited or acquired immunodeficiencies are therefore susceptible to specific gastro-intestinal infections, depending on which components of their immune system are affected.

Organism factors

The first requirement of gastro-intestinal pathogens is that they are able to adhere to the gut wall and colonise the intestine. The symptoms of gastro-intestinal infection can then be mediated by various mechanisms (see Table 37.1).

Toxins

Toxins produced by gastro-intestinal pathogens can be classified as enterotoxins, neurotoxins and cytotoxins. Enterotoxins act on intestinal mucosal cells to cause net loss of fluid and electrolytes. The classic enterotoxin-mediated disease is cholera, the result of infection with toxigenic serotypes of *Vibrio cholerae*. Many other bacteria produce enterotoxins, including enterotoxigenic *E. coli* and *Clostridium perfringens*. The emetic toxins of *S. aureus* and *Bacillus cereus* are neurotoxins that induce vomiting by an action on the central nervous system. The symptoms of botulism are mediated by a neurotoxin that blocks release of acetylcholine at nerve endings. Cytotoxins cause mucosal destruction and inflammation (see later). The pathogenicity of *C. difficile* is mediated by two exotoxins, TcdA and TcdB, both of which are potent cytotoxic enzymes that damage the human colonic mucosa. Verotoxins are potent cytotoxins that cause direct damage to small-vessel endothelial cells, which is exacerbated by stimulation of production of inflammatory mediators by non-endothelial cells. This causes multiorgan microvascular injury, expressed most commonly as haemorrhagic colitis and HUS.

Mucosal damage

Cytotoxins are important in mediating mucosal invasion, but other mechanisms are also involved. Enteropathogenic *E. coli* causes diarrhoea by damaging microvilli when it adheres to the intestinal mucosa. Organisms such as *Shigella* and enteroinvasive *E. coli* express surface proteins that facilitate mucosal invasion. Diarrhoea due to mucosal damage may be due to reduction in the absorptive surface area or the presence of increased numbers of immature enterocytes which are secretory rather than absorptive.

Systemic invasion

The lipopolysaccharide outer membrane and possession of an antiphagocytic outer capsule are important virulence factors in invasive *Salmonella* infections.

Clinical manifestations

Many cases of gastro-intestinal infection are asymptomatic or cause subclinical illness. Gastroenteritis is the most common syndrome of gastro-intestinal infection, presenting with symptoms such as vomiting, diarrhoea and abdominal pain. The term 'dysentery' is sometimes applied to infections with *Shigella* (bacillary dysentery) and *Entamoeba histolytica* (amoebic dysentery), where severe colonic mucosal inflammation causes frequent diarrhoea with blood and pus. Table 37.2 shows the most important causative agents of gastroenteritis together with a brief description of the typical illness that each causes. However, the symptoms experienced by individuals infected with the same organism can differ considerably. This is important because it means that it is rarely possible to diagnose the cause of gastroenteritis on clinical grounds alone.

Gastro-intestinal manifestations of infection with VTEC range from non-bloody diarrhoea to haemorrhagic colitis. In addition, VTEC are the most important cause of HUS, a serious complication which is most common in young children and the elderly. HUS is defined by the triad of microangiopathic haemolytic anaemia, thrombocytopenia and acute renal dysfunction. The mortality is about 5% and up to half the survivors suffer long-term renal damage.

The clinical spectrum of CDI ranges from asymptomatic carriage to life-threatening pseudomembranous colitis (so-called because yellow-white plaques or membranes consisting of fibrin, mucus, leucocytes and necrotic epithelial cells are found adherent to the inflamed colonic mucosa).

Enteric fever, resulting from infection with *S. enterica* serovars Typhi and Paratyphi, presents with symptoms such as headache, malaise and abdominal distension after an incubation

Table 37.2 Characteristic clinical features of various causes of gastroenteritis

Causative agent	Incubation period	Symptoms (syndrome)
Campylobacter	2–5 days	Bloody diarrhoea Abdominal pain Systemic upset
Salmonella	6–72 h	Diarrhoea and vomiting Fever; may be associated bacteraemia
Shigella	1–4 days	Diarrhoea, fever (bacillary dysentery)

Escherichia coli
  Enteropathogenic
  Enterotoxigenic
  Enteroinvasive
	
	12–72 h
	1–3 days
	1–3 days
		
		Infantile diarrhoea
		Traveller's diarrhoea
		Similar to Shigella

Verotoxin-producing	1–3 days	Bloody diarrhoea (haemorrhagic colitis) Haemolytic uraemic syndrome
Staphylococcus aureus	4–8 h	Severe nausea and vomiting
Clostridium perfringens	6–24 h	Diarrhoea

Bacillus cereus
  Short incubation period
  Long incubation period
	
	1–6 h
	6–18 h
		
		Vomiting
		Diarrhoea

Vibrio cholerae O1, O139	1–5 days	Profuse diarrhoea (cholera)
Vibrio parahaemolyticus	12–48 h	Diarrhoea, abdominal pain
Clostridium difficile	Usually occurs during/just after antibiotic therapy	Diarrhoea, abdominal pain, pseudomembranous enterocolitis
Giardia lamblia	1–2 weeks	Watery diarrhoea
Cryptosporidium	2 days–2 weeks	Watery diarrhoea
Entamoeba histolytica	2–4 weeks	Diarrhoea with blood and mucus (amoebic dysentery), liver abscess
Viruses	1–2 days	Vomiting, diarrhoea Systemic upset

period of 3–21 days. During the first week of the illness, the temperature gradually increases, but the pulse characteristically remains slow. Without treatment, during the second and third weeks, the symptoms become more pronounced. Diarrhoea develops in about half of cases. Examination usually reveals splenomegaly, and a few erythematous macules (rose spots) may be found, usually on the trunk. Serious gastro-intestinal complications such as haemorrhage and perforation are most common during the third week. Symptoms begin to subside slowly during the fourth week. In general, paratyphoid fever is less severe than typhoid fever.

Botulism typically presents with autonomic nervous system effects, including diplopia and dysphagia, followed by symmetrical descending motor paralysis. There is no sensory involvement.

Gastro-intestinal infections are often followed by a period of convalescent carriage of the pathogen. This usually lasts for no more than 4–6 weeks but can be for considerably longer, especially for *Salmonella.*

Investigations

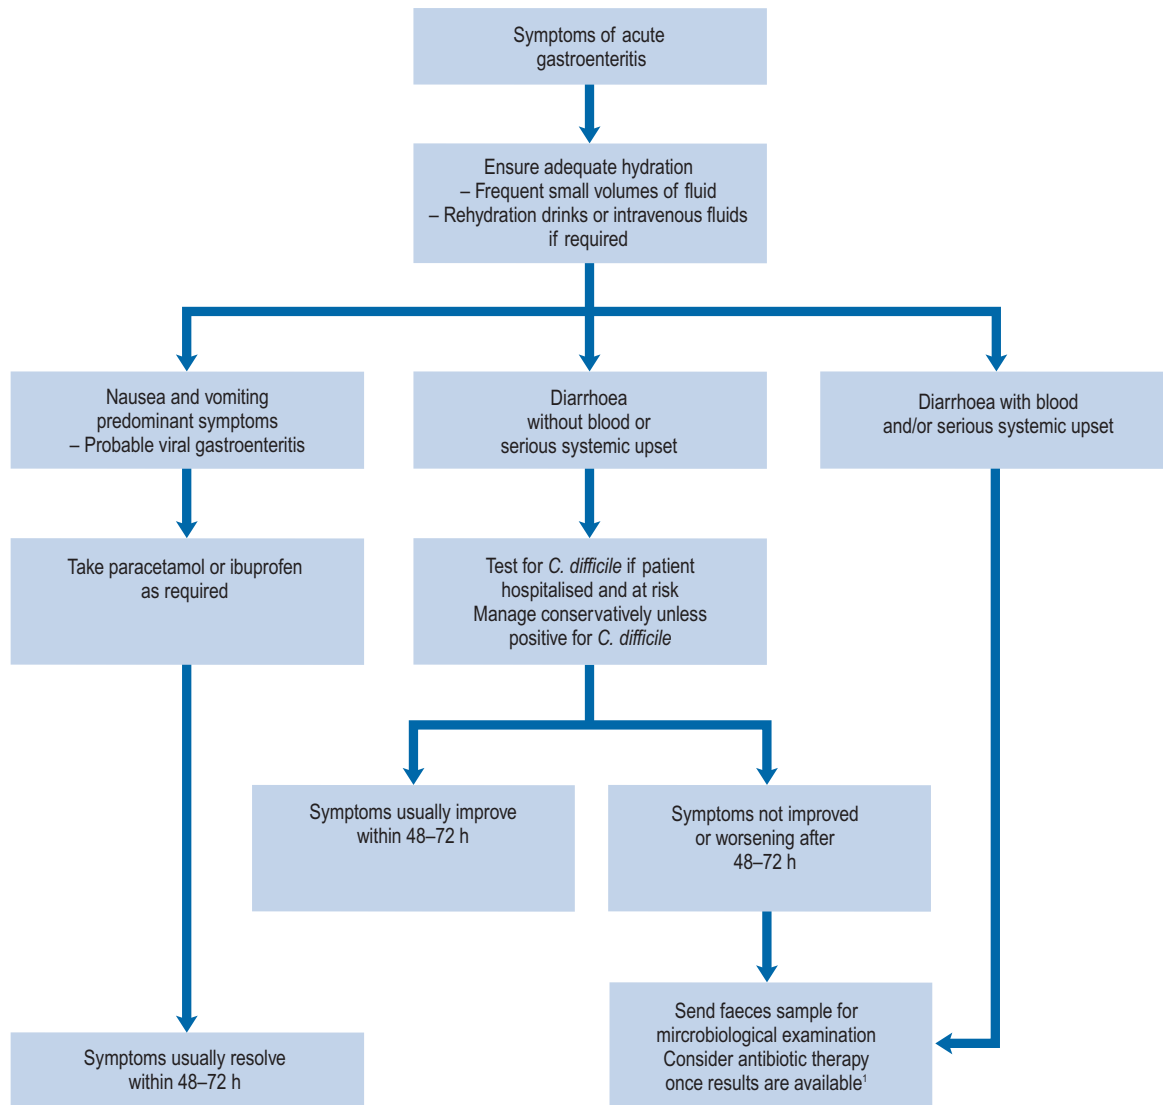
Many cases of gastroenteritis outside hospital are mild and short lived, and microbiological investigation may not be necessary. However, investigations are always recommended where antibiotic therapy is being considered (Fig. 37.1), where there are public health concerns (e.g., if the sufferer works in the food industry) and for gastro-intestinal infections in hospitalised patients.


Fig. 37.1 Pathway for the investigation and management of patients with symptoms of acute gastroenteritis.

The mainstay of investigation of diarrhoeal illness is examination of faeces. Bacterial infections are usually diagnosed by stool culture. Various selective culture media designed to suppress growth of normal faecal organisms and/or enhance the growth of a particular pathogen are used. When sending specimens to the laboratory, it is important that details of the age of the patient, the clinical presentation and recent foreign travel are provided so that appropriate media for the likely pathogens can be selected. Several tests are available for rapid detection of *C. difficile* toxin, or of toxigenic *C. difficile*, in faeces: early and accurate diagnosis is crucial for the control of *C. difficile* in hospitals. Sigmoidoscopy is used to diagnose pseudomembranous colitis.

Various other procedures are sometimes useful in investigating patients with suspected bacterial gastroenteritis. Blood cultures should be taken from patients with severe systemic upset and are especially important when enteric fever is suspected. In enteric fever, the causative organism may also be cultured from urine or bone marrow. In *S. aureus* and *B. cereus* food poisoning, the pathogen can sometimes be isolated from vomitus. In cases of food poisoning, suspect foods may also be cultured. In general, serological investigations are of little value in the diagnosis of bacterial gastroenteritis. However, demonstration of serum antibodies to *E. coli* O157 can be helpful in confirming the cause of the HUS. Serological tests for typhoid and paratyphoid fever are available, but the results must be interpreted with caution. Botulism is diagnosed by demonstration of toxin in serum.

Parasitic infestations are usually detected by microscopic examination of faeces. Electron microscopy has been largely superseded by immunological and molecular-based detection techniques for detection of enteric viruses.

Treatment

Many gastro-intestinal infections are mild and self-limiting and never reach medical attention. Where treatment is required, there are three main therapeutic considerations. Fluid and electrolyte replacement is the cornerstone of treatment of diarrhoeal disease. Most patients can be managed with oral rehydration regimens, but severely dehydrated patients require rapid volume expansion with intravenous fluids. Symptomatic treatment with antiemetics and anti-motility (antidiarrhoeal) agents is sometimes used, especially as self-medication. Antimicrobial agents may be useful both in effecting symptomatic improvement and in eliminating faecal carriage of pathogens and therefore reducing the risk of transmitting infection to others.

Antiemetics and antidiarrhoeal drugs are discussed in Chapters 34 and 14, respectively. This chapter focuses on the place of antibiotic therapy in gastro-intestinal infections.

Antibiotic therapy

The requirement for antibiotic treatment in gastro-intestinal infection depends on the causative agent, the type and severity of symptoms and the presence of underlying disease. Antibiotics are ineffective in some forms of gastroenteritis, including bacterial intoxications and viral infections. For many other infections, such as salmonellosis and campylobacteriosis, effective agents are available, but antimicrobial therapy is often not clinically necessary. Serious infections such as enteric fever always require antibiotic therapy.

Conditions for which antibiotic therapy is not available or not usually required

The symptoms of *S. aureus* and short incubation period *B. cereus* food poisoning and botulism are usually caused by ingestion of preformed toxin, and therefore antibiotic therapy would not influence the illness. Pathogens such as *C. perfringens*, *Vibrio parahaemolyticus* and enteropathogenic *E. coli* usually cause a brief self-limiting illness that does not require specific treatment.

None of the presently available antiviral agents are useful in viral gastroenteritis. While most viral infections are self-limiting, chronic viral gastroenteritis can occur in immuno-compromised patients. Where possible, immunosuppression should be reduced. Immunoglobulin-containing preparations, administered orally or directly into the duodenum via a nasogastric tube, have also been reported to be effective in managing chronic viral gastroenteritis in immunocompromised patients. As well as human serum immunoglobulin, antibodies from other species (e.g. immunised bovine colostrum) have been used. Immunotherapy of viral gastroenteritis remains experimental, and dosages and frequency of administration of immunoglobulin preparations cannot be recommended (Mohan and Haque, 2002).

At least one study has found that the risk of HUS in children with diarrhoea due to VTEC was much higher in those who received antibiotics. On that basis, it is advised in the UK that antibiotics are contraindicated in children with VTEC infection (National Collaborating Centre for Women's and Children's Health, 2009).

Conditions for which antimicrobial therapy may be considered

The place for antibiotics in the management of uncomplicated gastroenteritis due to bacteria such as *Salmonella* and *Campylobacter* is not clear cut. Certain antibiotics are reasonably effective in reducing the duration and severity of clinical illness and in eradicating the organisms from faeces. However, many microbiologists are cautious about the widespread use of antibiotics in diarrhoeal illness because of the risk of promoting antibiotic resistance (Sack et al., 1997). Another difficulty with respect to antibiotic prescribing is that it is not usually possible to determine the aetiological agent of diarrhoea on clinical grounds, and stool culture takes at least 48 h. Patients with severe illness, especially systemic symptoms, may require antibiotic therapy before the aetiological agent has been established. In such circumstances, a fluoroquinolone antibiotic such as ciprofloxacin would usually be the most appropriate empiric agent, at least in patients in whom CDI is considered unlikely or has been excluded. Otherwise, it is reasonable to limit antibiotic use to microbiologically proven cases where there is serious underlying disease and/or continuing severe symptoms. Antibiotics may also be used to try to eliminate faecal carriage, for example, in controlling outbreaks in institutions, or in food handlers who may be prevented from returning to work until they are no longer excreting gastro-intestinal pathogens.

Campylobacteriosis. Erythromycin is effective in terminating faecal excretion of *Campylobacter*. Some studies have shown that treatment commenced within the first 72–96 h of illness can also shorten the duration of clinical illness, especially in patients with severe dysenteric symptoms. The recommended dosage for adults is 250–500 mg four times a day orally for 5–7 days, and for children 30–50 mg/kg/day in four divided doses. Clarithromycin 250–500 mg (children under 1 year, 7.5 mg/kg; 1–2 years, twice a day; 3–6 years, 125 mg; 7–9 years, 5–7 days) or azithromycin 500 mg (children 10 mg/kg) once daily for 3 days are also effective. Ciprofloxacin, at a dose of 500 mg twice daily orally for adults, may also be effective in *Campylobacter* enteritis. However, whereas resistance rates to erythromycin have generally remained below 5%, resistance to ciprofloxacin has emerged, exceeding 10% in the UK and 50% in some countries (Dingle et al., 2005).

Salmonellosis. Most cases of *Salmonella* gastroenteritis are self-limiting and antibiotic therapy is unnecessary. However, antimicrobial therapy of salmonellosis is routinely recommended for infants aged under 6 months and immunocompromised patients, who are susceptible to complicated infections. Most antibiotics, even those with good *in vitro* activity, do not alter the course of uncomplicated *Salmonella* gastroenteritis. However, the fluoroquinolones, such as ciprofloxacin, can often shorten both the symptomatic period and the duration of faecal carriage. Ciprofloxacin resistance is now seen in up to 10% of non-typhoidal serovars of *S. enterica* in some

countries but is still uncommon in the UK (Murray et al., 2005). The recommended dose of ciprofloxacin for adults is 500 mg twice daily orally for 1 week. Fluoroquinolones are not licensed for this indication in children, although there is increasing evidence that they can safely be given to children. The recommended dose of ciprofloxacin in childhood is 7.5 mg/kg twice daily orally. Trimethoprim at a dose of 25–100 mg twice daily orally may be used in children if it is preferred not to use a fluoroquinolone.

Ciprofloxacin given orally at a dose of 500–750 mg twice daily in adults (7.5–12.5 mg/kg twice daily in children) or 200 mg intravenously twice daily in adults (5–7.5 mg/kg twice daily in children) is recommended for invasive salmonellosis. Alternative agents include ampicillin or amoxicillin, trimethoprim or chloramphenicol (see under enteric fever). However, resistance to these agents is more common than resistance to ciprofloxacin, and they are not recommended as empiric therapy.

E. coli infections. While most infections with enteropathogenic *E. coli* can be managed conservatively, small trials suggest that trimethoprim may be effective, especially in controlling nursery or hospital outbreaks. On the basis that enteroinvasive *E. coli* are closely related to *Shigella* and cause a similar clinical syndrome, similar therapy may be appropriate. Antibiotic therapy for traveller's diarrhoea caused by enterotoxigenic *E. coli* infection is often unnecessary, but troublesome symptoms will often respond to a single dose of ciprofloxacin or azithromycin, the need for further doses depending on clinical response. Alternatively, a 3–5 day course of trimethoprim may be given, although resistance is becoming increasingly common in some areas. Rifaximin is a new non-absorbable antibiotic that is available in a number of countries. It appears to be as effective as ciprofloxacin in treating *E. coli*-predominant traveller's diarrhoea but is ineffective in patients with inflammatory or invasive enteropathogens (Robins and Wellington, 2005). The dose for adults is 200 mg three times per day for 3 days.

Conditions for which antimicrobial therapy is usually indicated

Shigellosis. *Shigella sonnei*, which accounts for most cases of shigellosis in the UK and most other industrialised countries, usually causes a mild self-limiting illness. Even if not required on clinical grounds, antibiotic therapy for shigellosis is usually recommended in order to eliminate faecal carriage, and therefore prevent person-to-person transmission. In contrast to salmonellosis, a number of antibiotics may be effective in shortening the duration of illness and terminating faecal carriage. This is especially true of strains of *S. sonnei* that are endemic in industrialised countries, whereas in developing countries, *Shigella* species that are multiple antibiotic resistant are an increasing problem. The fluoroquinolones are highly effective in shigellosis and resistance is rare; therefore, they are often considered to be the treatment of choice, especially in adults and/or for treating imported infections. The dose of ciprofloxacin is 500 mg twice daily orally in adults (7.5 mg/kg twice daily in children). Amoxicillin is an alternative first-line

drug for *S. sonnei* infections acquired in the UK, where around 90% of isolates are susceptible. The dose of amoxicillin is 250–500 mg three times daily in adults, and 62.5–125 mg three times daily in children. Azithromycin (doses as for campylobacteriosis) is increasingly recommended as an alternative agent for shigellosis, especially in children (Jain et al., 2005). Third-generation cephalosporins such as ceftriaxone are another option for severe shigellosis. Trimethorpim resistance is now common, so this agent can no longer be recommended as empiric therapy. Antibiotic therapy is usually given for a maximum of 5 days.

Enteric fever. Treatment should be commenced as soon as a clinical diagnosis of enteric fever is made. Fluoroquinolones remain widely used as the first-choice treatment for typhoid and paratyphoid fevers. When treating isolates that are fully sensitive, the clinical response is at least as rapid as with the older treatments, there is a lower relapse rate, and convalescent faecal carriage is shortened. However, the proportion of isolates with reduced susceptibility to fluoroquinolones has increased to around 75%. Although most of these isolates have minimum inhibitory concentration (MIC) values below those regarded as fully resistant, treatment failures have been reported. Resistance to other antibiotics that have been commonly used to treat enteric fever, such as co-trimoxazole, chloramphenicol and ampicillin, is now frequent. These agents therefore cannot be recommended as alternatives to fluoroquinolones for empiric treatment of enteric fever, but may be useful in patients with bacterial isolates that are confirmed as sensitive. Doses of ciprofloxacin are as outlined for non-typhoidal salmonellosis. The usual dose of chloramphenicol is 50 mg/kg/day in four divided doses, and for ampicillin 100 mg/kg/day in four divided doses. Two weeks of antibiotic therapy is usually recommended, although shorter courses of ciprofloxacin (7–10 days) may be as effective.

Alternative agents that have been reported to be successful where treatment failure with fluoroquinlones has occurred include intravenous carbapenems or third-generation cephalosporins (e.g. ceftriaxone 75 mg/day; maximum dose 2.5 g/day) or oral azithromycin at a dose of 20 mg/kg/day (maximum 1000 mg) for at least 5 days. Time taken for clearance of bacteraemia may be longer with azithromycin, but the relapse rate appears to be lower than with β-lactam antibiotics such as ceftriaxone. There is some evidence that gatifloxacin, a new-generation fluoroquinolone, may be more effective than ciprofloxacin or ofloxacin in the treatment of infections where isolates have decreased fluoroquinolone susceptibility.

Chronic carriers of Salmonella. Patients may become chronic carriers after *Salmonella* infection, especially in the presence of underlying biliary tract disease. Oral ciprofloxacin 500–750 mg twice daily continued for 2–6 weeks is usually effective in eradicating carriage and has largely superseded the use of oral amoxicillin at a dose of 3 g twice daily.

Cholera. Fluid and electrolyte replacement is the key aspect of the management of cholera. However, antibiotics do shorten the duration of diarrhoea and therefore reduce the overall fluid loss, and also rapidly terminate faecal excretion of the organism. Effective agents include tetracyclines, erythromycin, trimethoprim, ampicillin or amoxicillin,

chloramphenicol, ciprofloxacin and furazolidine. However, antibiotic resistance is being increasingly seen, and in particular, *V. cholerae* O139 is intrinsically resistant to furazolidine and trimethoprim. Choice of antibiotics is therefore governed by knowledge of local resistance patterns, which may vary between outbreaks. Tetracycline 250 mg four times daily, or doxycycline 100 mg once daily by mouth, is probably the most widely used therapy in adults. Ampicillin, amoxicillin or erythromycin are generally the preferred agents for children. Although clinical cure can be achieved after a single dose of antibiotics, treatment is usually given for 3–5 days to ensure eradication of *V. cholerae* from faeces.

***C. difficile* infection.** The first objective is to diagnose CDI as soon as possible so that appropriate treatment and infection control measures can be put in place. Clinicians must consider the diagnosis in any patient where there is no clear alternative diagnosis for their diarrhoea. Stool samples must be sent to the laboratory immediately, and the laboratory must make testing available 7 days per week. Once the diagnosis is confirmed, attention must be paid to the patient's hydration and nutrition, non-essential antibiotic therapy or gastro-intestinal active drugs must be stopped and the patient's condition closely monitored. Although mild cases may resolve without specific therapy, treatment of all hospitalised patients with diarrhoea due to *C. difficile* is recommended, to shorten the duration of illness and to reduce environmental contamination and therefore the risk of nosocomial transmission.

Oral metronidazole 400 mg three times daily for 10 days is the treatment of choice for mild to moderate CDI. For severe CDI, oral vancomycin is recommended at a dose of 125 mg four times daily for 10 days. In patients unable to take oral medication, either drug can be administered via a nasogastric tube. Where there is no response to initial treatment, the dose of vancomycin can be increased to up to 500 mg four times daily, together with intravenous metronidazole 500 mg three times daily. Addition of oral rifampicin (300 mg twice daily) or administration of intravenous immunoglobulin (400 mg/kg) can also be considered.

Recurrence of symptoms occurs in about 20% of patients treated for CDI. Although some recurrences are due to germination of spores that have persisted in the colon since the original infection, it is recognised that some of these cases are due to reinfection, rather than relapse caused by the original strain (Loo et al., 2004). Most recurrences respond to a further 10–14 day course of metronidazole or vancomycin, but a few patients experience repeated recurrences. There is no reliable means of managing these patients. Options include:

- a supervised trial of anti-motility agents alone (if there are no abdominal symptoms or signs of severe CDI)
- tapering or pulse therapy with oral vancomycin given for 4–6 weeks
- a 2-week course of oral vancomycin 125 mg four times daily and oral rifampicin 300 mg twice daily
- intravenous immunoglobulin, especially if the patient's albumin status worsens
- donor stool transplant.

Trial data do not currently support the use of probiotics for the treatment or prevention of CDI (Department of Health and Health Protection Agency, 2009).

Cryptosporidiosis. Cryptosporidiosis in immunocompetent individuals is generally self-limiting. However, in immunosuppressed patients, severe diarrhoea can persist indefinitely and can even contribute to death. HIV-infected patients on highly active antiretroviral therapy (HAART) now have a much lower incidence of cryptosporidiosis due to immune reconstitution, and possibly a direct anti-cryptosporidium effect of protease inhibitors. There is no reliable antimicrobial therapy. Azithromycin, which is readily prescribable, is partially effective at a dose of 500 mg once daily (10 mg/kg once daily in children). Treatment should be continued until *Cryptosporidium* oocysts are no longer detectable in faeces (typically 2 weeks), to minimise the risk of relapse post-treatment. Occasionally, therapy has to be continued indefinitely to prevent relapse. Most other agents that have been recommended for treatment of cryptosporidiosis, for example, nitazoxanide, spiramycin, paromomycin and letrazuril, are not licensed in the UK. These can usually be sourced from special order manufacturing or importing companies (Smith and Corcoran, 2004). Of these agents, nitazoxanide has FDA approval in the USA, and has been shown to be effective in clinical trials at a dose of 500 mg twice daily (adults and children aged 12 years and over) for 3 days (children 1–3 years 100 mg bd; 4–11 years 200 mg bd). However, it is not effective unless the patient is able to mount an appropriate immune response.

Giardiasis. Metronidazole is the treatment of choice for giardiasis. Various oral regimens are effective, for example, 400 mg three times daily (7.5 mg/kg in children) for 5 days, or 2 g/day (children 500 mg to 1 g) for 3 days. Alternative treatments are tinidazole 2 g as a single dose, or mepacrine hydrochloride 100 mg (2 mg/kg in children) three times daily for 5–7 days. Nitazoxanide is a new thiazolide antiparasitic drug (discussed under cryptosporidiosis) that has also been licensed for treatment of giardiasis in some countries, but is not currently available in the UK. A single course of treatment for giardiasis has a failure rate of up to 10%. A further course of the same or another agent is often successful. Sometimes, repeated relapses are due to reinfection from an asymptomatic family member. In such cases, all affected family members should be treated simultaneously.

Amoebiasis. The aim of treatment in amoebiasis is to kill all vegetative amoebae and also to eradicate cysts from the bowel lumen. Metronidazole is highly active against vegetative amoebae and is commonly the treatment of choice for acute amoebic dysentery and amoebic liver abscess. The dose for adults is 800 mg (children 100–400 mg) three times daily for 5–10 days. To eradicate cysts, metronidazole therapy is followed by a 5-day course of diloxanide furoate 500 mg three times daily (20 mg/kg daily in three divided doses for children). Tinidazole has recently been shown to reduce clinical failure and be better tolerated than metronidazole (Gonzales et al., 2009). The dose of tinidazole for adults is 2 g daily for 2–3 days, and for children, 50–60 mg/kg daily for 3 days.

Asymptomatic excretors of cysts living in areas with a high prevalence of *E. histolytica* infection do not merit treatment

because most individuals quickly become reinfected. However, asymptomatic excretors of cysts in Europe or North America are usually treated with diloxanide furoate for 5–10 days: metronidazole and tinidazole are relatively ineffective in this situation.

Patient care

People excreting gastro-intestinal pathogens are potentially infectious to others. Liquid stools are particularly likely to contaminate the hands and the environment. All cases of gastro-intestinal infection should be excluded from work or school at least until the patients are symptom free; hospitalised patients should be isolated in a single room. Patients should be advised on general hygiene, and in particular, on thorough handwashing and drying after visiting the toilet and before handling food.

In most countries, many gastro-intestinal infections are statutorily notifiable. Following notification, the authorities will judge whether the implications for public health merit investigation of the source of infection, contact screening or follow-up clearance stool samples from the original case.

Common therapeutic problems in the management of gastro-intestinal infection are summarised in Table 37.3. Problems associated with specific gastro-intestinal infections are summarised in Table 37.4.

Table 37.3 Practice points: general problems with treatment of gastro-intestinal infections

Problems	Resolution
Difficult or impossible to make a rapid aetiological diagnosis	Hospital laboratories are expected to offer rapid testing for *C. difficile* 7 days per week
New, more accurate, diagnostic tests for viral gastroenteritis are becoming more widely available	Few other recent improvements in the diagnosis of bacterial or parasitic infections
Clinical effectiveness and cost-effectiveness of antibiotic therapy for many bacterial gastro-intestinal infections are not clearly established	Without reliable data showing benefit, antimicrobial therapy is not used in the majority of infections
No specific therapies for viral gastroenteritis	Infections in otherwise healthy individuals are generally self-limiting Various non-evidence-based experimental treatments have been used to manage immunocompromised patients with protracted diarrhoea
Acute illness may be followed by a period of non-infective diarrhoea	Cautious use of antidiarrhoeal medication may be indicated at this stage

Table 37.4 Practice points: problems with treatment of specific gastro-intestinal infections

Infection	Antibiotic	Problems	Resolution
Campylobacteriosis	Erythromycin	Not always effective, especially if commenced >72 h after onset of symptoms	Reserve therapy for cases where symptoms are severe or worsening at time of diagnosis
	Ciprofloxacin[a]	Up to 50% of strains are resistant	Use only as a second-line agent for isolates that have been shown to be sensitive
Salmonellosis	Ciprofloxacin[a]	Not always effective Resistance is increasing	Reserve therapy for cases where symptoms are severe or worsening at time of diagnosis
Enteric fever	Ciprofloxacin[a]	Resistance is increasing	Alternative therapies must be guided by antibiotic sensitivities of the isolate
	Ampicillin or amoxicillin	Resistance to these agents now common	Ciprofloxacin[a] now generally regarded as treatment of choice
	Chloramphenicol	Higher incidence of chronic carriage and relapse than with ciprofloxacin	
Shigellosis	Trimethoprim	Resistance is increasing	Therapy should be guided by antibiotic sensitivities of the isolate. Most trimethoprim-resistant strains are ciprofloxacin sensitive

Table 37.4 Practice points: problems with treatment of specific gastro-intestinal infections—cont'd

Infection	Antibiotic	Problems	Resolution
Clostridium difficile	Metronidazole	Relapse rate up to 20%	Repeat course of treatment, or treatment with vancomycin
	Vancomycin	May be more effective, but much more expensive, than metronidazole Risk of promoting emergence and spread of vancomycin-resistant enterococci Relapse may occur	Generally reserved as a second-line agent, for example, where no response to metronidazole, or for patients with severe infection Repeat course of treatment; various treatment options for patients with repeated relapse
Cryptosporidiosis	Azithromycin	Not always effective Recommended only for patients who are immunocompromised or have unusually severe or protracted symptoms	Long-term therapy may be required to control symptoms Possible alternative agents are not licensed in UK

^aCiprofloxacin is not licensed for general paediatric use; it is widely used to treat gastro-intestinal infections in children.

Case studies

Case 37.1

A 12-year-old boy is admitted to hospital with a history of fever, weight loss and malaise 1 week after returning from visiting relatives in Pakistan. Whilst there he was diagnosed as having typhoid fever, and although details are sketchy, it seems that he received treatment with ciprofloxacin. The only other medical history of note is that he experienced an anaphylactic reaction after taking penicillin 4 years ago. Twenty-four hours after admission, *S. enterica* serovar Typhi is isolated from a blood culture.

Questions

1. Why might the patient not have responded fully to the treatment given in Pakistan?
2. Which antibiotic would now be most appropriate as empiric therapy?

Answers

1. Strains of *S. enterica* serovar Typhi that have reduced susceptibility to fluoroquinolones are common in the Indian subcontinent. Although these strains are not usually fully fluoroquinolone resistant, treatment failures have been reported, even when an appropriate dose regimen has been used: in this case, there is not even any assurance that the treatment regimen in Pakistan was adequate.
2. Given the lack of assurance of the adequacy of the ciprofloxacin treatment in Pakistan, one option would be to re-treat with ciprofloxacin. However, given the high likelihood that the strain will have reduced susceptibility to ciprofloxacin, it would be more logical to use an alternative agent. Of those, carbapenems and cephalosporins are beta-lactam antibiotics that would be best avoided, given

the history of anaphylaxis following penicillin exposure. Azithromycin would appear, therefore, to be the empiric treatment of choice in this case.

Case 37.2

A mother brings her 6-year-old daughter to her primary care doctor because she has a 2-day history of bloody diarrhoea and abdominal pain. The family had been on a farm visit the previous weekend and had eaten food when there. The mother is anxious for her child to be treated with antibiotics because they will be going on their summer holiday in one week.

Questions

1. Give three possible infective causes of the girl's symptoms.
2. How should the clinician respond to the mother's request for antibiotics?

Answers

1. The two commonest bacterial gastro-intestinal infections, campylobacteriosis and salmonellosis, can both present in this way. Many other bacterial and protozoan causes of gastroenteritis can also cause similar symptoms. One bacterium that is especially important to consider in this case, where there is a history of a farm visit, is *E. coli* O157. Every effort should be made to obtain a stool sample from the patient for microbiological examination.
2. It would not be appropriate to treat this girl's symptoms empirically with antibiotics for a number of reasons. First, antibiotic therapy may make no difference to the speed of clinical resolution; second, where antibiotics are justified, the choice of drug will depend on the aetiological agent; and third, antibiotics are contraindicated in infection with *E. coli* O157, which must feature in the differential diagnosis in this case.

Case 37.3

A businessman is planning a short trip to Egypt. During previous visits to the area, he has experienced troublesome diarrhoea despite being careful about hygiene. Although the diarrhoea has not made him seriously unwell, it has caused him considerable inconvenience during business discussions.

Question

Are there any antimicrobials that he could take to prevent this problem?

Answer

Although traveller's diarrhoea is not usually serious, it can cause considerable inconvenience whether the sufferer is travelling for leisure or business reasons. Simple measures that can help prevent traveller's diarrhoea include taking care with food and drinks (only bottled water from reputable sources should be used). There are two approaches to antibiotic use in traveller's diarrhoea. Either the drug can be taken prophylactically to try to prevent diarrhoea developing, or treatment can be commenced with the onset of diarrhoea. The latter approach is generally preferred because it limits unnecessary exposure to antibiotics and the response to treatment is usually rapid. However, there are instances such as in this case where the inconvenience of even short-lived diarrhoea may be great enough to justify use of prophylaxis.

The choice of antibiotics for traveller's diarrhoea has been made more complicated by the increasing prevalence of antibiotic resistance in many developing countries. Drugs such as amoxicillin or trimethoprim no longer have a role. A fluoroquinolone, such as ciprofloxacin, still represents a reasonable first choice, with azithromycin as a possible alternative in areas where fluoroquinolone resistance is known to be common. For travellers from countries where it can be prescribed, rifaximin may be the agent of choice. For travellers to areas where infections such as amoebic dysentery or giardiasis are common, it may be appropriate to take a supply of metronidazole that can be started if there is no response to the first-line antibacterial prophylaxis.

Case 37.4

An 80-year-old woman on an elderly care ward develops watery diarrhoea and abdominal pain 4 days after commencing therapy with ciprofloxacin for a urinary tract infection. *C. difficile* toxin is detected in a stool sample. Five patients on that ward have also had *C. difficile*-associated diarrhoea during the past 2 months.

Questions

1. How should this patient be managed?
2. What measures might be taken to try to reduce the number of cases of *C. difficile*-associated diarrhoea on the ward?

Answers

1. Treatment with ciprofloxacin should be discontinued. Four-day antibiotic therapy for a urinary tract infection will often suffice, but if further treatment is required, an antibiotic that is less likely to disturb the bowel flora should be prescribed. Metronidazole is the preferred first-line treatment for mild to moderate CDI. The patient should be closely monitored for the frequency and severity of the diarrhoea. Oral vancomycin might be indicated later if her illness became more severe. The patient should be isolated to reduce the risk of spread of the infection.
2. There are two elements to control of *C. difficile* in hospitals. First, it is necessary to ensure that antibiotic prescribing is rational. There should be an antibiotic-prescribing policy that minimises use of antibiotics in general, and in particular, restricts use of antibiotics that are associated with a high risk of *C. difficile* (2nd- and 3rd-generation cephalosporins, clindamycin and fluoroquinolones). Compliance with the policy must be assured through measures such as checking of prescriptions, multidisciplinary antibiotic ward rounds, education of prescribers, and audits of antibiotic prescribing. Second, strict infection control precautions must be enforced, along with improved standards of environmental cleanliness, to reduce the risk of patients being exposed to the bacterium.

38 Infective meningitis

J. W. Gray

Key points

- The causative agents of meningitis are related to the age of the patient and the presence of underlying disease.
- The most common cause of early-onset neonatal meningitis is the group B streptococcus. Other important causes of neonatal meningitis include *Escherichia coli* and *Listeria monocytogenes.*
- Outside the neonatal period, *Neisseria meningitidis* and *Streptococcus pneumoniae* are the major causes of infective meningitis, accounting for around 75% of confirmed cases.
- Antibiotic treatment of meningitis requires attainment of adequate concentrations of bactericidal antibiotics in the cerebrospinal fluid (CSF).
- Suitable therapies for neonatal meningitis are ampicillin or amoxicillin, combined with either an aminoglycoside or a cephalosporin such as cefotaxime or ceftazidime.
- Increasing resistance to penicillins and concerns about the toxicity of chloramphenicol have led to the widespread use of cefotaxime or ceftriaxone as empiric therapy for meningitis outside the neonatal period.
- Because of the potentially rapid progression of the disease, patients with suspected meningococcal infection should receive emergency therapy with penicillin before admission to hospital.
- Close contacts of patients with meningococcal, and in some circumstances *Haemophilus influenzae* type b, disease should receive chemoprophylaxis.
- There is increasing evidence of the benefit of steroids as adjunctive therapy in the management of bacterial meningitis.
- Introduction into the routine immunisation schedule of vaccines against *H. influenzae* type b, *N. meningitidis* group C and common *S. pneumoniae* serotypes has markedly reduced the incidence of meningitis due to these bacteria.

Fig. 38.1 The meninges covering the brain and spinal cord and the flow of cerebrospinal fluid (arrowed) (modified from Ross and Wilson (1981), by permission of Churchill Livingstone).

The brain and spinal cord are surrounded by three membranes, which from the outside inwards are the dura mater, the arachnoid mater and the pia mater. Between the arachnoid mater and the pia mater, in the subarachnoid space, is found the cerebrospinal fluid (CSF) (Fig. 38.1). This fluid, of which there is ~150 mL^{-1} in a normal individual, is secreted by the choroid plexuses and vascular structures which are in the third, fourth and lateral ventricles. CSF passes from the ventricles via communicating apertures to the subarachnoid space, after which it flows over the surface of the brain and the spinal cord (see Fig. 38.1). The amount of CSF is controlled by resorption into the bloodstream by vascular structures in the subarachnoid space, called the arachnoid villi. Infective meningitis is an inflammation of the arachnoid and pia mater

associated with the presence of bacteria, viruses, fungi or protozoa in the CSF. Meningitis is one of the most emotive of infectious diseases, and for good reason: even today, infective meningitis is associated with significant mortality and risk of serious sequelae in survivors.

Aetiology and epidemiology

In the UK, around 1500 cases of meningitis are notified annually. However, this almost certainly under represents the true incidence of meningitis. Viruses are the most common cause of meningitis, and are often less serious than bacterial or fungal forms of the disease.

Bacterial meningitis

Although bacterial meningitis occurs in all age groups, it is predominantly a disease of young children, with 40–50% of all cases occurring in the first 4 years of life. Two bacteria, *N. meningitidis* and *S. pneumoniae*, account for about 75% of cases. However, the pattern of micro-organisms causing meningitis is related to the age of the patient and the presence of underlying disease.

N. meningitidis is the most common cause of bacterial meningitis from infancy through to middle age, with peaks of incidence in the under-5-year age group and in adolescents. There are several serogroups of *N. meningitidis*, including A, B, C, W135 and Y. In the late twentieth century, serogroups B and C accounted for 60–65% and 35–40% of infections in the UK, respectively. However, with the introduction of vaccination against *N. meningitidis* serogroup C (MenC) into the routine immunisation programme in 1999, serogroup B now accounts for well over 80% of all meningococcal disease. There is currently no vaccine available for *N. meningitidis* serogroup B. Serogroups A and W135 predominate in Africa and the Middle East. A quadrivalent vaccine against serogroups A, C, W135 and Y is available to protect travellers to countries of risk. *S. pneumoniae* is the most common cause of meningitis in adults aged over 45 years, but almost half of all cases of pneumococcal meningitis occur in children aged under 5 years. It has a poorer outcome than meningococcal meningitis. Vaccination against the most common serotypes of *S. pneumoniae* using a conjugate vaccine was added to the routine childhood immunisation programme in the UK in 2006: the original 7-valent vaccine was then replaced by a 13-valent vaccine in Spring 2010. A different 23-valent polysaccharide vaccine is available for certain patient groups at risk of pneumococcal infection.

Haemophilus influenzae type b (Hib) was once the major cause of bacterial meningitis in children aged 3 months to 5 years, but introduction of routine immunisation in 1992 has almost eliminated Hib disease in the UK and other developed countries.

Although patients with meningococcal or Hib meningitis are potentially infectious, most cases of meningitis due to these bacteria are acquired from individuals who are asymptomatic nasopharyngeal carriers. People living in the same household as a patient with meningococcal disease have a 500–1200-fold increased risk of developing infection if they do not receive chemoprophylaxis (see later). Susceptible young children who are household contacts of a case of Hib disease have a similarly increased risk of becoming infected. Epidemics of meningococcal disease sometimes occur. In developed countries, these take the form of clusters of cases among people living in close proximity (e.g. in schools or army camps) or in a particular geographical area. In Africa, large epidemics with many thousands of cases occur, usually during the dry season.

In the neonatal period, group B streptococci are the most common cause of bacterial meningitis. Other causes of neonatal meningitis include *Escherichia coli* and other *Enterobacteriaceae, Listeria monocytogenes*, *Staphylococcus aureus* and enterococci. In most cases, infection is acquired from the maternal genital tract around the time of delivery, but transmission between patients can also occur in hospitals.

L. monocytogenes is also an occasional cause of meningitis in immunocompromised patients. Meningitis can also occur as a complication of neurosurgery, especially in patients who have ventriculoatrial or ventriculoperitoneal shunts. Coagulase-negative staphylococci are the major causes of shunt-associated meningitis, but other bacteria are important, including *Enterobacteriaceae* and *S. aureus*. Meningitis due to *S. aureus* may also be secondary to trauma, or local or haematogenous spread from another infective focus. Meningitis may also be a feature of multisystem bacterial diseases such as syphilis, leptospirosis and Lyme disease.

The decline in the incidence of tuberculous meningitis in developed countries has mirrored the fall in the incidence of tuberculosis in these countries. Tuberculous meningitis may occur as part of the primary infection or as a result of recrudescence of a previous infection.

Viral meningitis

Human enteroviruses such as echoviruses and Coxsackie viruses account for about 70% of cases of viral meningitis in the UK. Herpes simplex and varicella zoster viruses account for most other cases. Occasional causes of viral meningitis include mumps virus and human immunodeficiency viruses.

Fungal meningitis

In Europe, fungal meningitis is rare in individuals without underlying disease. *Candida* species are an occasional cause of shunt-associated meningitis. *Cryptococcus neoformans* has emerged as an important cause of meningitis in patients with late-stage HIV infection and other severe defects of T-cell function. With greater use of fluconazole for oral candidiasis, and especially the advent of highly active antiretroviral therapy, cryptococcosis has become much less common in developed countries. However, in sub-Saharan African countries with the highest HIV prevalence, cryptococcus is the leading cause of infective meningitis. In certain other areas of the world, infections with fungi such as *Coccidioides immitis* and *Histoplasma capsulatum* are endemic.

Pathophysiology

Most cases of bacterial meningitis are preceded by nasopharyngeal colonisation by the causative organism. In most colonised individuals, infection will progress no further, but in susceptible individuals the organism invades the submucosa by circumventing host defences (e.g. physical barriers, local immunity, phagocytes) and gains access to the CNS by invasion of the bloodstream and subsequent haematogenous seeding of the CNS. Other less common routes by which micro-organisms can reach the meninges include:

- direct spread from the nasopharynx
- blood-borne spread from other foci of colonisation or infection
- abnormal communications with the skin or mucous membranes, for example skull fractures, anatomical defects or a meningocoele
- spread from an infected adjacent focus, for example brain abscess, tuberculoma, infected paranasal air sinus or infection of the middle ear.

Once in the subarachnoid space, the infection spreads widely and incites a cascade of meningeal inflammation. The cerebral tissue is not usually directly involved although cerebral abscess may complicate some types of meningitis.

The micro-organisms that most frequently cause meningitis are capable of doing so because they have a variety of virulence factors, including mechanisms for:

- attachment to host mucosal surfaces
- evasion of phagocytosis and other host defences
- meningeal invasion
- disruption of the blood–brain barrier
- induction of pathophysiological changes in the CSF space
- secondary brain damage.

Overall, the net result of infection is vascular endothelial injury and increased blood–brain barrier permeability leading to the entry of many blood components into the subarachnoid space. This contributes to cerebral oedema and elevated CSF protein levels. In response to the cytokine response, neutrophils migrate from the bloodstream into the CSF. Cerebral oedema contributes to intracranial hypertension and a consequent decrease in cerebral blood flow. Anaerobic metabolism ensues, which contributes to increased lactate and decreases glucose concentrations. If this uncontrolled process is not modulated by effective treatment, transient neuronal dysfunction or permanent neuronal injury results.

Clinical manifestations

Acute bacterial meningitis usually presents with sudden-onset headache, neck stiffness, photophobia, fever and vomiting. On examination, Kernig's sign may be positive. This is resistance to extension of the leg when the hip is flexed, due to meningeal irritation in the lumbar area. Where meningitis is complicated by septicaemia, there may be septic shock. The presence of a haemorrhagic skin rash is highly suggestive, but not pathognomic, of meningococcal infection. Untreated patients with bacterial meningitis deteriorate rapidly, with development of seizures, focal cerebral signs and cranial nerve palsies. Finally, obtundation and loss of consciousness herald death.

In infants with meningitis, the early physical signs are usually non-specific and include fever, diarrhoea, lethargy, feeding difficulties and respiratory distress. Focal signs such as seizures or a bulging fontanelle usually only occur at a late stage.

Viral meningitis usually presents with acute onset of low-grade fever, headache, photophobia and neck stiffness. Unless they develop encephalitis, patients usually remain alert and oriented.

Although tuberculous and fungal meningitis sometimes present acutely, these infections typically have a more indolent course. The early stages of the diseases are dominated by general symptoms such as malaise, apathy and anorexia. As they progress, symptoms and signs more typical of meningitis usually appear.

Diagnosis

The definitive diagnosis of meningitis is established by detection of the causative organism and/or demonstration of biochemical changes and a cellular response in CSF. CSF is obtained by lumbar puncture, where a needle is inserted between the posterior space of the third and fourth lumbar vertebrae into the subarachnoid space. Before performing lumbar puncture, the possibility of precipitating or aggravating existing brain herniation in patients with intracranial hypertension must be considered. A CT scan should be performed before undertaking lumbar puncture if any neurological abnormalities are present.

In health, the CSF is a clear colourless fluid which, in the lumbar region of the spinal cord, is at a pressure of 50–150 mmH$_2$O. There may be up to 5 cells/μL, the protein concentration is up to 0.4 g/L and the glucose concentration is at least 60% of the blood glucose (usually 2.2–4.4 mmol/L). Table 38.1 shows how the cell count and biochemical measurements can be helpful in determining the type of organism causing meningitis.

In bacterial and fungal meningitis, organisms may be visible in Gram-stained smears of the CSF. The common causes of bacterial meningitis are easily distinguished from each other by their Gram stain appearance. Special stains, such as the Ziehl–Neelsen method, are necessary to visualise mycobacteria. However, only small numbers of mycobacteria are present in the CSF in tuberculous meningitis and direct microscopy is often unrevealing. Although cryptococci can be visualised by Gram staining, they are often more easily seen with India ink staining, which highlights their prominent capsules.

Regardless of the microscopic findings, CSF should be cultured to try to confirm the identity of the causative organism and to facilitate further investigations such as antibiotic sensitivity testing and typing. Special cultural techniques are required for mycobacteria, fungi and viruses. Cultures of other

Table 38.1 Cellular and biochemical responses in different forms of infective meningitis

Type of meningitis	Cell count	Protein (g/L)	Glucose
Bacterial	Predominantly polymorphs, 500–2000 μL⁻¹ (lymphocytes may predominate in early or partially treated cases)	1–3	<50% blood glucose
Tuberculous	Predominantly lymphocytes, 100–600 μL⁻¹	1–6	<50% blood glucose
Viral	Predominantly lymphocytes, 50–500 μL⁻¹	0.5–1	Usually normal
Cryptococcal	Predominantly lymphocytes, 50–1000 μL⁻¹	1–3	<50% blood glucose

sites are sometimes helpful. In suspected bacterial meningitis, blood for culture should always be obtained. Bacteraemia occurs in only 10% of patients with meningococcal meningitis but is more common in most other forms of meningitis. In suspected meningococcal disease, culture of a nasopharyngeal swab may be helpful because antibiotic penetration at this site is less. It increases the chances of isolating meningococci when antibiotics were administered to the patient before presentation to hospital.

Non-culture-based methods are increasingly used to investigate the aetiology of meningitis. In particular, molecular amplification techniques such as polymerase chain reaction (PCR) are now widely used to detect meningococci, pneumococci, *Mycobacterium tuberculosis* and various viruses, including herpes simplex viruses and enteroviruses.

Serum antibodies to *N. meningitidis* and various viruses may be detected, but these investigations usually depend on demonstration of seroconversion between two samples collected a week or more apart, and are therefore undertaken more for public health than clinical reasons. Patients with tuberculous meningitis may have a positive Mantoux test or an interferon-gamma release assay.

Drug treatment

Acute bacterial meningitis is a medical emergency that requires urgent administration of antibiotics. Other considerations in some forms of meningitis include the use of adjunctive therapy such as steroids, and the administration of antibiotics to prevent secondary cases.

Antimicrobial therapy

Pharmacokinetic considerations

The antimicrobial therapy of meningitis requires attainment of adequate levels of bactericidal agents within the CSF. The principal route of entry of antibiotics into CSF is by the choroid plexus; an alternative route is via the capillaries of the central nervous system into the extracellular fluid and hence into the ventricles and subarachnoid space (see Fig. 38.1). The passage of antibiotics into CSF is dependent on the degree of meningeal inflammation and integrity of the blood–brain

barrier created by capillary endothelial cells, as well as the following properties of the antibiotic:

- lipid solubility (the choroidal epithelium is highly impermeable to lipid-insoluble molecules)
- ionic dissociation at blood pH
- protein binding
- molecular size
- concentration of the drug in the serum.

Antimicrobials fall into three categories according to their ability to penetrate the CSF:

- those that penetrate even when the meninges are not inflamed, for example chloramphenicol, metronidazole, isoniazid and pyrazinamide
- those that generally penetrate only when the meninges are inflamed, and used in high doses, for example most β-lactam antibiotics, the quinolones and rifampicin
- those that penetrate poorly under all circumstances, including the aminoglycosides, vancomycin and erythromycin.

Recommended regimens

Clinical urgency determines that empirical antimicrobial therapy will usually have to be prescribed before the identity of the causative organism or its antibiotic sensitivities are known. Consideration of the epidemiological features of the case, together with microscopic examination of the CSF, is often helpful in identifying the likely pathogen. However, empiric therapy is usually with broad-spectrum antimicrobial therapy to cover all likely pathogens, at least until definitive microbiological information is available. For the purpose of selecting empiric antimicrobial therapy, patients with acute bacterial meningitis can be categorised into four broad groups: neonates and infants aged below 3 months; immunocompetent older infants, children and adults; immunocompromised patients; and those with ventricular shunts.

Antibiotics for meningitis in neonates and infants aged below 3 months. The most important pathogens in neonates include group B streptococci, *E. coli* and other *Enterobacteriaceae*, *L. monocytogenes*. In many centres, a third-generation cephalosporin such as cefotaxime or ceftazidime, along with amoxicillin or ampicillin, is the empiric therapy of choice for neonatal meningitis (Galiza and Heath, 2009). Cephalosporins

penetrate into CSF better than aminoglycosides, and their use in Gram-negative bacillary meningitis has contributed to a reduction in mortality to less than 10%. Other centres continue to use an aminoglycoside, such as gentamicin, together with benzylpenicillin, ampicillin or amoxicillin as empiric therapy. This approach remains appropriate, especially in countries such as the UK where group B streptococci are by far the predominant cause of early-onset neonatal meningitis. Whichever empiric regimen is used, therapy can be altered as appropriate once the pathogen has been identified. Suitable dosages are shown in Table 38.2.

In infants outside the immediate neonatal period, the classic neonatal pathogens account for a decreasing number of cases of meningitis and the common bacteria of meningitis in childhood (see later) become increasingly important. Amoxicillin or ampicillin plus cefotaxime or ceftriaxone is the recommended treatment. Therapy with amoxicillin or ampicillin and gentamicin is unsuitable for this age group because it provides inadequate cover against *H. influenzae*.

Antibiotics for meningitis in older infants, children and adults. Antimicrobial therapy has to cover *S. pneumoniae*, *N. meningitidis* and, in children aged below 5 years, *H. influenzae* (Yogev and Guzman-Cottrill, 2005). Achievable antibiotic CSF concentrations are compared with the susceptibilities of the common agents of meningitis in Table 38.3.

Third-generation cephalosporins, such as cefotaxime, are now widely used in place of the traditional agents of choice, chloramphenicol, ampicillin, amoxicillin and penicillin (see Table 38.2). This change has stemmed from concern over the rare but potentially serious adverse effects of chloramphenicol and the emergence of resistance to penicillin, ampicillin and chloramphenicol among *S. pneumoniae* and *H. influenzae* in particular. Chloramphenicol resistance and reduced susceptibility to penicillin have also been reported in *N. meningitidis*. The third-generation cephalosporins have a broad spectrum of activity that encompasses not only the three classic causes of bacterial meningitis but also many other bacteria that are infrequent causes of meningitis. However, cephalosporins are inactive against *L. monocytogenes*, and amoxicillin or ampicillin should be added where it is possible that the patient may have listeriosis, for example in elderly patients, or where Gram-positive bacilli are seen on Gram stain. Although earlier-generation cephalosporins such as cefuroxime achieve reasonable CSF penetration and are active against the agents of meningitis *in vitro*, they do not effectively sterilise the CSF and should not be used to treat meningitis.

Ceftriaxone is a third-generation cephalosporin with a spectrum of activity comparable to that of cefotaxime. However, because of the potential for calcium chelation *in vivo*, ceftriaxone must not be administered within 48 h of the completion

Table 38.2 Suitable antibiotic regimens for treatment of acute bacterial meningitis in different age groups

Age group	First-choice antibiotic therapy	Alternative therapies
Neonates, aged <8 days	Ampicillin, 50 mg/kg twice daily or amoxicillin 25 mg/kg twice daily and cefotaxime 50 mg/kg twice daily or ceftazidime 50 mg/kg twice daily	Benzylpenicillin 50 mg twice daily and ampicillin 50 mg/kg twice daily or amoxicillin 25 mg/kg twice daily and gentamicin 2.5 mg/kg twice daily
Neonates, aged 8–28 days	Ampicillin 50 mg/kg four times daily or amoxicillin 25 mg/kg three times daily and cefotaxime 50 mg/kg three times daily or ceftazidime 50 mg/kg three times daily	Benzylpencillin 50 mg three or four times daily or ampicillin 50 mg/kg three or four times daily or amoxicillin 25 mg/kg three times daily and gentamicin 2.5 mg/kg three times daily
Infants, aged 1–3 months	Ampicillin 50 mg/kg four times daily or amoxicillin 25 mg/kg three times daily and cefotaxime 50 mg/kg three times daily or ceftriaxone 75–100 mg/kg once daily	
Infants and children aged >3 months[a]	Cefotaxime 50 mg/kg three times daily or ceftriaxone[b] 75–100 mg/kg once daily	Ampicillin 50 mg/kg four times daily or amoxicillin 25 mg/kg three times daily or benzylpenicillin[c] 30 mg/kg 4-hourly and chloramphenicol[d] 12.5–25 mg/kg four times daily
Adults	Cefotaxime[e] 2 g three times daily or ceftriaxone[b,e] 2–4 g once daily	Benzylpenicillin 2.4 g 4-hourly or ampicillin 2–3 g four times daily or amoxicillin 2 g three or four times daily and chloramphenicol[d] 12.5–25 mg/kg four times daily

[a]Calculated doses for children should not exceed maximum recommended doses for adults.
[b]Ceftriaxone should not be administered to neonates within 48 h of completion of infusions of calcium-containing solutions; caution should be exercised in older age groups.
[c]Benzylpenicillin is inactive against *H. influenzae* and should therefore not be used in children aged <5 years.
[d]Monitoring of serum chloramphenicol levels is recommended, especially in children aged ≤4 years.
[e]Add ampicillin or amoxicillin to cover *L. monocytogenes* in elderly patients or where Gram-positive bacilli seen in CSF.

Table 38.3 Achievable CSF concentrations of antibiotics in meningitis and MIC values for common central nervous system pathogens

Antibiotic	CSF:serum ratio	Peak CSF level (mg/L)	MIC_{90} (mg/L) values for		
			N. meningitidis	*H. influenzae*	*S. pneumoniae*
Ampicillin	1:10	10	0.02	0.25	0.05
Benzylpenicillin	1:20	1.5	0.02	1.0	0.02
Cefotaxime	1:20	10	0.01	0.06	0.25
Ceftriaxone	1:15	15	0.01	0.06	0.12
Chloramphenicol	1:2	15	1.0	1.0	2.5
Ciprofloxacin	1:5	0.6	0.004	0.015	1.0
Daptomycin	1:20	3.0	>4.0	>4.0	0.25
Gentamicin	1:40	<0.5	2.0	0.5	16
Imipenem	1:15	2.0	0.1	1.0	0.05
Linezolid	1:1.25	5.0	>8.0	>8.0	2.0
Meropenem	1:15	4.0	0.03	0.1	0.1
Rifampicin	1:20	1.0	0.5	1.0	2.0
Vancomycin	1:40	1.0	>4.0	>4.0	0.2

MIC_{90}, minimum concentration of antibiotic that is inhibitory for 90% of isolates; CSF, cerebrospinal fluid.

of infusions of calcium-containing solutions in neonates. The risk of precipitation is much lower in patients >28 days of age. Nevertheless, caution should still be exercised when treating older age groups, especially in the early treatment of meningococcal infections (where calcium-containing products are commonly used for resuscitation).

In meningitis due to *N. meningitidis* and *H. influenzae*, prompt administration of chemoprophylaxis to eliminate nasopharyngeal carriage can reduce the risk of secondary cases in close contacts of the case.

N. meningitidis. In view of the potentially rapid clinical progression of meningococcal disease, it is recommended that treatment should begin with the emergency administration of benzylpenicillin. Primary care clinicians should give penicillin while arranging transfer of the patient to hospital. The dose is 1200 mg for adults and children aged 10 years and above, 600 mg for children aged 1–9 years and 300 mg for children aged below 1 year. Ideally, this should be given intravenously. The intramuscular route is less likely to be effective in shocked patients but can be used if venous access cannot be obtained. The only contraindication is allergy to penicillin, where cefotaxime (1 g for adults, 50 mg/kg for children aged <12 years) or chloramphenicol (1.2 g for adults, 25 mg/kg for children aged <12 years) may be given, if available. However, it is not recommended that primary care clinicians routinely carry these alternative antibiotics.

Strains of *N. meningitidis* with reduced sensitivity to penicillin are well known and presently account for 5–10% of isolates in Europe and the USA. In general, these cases respond to treatment with adequate doses of benzylpenicillin, and failure of penicillin treatment has rarely been reported. Nevertheless, cefotaxime and ceftriaxone are now widely used in preference to benzylpenicillin or chloramphenicol.

S. pneumoniae. Benzylpenicillin was once widely regarded as the treatment of choice for pneumococcal meningitis. However, pneumococci resistant to penicillin have emerged across the world, presenting a major therapeutic challenge in view of the severity of pneumococcal meningitis.

Although currently only about 5% of pneumococci in the UK are penicillin resistant, the frequency of resistance is increasing, and resistance rates of more than 50% have been reported in other countries, including Spain, Hungary and South Africa. Penicillin resistance in pneumococci is defined in terms of the minimum inhibitory concentration (MIC) of penicillin. Most strains have a MIC value of 0.1–2.0 mg/L and are defined as having moderate resistance; strains with an MIC value of more than 2 mg/L are considered highly resistant. This distinction is relevant for less serious infections with moderately resistant strains, which may still respond to adequate doses of some β-lactam antibiotics, such as cefotaxime, ceftriaxone or a carbapenem. However, the clinical outcome of meningitis with penicillin-resistant pneumococci treated

with a β-lactam antibiotic as monotherapy is less good. For this reason, many guidelines, including those produced by the Infectious Diseases Society of America, now recommend therapy with a combination of a third-generation cephalosporin and vancomycin (McIntosh, 2005). This approach has not been adopted universally in the UK but should certainly be considered for patients who might have acquired their infection in a location where the incidence of penicillin resistance is high. Where vancomycin is given intravenously to treat meningitis, it is important to aim for trough serum levels of 15–20 mg/L because of the limited CSF penetration of vancomycin. Another problem is the emergence of pneumococci that are tolerant to vancomycin, that is, they are able to survive, but not proliferate, in the presence of vancomycin. Although such strains are uncommon, the outcome of meningitis treated with vancomycin is poor (Cottagnoud and Tauber, 2004).

Other antibiotics may be useful in treating pneumococcal meningitis. Use of rifampicin in combination with a cephalosporin and/or vancomycin is sometimes recommended, but there are few data confirming this can improve the response rate in either penicillin-sensitive or -resistant pneumococcal meningitis. The dose of rifampicin is 600 mg twice daily in adults or 10 mg/kg (maximum 600 mg) twice daily in children. Chloramphenicol is a suitable alternative to penicillin for treatment of meningitis due to penicillin-sensitive strains, for example in patients who are penicillin allergic. However, chloramphenicol is not recommended for treating penicillin-resistant pneumococcal meningitis: although isolates may appear sensitive to chloramphenicol on routine laboratory testing, bactericidal activity is often absent and the clinical response is usually poor.

Consideration of alternative antibiotics for treatment of penicillin-resistant pneumococcal meningitis is largely based on case reports rather than clinical trials. Success has been reported with meropenem as monotherapy, and in conjunction with rifampicin. Moxifloxacin is a new-generation quinolone antibiotic with enhanced activity against Gram-positive bacteria, including *S. pneumoniae*, which has shown promise in experimental pneumococcal meningitis. Linezolid has excellent CSF penetration but does not have bactericidal activity, and clinical experience in treating meningitis has been variable (Rupprecht and Pfister, 2005).

Daptomycin is an interesting option that has potent bactericidal activity against penicillin-sensitive and -resistant pneumococci, but without being bacteriolytic. This may be an advantage in that bacterial intracellular components that contribute to the inflammatory response are not liberated by bacterial killing. Indeed, in treating experimental pneumococcal meningitis, daptomycin gives a better clinical outcome than conventional treatment.

The unpredictable nature of the response to therapy of penicillin-resistant pneumococcal meningitis means that patients require close observation during treatment, for example monitoring of C-reactive protein (CRP). Repeat examination of CSF during therapy should also be considered.

H. influenzae. A third-generation cephalosporin such as cefotaxime or ceftriaxone is generally the treatment of choice for *H. influenzae* meningitis. These agents have superseded the traditional therapies of chloramphenicol and/or ampicillin or amoxicillin.

Other bacteria. Meningitis in immunocompetent individuals is rarely due to other bacteria. The definitive treatment for these individuals should be determined on an individual basis in the light of careful clinical and microbiological assessment.

Chemoprophylaxis against meningococccal and Hib infection. In meningococcal meningitis, spread between family members and other close contacts is well recognised; these individuals should receive chemoprophylaxis as soon as possible, preferably within 24 h. Sometimes, chemoprophylaxis may be indicated for other contacts, but the decision to offer prophylaxis beyond household contacts should only be made after obtaining expert advice (Box 38.1). Of the antibiotics conventionally used to treat meningococcal infections, only ceftriaxone reliably eliminates nasopharyngeal carriage; where another antibiotic has been used for treatment, the index case also requires chemoprophylaxis. A number of antibiotics are suitable as prophylaxis (Box 38.2).

Box 38.1 Indications for chemoprophylaxis in contacts of cases of infection with *N. meningitidis* or *H. influenzae* type b

Neisseria meningitidis
Household and other close contacts: prophylaxis usually initiated as soon as possible by clinicians caring for the patient

- Persons who have slept in the same house as the patient at any time during the 7 days before the onset of symptoms
- Boy/girl friends of the patient
- Unless treated with ceftriaxone (which reliably eliminates nasopharyngeal carriage), the index patient should also receive antibiotic prophylaxis as soon as he or she is able to take oral medication

Healthcare workers: prophylaxis should only be initiated after consultation with hospital infection control team or public health doctor

- Individuals who have administered mouth-to-mouth resuscitation or had some other form of prolonged close face-to-face contact with the patient
- Other contacts: prophylaxis should be initiated by a public health doctor
- Schools, nurseries, universities and other closed communities where two or more linked cases have occurred

Invasive *Haemophilus influenzae* type b infection
Household and other close contacts: prophylaxis usually initiated as soon as possible by clinicians caring for the patient

- Indicated only where there is another child aged less than 4 years who has not been immunised in the same household as the index patient. In such circumstances, prophylaxis should be given to all household contacts aged 1 month or older, unless there are contraindications. The index patient should also receive antibiotic prophylaxis as soon as he or she is able to take oral medication

Other contacts: prophylaxis very rarely necessary and should only be initiated by a public health physician

---

Box 38.2 Recommended prophylactic regimens for contacts of cases of infection with *N. meningitidis* or *H. influenzae* type b

Meningococcal infection

Ciprofloxacin[a] (oral)

Children aged 1 month – 4 years	125 mg as a single dose
Children aged 5–12 years	250 mg as a single dose
Adults	500 mg as a single dose

Rifampicin (oral)

Children aged <1 year	5 mg/kg twice daily on 2 consecutive days
Children aged 1–12 years	10 mg/kg (max 600 mg) twice daily on 2 consecutive days
Adults	600 mg twice daily on 2 consecutive days

Azithromycin[a] (oral)

Pregnant women	500 mg as a single dose

Ceftriaxone[a] (intramuscular)

Children aged <12 years	125 mg as a single dose
Adults	250 mg as a single dose

Invasive *Haemophilus influenzae* type b infection

Rifampicin (oral)

Children aged 1–3 months	10 mg/kg once daily for 4 days
Children aged >3 months	20 mg/kg once daily (max 600 mg) for 4 days
Adults[b]	600 mg once daily for 4 days

[a]Not licensed for this indication.
[b]For pregnant women, obtain expert advice.

Ciprofloxacin is now widely recommended for contacts of all ages (including pregnant and breast-feeding women) because of the convenience of single-dose administration and, unlike rifampicin, it does not interact with oral contraceptives and is readily available in community pharmacies. Although anaphylactoid reactions have been reported to occur in individuals receiving ciprofloxacin as chemoprophylaxis, none of these reactions has been fatal. If the strain is confirmed as group C (or A, W135 or Y), vaccination is normally offered to contacts who were given prophylaxis. There is no need to vaccinate the patient. There is currently no vaccine that protects against group B disease, which accounts for about 70% of cases of meningococcal disease in Europe.

Chemoprophylaxis against Hib infection is usually only indicated where there is an unimmunised child in the vulnerable age group in the household (see Box 38.1). Only rifampicin has been proved to be effective in eliminating nasopharyngeal carriage (see Box 38.2). Unimmunised household contacts aged below 4 years should also receive Hib vaccine. The index case should also receive rifampicin in order to eliminate nasopharyngeal carriage, and should be immunised, irrespective of age.

Antibiotics for meningitis in special groups

Immunocompromised host. In the immunocompromised neutropenic patient, the meninges can become infected. Possible causes of meningitis include *Enterobacteriaceae* and *Pseudomonas aeruginosa*, as well as the classic bacterial causes of meningitis. The choice of therapy is governed by the need to attain broad-spectrum coverage, using agents with good CSF penetration. Meropenem may now be the drug of choice for meningitis in this setting, although many other regimens are also appropriate.

Patients with cellular immune dysfunction are vulnerable to meningitis due to *L. monocytogenes* and *C. neoformans*. Ampicillin or amoxicillin, along with cefotaxime or ceftriaxone, is recommended as empirical antibacterial therapy for meningitis in these patients. Definitive treatment of listeria meningitis is normally with high-dose ampicillin (3 g four times daily) or amoxicillin (2 g four times daily), with the addition of gentamicin in order to obtain a synergistic effect. The most appropriate treatment for patients who are penicillin allergic, or in the rare circumstance of infection with a strain that is ampicillin resistant, is uncertain and specialist microbiological advice should be sought. Specific therapies for cryptococcal meningitis are described in detail as follows.

Splenectomised patients are susceptible to invasive infections with encapsulated bacteria, including *S. pneumoniae* and Hib. Standard therapy with either cefotaxime or ceftriaxone is appropriate.

Shunt-associated meningitis. Patients who have a ventricular shunt are at increased risk of meningitis. Shunt-associated infections are classified according to the site of initial infection. Internal infections, where the lumen of the shunt is colonised, constitute the majority of cases. External shunt infections involve the tissues surrounding the shunt. Most internal shunt infections are caused by coagulase-negative staphylococci. *S. aureus* and *Enterobacteriaceae* account for most external infections. It is generally held that management of shunt infections should include shunt removal, as well as antibiotic therapy (Infection in Neurosurgery Working Party, 2000), although the need for this has been questioned (Arnell et al., 2007). Appropriate antimicrobial regimens are shown in Table 38.4.

Tuberculous meningitis. The outcome in tuberculous meningitis relates directly to the severity of the patient's clinical condition on commencement of therapy. A satisfactory response demands a high degree of clinical suspicion such that appropriate chemotherapy is initiated early, even if tubercle bacilli are not demonstrated on initial microscopy. Most currently used antituberculous agents achieve effective concentrations in the CSF in tuberculous meningitis. Detailed discussion of antituberculous therapy is given in Chapter 40. Adjunctive steroid therapy is of value in patients with more severe disease, particularly those who suddenly develop cerebral oedema soon after starting treatment or who appear to be developing a spinal block. However, routine use of steroids is not recommended. They may suppress informative changes in the CSF and interfere with antibiotic penetration by restoring the blood–brain barrier. Early neurosurgical management of hydrocephalus by means of a ventriculoperitoneal or ventriculoatrial shunt is also important in improving the prospects for neurological recovery.

Cryptococcal meningitis. The standard treatment of cryptococcal meningitis is amphotericin B, given intravenously at a dose of 0.7–1.0 mg/kg/day, with or without flucytosine 100 mg/kg/day, for 6–10 weeks. Addition of flucytosine results in quicker clearance of yeasts from the CSF, although it is debatable whether this results in improved clinical outcome. Lipid formulations of amphotericin B, such as liposomal

Table 38.4 Antimicrobial regimens for treatment of shunt meningitis

Type of infection	First-choice antibiotic regimen	Other antibiotic regimens	Duration of therapy before reshunting
Internal shunt infection caused by Gram-positive bacteria	Intraventricular vancomycin + intravenous or oral rifampicin	Substitute flucloxacillin or intravenous vancomycin for rifampicin in cases of rifampicin resistance, except in the case of enterococci, where an aminoglycoside (e.g. gentamicin) should be used	7–10 days intravenous
External shunt infection caused by *S. Aureus*	As earlier, with the addition of intravenous flucloxacillin	Substitute intravenous vancomycin for flucloxacillin in the case of methicillin resistance (MRSA)	12–14 days
Enterobacteriaceae	Intravenous cefotaxime ± an aminoglycoside + intraventricular aminoglycoside	Substitute ceftazidime or meropenem for cefotaxime in the case of cefotaxime resistance	14 days
Polymicrobial ventriculoperitoneal shunt infections	Intravenous amoxicillin, metronidazole, cefotaxime ± an aminoglycoside + intraventricular aminoglycoside	Seek specialist advice	14 days
Candida	Intravenous amphotericin B + flucytosine	Intravenous fluconazole	10–14 days (antifungal fungal therapy should continue for 1 week after reshunting)

amphotericin B, at doses of 4–6 mg/kg/day have comparable efficacy to, and fewer side effects than, conventional amphotericin B at a dose of 0.7 mg/kg. As an alternative to prolonged therapy with two potentially toxic drugs, 2 weeks therapy with amphotericin B and flucytosine may be given, followed by consolidation therapy with fluconazole 400 mg/day for at least 10 weeks. Initial treatment with fluconazole 400–800 mg/day plus flucytosine is clinically inferior to amphotericin B-based regimens, and in any case is no better tolerated than amphotericin B-based regimens. Regular haematological and biochemical monitoring is recommended during treatment, along with measurement of serum concentrations of flucytosine (which should not exceed 80 mg/L).

The clinical response to treatment of cryptococcal meningitis is slow, and it often takes 2 or 3 weeks to sterilise the CSF. Monitoring of intracranial pressure is essential, with large-volume CSF drainage indicated if the opening pressure reaches 250 mmHg. Serial CSF cultures are occasionally helpful in following the response to treatment, but monitoring of cryptococcal antigen titres in serum or CSF is of little value.

Patients with HIV infection treated for cryptococcal meningitis should then receive fluconazole indefinitely, or at least until immune reconstitution occurs. The dose of fluconazole may be reduced to 200 mg/day, depending on the patient's clinical condition (Bicanic and Harrison, 2004). Itraconazole offers less good CSF penetration than fluconazole, but is a suitable alternative as maintenance therapy at a dose of 200–400 mg/day for patients unable to tolerate fluconazole. Clinical data with newer triazoles such as voriconazole and posaconazole remain limited, but these agents may be useful, especially in the rare situation of fluconazole-resistant cryptococcal meningitis. The echinocandin class of antifungals does not possess useful activity against *Cryptococcus*.

Viral meningitis. None of the currently available antiviral agents has useful activity against human enteroviruses, the commonest causes of viral meningitis (Big et al., 2009). Fortunately, however, the condition is usually self-limiting. The viruses that commonly cause this condition, herpes simplex and varicella zoster meningoencephalitis, are treated with high-dose aciclovir, 10 mg/kg three times daily for at least 10 days (adults and children aged 12 years and over). For younger children, the recommended doses are 20 mg/kg three times daily for infants up to age 3 months, and 500 mg/m² three times daily for those aged 3 months to 12 years.

Steroids as adjunctive therapy in bacterial meningitis. In pharmacological doses, corticosteroids, and in particular dexamethasone, regulate many components of the inflammatory response and also lower CSF hydrostatic pressure. However, by reducing inflammation and restoring the blood–brain barrier, they may reduce CSF penetration of antibiotics. The benefits of steroids in the initial management of meningitis due to *M. tuberculosis* and Hib are well established, although in other forms of bacterial meningitis the evidence has been less compelling. Methodological flaws have been identified in older studies where no benefit was seen from use of adjunctive steroid therapy. Recent work has found that adjunctive dexamethasone therapy reduces the rate of unfavourable outcomes from 25% to 15% in adults with bacterial meningitis. In this series, adjunctive treatment with dexamethasone was given before or with the first dose of antibiotics, without serious adverse effects. Overall, corticosteroids significantly reduce rates of mortality, severe hearing loss and neurological sequelae. The use of adjunctive dexamethasone is now recommended for children and adults with community-acquired bacterial meningitis, regardless of bacterial aetiology (Brouwer et al., 2010). Adjunctive therapy

should be initiated before or with the first dose of antibiotics and continued for 4 days. The recommended dose for adults is 10 mg four times daily for 4 days (children 0.15 mg/kg four times daily for 4 days).

Intrathecal and intraventricular administration of antibiotics. Intrathecal administration, that is, administration into the lumbar subarachnoid space, of antibiotics was once widely used to supplement levels attained by concomitant systemic therapy. However, there is little evidence for the efficacy of this route of delivery, and it is now rarely used. In particular, it produces only low concentrations of antibiotic in the ventricles and therefore does little to prevent ventriculitis, one of the most serious complications of meningitis. Direct intraventricular administration of antibiotics in meningitis is important in certain types of meningitis, especially where it is necessary to use an agent, for example vancomycin or an aminoglycoside, that penetrates CSF poorly (Shah et al., 2004). The most common situation is in shunt-associated meningitis, where multiple antibiotic-resistant coagulase-negative staphylococci are the major pathogens, and where conveniently the patient will often have an external ventricular drain through which antibiotics can be administered.

There are considerable differences in recommended doses of antibiotics for intrathecal or intraventricular administration. A dose of 15–20 mg vancomycin per day is recommended for treatment of shunt-associated meningitis in adults with an extraventricular drain, and 10 mg/day for neonates and children. The paediatric dose may need to be reduced to 5 mg/day if ventricular size is reduced, or increased to 15–20 mg/day if the ventricular size is increased. In all patients, the dose frequency should be decreased to once every 2–3 days if CSF is not draining freely. The CSF vancomycin concentration should be measured after 3–4 days, aiming for a trough concentration of <10 mg/L. Recommended doses of antibiotics are otherwise largely based on anecdotal experience (Table 38.5).

Patient care

Common problems in the treatment of meningitis are set out in Table 38.6.

Table 38.5 Daily[a] doses (mg) of gentamicin and vancomycin for intraventricular administration

Antibiotic	Adult	Child ≥2 years	Child <2 years
Gentamicin	1.0[b]	1.0	1.0
Vancomycin	15–20	10[c]	10[c]

[a]If CSF is not draining freely, reduce dose frequency to once every 2–3 days.
[b]Dose can be increased to up to 5 mg in the most severe cases.
[c]Reduce dose to 5 mg if ventricular size is reduced, or increase to 15–20 mg/day if ventricular size is increased.

Table 38.6 Practice points in infective meningitis

Infection	Antibiotic	Common problems	Resolution
Bacterial meningitis	Chloramphenicol	Risk of serious toxicity, especially in neonates	Avoid use if possible Close monitoring of serum levels where use essential
Neonatal meningitis	Aminoglycosides (e.g. gentamicin)	Poor CSF penetration provides unreliable activity against Gram-negative bacteria Unpredictable neonatal pharmacokinetics (especially preterm neonates)	Substitute with, or add, an antibiotic with better CSF penetration (e.g. a cephalosporin) Close monitoring of serum levels
S. pneumoniae meningitis	Penicillin Cefotaxime or ceftriaxone Vancomycin (intravenous)	Resistance is increasing Treatment failure in meningitis due to penicillin Resistant strains Unreliable CSF penetration	Use cefotaxime or ceftriaxone ± vancomycin as empiric therapy Add rifampicin or vancomycin Consider one of the newer antibiotics with good activity against multiresistant Gram-positive bacteria
L. monocytogenes meningitis	Any	Relapse rate up to 10% after short courses of therapy	Give prolonged therapy (usually 3–4 weeks)
Cryptococcal meningitis	Amphotericin B Flucytosine Fluconazole	High incidence of side effects, for example fever, nausea, vomiting, anaemia, hypokalaemia, impaired renal function Risk of side effects, for example deranged liver function, bone marrow depression Low cure rate when used as monotherapy (except as consolidation therapy)	Change to lipid-based preparation of amphotericin B, or replace with fluconazole Close monitoring of serum levels Combine with flucytosine

Prevention of person-to-person transmission

Patients with meningitis may be infectious to others. Neonates with meningitis usually have generalised infections, and the causative organisms can often be isolated from body fluids and faeces. Babies with meningitis should therefore be isolated to prevent infection spreading to other patients. Patients with meningococcal or Hib meningitis should be isolated until after at least 48 h of antibiotic therapy. Contacts of these patients may be asymptomatic carriers and potentially infectious to others and/or at risk of developing invasive infection themselves. Chemoprophylaxis and vaccination can reduce these risks (see earlier). Patients with most other types of meningitis do not represent a significant infectious hazard, and enhanced infection control precautions are not usually necessary.

Case studies

Case 38.1

A 4-week-old premature infant presents on the hospital neonatal unit with poor feeding, fever and increasing drowsiness. Lumbar puncture reveals 1200 WBC/μL (80% of which are polymorphs), and low glucose and elevated protein levels. No organisms are seen on a Gram-stained smear of the CSF. The diagnosis is acute purulent meningitis.

Questions

1. What are the likely aetiological agents?
2. Which other investigations other than CSF culture might help in establishing the aetiological diagnosis?
3. What empiric antibiotic therapy should be commenced?

Answers

1. At 4 weeks of age, the possible causes include neonatal pathogens (group B streptococci, *Escherichia coli* and *Listeria monocytogenes*), nosocomial pathogens such as *Staphylococcus aureus* and Gram-negative bacilli and the usual causes of meningitis in older infants (especially *Neisseria meningitidis* and *Streptococcus pneumoniae*). Most group B streptococcal disease presents in the first few days of life, whilst listeria meningitis is very uncommon, meaning that of the neonatal pathogens there is a greater likelihood of Gram-negative bacillary meningitis.
2. It is important to collect blood cultures because neonatal meningitis is not uncommonly accompanied by bacteraemia. Molecular tests on CSF may be undertaken, but the commonly used tests are not directed against the most likely pathogens in this case. The results of any recent cultures from other anatomic sites may also be useful, especially in ensuring that empiric antibiotic therapy is active against potential pathogens the baby is known to harbour.
3. Given the range of potential pathogens, a combination of ampicillin or amoxicillin plus cefotaxime or ceftazidime would be the treatment of choice, unless the patient is known to be colonised with antibiotic-resistant bacteria such as MRSA or Gram-negative bacteria.

Case 38.2

A 70-year-old man is being treated for meningitis due to *Streptococcus pneumoniae* that is moderately resistant to penicillin (MIC value 0.75 mg/L). Despite 7 days' treatment with intravenous vancomycin and cefotaxime, there has been little improvement in his clinical condition. A CT scan has shown meningeal inflammation consistent with meningitis, but no evidence of intracranial complications that might explain his poor clinical response. The most recent trough (predose) serum vancomycin concentration was 5.3 mg/L.

Questions

1. Why might there have been an inadequate response to treatment with cefotaxime and vancomycin?
2. What options are there to modify his antimicrobial therapy?

Answers

1. CSF penetration of vancomycin is poor and the serum vancomycin concentration in any case low. It is therefore doubtful that the vancomcyin concentration in the CSF would be bactericidal. Even if the vancomycin concentration in CSF were adequate, the infection may be due to a vancomycin-tolerant strain of *S. pneumoniae*. Tolerant strains appear fully sensitive to vancomycin by routine laboratory antimicrobial susceptibility testing. Cefotaxime alone may not adequately treat infections with penicillin-resistant pneumococci.
2. It is important to optimise the patient's treatment as quickly as possible. He might respond to increasing the dose of vancomycin with or without addition of rifampicin. However, these strategies give little assurance of success. It would probably be preferable to switch to an alternative agent. Meropenem is probably the agent with which there is most experience, which could continue to be combined with an increased dose vancomycin for extra assurance. Linezolid or daptomycin would be alternative options.

Case 38.3

An 18-year-old man is referred as an emergency with suspected meningitis. He was given intravenous penicillin by the primary care doctor before admission to hospital. On examination he is fully conscious, and neck stiffness is elicited. He is haemodynamically stable and no rash is present.

Questions

1. What investigations would you undertake to establish the diagnosis?
2. What treatment would you give?
3. What further action will be required if a diagnosis of meningococcal meningitis is likely?

Answers

1. Blood cultures and a nasopharyngeal swab for culture should be collected. There are no clinical contraindications to lumbar puncture, and in most centres this would be undertaken without a prior CT scan. The white cell count and glucose and protein concentrations in the CSF should be measured. A Gram stain should be undertaken, which may give immediate information on the likely identity of the pathogen, as well as culture and PCR. Some laboratories might also undertake antigen testing to try to establish an early aetiological diagnosis.

2. Antibiotic treatment should be with a third-generation cephalosporin (cefotaxime or ceftriaxone). The latter should be entirely safe to use in this situation given that it sounds unlikely that the patient will have required resuscitation with calcium-containing fluids. In addition, adjunctive therapy with dexamethasone, for which there appear to be no contraindications, should be considered.

3. Meningitis is a notifiable disease. If a diagnosis of meningococcal meningitis is considered likely, then prophylaxis should be offered to the patient and to close contacts as soon as possible to eliminate nasopharyngeal carriage and prevent secondary cases.

Case 38.4

A 46-year-old renal transplant recipient received 2 weeks treatment with amphotericin and flucytosine, and was then switched to fluconazole which he has received for a further 6 weeks (latterly as a hospital out-patient). However, after complaining of headaches, a repeat lumbar puncture has been undertaken and has shown that cryptococci are still present in the CSF.

Questions

1. Give three reasons why his treatment to date might have failed.
2. How would you now manage the situation?

Answers

1. It may be that the patient has not been adherent with his medication; the initial 2-week course of treatment with amphotericin may have been too short; or the infecting strain of *Cryptococcus* may be fluconazole resistant.

2. The first step should be to readmit the patient and recommence treatment with amphotericin and flucytosine. The microbiology laboratory should be asked to determine the sensitivity of the patient's isolate to fluconazole. Once that result has been ascertained, it will be possible to plan the patient's longer term management. Options would include completing a full course of amphotericin and flucytosine, or switching to one of the new triazoles such as posaconazole at some point. Close monitoring of the patient's response will be required.

39 Surgical site infection and antimicrobial prophylaxis

P. Howard and J. A. T. Sandoe

Key points

- Surgical site infection is a major cause of mortality and morbidity.
- Development of surgical site infection is a complex process influenced by host, operative and microbial factors.
- The microbial cause of surgical site infection varies with type of procedure but *Staphylococcus aureus* remains the most commonly implicated pathogen.
- Surveillance of surgical site infection is necessary to benchmark and improve prevention strategies.
- Antimicrobial prophylaxis is just one of many approaches to reduce surgical site infection.
- Not all operations require antimicrobial prophylaxis.
- Antimicrobial prophylaxis should be used only where there is evidence of efficacy or expert consensus that benefits outweigh risks.
- The choice of antimicrobial prophylaxis depends on the operation, pharmacokinetics, pharmacodynamics and patient factors.
- The timing of antimicrobial administration is key to reducing surgical site infection.
- Pharmacists are unlikely to see many patients before surgery; they must therefore develop systems to ensure that appropriate antimicrobial prophylaxis is given at the right time.

Surgery is the branch of medical science that treats injury or disease or improves bodily function through operative procedures. Surgery has been used for thousands of years but has always been complicated to some extent by infection. Currently, surgery is an integral part of the management of many medical conditions and remains the definitive treatment for many cancers. Infections developing at the site of invasive surgical procedures are frequently referred to as surgical site infections. Surgical site infections occur when pathogenic micro-organisms contaminate a surgical wound, multiply and cause tissue damage. The term 'surgical site infection' encompasses not only infection at the site of incision but also infections of implants, prosthetic devices and adjacent tissues involved in the operation.

Epidemiology

In England, there are over nine million operations and interventions undertaken each year. Over 50% of these are performed as day cases and many patients are admitted on the day of surgery (Health and Social Care Information Centre, 2009). Healthcare-associated infections (HCAIs), including surgical site infections, complicate around 7% of all hospital admissions (HIS/ICNA, 2007). Surgical site infections are of major clinical importance because they account for 14–16% of all healthcare-associated infections (HPS, 2009; Public Accounts Committee, 2009) and are associated with considerable morbidity and mortality. One-third of peri-operative deaths are related to surgical site infections (Astagneau et al., 2001). It has been estimated that surgical site infections double the length of hospital stay (Coello et al., 2005). While surgical site infections can be common in some procedures, the incidence can be minimised by the care provided before and after the operation, together with the skill of the surgeon (HPS, 2009).

Surveillance

Monitoring the incidence of surgical site infections is hampered by the lack of agreed measuring systems. In particular, to monitor the rates of surgical site infection within an organisation, or to benchmark between organisations, there needs to be a standard approach to diagnosis. Criteria for such a definition have been developed by the Centres for Disease Control and Prevention (CDC) (Mangram et al., 1999) and these are presented in Table 39.1. More detailed surgical site infection scoring systems have been developed but these are time consuming to use.

Mandatory surveillance for surgical site infections in orthopaedic surgery in the UK was introduced in 2003. In addition, Scotland monitors most other common procedures (http://www.hps.scot.nhs.uk) while in Wales caesarian section is also monitored (http://www.wales.nhs.uk). England has a voluntary reporting system for a broader range of operations (http://www.hpa.org.uk). All report their findings annually. Many surgical site infections, for example, those involving

Table 39.1 Criteria for defining surgical site infection (Mangram et al., 1999)

Type	Level	Signs and symptoms
Superficial incisional	Skin and subcutaneous tissue	Localised (Celsian) signs such as redness, pain, heat or swelling at the site of the incision or by the presence of pus within 30 days
Deep incisional	Fascial and muscle layers	Presence of pus or an abscess, fever with tenderness of the wound, or a separation of the edges of the incision exposing the deeper tissues within 30 days (or 1 year if an implant used)
Organ or space infection	Any part of the anatomy other than the incision that is opened or manipulated during the surgical procedure, for example, joint or peritoneum	Loss of function of a joint, abscess in an organ, localised peritonitis or collection. Ultrasound or CT scans confirm infection. Within 30 days (or 1 year if implant is used)

prosthetic joints, often develop late (>28 days post-operation), so post-discharge surveillance schemes are essential. Patients need to be aware how a surgical site infection may present after discharge from hospital. Surveillance of surgical site infections and feedback to the surgical team has been shown to reduce rates of infection (Gastmeier et al., 2005).

Risk factors

Surgical site infections can be categorised into three groups: superficial incisional, deep incisional and organ or space (Fig. 39.1) Whether a wound infection occurs after surgery depends on a complex interaction between the following:

- Procedure-related factors, for example, implantation of foreign bodies, degree of trauma to host tissues and experience of surgeon
Fig. 39.1 Schematic representation of the anatomical classification of surgical site infection (Horan et al., 1992). Reproduced with permission from the University of Chicago Press.

- Patient related factors, for example, host immunity, nutritional status and the presence or absence of diabetes
- Microbial factors (tissue adherence and invasion)
- Peri-operative antimicrobial prophylaxis.

A system to stratify operative wounds by the expected level of bacterial contamination (Table 39.2) was developed to help predict likely infection rates (Mangram et al., 1999). A number of other factors have also been found to affect the incidence of surgical site infection and are discussed below.

Prosthetic implants

Medical implants have a detrimental effect on host defences such that a lower bacterial count is needed to initiate infection. Hence, there is a greater risk of infection during implant surgery. Bacteria growing on an abiotic surface, such as a prosthetic hip implant or heart valve, together with a protective layer of microbial polymers are known as a biofilm (Donlan and Costerton, 2002). Antimicrobials are frequently ineffective against micro-organisms growing in biofilms, making treatment of implant infections problematic and their prevention even more important.

Duration of surgery

The longer the operation, the greater is the risk of wound infection. This, in turn, may be influenced by the experience (Fig. 39.2) speed and skill of the surgeon and is additional to the classification of the operation by risk of infection, for example, clean, contaminated, dirty or infected.

Patient related factors

A number of patient related factors are known to influence the likelihood of developing a surgical site infection and include the following:

- Wound potential for infection, for example, clean, contaminated, dirty or infected site
- Physical status of patient (Table 39.3)
- Duration of procedure.

Table 39.2 Classification of surgical procedures by risk of infection (Mangram et al., 1999)

Type of procedure	Definition	Wound infection rate (%)	Example	Need for prophylaxis
Clean	Atraumatic; no inflammation encountered, no break in technique; gastro-intestinal, genitourinary and respiratory tracts not entered	1.5–4.2	Inguinal hernia repair	Not usually required
Contaminated	Gastro-intestinal or respiratory tract entered but without spillage; oropharynx, appendectomy, sterile genitourinary or biliary tract entered; minor break in technique	<10	Cholecystectomy (no spillage)	Usually required
Clean-contaminated	Acute inflammation; infected bile or urine; gross spillage from gastro-intestinal tract; major lapse in technique; fresh traumatic wound (12–24 h)	10–20	Appendicectomy	Required
Dirty and infected	Established infection; transection of clean tissues to enable collection of pus; traumatic wound with retained devitalised tissue; faecal contamination; delayed treatment	20–40	Sigmoid colectomy (Hartmann's procedure) for faecal peritonitis	Treatment required (not prophylaxis)

For each surgical procedure, a score of 0–3 is allocated to represent the number of risk factors present. Patients with a score of 0 are at the lowest risk of developing a surgical site infection, while those with a score of 3 have the greatest risk (Table 39.4). Use of this risk index allows comparison of similar patient groups in terms of surgical site infection risk over time. The risk index is a significantly better predictor of surgical-wound risk than the traditional wound classification system and performs well across a broad range of operative procedures.

Other factors

There are a number of other risk factors that may increase the risk of a surgical site infection (Table 39.5) for an individual patient but the impact has not been quantified to the extent of those risk factors discussed above.
ST = Speciality registrar grade, number represents years of training

Fig. 39.2 Surgical site infection rate by grade of operator for orthopaedic surgery 2008 (Health Protection Scotland, 2009). Reproduced with kind permission from Health Protection Scotland.

Table 39.3 American Society of Anesthesiology (ASA) classification of physical status (Mangram et al., 1999)

ASA score	Physical status
1	A normal healthy patient
2	A patient with mild systemic disease
3	A patient with a severe systemic disease that limits activity but is not incapacitating
4	A patient with an incapacitating systemic disease that is a constant threat to life
5	A moribund patient that is not expected to survive 24 h with or without operation

Table 39.4 Risk index based on presence of co-morbidity and duration of operation (Culver et al., 1991)

Risk index	Infection rate (%)
0	1.5
1	2.9
2	6.8
3	13.0

Table 39.5 Patient and operative risk factors for surgical site infection

Patient risk factors	Operative risk factors
Advanced age	Tissue ischaemia
Malnutrition	Lack of haemostasis
Obesity	Tissue damage, for example, crushing by surgical instruments
Concurrent infection	Presence of necrotic tissue
Diabetes mellitus	Presence of foreign bodies including surgical materials
Liver impairment	
Renal impairment	
Immune deficiency states	
Prolonged preoperative stay	
Blood transfusion	
Smoking	

Smoking

Smoking increases the risk of developing a wound infection (Myles et al., 2002). The mechanism is not known but tobacco use may delay wound healing via the vasoconstricting effects of nicotine and thus increase the risk of infection (Myles et al., 2002).

Diabetes mellitus

Long-term diabetes does not appear to have any impact on the risk of developing a surgical site infection. However, perioperative fluctuations in blood glucose for up to 48 h have been shown to double the infection risk in cardiac patients (Latham et al., 2001).

Age

Increasing age is associated with an increased risk of surgical site infection. However, there is debate whether age serves simply as a marker for underlying disease or whether the
Fig. 39.3 Relative risk of surgical site infection by age group, 2003–2007, adjusted for surgical category (reference age group <45 years) (HPA, 2008). Reproduced with kind permission from Health Protection Agency.

decline in immune function with age is the significant factor. A study of 72,000 patients in the USA, which adjusted for hospital type, procedure, duration, wound class and physical status of the patient, showed a 1.1% increase in surgical site infection per year of age from the age of 18 to 65 years, but a 1.2% decrease in individuals over 65 years (Kaye et al., 2005). In contrast, the findings of the English surgical site infection surveillance scheme (Fig. 39.3) indicated that the chance of getting a surgical site infection were 37% higher for a 65-year-old person compared to a 45-year-old person (HPA, 2008).

Pathogenesis

Most surgery involves an incision through one of the body's protective barriers, typically the skin or other epithelial surface such as the conjunctiva or tympanic membrane. When intact, these provide an excellent barrier to entry of both exogenous and endogenous bacteria into other epithelial surfaces including the mucosal surfaces of the gastro-intestinal and genitourinary tracts, which, when intact, prevent entry of the luminal contents into the surrounding tissues and organs.

Any surgical operation will breach at least one of the surfaces mentioned and allow entry of bacteria. Whether an infection follows depends on the ability of other defences to kill the invading bacteria. Important host mechanisms include antibodies, complement and phagocytes.

Development of a surgical site infection depends on survival of the contaminating micro-organism in a wound site at the end of a surgical procedure; the pathogenicity and number of these micro-organisms; and the host's immune response. Most micro-organisms are from the host (endogenous), but are occasionally introduced via surgical instruments, the environment or contaminated implants (exogenous). The likely invading micro-organism varies according to the type of surgery (Table 39.6). Data for

Table 39.6 Likely pathogens in post-operative wound infections

Category of surgery	Most likely pathogen(s)
Clean	
Cardiac/vascular/orthopaedic	Coagulase-negative staphylococci, *S. aureus*, Gram-negative bacilli
Breast	*S. aureus*
Clean-contaminated	
Burns	*S. aureus, Pseudomonas aeruginosa*
Head and neck	*S. aureus, Streptococcus* spp., anaerobes (from oral cavity)
Gastro-intestinal tract	Coliforms, anaerobes (*Bacteroides fragilis*)
Urogenital tract	Coliforms, *Enterococcus* spp.
Dirty	
Ruptured viscera	Coliforms, anaerobes (*B. fragilis*) *S. aureus*
Traumatic wound	*Streptococcus pyogenes, Clostridium* spp.

England from 2003 to 2007 has shown that the predominant organism was *Staphylococcus aureus*, which accounted for 38% of all surgical site infections (Fig. 39.4); 64% of these were caused by a meticillin-resistant strain (MRSA). The proportion of surgical site infections caused by *S. aureus*

was highest in hip hemiarthroplasty (57%), followed by limb amputation (54%) and open reduction of long bone fracture (52%). *Enterobacteriaceae* (coliforms) caused the second largest group of infections, accounting for 21% of all surgical site infections. These were the prominent causes of surgical site infections in three categories: large bowel surgery (33%), coronary artery bypass graft (32%) and small bowel surgery (30%).

Although there was a significant reduction in the risk of a surgical site infection for all categories over the 5 year period monitored, there was no change in the proportion of *S. aureus*, infections that were due to MRSA. Infection control measures including the introduction of mandatory MRSA screening for elective patients in 2009 should improve this. Known or previous MRSA carriers can be 'decolonised' and appropriate prophylactic antimicrobials administered that cover MRSA (e.g. teicoplanin).

Prevention of surgical site infection

The evidence that supports interventions to minimise surgical site infection has been highlighted in national guidelines (NICE, 2008a) and categorised into four areas: information to patients, preoperative phase, peri-operative phase and post-operative phase (Table 39.7). When selecting antimicrobial prophylaxis regimens or evaluating potential prophylaxis failures, it is important to ensure that all four aspects of prevention have been addressed.

CNS = coagulase negative staphylococci
MSSA = meticillin-sensitive *S. aureus*
MRSA = meticillin-resistant *S. aureus*

Total number of organisms reported = 5178
Fig. 39.4 Surgical site infection isolated organisms 2003–2007 (HPA, 2008).

Table 39.7 Recommendations for the prevention and treatment of surgical site infections (NICE, 2008a)

Category	Recommendation
Information for patients and carers	How to recognise a surgical site infection and what to do
Preoperative phase	Patient preparation: pre-op washing, hair removal, nasal MRSA decontamination and bowel preparation Antimicrobial prophylaxis guidance Staff preparation and theatre movement
Intra-operative phase	Operating team preparation Patient skin preparation Maintaining patient homeostasis Wound dressings
Post-operative phase	Dressing and cleansing the wound Antimicrobial treatment for surgical site infection Debridement of surgical site infections

Antimicrobial prophylaxis

In the early 1960s, it was demonstrated, using a guinea-pig model, that surgical-wound infection could be reduced by administration of an antimicrobial just before an incision was made, but the beneficial effect disappeared if antimicrobial administration was delayed by 3–4h after the incision (Burke, 1961). Since then, many clinical trials have indicated the benefit of maintaining adequate antimicrobial tissue levels from the time of initial surgical incision until closure.

There are potential adverse consequences to the administration of antimicrobials for both the individual and the population. For the individual, side effects, ranging from antimicrobial associated diarrhoea or thrush to life-threatening allergic reactions, may arise. From the population perspective, the development of antimicrobial resistant bacteria is a concern. Antimicrobial prophylaxis should, therefore, only be offered to patients where there is evidence or, in the absence of evidence, expert consensus that the potential benefits of prophylaxis outweigh the risks.

The number of patients that need to be treated with antimicrobial agents to prevent one infection in the different types of surgery are presented in Table 39.8.

The infection risk associated with a particular surgical procedure and evidence of efficacy should be used to determine whether antimicrobial prophylaxis is to be administered. Not all surgical procedures warrant antimicrobial prophylaxis.

Choice of antimicrobial

Once it has been determined that antimicrobial prophylaxis is required, the next step is to select an appropriate agent(s). The choice of antimicrobial should take into account the following:

- Likely infecting organisms (procedure specific)
- Local susceptibility of potential pathogens to antimicrobials
- Pharmacokinetics, for example, penetration of antimicrobial to the site(s) in question
- Patient allergy to penicillins or other antimicrobials
- Administration time (bolus better than infusion)
- Drug cost
- Carriage of resistant organisms, for example, methicillin-resistant *S. aureus* (MRSA)
- Prevalence of *Clostridium difficile* infection in the hospital.

The majority of clinical trials that have demonstrated the benefit of antimicrobial prophylaxis are outdated, and probably do not reflect current surgical practice. First and second generation cephalosporins (cefazolin and cefuroxime) have been the mainstay of agents studied (Bratzler and Houck, 2004). There are advantages and disadvantages with using cephalosporins. The advantages include a low anaphylaxis risk, but they have the disadvantage of excessive or inadequate spectrum of cover depending on the operation (Morgan, 2006) and a strong association with *Clostridium difficile* infection. Many antimicrobials used in prophylaxis have not been extensively studied in clinical trials, but are selected on a theoretical basis of their antimicrobial spectrum (see Tables 39.9–39.11).

Table 39.8 Example of number needed to treat (NNT) for antimicrobial prophylaxis (SIGN, 2008)

Type of surgery	Operation	NNT	Outcome
Upper GI surgery	Stomach and duodenal surgery	5	Wound infection
Lower GI surgery	Colorectal surgery	4	Wound infection and intra-abdominal abscesses
Gynaecological	Caesarian section	19	Wound infection
Orthopaedic	Arthroplasty (hip replacement)	42	Hip infection

NNT is the number of patients that need to be treated to prevent one infection compared to receiving no antimicrobials.

Table 39.9 Antimicrobial susceptibility of common pathogens (adapted from SIGN, 2008)

Surgical site infection for a skin wound at any site	
S. aureus	Highly variable (30–60% susceptible) to flucloxacillin therefore MRSA screening essential
Beta haemolytic Streptococci (BHS)	90% susceptible to penicillins, macrolides or clindamycin
Additional pathogens by site of infection	
Head and neck surgery	
Oral anaerobes	95% susceptible to metronidazole or co-amoxiclav
Operations below the diaphragm	
Anaerobes	95% susceptible to metronidazole or co-amoxiclav
E. coli and other Enterobacteriaceae	80–90% of *E. coli* sensitive to cefuroxime, co-amoxiclav (or other β-lactam with inhibitor combination) or gentamicin
Insertion of a prosthesis, graft or shunt	
Coagulase-negative Staph (CNS) *S. aureus*, diphtheroids	Two-thirds of CNS are methicillin-resistant, but β-lactams may still be used but preferably with a second agent with staphylococcal cover, for example, gentamicin, or a glycopeptide used instead. See above for *S. aureus*.

Timing and duration

Timing of antimicrobial administration is one of the most important aspects of prophylaxis regimens. Animal studies and latterly clinical observational studies have shown that prophylaxis is most effective when given immediately before an operation (within 30 min of induction of anaesthesia), so that antimicrobial activity is present for the duration of the operation and for about 4 h afterwards. Antimicrobials given too early prior to surgery are associated with prophylaxis failure, presumably because serum and tissue levels are not sustained during the surgical procedure. Similarly, for each hour antimicrobial administration was delayed after the start of the operation there was an increased rate of wound infection. This suggests bacterial replication, once commenced, cannot be eliminated by antimicrobial regimens designed for prophylaxis. The microbiological basis for these observations is likely to be that bacterial reproduction at a logarithmic rate follows a lag phase of relatively little increase in bacterial population. The lag phase for wound infection bacteria lasts typically 3–4 h. If bacteria inoculated into a wound can be killed or inhibited by antimicrobials given early, the immune system can kill the remaining organisms. However, if antimicrobials are given only when the growth curve has entered the logarithmic phase, the chances of successful prophylaxis are reduced.

Formerly, protocols for prophylaxis extended for several post-operative days. Now, single dose schedules are increasingly common with greater emphasis on ensuring immediate preoperative administration. As surgery may

Table 39.10 Micro-organisms commonly isolated from surgical site infections and prophylactic antimicrobials used in common surgical procedures (Prtak and Ridgway, 2009)

Surgical procedure	Most common micro-organisms	Examples of prophylactic IV antimicrobials
Gastro-intestinal	Bowel flora	
• Upper gastro-intestinal tract	*S. aureus*, Gram-negative bacilli	Co-amoxiclav or cefuroxime or gentamicin
• Biliary	*S. aureus*, Gram-negative bacilli (enterococci, anaerobes)	Co-amoxiclav or cefuroxime and metronidazole or gentamicin and metronidazole
• Colorectal/appendicectomy	*S. aureus*, Gram-negative bacilli, anaerobes	Co-amoxiclav or cefuroxime and metronidazole or gentamicin and metronidazole
Urogenital		
• Transrectal biopsy	*S. aureus*, Gram-negative bacilli, anaerobes	Co-amoxiclav or cefuroxime and metronidazole or gentamicin and metronidazole
• Transurethral resection of prostate	*S. aureus*, Gram-negative bacilli, enterococci	Co-amoxiclav or cefuroxime or gentamicin
Obstetric/gynaecological		
• Caesarean section	*S. aureus*, Gram-negative bacilli, streptococci (anaerobes)	Co-amoxiclav or cefuroxime and metronidazole
• Hysterectomy	*S. aureus*, Gram-negative bacilli, anaerobes	Co-amoxiclav or cefuroxime and metronidazole
Vascular		
• Reconstructive arterial surgery	Skin flora: primarily staphylococci	Co-amoxiclav or cefuroxime
• Amputation	*S. aureus*, anaerobes if gangrenous	Co-amoxiclav or cefuroxime and metronidazole or vancomycin and metronidazole
Orthopaedic		
• Joint replacement surgery	Skin flora: primarily staphylococci	Co-amoxiclav or cefuroxime or flucloxacillin and gentamicin

If patient has previously had MRSA or is at high risk (e.g. nursing home resident), use teicoplanin or other gylcopeptide.
For β-lactam allergy, replace co-amoxiclav or cefuroxime with teicoplanin +/− ciprofloxacin.

Table 39.11 Suggested cephalosporin-free antimicrobial prophylaxis for surgical site infection (adapted from SIGN, 2008)

Type of surgery	Suggested antimicrobials	Alternatives for penicillin allergy
Cardiothoracic	Flucloxacillin +/– gentamicin	Teicoplanin or Co-trimoxazole
ENT, maxillofacial and oral	Amoxicillin + metronidazole or Co-amoxiclav	Clarithromycin +/– metronidazole or Clindamycin
Gynaecology	Gentamicin + metronidazole	
Lower GI	Gentamicin + metronidazole	
Obstetrics	Co-amoxiclav	Clarithromycin +/– metronidazole or Clindamycin
Orthopaedic	Flucloxacillin +/– gentamicin	Teicoplanin or Co-trimoxazole
Thoracic	Flucloxacillin or Co-amoxiclav	
Upper GI	Gentamicin	
Urology	Gentamicin	
Vascular	Flucloxacillin +/– gentamicin (+metronidazole for amputations)	Co-trimoxazole or Teicoplanin
GI = gastro-intestial		

Fig. 39.5 Timing of antimicrobial prophylaxis administration and infection rate. Study A: The timing of prophylactic administration of antibiotics and the risk of surgical-wound infection (Classen et al., 1992). Study B: Trial to reduce antimicrobial prophylaxis errors (Steinberg et al., 2009). Taken from Mandell et al. (2010). Reproduced with kind permission from Elsevier.

be delayed at short notice, sometimes between the time the patient leaves the ward and arrives at the theatre, it is sensible for the administration of antimicrobials to be transferred from ward staff to the operating team when prophylaxis can be given around the time of induction of anaesthesia.

The optimum time to administer prophylactic antimicrobials before incision is probably 30 min, but national recommendations vary from less than 30 min (SIGN, 2008) to 60 min (NICE, 2008a) prior to incision. Figure 39.5 represents the two major studies undertaken to identify the optimum time for administration of prophylaxis. Both studies determined that post-incision administration of antimicrobials significantly increased the risk of surgical site infection.

Historically, the only occasion where antimicrobial administration has been delayed to after the incision is Caesarian section, where antimicrobials are given after cross clamping the umbilical cord to prevent drug delivery to the neonate. However, it is recognised that this does not provide the mother with adequate tissue levels at the time of incision and two studies have shown that antimicrobials can be given safely before incision without adversely affecting the neonate (Sullivan et al., 2007; Thigpen et al., 2005).

When a tourniquet is used during orthopaedic procedures to minimise bleeding, the antimicrobial should be infused before inflating the tourniquet. This ensures adequate tissue levels are achieved at the site of surgery (Bratzler and Houck, 2004).

Certain practical issues should be considered when selecting an antimicrobial, for example, the requirement for intravenous infusion or safe intravenous bolus administration. An antimicrobial, which requires to be administered over a long period, for example, vancomycin 1 g over nearly 2 h, is much less likely to be given completely compared to teicoplanin, which is administered as a bolus.

To improve the timing of antimicrobial prophylaxis administration, the World Health Organisation (WHO) have introduced a question in their surgical safety checklist. The question *'Has antimicrobial prophylaxis been given within the last 60 minutes?'* is to be asked aloud before incision.

Repeat doses

Although single dose prophylaxis regimens are widely advocated (DH/HPA, 2008; NICE, 2008a; SIGN, 2008), many surgeons continue to use prolonged courses of 'prophylaxis' often for several days, without a clear evidence base. For some procedures, the optimum duration of prophylaxis is not known and 24–48 h prophylaxis is considered acceptable, for example, for open heart surgery (SIGN, 2008).

Where single dose prophylactic regimens have been adopted, the need for dosage adjustment in patients with reduced ability to excrete the drug (usually due to renal impairment) becomes unnecessary. This is because it is unlikely that single doses will have significant dose related adverse effects and idiosyncratic reactions are dose independent. Although the half-life of many drugs used is relatively short (1–2 h in normal volunteers), surgical patients often have slower clearance of antimicrobials from the blood. This concept will probably also hold true for prophylactic regimens lasting up to 48 h.

There are some situations in which it is necessary to prescribe additional doses of antibiotics to achieve the aim of adequate tissue levels at the time of wound closure. The additional doses may be needed when there is significant blood loss (>1500 mL) as plasma is effectively diluted by intra-operative transfusions and fluid replacement. Long operations may also need extra antimicrobial doses during the operation, but additional doses post-operatively do not provide an additional prophylactic benefit.

Antimicrobial administration by hospital theatre staff has practical implications for the route of administration. Ward-based administration of prophylaxis can be given orally if appropriate preparations exist, but this is impractical in sedated or unconscious patients. The oral route tends to suffer from variable absorption, especially in the presence of anaesthetic premedication, and this also makes it unsatisfactory. The intravenous route is the most reliable way of ensuring effective serum levels and is the only route supported by a substantial body of evidence.

A schematic model for the tissue concentration time profile of an antimicrobial agent used to prevent surgical site infection is presented in Fig. 39.6. After an initial dose of the antimicrobial agent, tissue concentrations reach their peak rapidly, with a subsequent decline over time. The goal of prophylaxis is for the antimicrobial tissue concentration to remain above the minimum inhibitory concentration (MIC) for the specific pathogens at the time of incision and throughout the procedure. The antimicrobial should be readministered during prolonged procedures to prevent a period where tissue concentrations are below the MIC (grey area). Failure to readminister antimicrobials appropriately may result in a period during which the wound is vulnerable. Recommendations for peri-operative re-dosing schedules are presented in Table 39.12. General guidance is to repeat doses of antimicrobials at intervals of 1–2 half-lives.

β-Lactam allergy

Penicillin and cephalosporin antibiotics have been the cornerstone of antimicrobial prophylaxis to prevent surgical site infections. Patients reported to be allergic to β-lactam
Fig. 39.6 Schematic presentation of tissue antibiotic concentration over time (Mandell et al., 2010). Reproduced with kind permission from Elsevier.

antibiotics or other antimicrobials need to be carefully assessed, as alternatives may not be optimal. Alternatives are often glycopeptides, for example, teicoplanin or vancomycin, which are more expensive, often need to be given by infusion (vancomycin) and can increase selection for resistant bacteria. The prevalence of penicillin allergy in the general population is unknown. The incidence of self reported penicillin allergy ranges from 1% to 10%, with the frequency of life-threatening anaphylaxis estimated at 0.01–0.05% (or 1–5 in 10,000). More than 80% of patients with a self reported allergy to penicillin have no evidence of IgE antibodies on skin testing. Important details of an allergic reaction include signs, symptoms, severity, history of prior reaction, time course of allergic event, temporal proximity to administered drug, route of administration, other medication being taken and adverse events to other medication (Park and Li, 2005). Reactions to penicillins and other β-lactams occur because of allergy to the parent compound or the metabolites. The cross sensitivity between penicillins and cephalosporins is unknown, but has been variably reported to be up to 10%. Early cephalosporin preparations were contaminated with penicillins probably leading to an over estimate of cross sensitivity (Saxon et al., 1987). As the generation of the cephalosporin increases, the likelihood of cross sensitivity decreases (Pichichero and Casey, 2007). Those with a penicillin allergy showed an increased risk of allergic reaction to a first generation cephalosporin. First generation cephalosporins share a similar side chain to penicillin and amoxicillin. However, cross sensitivity to second and third generation cephalosporins was lower. The different side chains appear to play a more dominant role than the β-lactam ring in allergy.

Recent prospective studies have shown that the cross-reactivity to carbapenems and monobactams is very small. It is around 1% for imipenem and meropenem, and no cross-reaction has been reported for aztreonam (Frumin and Gallagher, 2009).

Table 39.12 Time for peri-operative re-dosing of antimicrobials (adapted from Bratzler and Houck, 2004; Gilbert et al., 2009)

Antimicrobials	Peak serum level (mg/L)	Half-life (h)	Time to redose
Cefuroxime 1.5 g IV	100	1.5	3 to 4 h
Ciprofloxacin 400 mg IV	4.6	4	4 to 8 h
Co-amoxiclav 1.2 g	Unknown	1.4 AM/1.1 CL	3 to 4 h
Co-trimoxazole 960 mg IV	9 TMP/105 SMX	7–12 TMP/8–15 SMX	8 to 12 h
Flucloxacillin 1 g IV	120–350	0.5	3 h
Gentamicin	N/A as many doses used	2.5	3 to 6 h unless >2 mg/kg; then do not redose
Metronidazole 500 mg IV	20–25	6–14	6 to 8 h
Vancomycin 1 g IV	20–50	4–6	6 to 12 h
Teicoplanin 200 mg IV	20	90–157	12 h

AM, amoxicillin; CL, clavulanic acid; TMP, trimethoprim; SMX, sulphamethoxazole.

The increased use of penicillins rather than first or second generation cephalosporins for surgical site infection prophylaxis is increasing the potential for adverse reactions. In addition, the current nomenclature for penicillin combinations, for example, co-amoxiclav, can often make it more difficult for staff to recognise penicillin containing antimicrobials. Current guidance on the use of β-lactams in patients with penicillin allergy is detailed in Table 39.13.

Topical or local antimicrobial prophylaxis

Many surgical procedures involving the use of implants or prostheses now use topical antimicrobials to prevent late surgical site infection. Examples include antimicrobial loaded cement for fixing hip and knee joint replacements into bone. Gentamicin is the only antimicrobial in commercially available products in the UK. Surgeons do add other antimicrobial agents, especially if replacing an infected prosthesis with choice based on culture and sensitivities.

In vascular surgery, synthetic grafts bonded with or soaked in rifampicin are frequently used, despite evidence showing that there was no decrease in infection rates at 1 month and 2 years (Stewart et al., 2006). There is some evidence to support the local delivery of gentamicin into wounds via collagen fleece impregnated with gentamicin and further research into this was recommended (NICE, 2008a); however, two recent randomised controlled trials have shown it not to be efficacious (Bennett-Guerrero et al., 2010a,b) The use of topical cefotaxime in contaminated surgery has been shown not to decrease peritonitis, and should not be used.

Case Studies

Case 39.1

A patient is due to have an elective total hip replacement. As part of the routine, pre-admission screening is done, during which swab samples are taken. The patient is identified as being MRSA positive. The patient receives a five-day course of nasal mupirocin and topical chlorhexidine washes as 'decolonisation therapy' prior to the admission. The unit normally uses single dose co-amoxiclav as prophylaxis.

Question

Should there be a change to the routine antimicrobial prophylaxis for this patient?

Answer

A change to the routine antimicrobial prophylaxis should be recommended because co-amoxiclav is not active against MRSA. The commonly used terms 'decolonisation therapy' and 'MRSA eradication' falsely give the impression that this regimen eradicates MRSA carriage. In reality, it should be called 'suppression therapy' because these agents reduce the numbers of bacteria present

Table 39.13 Guidance on the use of β-lactam antibiotics in patients with penicillin allergy recommended by BNF (Joint Formulary Committee, 2010)

Allergic reaction	Action
Immediate hypersensitivity reaction to a penicillin	Avoid penicillins and cephalosporins
Minor rash – localised or widespread but delayed (>72 h)	Avoid penicillins, but cephalosporins are safe to use

but often fail to eradicate MRSA carriage. *S. aureus* is still the predominant cause of surgical site infection and this patient remains at risk of an MRSA surgical site infection. As a consequence an agent that is active against MRSA should be used. Glycopeptides are the recommended antimicrobial class in this situation and there are two options: teicoplanin and vancomycin. Vancomycin needs to be given as an infusion at a maximum rate of 10 mg/min, which means that administering a 1-g dose will take nearly 2 h and may be impractical before skin incision. Teicoplanin can be given as a bolus, so is the best choice. Teicoplanin 400 mg intravenously can therefore be used instead of vancomycin 1 g intravenous. Where bone cement is required to secure the prosthesis, a commercially prepared bone cement containing gentamicin should also be used. Ideally, all antimicrobial prophylaxis guidelines or protocols should contain an option for MRSA positive patients. Administration of appropriate regimens is facilitated by MRSA screening of all elective patients.

Case 39.2

A patient with a severe allergy to penicillin is admitted for a hemicolectomy for cancer of the colon. The unit uses a single dose co-amoxiclav regime as antimicrobial prophylaxis for large bowel surgery.

Question

The junior hospital doctor asks your advice as to the antimicrobials to use instead of co-amoxiclav? What advice would you give?

Answer

Colorectal surgery still carries one of the highest surgical site infection rates of up to 10% for elective procedures. The usual bacteria found in these surgical site infections are *S. aureus*, gram-negative bacilli (e.g. *E. coli*) and anaerobes. Options for treatment include gentamicin and metronidazole, or ciprofloxacin and metronidazole. Centres that have a problem with *Clostridium difficile* infection may prefer to use gentamicin and metronidazole. There is evidence for the use of single dose regimes.

Case 39.3

A 73-year-old lady is seen in pre-admission clinic for assessment prior to a knee replacement. She has recently had *Clostridium difficile* infection in the community after being treated with a 1-week course of co-amoxiclav. She is asymptomatic now. The surgical team is reluctant to use its usual antimicrobial prophylaxis regime of co-amoxiclav, or cefuroxime or ciprofloxacin.

Question

The anaesthetist assessing the patient in pre-assessment clinic asks your advice on what to prescribe. The lady is currently being screened for MRSA. What advice would you give?

Answer

The most common pathogens in knee replacement surgical site infections are *S. aureus* and coagulase-negative staphylococci, although infection rates are low (0.2%, e.g. in Scotland). Depending on the result of the MRSA screening test, there will be different answers. If the lady is colonised with MRSA, she could receive a single dose of teicoplanin. Options for prophylaxis include flucloxacillin with gentamicin or teicoplanin, although the latter does not cover gram-negative bacteria. The use of gentamicin-containing cement would be recommended.

Case 39.4

A 72-year-old man is due for elective transurethral resection of the prostate (TURP) and is currently well with no signs of a urinary tract infection. Routine prophylaxis for surgical site infections on the unit is co-amoxiclav. The patient is known to have had a mitral valve replacement 2 years ago.

Question

You are asked whether the antimicrobial prophylaxis should be amended to cover this? What advice would you give?

Answer

NICE guidelines no longer recommend prophylaxis for patients at risk of endocarditis undergoing investigations involving the oral, gastro-intestinal or urogenital tract, in the absence of local infection (NICE, 2008b). The usual prophylaxis for this regimen should be recommended. If the patient had a urinary tract infection, this should ideally be treated before surgery.

40 Tuberculosis

L. K. Nehaul

Key points

- In 2008, there were an estimated 9 million cases of tuberculosis (TB) and 2 million deaths from the disease worldwide.
- One-third of the world's population is infected with the tubercle bacillus.
- Adequate and effective treatment is essential to treat the individual, control the spread of TB and minimise the occurrence of drug-resistant disease.
- TB is caused by infection with *Mycobacterium tuberculosis*, *M. bovis* and *M. africanum*. *M. tuberculosis* accounts for around 99% of isolates in the UK.
- TB infection usually occurs by the respiratory route.
- People with HIV infection have an increased risk of developing active TB disease if co-infected with tubercle bacilli.
- Certain medical risk factors increase the risk of TB.
- Most treatment regimens in the developed world are of 6 months' duration and contain isoniazid, rifampicin and pyrazinamide, with ethambutol or streptomycin.
- Rifampicin, isoniazid and pyrazinamide are all potentially hepatotoxic. Isoniazid may cause a dose-dependent peripheral neuropathy, while ocular toxicity is the most important side effect of ethambutol.
- Multidrug-resistant TB is a problem in many parts of the world; extensively drug-resistant TB was first reported in 2006.

Introduction

Tuberculosis (TB) is a bacterial infection, treatable by anti-TB drugs. It is a global problem, with the incidence varying across the world. In 1993, an increase in reported cases of TB in countries across all continents led the World Health Organization (WHO) to declare TB a global emergency. The burden of TB in many countries is compounded in those who have co-infection with the human immunodeficiency virus (HIV). Of additional concern has been the increase in multidrug-resistant tuberculosis (MDR-TB), with outbreaks in different parts of the world. In 2006, the emergence of extensively drug-resistant tuberculosis (XDR-TB) was first reported. The treatment of drug-resistant TB is complex, costlier and of a longer duration than drug-susceptible cases.

Adequate and effective treatment is essential, both clinically for patients and also to control TB, as the BCG vaccine does not prevent infection. Successful control depends on a close working collaboration between clinical, microbiological, pharmacy, infection control and public health teams in managing patients and their contacts, and a shared understanding with primary care teams as to the role of all health professionals involved in TB.

Clinical and public health practice for bringing TB under control in the UK is underpinned by guidance from National Institute for Health and Clinical Excellence (2006) and the Joint Committee on Vaccination and Immunisation (Department of Health, 2006).

Aetiology

TB is caused by tubercle bacilli, which belong to the genus *Mycobacterium*. These form a large group but only three relatives are obligate parasites that can cause TB disease. They are part of the *Mycobacterium tuberculosis* complex. The UK data for 2008 show that *M. tuberculosis* was isolated in 99% of confirmed cases, *M. bovis* in 0.4% and *M. africanum* in 0.5% that year (Health Protection Agency, 2009).

Mycobacterium species include:

- *M. tuberculosis* complex*: M. tuberculosis*, *M. bovis*, *M. africanum*
- *Mycobacteria other than tuberculosis:* Around 15 are recognised *as pathogenic to humans and some cause* pulmonary disease resembling TB. They have been found in soil, milk and water. They are also referred to as atypical mycobacteria.
- *Mycobacterium leprae:* The cause of leprosy.

Clinical aspects

Infection with tubercle bacilli occurs in the vast majority of cases by the respiratory route. The lung lesions caused by infection commonly heal, leaving no residual changes except occasional pulmonary or tracheobronchial lymph node calcification (Heymann, 2004). About 5% of those initially infected will develop active primary disease (Hawker et al., 2005). This can include pulmonary disease, through local progression in the lungs, or by lymphatic or haematogenous spread of bacilli, to pulmonary, meningeal or other extrapulmonary

involvement, or lead to disseminated disease (miliary TB). In the other 95%, the primary lesion heals without intervention but in at least one-half of patients, the bacilli survive in a latent form, which may then reactivate later in life. Infants, adolescents and immunosuppressed people are more susceptible to the more serious forms of TB such as miliary or meningeal TB.

Pulmonary (respiratory) TB is more common in the UK than extrapulmonary (non-respiratory) TB. Sites of extrapulmonary disease include the pleura, lymph nodes, pericardium, kidneys, meninges, bones and joints, larynx, skin, intestines, peritoneum and eyes. In the UK, the lymph nodes are the most common site for extrapulmonary disease. In 2008, 55% of cases were pulmonary and 21% involved the extrathoracic lymph nodes.

Pulmonary TB may arise from exogenous reinfection or endogenous reactivation of a latent focus remaining from the initial infection. If untreated, about 65% of patients will die within 5 years, the majority of these within 2 years. Completion of chemotherapy using drugs to which the tubercle bacilli are sensitive almost always results in a cure, even with HIV infection.

Incubation period

The incubation period from infection to demonstrable primary lesion or significant tuberculin reaction ranges from 2 to 10 weeks. Latent infection may persist for a lifetime. HIV infection appears to shorten the interval for the development of clinically apparent TB.

Transmission

Transmission occurs through exposure to tubercle bacilli in air-borne droplet nuclei produced by people with pulmonary or respiratory tract TB during expiratory efforts such as coughing or sneezing. In general, only the respiratory forms of TB (tuberculosis of the larynx is highly contagious but rarely seen in the UK) are infectious. Most infections are acquired from adults with post-primary pulmonary TB. The greatest risk of infection is to close, prolonged contacts, mainly household contacts. Between 90% and 95% of cases of TB in children are non-infectious (Davies, 2003). TB cannot be acquired from individuals with latent TB infection (LTBI).

Patients should be considered infectious if they have sputum smear-positive pulmonary disease (i.e. they produce sputum containing sufficient tubercle bacilli to be seen on microscopic examination of a sputum smear) or laryngeal TB. Patients with smear-negative pulmonary disease (three sputum samples) are less infectious than those who are smear positive. The relative transmission rate from smear-negative compared with smear-positive patients has been estimated to be 0.22 (British Thoracic Society, 2000).

Risk groups

Certain groups are at increased risk of LTBI and possibly TB disease if exposed. These include:

- close contacts of patients with TB, especially those with sputum smear-positive pulmonary disease

---

> **Box 40.1** Examples of factors that increase risk of developing active tuberculosis if infected
>
> - HIV positive
> - Injecting drug users
> - Solid organ transplantation, jejunoileal bypass or gastrectomy
> - Haematological malignancy, for example leukaemia and lymphomas
> - Chronic renal failure or receiving haemodialysis
> - Receiving anti-TNFα treatment
> - Silicosis

- casual contacts (e.g. work colleagues) if they are immunosuppressed
- people from countries with a high incidence of TB (40/100,000 population or greater).

People with certain medical conditions are at increased risk of developing active TB if they have LTBI. These medical risk factors are set out in Box 40.1.

Impact of HIV infection

People with HIV infection have an increased risk of developing TB if exposed to infection. The estimated annual risk of TB in those with HIV infection and TB co-infection is around 10% as opposed to a 10% lifetime chance in someone infected with TB, but not HIV.

Drug-resistant TB

MDR-TB is caused by bacteria that are resistant to at least isoniazid and rifampicin, the most effective anti-TB drugs. MDR-TB results from either primary infection with resistant bacteria or may develop in the course of a patient's treatment.

XDR-TB is a form of TB caused by bacteria that are resistant to isoniazid and rifampicin, that is, MDR-TB, as well as any fluoroquinolone and any of the second-line anti-TB injectable drugs including amikacin, kanamycin or capreomycin (WHO, 2010).

Epidemiology

Epidemiology is a measure of the occurrence of a disease in different populations. It helps to identify population groups at increased risk of TB. The key measures for TB are the number of new cases in a specified period of time, usually 1 year, and the incidence rates, that is, new cases per 100,000 of the population. Incidence rates are a good comparative measure of differences in the occurrence of TB between countries or different sub-groups in the population, as they take into account the size of those groups. TB surveillance, which involves monitoring its occurrence and epidemiology, is an essential component of TB control programmes, because it helps to evaluate their effectiveness in reducing disease rates.

Global

Globally, it is estimated that TB causes about 2 million deaths worldwide each year. One-third of the world's population is infected with the tubercle bacillus. It is becoming the leading cause of death among HIV-positive people. Over 4 million cases of TB disease are notified annually although the estimated number of new cases is put at 9 million. The majority of cases occur in poor countries in the southern hemisphere (WHO, 2009).

The numbers of cases estimated to have occurred in 2008, globally and by WHO region, is presented in Table 40.1. Most cases of TB are in South East Asia, although the highest rates are in Africa.

In 2008, it was estimated that 440,000 people had MDR-TB worldwide, and one-third of these died. The brunt of the MDR-TB epidemic is borne by Asia, with almost 50% of cases worldwide estimated to occur in China and India. However, in some areas of the world, up to one in four people have drug-resistant TB. For example, 28% of all people newly diagnosed with TB in one region of North-Western Russia had the multidrug-resistant form of the disease (WHO, 2010).

UK

In the UK, since the late 1980s, there have been changes in the epidemiology of TB. Following a decrease in notifications over several decades, from the late 1980s cases of TB started to increase again.

A total of 8655 cases were reported in 2008 (Health Protection Agency, 2009). The overall rate across all population groups was 14.1 per 100,000 population. Of all cases, 39% occurred in the London region, where the rate was 44.3 per 100,000 population. Nineteen primary care organisations in England had a rate of 40 per 100,000 or over, all of which were in major urban areas. Rates of TB in England outside London varied from 5.7 per 100,000 in South-West England to 18.7 per 100,000 in the West Midlands. Incidence rates per 100,000 population were 8.7 in Scotland, 5.8 in Wales and 3.3 in Northern Ireland. The majority of cases (72%) were in the population born outside the UK and in those aged 16–44 years (61%). The TB rate was higher in those born abroad than among those born in the UK (86 compared with 4.4 per 100,000). This reflected higher rates of TB in people from high-incidence countries, mainly South Asia. The risk of TB is highest in the 5 years after arrival in the UK. TB can also occur as a travel-related disease in UK residents from high-incidence countries, who return to visit their country of birth and are exposed to TB. The numbers of cases by region in England, Wales and Northern Ireland, in 2008, is shown in Table 40.2.

Diagnosis

Symptoms

The symptoms and signs of TB include:

- Cough for 3 weeks or more/productive cough
- Sputum usually mucopurulent or purulent
- Haemoptysis not always a feature
- Fever may be associated with night sweats
- Tiredness
- Weight loss variable
- Anorexia variable
- Malaise.

Awareness of the disease

Awareness of TB on the part of health care professionals and of people in high-risk communities is essential to its control. Early diagnosis, especially of pulmonary TB, followed by prompt commencement of treatment can reduce the period of infectivity to other people, especially susceptible contacts, who might be at risk of the more serious forms of TB disease. Such contacts can include children in nurseries or schools or immunosuppressed patients in a hospital setting. Health care

Table 40.1 Estimated epidemiological burden of tuberculosis incidence globally and by WHO region (*Source*: WHO, 2010)

WHO region	Numbers (000s), 2008 (lower and upper bounds)	Rates per 100,000 population, 2008 (lower and upper bounds)
Africa	2800 (2700–3000)	350 (330–370)
Americas	280 (260–300)	31 (29–33)
Eastern Mediterranean	650 (580–740)	110 (99–130)
Europe	430 (400–460)	48 (45–51)
South-East Asia	3200 (2800–3700)	180 (160–210)
Western Pacific	1900 (1700–2200)	110 (95–130)
Global	9400 (8900–9900)	140 (130–150)

Table 40.2 Tuberculosis case reports and rates by UK region/country 2008 (adapted from Health Protection Agency, 2009)

UK region/country	Number of cases	Rate per 100,000 population
London	3376	44.3
West Midlands	1012	18.7
North West	745	10.8
Yorkshire and the Humber	647	12.4
East Midlands	517	11.7
South East	719	8.6
East of England	478	8.3
South West	297	5.7
North East	179	7.0
England	7970	15.5
Scotland	452	8.7
Wales	174	5.8
Northern Ireland	59	3.3

professionals should be particularly alert to symptoms suggestive of TB in health care workers or people working in childcare or institutional settings, and initiate investigations at the earliest possible opportunity. Such action can lead to the diagnosis of TB before it becomes infectious, thereby protecting vulnerable contacts.

TB should be considered in the differential diagnoses of patients with a chronic cough for which there is no other likely cause, or in individuals with chest infections not responding to treatment.

Clinical diagnosis

The clinical diagnosis of TB disease is based on the symptoms and signs in the patient together with chest radiography, microscopy of sputum (for acid-fast bacilli) followed by culture and tuberculin skin testing. Blood-based immunological tests, introduced in the last few years, will play an increasingly important role in TB diagnosis. These tests can distinguish between TB infection and previous BCG vaccination.

Investigations

Investigations are essential to confirm clinically suspected TB and should be arranged even if the diagnosis is strongly suspected on clinical grounds. Microbiological tests are crucial, especially for pulmonary disease, as they facilitate both the clinical and public health management of TB and ensure the appropriate implementation of infection control procedures for cases managed in healthcare settings.

Microbiological

Microbiological investigations are undertaken to assess the infectious state of the patient, and distinguish between infection with mycobacteria causing TB and other mycobacteria. They also determine the drug-susceptibility patterns of the infecting organisms, to ensure that the drugs prescribed will be effective in treating the individual patient. Investigations comprise microscopy, culture, drug-susceptibility testing and strain typing.

Direct microscopy of sputum is the simplest and quickest method of detecting the infectious patient, by looking for acid-fast bacilli. A minimum of three sputum samples, one of which should be early morning, should be collected from patients with suspected respiratory TB.

Direct microscopy is not as useful in non-pulmonary disease, any specimens taken should be sent for culture.

If conventional culture methods are used, such as the Lowenstein–Jensen medium, growth may take up to 6 weeks. Modern liquid cultures can produce results more quickly. Polymerase chain reaction (PCR)-based tests can also detect *M. tuberculosis* complex in clinical specimens.

A rapid test is available for assessing rifampicin resistance in individuals thought to have drug-resistant TB. A positive result indicates the need to assess susceptibility to other first-line anti-TB drugs. Drug-susceptibility testing still needs to be done on isolates grown on culture media.

DNA fingerprinting, or strain typing, is useful in the public health management of TB. In 2010, a new method, mycobacterial interspersed repetitive unit/variable number of tandem repeats (MIRU/VNTR) 24-loci strain typing, became available in the UK. Strain typing will help in establishing links between cases not previously identified, disproving links between apparent clusters of cases, and also in detecting cross-contamination in laboratories.

Tuberculin testing

Tuberculin testing is used to detect LTBI. Only the Mantoux test is now used but it should be carried out by health care professionals trained and experienced in its use. The standard Mantoux test consists of an intradermal injection of 2 TU of Statens Serum Institute (SSI) tuberculin RT23 in 0.1 mL solution for injection. In this test, 0.1 mL of the appropriate solution is injected intradermally, usually on the forearm, so that a bleb of around 7 mm is produced. The results are read 48–72 h later, although a valid reading can be obtained up to 96 h later. The transverse diameter of the area of induration is measured with a ruler and the result recorded in millimetres.

The interpretation of the test will depend on the clinical circumstances, including a past history of TB or exposure to TB. A diameter of induration of less than 6 mm is negative, that is, there is no significant hypersensitivity to tuberculin protein.

In the absence of specific risk factors for TB, induration of between 6 and 15 mm diameter may be due to previous TB infection, or BCG vaccination or exposure to non-tuberculous mycobacteria. An induration of more than 15 mm is strongly suggestive of TB infection or disease.

Chest radiography

The chest radiograph is a non-specific diagnostic tool, as TB may present as virtually any abnormality on chest radiography. This is why microbiological evidence of confirmation should be sought. Pulmonary TB may appear as broncho-pneumonia with confluent shadowing, without cavitation. Cavitation may be seen, the incidence can vary between 10% and 30%. Uncharacteristic radiological patterns may occur in the presence of HIV infection (Davies, 2003).

Diagnosis in people with HIV

TB can occur early in the course of HIV infection and may therefore be diagnosed before the patient is known to be HIV positive. The possibility of HIV infection in people with TB should therefore be considered, and testing for the virus is appropriate in those with risk factors for HIV.

Early in the course of HIV infection, before serious immunodeficiency occurs, TB is more likely to present with typical clinical features, and a positive tuberculin skin test, with cavitation and/or pleural disease on chest radiography. In the late stages of HIV infection, atypical presentations are more likely with unusual chest findings and extrapulmonary disease. The chest radiograph may be normal in up to 40% of cases.

Public health action

TB is a statutorily notifiable communicable disease in the UK. Cases should be notified on clinical suspicion by the attending doctor to the 'Proper Officer' for communicable disease control of the local authority where the patient resides. This is usually the local Consultant in Communicable Disease Control. In Scotland, notifications are made to the Health Board. Notification enables public health action to be initiated and involves investigation of prolonged, close contacts who might be at risk of infection, mainly those living in the same household as the patient, to assess them for LTBI or active TB disease. It may also enable the source of the infection to be found and treated.

Latent TB infection (LTBI) is not notifiable. Public health action is not taken for infections caused by 'mycobacteria other than TB'.

Treatment

In treating TB, a number of factors are important:

- Choice of drugs
- Length of treatment

- Co-morbidity especially HIV infection, liver and renal diseases
- Adherence to treatment by the patient.

It is important to tailor the management of the patient according to his or her situation, rather than just focus on the drug treatment of TB, as other factors in the patient's life may affect adherence.

Drug treatment

Treatment with anti-TB drugs has two main purposes:

- to cure people with TB, provided the bacilli are drug sensitive;
- to control TB, by either preventing the development of infectious forms or reducing the period of infectivity of people with infectious disease.

TB had started to decline in the UK before the advent of chemotherapy, probably due to improved nutrition and social conditions. With the advent of effective anti-TB chemotherapy, patients no longer needed treatment in a sanatorium. Results with regimens containing isoniazid together with p-aminosalicylate (PAS) or ethambutol, and sometimes streptomycin, gave excellent results. Treatment was required for 18–24 months if relapse was to be prevented. The availability of pyrazinamide and, more importantly, rifampicin made shorter courses of treatment a possibility. Most regimens in the developed world now contain isoniazid and rifampicin, which are the two most important drugs. These are prescribed together with pyrazinamide and possibly with another agent, such as ethambutol.

Bacterial characteristics

There are three populations of the *M. tuberculosis* (MTB) organism. The first population is that of the actively growing extracellular bacilli. Large numbers of bacilli can grow extracellularly in pulmonary cavities within liquefied caseous debris. This is the population in which drug resistance develops most rapidly. The second population consists of slow-growing or intermittently growing bacilli, which are inside macrophages. These are fewer in number, but the intracellular environment is acidic and many drugs are not active in these conditions. The third population is made up of slower-growing bacilli, which grow in solid caseous material. This environment is neutral in pH, but the penetration of drugs into this area can be compromised by a poor blood supply.

Rifampicin is the only drug that is bactericidal against all three populations. Isoniazid, streptomycin and the other aminoglycosides are bactericidal against extracellular bacilli. Isoniazid is also bactericidal against intracellular organisms. Pyrazinamide is bactericidal only against intracellular organisms and works well in an acidic pH. All other first-line TB drugs are bacteriostatic. Of the alternative drugs, which can be used in the treatment of drug-resistant TB, the quinolones have the highest bactericidal activity against *M. tuberculosis*.

When considering a treatment regimen for TB, it must be remembered that viable bacilli for slow-growing or intermittently growing populations may persist if drugs are not continued for an adequate period of time. The patient's condition can then relapse after chemotherapy is completed.

Treatment

The recommended standard treatment regimen for respiratory and most other forms of TB in the UK is:

- rifampicin, isoniazid, pyrazinamide and ethambutol for the initial 2 months (initial phase)
- a further 4 months of rifampicin and isoniazid (continuation phase).

A longer period of treatment than the standard 6 months is needed for meningeal TB and where there is direct spinal cord involvement.

Patients should be started on the standard treatment regimen on clinical diagnosis and the doses of the first-line anti-tuberculous agents are shown in Table 40.3. The drugs used can be changed if drug-susceptibility testing shows evidence of resistance.

The purpose of the concurrent use of four drugs in the initial phase is to reduce the bacterial population as rapidly as possible and prevent the emergence of drug-resistant bacteria. In general, daily dosing schedules are recommended. Combination tablets can be used and have the advantage of preventing accidental or inadvertent single drug therapy, which can lead to acquired drug resistance within weeks in active TB. It is important, however, to ensure the combination product contains the required dose of the constituent drugs.

Patients with suspected drug reactions or drug-resistant TB should always be referred back to the specialist physician and the healthcare team supervising their treatment.

Respiratory TB

Respiratory TB is defined as active TB affecting any of the following:

- lungs
- pleural cavity
- mediastinal lymph nodes
- larynx.

The standard 6-month regimen, as set out earlier, is recommended for the treatment of active respiratory TB in:

- adults not known to be HIV positive
- adults who are HIV positive
- children.

Table 40.3 Dosages of first-line anti-tuberculous agents[a]

Drug	Forms available	Dosage				Reduce dose in	
		Adults daily	Adults intermittent (doses per week)	Children daily	Children intermittent (doses per week)	Renal failure	Liver failure
Rifampicin	Capsules 150 mg, 300 mg[b] Liquid 100 mg in 5 mL Injection for infusion 300 mg	450 mg/kg (<50 kg) 600 mg (>50 kg)	15 mg/kg (3)	10 mg/kg	15 mg/kg (3)	No	Only in severe liver failure
Isoniazid	Tablets 50 mg[b] Injection 25 mg/mL Elixir (special order)[c]	300 mg	15 mg/kg (3)	5–10 mg/kg	15 mg/kg (3)	Only in severe liver failure	In patients with acute or chronic liver disease
Ethambutol[f]	Tablets 100 mg, 400 mg[b] Mixture[c]	15 mg/kg[d]		As adult dose	30 mg/kg (3)	Yes	No
Pyrazinamide	Tablets 500 mg	1.5 g (<50 kg) 2.0 g (≥50 kg)	2.0 g[d] (<50 kg) (3) 2.5 g[a] (≥50 kg)	35 mg/kg		Yes	No
Streptomycin	Injection 1 g	750 mg (<50 kg) 1 g (<50 kg)	750 mg–1 g[e]	15 mg/kg		Yes	No

[a]Some of the doses quoted are not licensed but have been recommended by the British Thoracic Society.
[b]Also available as combined oral preparations.
[c]Mixture may be prepared extemporaneously.
[d]Doses refer to patients under 50 kg. Reduce by 500 mg for patients weighing less than 50 kg.
[e]Drug levels should be monitored to prevent toxicity.
[f]Acute calculation is required to reduce the risk of toxicity.

TB of peripheral lymph nodes

Trials have shown that 6 months of treatment are just as effective as 9 months for fully susceptible bacilli. The standard 6-month treatment regimen is recommended.

Meningeal TB

Patients with active meningeal TB (tuberculous meningitis) should be treated with rifampicin and isoniazid for 12 months together with pyrazinamide, and normally ethambutol, for the first 2 months. Ethambutol (and streptomycin if used in preference) only reach cerebrospinal fluid through inflamed meninges.

Care must be exercised when ethambutol is used in unconscious patients as a decline in visual acuity, a known side effect of ethambutol, cannot be assessed.

Meningeal TB is a serious disease and treatment must be started promptly. The stage at which the disease is diagnosed, and treatment started, most affects prognosis. Therefore, it is often justified to start a therapeutic trial of anti-TB drugs in the absence of a definite diagnosis.

The use of glucocorticoids is also recommended in the management of meningeal TB and is commenced at the same time as anti-tuberculous drugs. Consideration should be given to their gradual withdrawal within 2–3 weeks of initiation. The recommended doses (National Institute for Health and Clinical Excellence, 2006) are:

- Adults: equivalent to prednisolone 20–40 mg if on rifampicin, otherwise 10–20 mg
- Children: equivalent to prednisolone 1–2 mg/kg, maximum 40 mg.

The more recent British Infection Society (BIS) guidelines for the diagnosis and treatment of TB of the central nervous system (CNS) in adults and children (Thwaites et al., 2009) recommend all patients with meningeal TB should receive adjunctive corticosteroids (dexamethasone) regardless of disease severity at presentation.

Bone and joint TB

The spine is the most common site for bone TB. Bone and joint TB are treated effectively with standard agents such as isoniazid and rifampicin for 6 months, together with pyrazinamide and a fourth drug, usually ethambutol in the initial phase (for 2 months). This recommendation covers active spinal TB and active TB at other bone and joint sites. Occasionally, surgery may be needed to either relieve spinal cord compression or correct spinal deformities.

Disseminated TB

Generalised (disseminated or miliary) TB must be treated promptly as there is appreciable mortality from delayed diagnosis and treatment. The standard 6-month regimen containing both isoniazid and rifampicin, with pyrazinamide and ethambutol in the first 2 months, is used. If there is evidence of CNS involvement, treatment should be the same as for meningeal TB.

Pericardial TB

Although TB of the pericardium is rare in the UK, it is potentially important because of the possibility of cardiac tamponade and constrictive pericarditis, which are associated with a significant morbidity and mortality. The standard 6-month treatment regimen is recommended for patients with active pericardial disease. Glucocorticoids should also be prescribed at the following doses (National Institute for Health and Clinical Excellence, 2006):

- Adults: a glucocorticoid equivalent to prednisolone at 60 mg/day
- Children: a glucocorticoid equivalent to prednisolone 1 mg/kg/day (maximum 40 mg/day), with gradual withdrawal of the glucocorticoid, starting within 2–3 weeks of initiation.

Treatment of TB in special circumstances

TB in children

The doses of drugs used in children are shown in Table 40.3. Doses are generally estimated to facilitate prescription of easily administered volumes of liquid or tablets of appropriate strength. Ethambutol should not routinely be used in young children, who would be unable to report visual disturbances should they occur. However, it may be used if there is toxicity or resistance to other agents.

Pregnancy

As there is a risk of TB to the fetus, treatment should be commenced whenever it is moderately or highly probable that a pregnant woman has TB. Standard therapy should be given, although streptomycin should not be used as it may be ototoxic to the fetus. It is considered safe for mothers to breast feed while taking anti-tuberculous treatment. Pyridoxine (vitamin B_6) supplementation (10–25 mg/day) is recommended for breastfeeding women taking isoniazid. Patients should be warned of the reduced effectiveness of oral contraceptives in regimens containing rifampicin, and advised to use other, non-hormonal contraceptives.

Renal disease

Patients with renal disease may be given isoniazid, rifampicin and pyrazinamide in standard doses as these drugs are predominantly eliminated by non-renal routes. Ethambutol undergoes extensive renal elimination and therefore dose reduction is needed. Monitoring serum concentrations has been suggested, but this might not be readily available in many centres. Streptomycin must be used with considerable caution to prevent toxicity and is best avoided in renal failure. Rifampicin may be given in standard doses to patients on dialysis. However, doses of the other agents need to be modified, and a number of different regimens have been suggested.

Liver disease

Monitoring of liver enzymes is recommended in patients with liver failure or in alcoholics because rifampicin, isoniazid and pyrazinamide are all potentially hepatotoxic. However, increases in transaminases at the start of anti-tuberculous treatment occur frequently. These are usually transient and not a reason for stopping treatment unless frank jaundice or hepatitis develops, in which case all drugs should be stopped. It is usually possible to restart treatment when transaminases have returned to pre-treatment levels.

Immunocompromised patients

Patients who are immunocompromised, including those with HIV infection, should be treated with normal first-line agents unless multidrug-resistant TB is suspected. Theoretically, these patients have a greater risk of relapse and may need to be treated for longer than the normal 6 months.

TB and HIV co-infection

Guidelines for the treatment of TB/HIV co-infection (Pozniak et al., 2009) recommend that co-infected patients are managed by a multidisciplinary team which includes physicians with expertise in the treatment of both TB and HIV.

If patients on anti-tuberculous therapy are started on highly active antiretroviral therapy (HAART), then antiretrovirals should be chosen to avoid interactions with TB therapy. The treatment for TB should only be modified when drug interactions with antivirals do not allow the optimal TB treatment regimen. In some cases, a longer duration of treatment for the TB may be needed.

Chemo-preventive therapy for TB is not recommended in HIV-infected patients. However, as HIV-infected people with LTBI are more likely to progress to active TB disease than people without HIV, the detection and treatment of a latent infection is important.

HAART is effective at reducing the incidence of new TB in HIV-infected people. HIV-positive patients should therefore be offered HAART.

Drug-resistant TB

Drug-resistant TB is a considerable problem worldwide. In the UK, however, the proportion of TB isolates showing resistance is low (in 2008, 6% were resistant to isoniazid, 1.5% resistant to rifampicin, and 6.8% resistant to any first-line drug). Drug resistance is an important issue in the management of TB as it may compromise the effectiveness of treatment and prolong the period during which patients are infectious to others. Isoniazid is the most usual agent to which resistance is seen. Multi-drug resistance is important because the main bactericidal drugs, isoniazid and rifampicin, are ineffective. Treatment has to be individualised, requires a complex regimen involving the use of multiple reserve drugs and can cost at least £50,000 to £70,000 each to treat (Table 40.4). It is recommended that treatment of these individuals is only carried out by physicians with experience in drug-resistant TB; in hospitals, when inpatient treatment is necessary, with appropriate isolation facilities (negative pressure rooms); and in close conjunction with specialist centres.

Monitoring treatment

In pulmonary TB, sputum examination and culture are the most sensitive markers of treatment success. Patients taking regimens containing rifampicin and isoniazid should be non-infectious within 2 weeks. If a patient does not become culture negative, it may be due to either drug resistance or non-adherence, the latter being more likely. Good adherence is essential if treatment is to be successful and checking this can be difficult, especially when a patient is unwilling to cooperate.

Adverse reactions

The major adverse reactions of the first-line drugs are shown in Table 40.5. Rifampicin, isoniazid and pyrazinamide are all potentially hepatotoxic, and liver function should be checked before treatment commences with these drugs. Transient increases in transaminases and bilirubin commonly occur at the start of treatment although there is no need to continue to monitor liver function in patients where pre-treatment liver function was normal. However, liver function tests must be measured if fever, malaise, vomiting or jaundice develop and all drugs should be stopped. Liver function should be allowed to return to normal, at which time treatment can be recommenced one drug at a time. Clinical hepatitis is rare although patients may complain of vague symptoms such as abdominal pain and malaise which may indicate impending hepatitis.

Rifampicin is usually well tolerated, but gastro-intestinal upsets, fever and rash can occur. It interacts with many medications, including methadone, protease inhibitors and non-nucleoside reverse transcriptase inhibitors used to treat HIV infection, macrolide antibiotics, warfarin and hormonal contraceptives. It will colour the urine orange-red within approximately 4 h of a dose.

Hypersensitivity reactions or rashes may occur with any of the drugs. However, the most important, although rare, is caused by rifampicin and can be quite severe. It is more prevalent during intermittent treatment and presents as a flu-like syndrome, sometimes with abdominal pain and respiratory symptoms. This usually resolves on reverting to a daily dosage. However, if more serious effects occur, such as renal impairment or haematological abnormalities, the drug should be stopped and never restarted.

Isoniazid can cause fever, skin rashes and a dose-dependent peripheral neuropathy, probably due to depletion of vitamin B_6. This reaction is rare at recommended doses, but certain patient groups which include problem drinkers ('alcoholics') and pregnant women are at greater risk and should receive pyridoxine supplementation at a dose of 10–25 mg/day.

Pyrazinamide can cause hepatitis. This is not increased when the drug is given with isoniazid and rifampicin in the standard 6-month treatment regimen. However, when hepatic

Table 40.4 Reserve drugs: dosages and side effects (British Thoracic Society Joint Tuberculosis Committee, 1998)

Drug (once daily)	Children	Adults	Main side effects
Streptomycin	15 mg/kg	15 mg/kg (max dose 1 g daily)	Tinnitus, ataxia, vertigo, renal impairment
Amikacin	15 mg/kg	15 mg/kg	As for streptomycin
Capreomycin		15 mg/kg	As for streptomycin
Kanamycin		15 mg/kg	As for streptomycin
Ethionamide or prothianamide	15–20 mg/kg	<50 kg, 375 mg twice a day ≥50 kg, 500 mg twice a day	Gastro-intestinal, hepatitis; avoid in pregnancy
Cycloserine		250–500 mg twice a day	Depression, fits
Ofloxacin		400 mg twice a day	Abdominal distress, headache, tremulousness
Ciprofloxacin		750 mg twice a day	As ofloxacin plus drug interactions
Azithromycin		500 mg	Gastro-intestinal upset
Clarithromycin		500 mg twice a day	As for azithromycin
Rifabutin		300–450 mg	As for rifampicin; uveitis can occur with drug interactions, for example macrolides. Often cross-resistance with rifampicin
Thiacetazone	4 mg/kg	150 mg	Gastro-intestinal, vertigo, conjunctivitis, rash. Avoid if HIV positive (Stevens–Johnson syndrome)
Clofazimine		300 mg	Headache, diarrhoea, red skin discolouration
PAS sodium	300 mg/kg	10 g every morning or 5 g twice a day	Gastro-intestinal, hepatitis, rash, fever

PAS, p-aminosalicylate.

Table 40.5 Major adverse reactions of first-line anti-tuberculous drugs

Drug	Common reaction	Uncommon reaction
Isoniazid		Hepatitis, cutaneous hypersensitivity, peripheral neuropathy
Rifampicin		Hepatitis, cutaneous reactions, gastro-intestinal reactions, thrombocytopaenic purpura, febrile reactions, 'flu syndrome'
Pyrazinamide	Anorexia, nausea, flushing	Hepatitis, vomiting, arthralgia, hyperuricaemia, cutaneous hypersensitivity
Ethambutol		Retrobulbar neuritis, arthralgia

toxicity occurs, liver enzymes are elevated for a longer time than with rifampicin or isoniazid. If patients have known pre-existing hepatic dysfunction, the use of pyrazinamide should be carefully considered.

Ethambutol ocular toxicity (optic neuritis) is by far the most important side effect of ethambutol. Some patients with pre-existing ocular problems, for example those with diabetes, may be at greater risk of toxicity. Daily doses of 30 mg/kg or more increase the likelihood of toxicity, as does the administration of standard daily doses (15–25 mg) to patients with impaired renal function.

Patients should be tested for both visual acuity and red-green colour discrimination before treatment. If toxicity develops, the drug must be stopped promptly. This should lead to a gradual improvement in vision. Permanent damage may occur if the drug is continued.

In children older than 5 years of age, a dose of ethambutol of 15 mg/kg has been shown to be safe (Trebucq, 1997). A baseline ophthalmological assessment is important in children as in adults and should be repeated after 1–2 months.

Chemoprophylaxis

The use of chemoprophylaxis is important in preventing vulnerable individuals with LTBI from developing active TB disease. Without chemoprophylaxis, 40–50% of infants and 15% of older children with LTBI will develop active TB disease in 1–2 years. Prophylaxis is usually with isoniazid alone for 6 months or rifampicin and isoniazid for 3 months. Detailed guidance as to when isoniazid or rifampicin and isoniazid should be used has been produced by National Institute for Health and Clinical Excellence (2006).

BCG vaccine

BCG vaccine contains a live, attenuated strain derived from *M. bovis.* It does not protect against infection, but it prevents the more serious forms of disease such as miliary TB and meningeal TB. The BCG immunisation programme in the UK is now a risk-based programme, the key part being a neonatal programme targeted at protecting those children most at risk of exposure to TB, particularly from the more serious forms of the disease (Department of Health, 2006). Most age groups require a Mantoux test prior to being offered BCG vaccine.

Patient care

It is possible to cure virtually all patients with TB infection or disease provided that an adequate regimen, to which the bacilli are susceptible, is prescribed and the patient complies with treatment. By far the largest cause of treatment failure is non-adherence by the patient. This has serious consequences: treatment may fail and disease may relapse, in some cases with resistant organisms. A patient with infectious TB who does not adhere to treatment is a public health hazard.

Factors affecting adherence

A number of studies have shown that adherence falls as the number of tablets to be taken per day increases, and falls still further if doses have to be taken frequently through the day. Ideally, the least number of tablets should be given. Patients may fail to adhere because they feel better and do not appreciate the need to continue with their medication. Lack of clarity of instructions, written, verbal or other, may compromise adherence, particularly if the patient is confused by conflicting advice from different health care professionals. Finally, adverse effects, or symptoms perceived to be adverse effects, may reduce adherence.

Improving patient adherence

Anti-TB therapy should be prescribed once a day using as few tablets as possible. Single daily dosing enables patients to fit their medication into their daily routine. Rifampicin and isoniazid are both well absorbed when taken on an empty stomach. However, absorption is reduced and delayed when taken with or after food. It is therefore recommended that both should be taken 1 h before food to rapidly achieve peak blood levels. It is usually recommended that patients take their medication before breakfast. Cueing tablet taking to a regular activity may improve adherence in some patients.

The number of tablets to be taken each day may be reduced by using combination preparations of which several are available. Some, for example Rifater®, contain ratios of rifampicin, isoniazid and pyrazinamide that differ slightly from the dosages recommended by the British Thoracic Society. Combination preparations may not be suitable for use in children as the required dose regimens differ from those of adults.

Formulation

With the exception of streptomycin, first-line agents are usually administered orally. There is a liquid preparation of rifampicin available for patients who cannot take tablets or capsules. In patients who are severely ill, and cannot take oral medication, rifampicin may be given intravenously, and isoniazid can be administered by both the intravenous and intramuscular routes.

Information for patients

Written instructions and/or patient information leaflets (PILs) may be offered to support verbal counselling if there is any doubt as to the patient's understanding. It should be emphasised that the disease will be cured, but this will take some months and the tablets will need to be taken as prescribed even if the patient feels better. Some patients will adhere initially while they are unwell but will fail to adhere later as they begin to feel better.

The occurrence of some adverse effects may require discontinuation of a drug, but others are harmless. The patient should be told which side effects to expect and which require referral to a member of the healthcare team. Again, written instructions may be helpful.

A number of patients from abroad have a poor command of English. TB Alert has produced leaflets on the treatment of TB for patients. These can be found at the TB Alert website (http://www.tbalert.org/), and are available in languages other than English.

On occasion, drugs which are not licensed for use in the UK although licensed abroad are prescribed for TB. These may be obtained on a named-patient basis through recognised specialist wholesalers. Patients who receive these medicines require specific counselling to help them understand the special circumstances surrounding their use and receive appropriate patient information.

Directly observed therapy (DOT)

DOT, where the patient is observed taking their anti-tuberculous medication by a health care professional, is not needed for most cases of active TB. A risk assessment for treatment adherence should be undertaken in all patients, and

DOT regimens considered where non-adherence to treatment might be a problem, for example in street- or shelter-dwelling homeless people with active TB and patients with a history of non-adherence. This latter group includes individuals with chronic alcohol or other social problems.

DOT regimens may be fully or partially intermittent. In the latter, four drugs (isoniazid, rifampicin, pyrazinamide and either ethambutol or streptomycin) are given daily for 2 months followed by rifampicin and isoniazid two or three times weekly for the subsequent 4 months. For most drugs, the doses are increased when given intermittently and these are shown in Table 40.3. Trials of intermittent regimens have shown treatment is as effective when given intermittently as when given daily.

Counselling points

It is now a requirement for patients to be provided with a PIL for medication they are taking. Patients should be advised to read the PIL. The TB doctor, nurse and pharmacist should provide them with other relevant information orally. Patients taking rifampicin should be told that the drug will cause a harmless discolouration of their urine and other body fluids, for example sweat and tears. The staining of tears is important if the patient uses soft contact lenses as these may be permanently stained. Gas-permeable and hard lenses are unaffected. Women using the oral contraceptive pill should be advised to use other non-hormonal methods of contraception for the duration of rifampicin treatment and for 8 weeks afterwards as the effectiveness of hormonal contraceptives is reduced by rifampicin.

Although ocular side effects are rare when ethambutol is taken in normal dosages, patients should be warned of this potentially serious side effect. They should be advised to stop the drug and report to their doctor if they notice any changes in vision, such as a reduction in visual acuity or changes in colour vision. This is especially important because visual changes are usually reversible on discontinuation of the drug but may be permanent if the drug is not stopped.

Case studies

Case 40.1

A man in his 40s is referred to a chest physician with a cough productive of sputum and a fever. A chest x-ray indicates bilateral pneumonia with apical involvement. A sputum smear reveals the presence of acid, alcohol-fast bacilli. His physician considers that TB is the most likely clinical diagnosis. This is subsequently confirmed microbiologically. The patient does not comply with treatment and needs to be admitted to hospital, but refuses. There are indications he might be disruptive if admitted into hospital.

Questions

1. What form of TB does this patient have?
2. What can be done to compel his admission to hospital?
3. Which groups of healthcare staff should be involved in arrangements for his admission to hospital?

Answers

1. This man has sputum smear-positive pulmonary TB, the infectious form of the disease, and poses a risk of infection to others.
2. Legal measures should be considered to have the patient compulsorily admitted to hospital. These are set out in the Public Health (Control of Diseases) Act 1984 for England and Wales, and the Health Protection Regulations 2010. This will involve an application to the magistrates court for compulsory admission to hospital under a legally binding order, to be signed by the magistrates. The hospital will need to have agreed to his admission.
3. He will need to be admitted to a side room. Given that he may be disruptive, a multidisciplinary team meeting should be held to agree a care plan in preparation for his admission. This should be discussed with the patient, including the reasons why he will need to be kept in isolation. This should take place prior to an application for a court order if the patient refuses admission to hospital.

Case 40.2

A woman in her 40s is admitted to hospital with shortness of breath. She has lived in sub-Saharan Africa. She subsequently develops a non-productive cough. Bronchial washings are smear negative for acid-fast bacilli, but *M. tuberculosis* is isolated from the sample. Early sputum samples are smear negative, but later samples are smear positive.

Questions

1. What form of TB does this patient have?
2. Should she be in isolation?
3. What treatment should she receive for her TB?
4. Is she at low or high risk for drug-resistant TB?
5. What further microbiological investigations would be essential?

Answers

1. She has pulmonary TB, indicated by her symptoms and chest x-ray.
2. She should be in isolation in a single room. If a risk assessment suggests she may have MDR-TB, advice should be sought from the Infection Prevention and Control Team as to whether she should be transferred to a negative pressure room.
3. She should be commenced on standard quadruple therapy, comprising rifampicin and isoniazid, supplemented with pyrazinamide and ethambutol for the first 2 months.
4. A history of residence in sub-Saharan Africa suggests she could be at risk of drug-resistant TB, in particular multiple drug-resistant TB. The change in sputum smear status, despite being on standard quadruple therapy, would certainly suggest drug resistance.
5. A PCR test should be done on the isolate to determine whether her infecting strains of tubercle bacilli are resistant to rifampicin. Tests should also be done to assess susceptibility to other drugs.

Case 40.3

A woman in her mid-20s is diagnosed as having sputum smear-negative pulmonary TB. Although she initially takes her anti-TB drugs, she does not attend follow-up clinics and her condition deteriorates. Her primary care doctor collects a sputum sample from her and persuades her to attend the chest clinic. The sputum smear is now positive and it is found she has continued to work, despite being advised not to do so.

Questions

1. What type of treatment regimen should be offered to this patient?
2. Who should be involved in planning this treatment regimen, and what arrangements should be put in place to ensure this works?
3. Should the patient's work contacts be screened?

Answers

1. Patients like this should receive supervised treatment (DOTS) three times a week in a convenient setting, such as at home.
2. There needs to be close collaboration between the physician responsible for treatment, the patient's primary care physician, TB nurse, pharmacist, the public health team and the health care professionals (often district nurses or health visitors in the UK) who will supervise treatment. The patient needs to be involved in discussions about these arrangements, as treatment will not be successful without her cooperation.
   The physician will need to adjust the treatment dosage in line with the thrice-weekly regimen, inform the general practitioner and ensure the correct prescriptions are issued. Those supervising treatment need a clear explanation of what is expected of them, including details of the drugs and dose, and duration of treatment. They also need to know what to do if the patient does not adhere.
3. The question of whether work contacts should be screened must be dealt with on an individual case basis. This usually involves the health protection (public health) team informing the patient of the need to inquire into work contacts, and getting the patient's agreement to approach a supervisor or manager in the workplace. A telephone conversation will provide initial information on the working environment and should be followed up by a visit if initial inquiries indicate a possible need to screen workplace contacts.

Case 40.4

A 40-year-old man with young children aged under 5 is diagnosed with infectious pulmonary TB, but is not taking his anti-tuberculous drugs. He has mental health problems for which he is on treatment and is a drug misuser. Arrangements are made for him to have home-based directly observed treatment (DOT) for TB, but these break down.

Questions

1. What other arrangements should be considered for his treatment?
2. What other options could be pursued if alternative arrangements cannot be put in place?
3. Might a community pharmacist have a role in assisting with the treatment of such a patient?

Answers

1. The mental health team responsible for his care could be asked if they would observe him taking treatment. However, they may be concerned about the possible risk to themselves from exposure to someone with infectious TB. The same difficulties could arise if admission to a secure mental health facility is considered. If the patient is not in contact with the drug service, their involvement is only possible if the patient agrees to engage with them.
2. If none of the options in (1) are possible in practice, the patient remains an infectious risk, especially to his children. The advice of child protection professionals should therefore be sought, and if necessary a referral made to social services. The children will not necessarily be taken into care, alternative ways of supporting child care will be sought but their safety is paramount.
3. Community pharmacists could have a role to play in supervising treatment and this should be discussed with them where appropriate. If they agree, arrangements can be put in place, including a discussion between the pharmacist and the patient as to the 'rules of engagement', that is what the patient can expect from the pharmacist and what the pharmacist expects from the patient.

HIV infection 41

H. Leake Date and M. Fisher

Key points

- Untreated infection with the human immunodeficiency virus (HIV) leads to a progressive deterioration in the cellular immune response. After initial seroconversion, the infected individual may appear asymptomatic for a number of years, before developing symptomatic disease and/or acquired immune deficiency syndrome (AIDS).
- Complications arising from HIV infection can manifest in a variety of ways, usually as opportunistic infections or malignancies that are uncommon in the immunocompetent population.
- The aim of the treatment of HIV infection is to reconstitute, or prevent further deterioration of the immune system, with the intention of improving the quality and quantity of life. Management of HIV-related complications primarily involves the treatment and prophylaxis of opportunistic diseases.
- Currently available antiretroviral (ARV) agents are classified by their mechanism of actions as nucleoside or nucleotide analogue reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), integrase inhibitors and entry inhibitors.
- Antiretroviral agents are given in combination, usually of at least three agents, to improve efficacy and reduce the development of viral resistance.
- Treatment regimens are frequently complex and many of the drugs have significant toxicities and interactions with other drugs and with food. A high level of adherence to therapy is vital to ensure efficacy and prevent the emergence of resistant virus.

Epidemiology

In June 1981, five cases of *Pneumocystis jiroveci* (formerly known as *carinii*) pneumonia (PCP) were described in homosexual men in the USA. Reports of other unusual conditions, such as Kaposi's sarcoma (KS), followed shortly. In each of these patients, there was found to be a marked impairment of cellular immune response, and so the term acquired immune deficiency syndrome, or AIDS, was coined. In 1984, a new human retrovirus, subsequently named human immunodeficiency virus (HIV), was isolated and identified as the cause of AIDS.

Although initially described in homosexual men, it soon became apparent that other population groups were affected, including intravenous drug users and haemophiliacs. During the first decade, the epidemic grew and the importance of transmission via heterosexual intercourse and from mother to child (vertical transmission) was increasingly recognised.

In the UK, since 1999 the number of new HIV diagnoses has been higher in heterosexuals than in men who have sex with men (MSM), although more recently this trend has been reversing, due to a decline in diagnoses among people infected heterosexually abroad (particularly from Sub-Saharan Africa). The majority of heterosexuals with HIV have acquired their infection in countries of high prevalence, whilst the majority of ongoing transmission within the UK is still amongst men who have sex with men. Additionally, there is an increasing proportion of individuals with HIV who are living into older age. It is postulated that the ageing process is accelerated in the context of HIV infection, with a resultant increase in co-morbidities, such as cardiovascular disease, osteoporosis and osteopaenia, cancer, cognitive impairment, and hepatic and renal dysfunction.

The impact of treatment advances on the incidence of AIDS-related illnesses and mortality has been dramatic. However, the absolute number of new AIDS diagnoses and HIV-related deaths in the UK has plateaued, largely due to late presentation and the failure to diagnose HIV infection amongst the asymptomatic population.

Although the number living with HIV globally continues to rise, there are encouraging trends (including in many low- and middle-income countries) of declining prevalence and a slower rate of increase in new infections. Significant progress has been made since 2000 in increasing access to antiretroviral therapies in resource-poor settings. Although choice of agents and facilities for monitoring may be limited, and locally produced generic formulations are often used, the resultant impact on mortality has been as dramatic as that seen previously in resource-rich countries.

The virus has been isolated from a number of body fluids, including blood, semen, vaginal secretions, saliva, breast milk, tears, urine, peritoneal fluid and cerebrospinal fluid (CSF). However, not all of these are important in the spread of infection and the predominant routes of transmission remain: sexual intercourse (anal or vaginal); sharing of unsterilised needles or syringes; blood or blood products in areas where supplies are not screened or treated; and vertical transmission *in utero*, during labour or through breast feeding.

Pathogenesis

HIV, in common with other retroviruses, possesses the enzyme reverse transcriptase and consists of a lipid bilayer membrane surrounding the capsid (Fig. 41.1). Its surface glycoprotein molecule

621
Fig. 41.1 Structure of the human immunodeficiency virus (HIV).

(gp120) has a strong affinity for the CD4 receptor protein found predominantly on the T-helper/inducer lymphocytes. Monocytes and macrophages may also possess CD4 receptors in low densities and can therefore also be infected. The process of HIV entry is more complex than originally thought, and in addition to CD4 attachment, subsequent binding to co-receptors such as CCR-5 or CXCR-4 and membrane fusion also occur (Fig. 41.2).

After penetrating the host cell, the virus sheds its outer coat and releases its genetic material. Using the reverse transcriptase enzyme, the viral RNA is converted to DNA using nucleosides. The viral DNA is then integrated into the host genome in the cell nucleus, where it undergoes transcription and translation, enabling the production of new viral proteins. New virus particles are then assembled and bud out of the host cell, finally maturing into infectious virions under the influence of the protease enzyme.

Immediately after primary HIV Infection (PHI, also known as 'seroconversion'), there is a very high rate of viral turnover. Equilibrium is then reached, at which stage the infection may appear to be clinically latent, but in fact, as many as 10,000 million new virions are produced each day.

Over time, as chronic infection ensues, cells possessing CD4 receptors, particularly the T-helper lymphocytes, are depleted

from the body. The T-helper cell is often considered to be the conductor of the 'immune orchestra' and thus, as this cell is depleted, the individual becomes susceptible to a myriad of infections and tumours. The rate at which this immunosuppression progresses is variable and the precise interaction of factors affecting it is still not fully understood. It is well recognised that some individuals rapidly develop severe immunosuppression, whilst others may have been infected with HIV for many years whilst maintaining a relatively intact immune system. It is likely that a combination of viral, host (genetic) and environmental factors contributes to this variation.

Clinical manifestations

The sequelae of untreated HIV infection can be broadly considered in five categories:

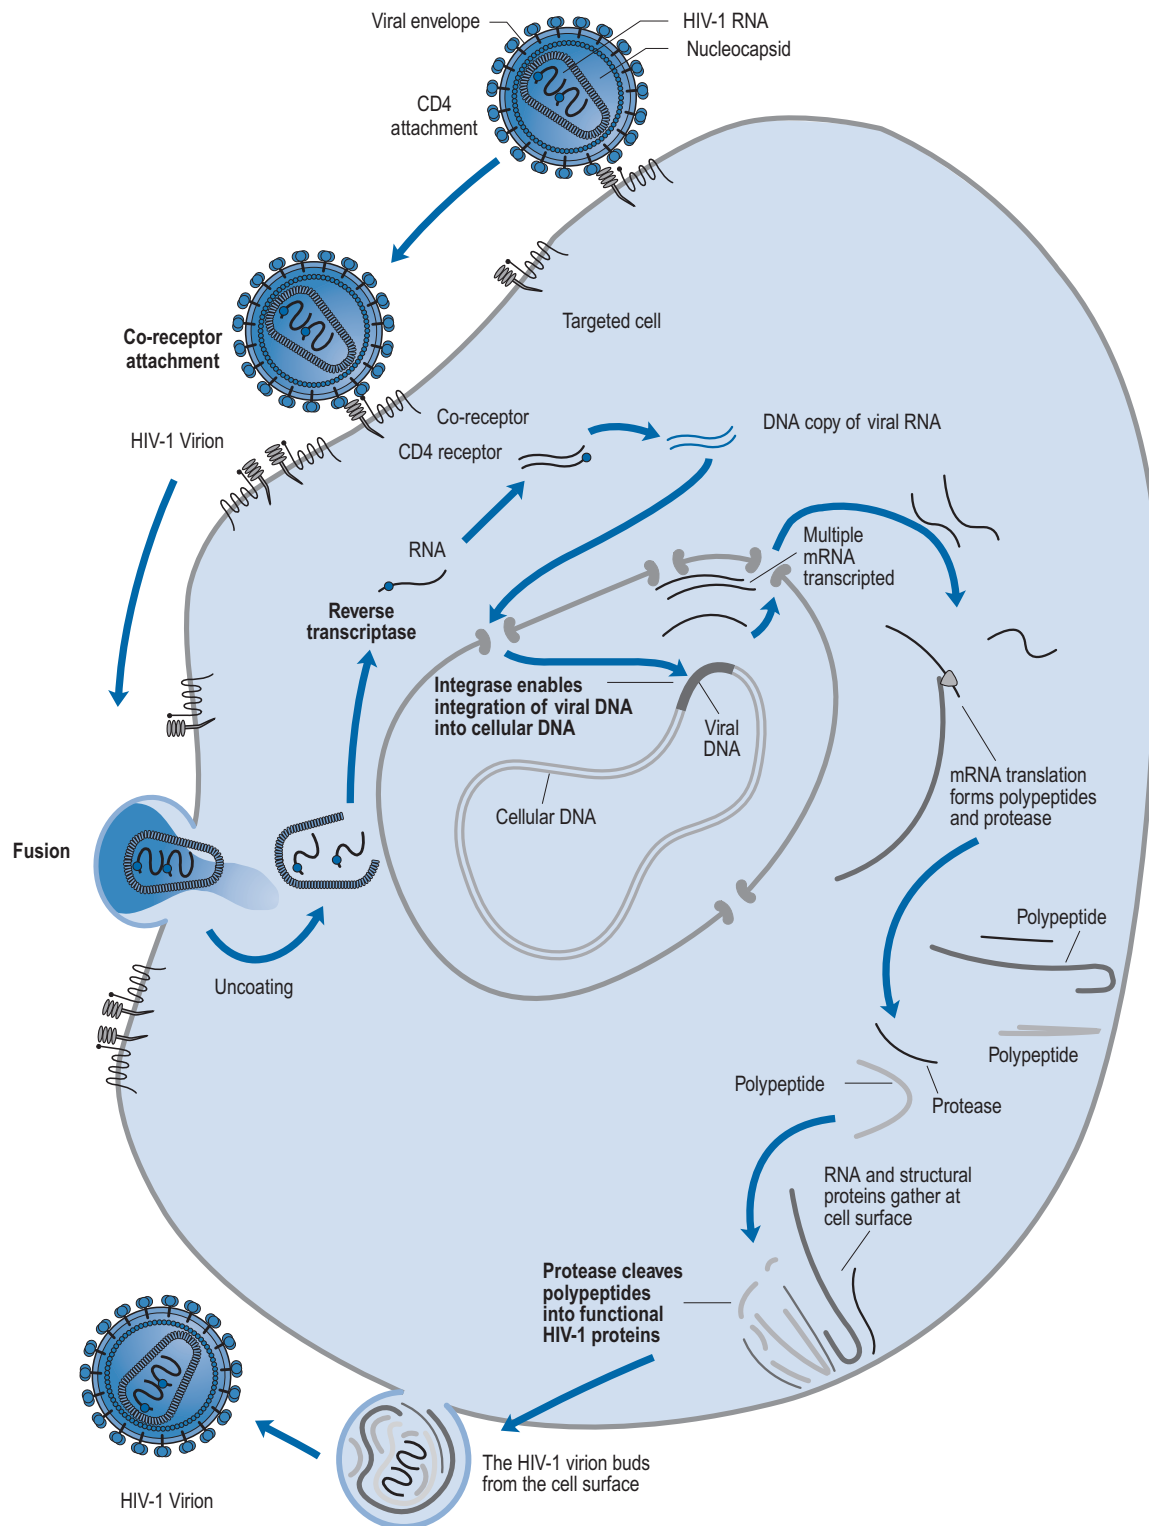
- Opportunistic infections, that is, infections that would not normally cause disease in an immunocompetent host, for example, *P. jiroveci* pneumonia and cytomegalovirus (CMV)
- Infections that can occur in immunocompetent patients but tend to occur more frequently, more severely and


Fig. 41.2 Lifecycle of HIV and the sites of action of currently available antiretroviral agents (in bold).

often atypically in the context of underlying HIV infection, for example, *Salmonella*, herpes simplex and *Mycobacterium tuberculosis*

- Malignancies, particularly those that occur rarely in the immunocompetent population, for example, Kaposi's sarcoma and non-Hodgkin's lymphoma

- Direct manifestations of HIV infection *per se*, for example, HIV encephalopathy, HIV myelopathy and HIV enteropathy
- Consequences of chronic immune activation including premature cardiovascular disease, neurocognitive dysfunction, bone mineral density loss.

In addition, approximately 70% of individuals develop a flu-like illness at seroconversion. This primary HIV infection (PHI) is characterised by fever, arthralgia, pharyngitis, rash and lymphadenopathy. Rarely, the degree of associated CD4 count depletion may be sufficient to result in development of an opportunistic illness such as oropharyngeal/oesophageal candidiasis or *P. jiroveci* pneumonia.

Opportunistic infections generally fall into two categories:

- DNA viruses, for example, CMV and JC virus
- Intracellular pathogens, for example, *P. jiroveci*, *Toxoplasma gondii* and *Mycobacterium avium*.

Although the clinical course of HIV disease varies with each individual, there is a fairly consistent and predictable pattern that enables appropriate interventions and preventive measures to be adopted. Patients can be classified into one of three groups according to their clinical status: asymptomatic, symptomatic or AIDS. Symptomatic disease is characterised by non-specific symptomatology such as fevers, night sweats, lethargy and weight loss, or by complications including oral candidiasis, oral hairy leucoplakia, and recurrent herpes simplex or herpes zoster infections. AIDS is defined by the diagnosis of one or more specific conditions including *P. jiroveci* pneumonia, *M. tuberculosis* infection and CMV disease.

Investigations and monitoring

Current and previous infections

The initial diagnosis of HIV infection is made by the detection of antibodies against HIV. With improved technology, it is usually possible to detect antibodies within 3–4 weeks of infection, although individuals are advised that a 'window period' of up to 3 months after exposure is required before infection can be excluded. After confirmation of HIV infection, the patient is usually tested for prior exposure to a number of potential pathogens, including syphilis, hepatitis A, B and C, CMV, varicella zoster (VZV), and *T. gondii*. This can enable subsequent treatment (in the case of undiagnosed syphilis), vaccination (if no prior exposure to hepatitis A, B, or VZV), prevention (if no prior exposure to *Toxoplasma* and CMV), prophylaxis (if previous exposure to *Toxoplasma*) and can aid subsequent diagnosis (according to CMV or *Toxoplasma* status).

CD4 count

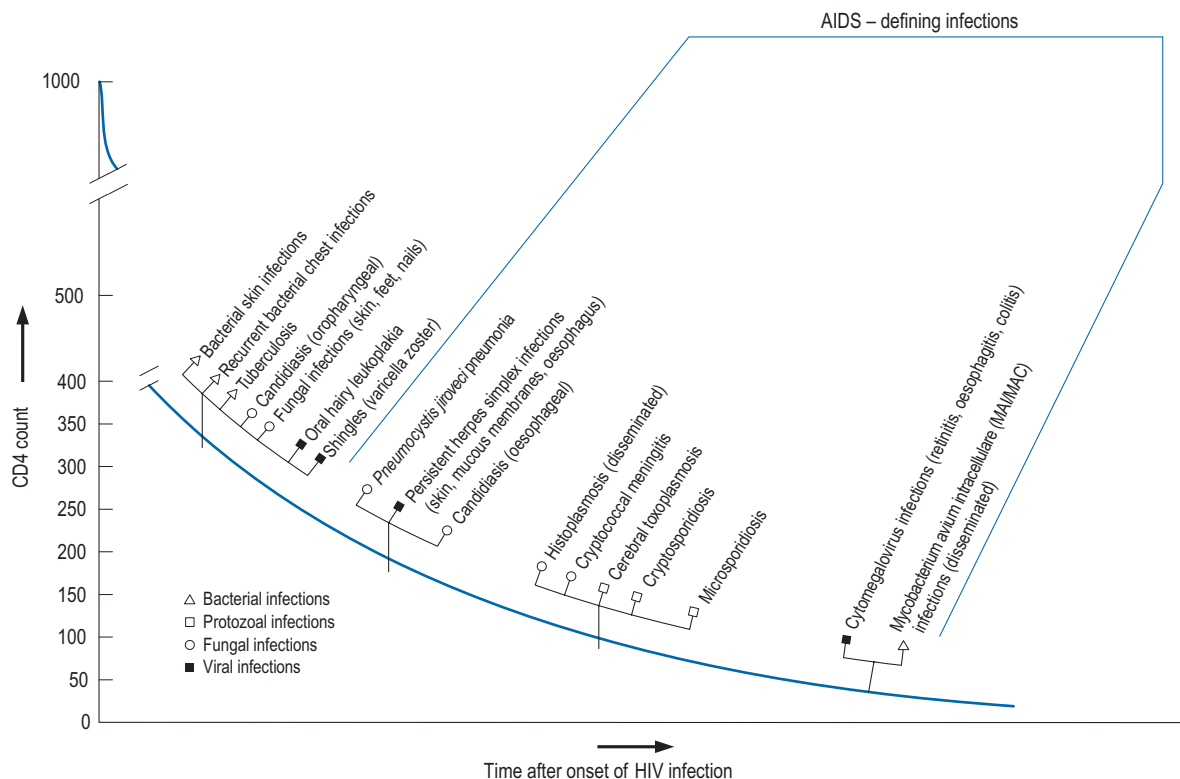
The level of immunosuppression is most easily estimated by monitoring a patient's CD4 count. This measures the number of CD4-positive T-lymphocytes in a sample of peripheral blood. The normal range can vary between 500 and 1500 cells/mm^3. As HIV disease progresses, the number of cells falls. Particular complications of HIV infection usually begin to occur at similar CD4 counts (Fig. 41.3) which can assist in


Fig. 41.3 Opportunistic complications of HIV infection and the CD4 count ranges at which they commonly occur.

differential diagnoses and enable the use of prophylactic therapies. For example, patients with a CD4 count of less than 200 cells/mm³ should always be offered prophylaxis against *P. jiroveci* pneumonia. Similarly, both patient and clinician are likely to use the CD4 count as the major indicator of when to consider starting antiretroviral therapy.

Viral load

The measurement of plasma HIV RNA (viral load) estimates the amount of circulating virus in the blood. This has been proven to correlate with prognosis, with a high viral load predicting faster disease progression (Mellors et al., 1997). Conversely, a reduction in viral load after commencement of antiviral therapy is associated with clinical benefit. This measure, in combination with the CD4 count, allows patients and clinicians to make informed decisions regarding when to start and when to change antiviral therapies, enabling the more effective use of such agents. There are on-line calculators utilising viral load and CD4 count to model risk of disease progression or death based on large cohort studies.

Resistance testing

Due to the implications of transmitted (primary) resistance, it is recommended that all patients have a genotypic HIV resistance test performed soon after diagnosis; this will ensure that appropriate initial therapy is selected. Further resistance tests should be performed at any subsequent virological failure to direct therapy choice.

Tropism testing

Viruses may enter the cell using the CCR5 co-receptor, the CXCR4 co-receptor or both co-receptors. Those which just use one co-receptor are known as CCR5-tropic or CXCR4-tropic viruses; those which can use both receptor types are called dual-tropic. Where a mixture of virus populations is present, the term mixed-tropic is used. Different methods of determining tropism are currently under evaluation. The tests must be performed in real time as viral tropism changes as the disease progresses. If CCR5 inhibitors are to be used, it is essential to determine that the virus is CCR5-tropic, that is, that there is no significant use of the CXCR4 receptor.

Drug treatment

The drug treatment of HIV disease can be classified as antiretroviral therapy, the management of opportunistic infections or malignancies, the management of 'non-HIV-related' co-morbidities, and symptom control. For the first decade of the epidemic, most of the available drugs and therapeutic strategies were aimed at treating or preventing opportunistic complications and alleviating HIV-related symptoms. Whilst these are still important, there has been a shift in emphasis towards treatment aimed at reducing the HIV viral load, restoring immune function and reducing the potential consequences of co-morbidities.

Due to the speed at which new antiretroviral agents are being developed, comprehensive data on drug interactions, side effects, etc., are often lacking. Thus, the ability to apply general pharmacological and pharmacokinetic principles, together with common sense, is required.

The treatment of many of the opportunistic complications of HIV comprises an induction phase of high-dose therapy, followed by maintenance and/or secondary prophylaxis using lower doses. This is due to the high rate of relapse or progression after a first episode of diseases such as *P. jiroveci* pneumonia, cerebral toxoplasmosis (toxoplasmic encephalitis), systemic cryptococcosis and CMV retinitis. Where a cost-effective agent with an acceptable risk/benefit ratio exists, primary prophylaxis may be offered to individuals who are deemed to be at high risk of developing a particular opportunistic infection, for example, *P. jiroveci* pneumonia prophylaxis. Discontinuation of prophylaxis, both primary and secondary, is now usually possible in individuals who demonstrate immunological restoration on Highly Active Antiretroviral Therapy (HAART).

Paradoxically, this immunological restoration may result in apparent clinical deterioration with opportunistic infections during the first few weeks after initiation of HAART. This is known as immune reconstitution inflammatory syndrome (IRIS).

The goals of therapy in HIV-positive individuals are to:

- improve the quality and duration of life;
- prevent deterioration of immune function and/or restore immune status;
- treat and/or prevent opportunistic infections;
- relieve symptoms.

Antiretroviral therapy

Antiretroviral therapy is currently one of the fastest evolving areas of medicine. The specific details of treatment will therefore continue to change as new drugs emerge, although it is likely that the following general principles will remain:

- A combination of three antiretroviral agents, selected on the basis of treatment history and resistance tests, should usually be prescribed to increase efficacy and reduce the development of drug-resistant virus
- Wherever possible, a regimen should contain at least one drug that penetrates the central nervous system and confers protection against HIV-related encephalopathy/dementia
- Treatment strategies should be adopted that sequence drug combinations, being mindful of potential cross-resistance and future therapy options
- Given the crucial importance of a high level of adherence to these therapies, the regimen adopted for a particular individual should, wherever possible, be tailored to suit the daily lifestyle.

Many organisations, such as the British HIV Association (BHIVA), the European AIDS Clinical Society (EACS) and

the International AIDS Society (IAS), produce regularly updated guidelines on the use of antiretroviral therapy, for example, Gazzard et al. (2008). These guidelines include the most up-to-date considerations of:

- when to start therapy;
- what to start with;
- how to monitor, including use of therapeutic drug monitoring and resistance testing;
- when to switch therapy;
- what therapy to switch to;
- treating individuals who have been highly exposed to multiple agents;
- managing individuals with significant co-morbidities, for example, tuberculosis or hepatitis B/C.

Most studies evaluating triple combinations of antiretrovirals have been designed with so-called surrogate marker endpoints, measuring the effect on laboratory parameters such as CD4 count and HIV viral load. These trials are generally smaller and shorter in duration than clinical endpoint studies that are powered to measure the impact on survival and disease progression. The first large clinical endpoint trial that demonstrated the superiority of a triple combination over dual therapy was undertaken by Hammer et al. (1997). Following the results of this trial, the standard approach, where treatment is indicated, has been to use a combination of at least three agents. The reduction in morbidity and mortality associated with HAART has been confirmed in routine clinical practice, as well as in other trials (e.g. Palella et al., 1998; Smit et al., 2006). Subsequent clinical trials have largely been for licensing purposes and/or have served to refine therapeutic choices rather than to change the paradigm of treatment. The concept of intermittent rather than continuous therapy was evaluated in the SMART study but shown to be linked with an increased risk of co-morbidities not previously thought to be associated with HIV (such as cardiovascular disease, hepatic and renal failure) as well as HIV disease progression (El-Sadr et al., 2006). The use of protease inhibitor (PI) 'monotherapy' compared to conventional triple therapy has been evaluated in a number of small studies, for example, Arribas et al. (2009), and is being investigated in longer-term strategic studies. A large international study of early versus deferred treatment, to attempt to address the question of when to initiate treatment, is ongoing.

When to start therapy

Current UK guidelines recommend starting antiretrovirals when the CD4 count drops below 350 cells/mm³. Therapy should be considered at a higher CD4 count in specific situations, for example, in the presence of an AIDS-defining illness or HIV-related morbidity.

Choosing and monitoring therapy

The majority of individuals are currently commenced on a combination of two nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) and a non-nucleoside reverse transcriptase inhibitor (NNRTI) or two NRTIs and a boosted PI. The term 'boosted PI' refers to a combination of one PI combined with a low dose (usually 100–200 mg once or twice daily) of ritonavir, another PI. The ritonavir does not directly add to the antiretroviral activity of the regimen; it is used purely as a pharmacokinetic enhancer of the other PI, by increasing the maximum plasma concentration, C_{max}, due to inhibition of cytochrome P450 enzymes in the gut wall and/or extending the half-life, $t_{1/2}$, by inhibition of hepatic cytochrome P450 enzymes. Triple NRTI therapy is no longer recommended, as it is associated with unacceptable rates of virological failure. Alternative strategies, such as NRTI-sparing regimens and boosted PI monotherapy, are currently only routinely recommended in a research setting. More recently, integrase inhibitors have been approved for initial therapy and may be used as an alternative to NNRTIs or PIs.

The aim of initial therapy is to achieve viral load suppression in the plasma to levels below the detection limits of available assays (40 or 50 copies/mL). Such virological suppression is almost invariably accompanied by an elevation in CD4 count and clinical evidence of immune reconstitution. Whilst sustained suppression over many years is usually possible, viral rebound may occur and is often accompanied by the development of resistance to one or more agents in the combination. Upon confirmed virological failure, a resistance test is performed which will help to identify to which agents the virus may have adapted and the extent to which any such resistance mutations may confer cross-resistance to other available drugs. A second-line regimen is then constructed, wherever possible utilising a new class of drug to which the individual has not previously been exposed. Upon virological failure of subsequent regimens, the therapeutic options available become increasingly complex, but with the availability of more agents targeting different parts of the virus life cycle, virological suppression is still usually possible and should remain the goal of treatment.

Many of the antiretrovirals, particularly the PIs and NNRTIs, exhibit a wide range of interactions, especially with other drugs that are metabolised by the cytochrome P450 enzyme system, including prescribed, 'over-the-counter', herbal and recreational drugs. HAART failure (detectable viral load and drug resistance) has been documented following co-administration of hepatic enzyme inducers, including non-prescribed agents such as St John's Wort. Conversely, serious and even fatal toxicities due to enzyme inhibition by the PIs continue to be reported. These include Cushing's syndrome following concomitant use of fluticasone or budesonide inhaler or nasal spray with a PI. This highlights the necessity of taking a comprehensive drug history prior to starting or switching HAART and ensuring patients and prescribers are aware of the need to check the interaction potential of new medicines. General prescribing guidelines for antiretrovirals are presented in Box 41.1 whilst details of common side effects and interactions of the currently available agents are summarised in Tables 41.1 to 41.5.

The routine use of therapeutic drug monitoring is not recommended but blood levels of PIs and NNRTIs should be measured in selected patients, for example, during pregnancy, where there is liver impairment and where there are concerns regarding potentially interacting drugs (Gazzard et al., 2008).

HIV mutates readily and resistance to some antiretrovirals, particularly reverse transcriptase inhibitors and integrase inhibitors, develops rapidly in the face of suboptimal treatment, for example, monotherapy or subtherapeutic blood levels. A high level of adherence to treatment is crucial to the sustained, successful outcome of antiretroviral regimens and has been the subject of much research. For example, in one study of people taking their first regimen containing nelfinavir, it was found that at least 95% adherence was required to achieve a sustained response in the majority (78%) of patients. The chances of treatment success declined as the level of adherence dropped, such that 80% of patients whose adherence was below 80% experienced virological failure. Virological success was also found to correlate with a better clinical outcome in terms of fewer hospitalisations, opportunistic infections and deaths (Paterson et al., 2000). Such clinical trial data have also been supported by clinical experience in the UK and elsewhere, although it has yet to be established if the level of adherence required is the same for all regimens and every patient. In view of this, patients should be advised to take HAART as close as possible to the same time every day and certainly within 1 hour of the agreed time each day. If they forget a dose, it should be taken as soon as they remember and then return to the original schedule.

There has been significant progress over recent years in reducing some of the physical burden of therapy, through the development of combination tablets and the use of strategies such as ritonavir boosting to reduce dietary restrictions and dosing frequency. Adherence aids such as pill boxes, medication record cards and alarms (e.g. on mobile phone) can also help to support adherence. However, practical issues are not the only barriers to adherence and the individual's health beliefs and motivation, particularly around HIV and antiretroviral therapy, should also be addressed before treatment is commenced, as these are likely to have a significant impact on outcome (Horne et al., 2004). Although there is little evidence to demonstrate what the optimal interventions to improve adherence are, multidisciplinary and multiagency approaches appear to be most useful (Poppa et al., 2003).

Treatment interruptions

For many reasons, including toxicity, cost and adherence, patients and clinicians have been interested in considering 'drug holidays' or treatment interruptions. However, this strategy is no longer recommended in routine practice (El-Sadr et al., 2006). It is now recognised that there are dangers associated with this approach because of CD4 decline, disease progression, mortality related to co-morbidities, for example, cardiovascular disease, and viral load rebound associated with increased transmission risk and a seroconversion-like syndrome. Further, as different anti-HIV medications have different half-lives, there may be a risk of functional monotherapy, particularly with NNRTIs, and the development of resistance if combinations are stopped abruptly in an unplanned fashion.

Post-exposure prophylaxis

Post-exposure prophylaxis (PEP) involves the use of antiretroviral drugs to prevent infection with HIV after possible exposure, which may be recommended after occupational injuries (DH, 2008) or sexual exposure (Fisher et al., 2006). Whilst PEP is a largely unproven and unlicensed indication for the drugs used, it is supported by animal model data and case–control studies. Where recommended in guidelines, PEP is usually commenced as a 3–5-day starter regimen of two NRTIs and a boosted PI, followed by an ongoing course for a total of 4-week post-exposure. It is believed this will reduce the likelihood of infection by at least 80%, although toxicity issues are not insignificant. Therefore, the decision to prescribe or take PEP must reflect a careful risk/benefit evaluation. Studies of pre-exposure prophylaxis (PREP), using one or two antiretrovirals (orally or topically) before potential exposure to HIV, have so far yielded mixed results, but may offer additional options to reduce transmission.

Nucleoside and nucleotide analogue reverse transcriptase inhibitors

NRTIs are phosphorylated intracellularly and then inhibit the viral reverse transcriptase enzyme by acting as a false substrate. Nucleotide analogues only require two intracellular phosphorylations, whereas activation of nucleoside analogues is a three-stage process. The NRTIs licensed in the UK are:

Abacavir (Ziagen®)
Didanosine (ddI, Videx®)
Emtricitabine (FTC, Emtriva®)
Lamivudine (3TC, Epivir®)
Stavudine (d4T, Zerit®)
Tenofovir (Viread®)
Zidovudine (AZT, Retrovir®)

Table 41.1 General prescribing points for nucleoside/nucleotide analogue reverse transcriptase inhibitors (NRTIs)

Drug, names, manufacturer	Dose and formulation	Administration	Major/common side effects	Significant drug interactions and important pharmacokinetic information
Atripla® (efavirenz + emtricitabine + tenofovir) Bristol Myers Squibb/ Gilead	One tablet od	Tablet contains efavirenz 600 mg, emtricitabine 200 mg + tenofovir 300 mg	See entries for individual drugs	See entries for individual drugs
Abacavir (ABC) Ziagen® ViiV	300 mg bd 600 mg od 300 mg tablets 20 mg/mL oral solution	Can be taken with or without food	Usually well tolerated – Rash, headache, nausea and vomiting, diarrhoea, reduced appetite are most common side effects – Should only be prescribed if HLA B*5701 negative to reduce risk of *hypersensitivity* (5% incidence in unscreened populations): see BNF/SPC for full details. *Patient must NEVER be rechallenged if abacavir withdrawn due to suspected hypersensitivity*. Discuss with HIV team if reaction suspected. Counsel patient – Lactic acidosis (see BNF for more details) – May increase risk of cardiovascular disease	• Metabolism of methadone may be altered • Rifampicin, phenytoin, phenobarbitone may decrease abacavir levels – unclear significance in clinical practice • Concomitant treatment with abacavir and pegylated interferon + ribavirin associated with an increase in the risk of non-response to anti-HCV therapy – avoid ABC in someone receiving HCV treatment
Combivir® (CBV) (zidovudine + lamivudine) ViiV	One tablet bd	Tablet contains 300 mg zidovudine + 150 mg lamivudine	See entries for individual drugs	See entries for individual drugs
Didanosine (ddI) Videx® Bristol Myers Squibb	If >60 kg, 400 mg od (with tenofovir = 250 mg od) If <60 kg, 250 mg od (with tenofovir = 200 mg od) 400, 250, 200 and 125 mg e-c capsules 25 mg 'buffered' tablets (minimum two tablets/dose) Suspension (named patient)	– Must be taken on an empty stomach (although no food restrictions when taken with tenofovir) – Buffered tablets must be chewed, crushed or dispersed before taking – May be taken with clear apple juice to improve tolerability	– Nausea, bloating, diarrhoea (all may be reduced with e-c formulation) – Dry mouth – Pancreatitis (incidence<1%) (caution in patients with 'high' alcohol intake or history of pancreatitis) – Liver failure rare but reported. Monitor LFTs – Peripheral neuropathy (incidence <10%) – Hyperuricaemia – Lactic acidosis (see BNF for more details) – Shown to increase risk of cardiovascular disease	• Reduce dose in renal impairment (consult product literature) • Tenofovir, ribavirin, ganciclovir and valganciclovir may increase ddI levels ⇒ potential ↑ risk of toxicity • Caution when taking ddI *tablets* together with drugs adsorbed by antacids. No interaction with ddI *capsules* • Caution with drugs associated with pancreatitis
Emtricitabine (FTC) Emtriva® Gilead	200 mg od 200 mg capsules 10 mg/mL oral solution	Can be taken with or without food	– Headache most common – Also nausea, diarrhoea, dizziness; harmless skin discoloration – especially in darker skins – Lactic acidosis (see BNF for more details)	• No clinically significant interactions noted so far • Reduce dose in renal impairment (consult product literature) • Has anti-HBV activity
Kivexa® (abacavir + lamivudine) ViiV	One tablet od	Tablet contains 600 mg abacavir + 300 mg lamivudine	See entries under individual drugs (*NB*: Patients who have had a hypersensitivity reaction to ABC must NEVER be rechallenged with ABACAVIR, KIVEXA or TRIZIVIR)	• See entries under individual drugs

Lamivudine (3TC) Epivir® ViiV	150 mg bd 300 mg od 150 and 300 mg tablets Oral solution (10 mg/mL)	Can be taken with or without food	Generally well tolerated – GI disturbances, headache, anaemia and neutropenia have been reported but not common – Lactic acidosis (see BNF for more details); – Recurrent hepatitis can occur in chronic hepatitis B carriers on discontinuation of 3TC	• *Reduce dose in renal impairment (consult product literature)* • Increased risk of neutropenia with high-dose co-trimoxazole and ganciclovir, valganciclovir or foscarnet • Has anti-HBV activity
Stavudine (D4T) Zerit® *Bristol Myers Squibb*	If >60 kg, 40 mg bd If <60 kg, 30 mg bd 20, 30 and 40 mg capsules Oral solution (1 mg/mL)	Can be taken with or without food	– Peripheral neuropathy (following discontinuation symptoms may worsen before improvement noted) – Pancreatitis (rare) – *Lactic acidosis (see BNF for more details)* – Associated with increased risk of lipoatrophy/ lipodystrophy syndrome	• Caution with drugs associated with peripheral neuropathy (e.g. didanosine, vincristine, thalidomide, isoniazid)
Tenofovir (TDF) Viread® Gilead	300 mg od Tenofovir disoproxil 245 mg tablet (equivalent to Tenofovir disoproxil fumarate 300 mg)	Can be taken with or without food Can be dispersed in water	– Diarrhoea, nausea and vomiting, flatulence and headache most common (incidence>10%) – Renal impairment and hypophosphataemia reported – monitor serum creatinine and phosphate	• Reduce dose in renal impairment (consult product literature) • Mostly eliminated unchanged in the urine – possible interactions with nephrotoxic drugs or drugs that are excreted renally (e.g. ganciclovir, cidofovir, probenecid) – monitor closely • Has anti-HBV activity
Trizivir® (abacavir + lamivudine + zidovudine) ViiV	One tablet bd	Tablet contains abacavir 300 mg, lamivudine 150 mg and zidovudine 300 mg	See entries under individual drugs (*NB*: Patients who have had a hypersensitivity reaction to ABC must NEVER be rechallenged with ABACAVIR, KIVEXA or TRIZIVIR.)	• See entries under individual drugs
Truvada® (tenofovir + emtricitabine) Gilead	One tablet od	Tablet contains emtricitabine 200 mg + tenofovir 300 mg Can be dispersed in water	See entries under individual drugs	• See entries under individual drugs
Zidovudine (AZT) Retrovir® ViiV	Usual dose 250 mg bd (300 mg bd in Combivir and Trizivir) 100, 250 mg capsules 50 mg/5 ml syrup iv infusion	Can be taken with or without food (take with/after food to improve GI tolerance)	– Nausea, vomiting, headache, fatigue and muscle pain more common in first few – weeks and usually wear off – Haematological toxicities (e.g. neutropenia, anaemia) may develop after ~6 weeks – Myopathy may be associated with long-term therapy (>12 months) – Lactic acidosis (see BNF for more details) – Associated with increased risk of lipoatrophy/ lipodystrophy syndrome	• Clarithromycin can ↓ AZT absorption • Rifampicin may decrease AZT levels – unclear significance in clinical practice • Phenytoin levels may be altered • Increased risk of toxicity with ribavirin, probenecid and myelotoxic drugs (e.g. ganciclovir/valganciclovir and high-dose co-trimoxazole)

od, once daily; bd, twice daily; e-c, enteric coated; iv, intravenous; GI, gastro-intestinal; BNF, British National Formulary; LFTs, liver function tests; HCV, hepatitis C virus; HBV, hepatitis B virus.

Table 41.2 General prescribing points for non-nucleoside reverse transcriptase inhibitors (NNRTIs)

Drug, names, manufacturer	Dose and formulation	Administration	Major/common side effects	Significant drug interactions and important pharmacokinetic information
Efavirenz (EFV) Sustiva® Bristol Myers Squibb	600 mg od (usually at night) – Increase to 800 mg od with rifampicin – Dose of oral solution: 720 mg od (24 ml) due to altered bio-availability 600 mg tablets 200 mg capsules 30 mg/mL oral solution	Can be taken with or without food. Manufacturer recommends taking on an empty stomach to improve tolerability Taken at night to minimise sedative effect, but can be taken during the day if preferred	– CNS disturbances (from sedation/feeling 'stoned'/dizzy and impaired concentration to vivid dreams, mood swings and hallucinations) – Caution in patients with previous or current psychiatric illness – Rash (in about 18% of adults) mostly in first 2 weeks, usually mild; severe rash rare – Raised LFTs – more common if hepatitis B or C co-infected – Hyperlipidaemia – monitor – Avoid in early pregnancy if possible – animal studies show teratogenic effects; effective contraception should be used	• Caution on stopping EFV-containing regimen due to long half-life • Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which affect these enzymes • Avoid clarithromycin, St John's Wort, ergotamines, caution with anticonvulsants • Mixed inhibitor and inducer of CYP450 enzymes – caution with other drugs metabolised by these enzymes; use alternatives wherever possible. Perform TDM on potentially affected drugs where indicated (e.g. phenytoin) • *Increases levels of midazolam* – avoid or start with low doses and titrate and monitor carefully; do not use in outpatients, caution in day case attenders (*NB*: Manufacturer advises avoid.) • May get altered levels of methadone, erectile dysfunction agents sildenafil (Viagra®), tadalafil (Cialis®), vardenafil (Levitra®) and warfarin (monitor INR) among others
Nevirapine (NVP) Viramune® Boehringer-Ingelheim	200 mg od for first 14 days, then 200 mg bd. 400 mg od unlicensed dose. 200 mg tablets 50 mg/5 ml oral suspension	Can be taken with or without food. If dosing interrupted for >7 days, NVP must be restarted at lead-in dose (200 mg od for 2 weeks)	– Rash (in about 20%; most common in first 6 weeks); severe rash rare but monitor closely – Raised LFTs/hepatitis (check every 2 weeks for first 2 months) – Caution on restarting NVP if previously discontinued due to rash or hepatitis/↑LFTs – See BNF for more details – Also nausea, headache, sedation, fatigue – Should not be started in women with CD4 >250 cells/mm³ or men with CD4 >400 cells/mm³: greater risk of rash-associated hepatic events	• *Caution on stopping NVP-containing regimen due to long half-life* • Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which may affect these enzymes • *Avoid St John's Wort, rifampicin, caution with anticonvulsants* • Inducer of cytochrome P450 – caution with other drugs metabolised by these enzymes; use alternatives wherever possible. Perform TDM on potentially affected drugs where indicated • *May get altered levels of methadone and warfarin (monitor INR)* • May decrease levels of erectile dysfunction agents sildenafil (Viagra®), tadalafil (Cialis®), vardenafil (Levitra®)
Etravirine (TMC-125) Intelence® Janssen	200 mg bd 400 mg od unlicensed dose 100 mg tablets	Take with food to improve bioavailability. Can be dispersed in water.	– Rash (in >10%) – severe rash (inc Steven-Johnson syndrome) reported but rare – Nausea – Diarrhoea, abdominal pain – Headache, pyrexia, fatigue	• *Caution on stopping etravirine-containing regimen due to long half-life* • Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which may affect these enzymes • *Avoid St John's wort, carbamazepine, clarithromycin, rifampicin* • Mixed inhibitor and inducer of cytochrome P450 enzymes – caution with other drugs metabolised by these enzymes; use alternatives wherever possible. Perform TDM on potentially affected drugs where indicated • *May get altered levels of methadone and warfarin (monitor INR)* • May get decreased levels of erectile dysfunction agents sildenafil (Viagra®), tadalafil (Cialis®), vardenafil (Levitra®)

od, once daily; bd, twice daily; BNF, British National Formulary; LFTs, liver function tests; TDM, therapeutic drug monitoring; INR, international normalised ratio.

Table 41.3 General prescribing points for protease inhibitors

Drug, names, manufacturer	Dose and formulation	Administration	Major/common side effects	Significant drug interactions and important pharmacokinetic information
Atazanavir (ATV) Reyataz® Bristol Myers Squibb	300 mg (with 100 mg ritonavir) od 400 mg (with 100 mg ritonavir) od with enzyme inducers or interacting meds 300, 200, 150 mg capsules	Take with or after food to enhance bioavailability	Most common: – Nausea, diarrhoea, headache, rash, jaundice Also – Hyperbilirubinaemia (may need dose ↓ or stop if ≥ Grade 3 or 4) – Raised LFTs – more common in Hepatitis B or C co-infection – Does not appear to ↑ lipids – ECG changes – Other protease inhibitor 'class side effects', for example, lipodystrophy syndrome: body shape changes (see BNF for more details)	• Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which may affect these enzymes – *rifampicin contraindicated, avoid St John's Wort* • Inhibits cytochrome P450 enzymes. Caution with other drugs metabolised by these enzymes as may get ↑ in levels. *Do NOT co-administer with simvastatin, ergotamines, antiarrhythmics* • *Increases levels of midazolam* – avoid or start with low dose and titrate and monitor carefully; do not use in outpatients, caution in day case attenders (*NB*: Manufacturer advises avoid.) • May increase levels of corticosteroids, including inhaled/intranasal steroids (avoid fluticasone and budesonide) • May require dose alteration of warfarin (monitor INR), methadone, bupropion (Zyban®) • *H₂ antagonists and proton pump inhibitors significantly decrease atazanavir levels* – discuss with specialist HIV team before co-prescribing. Avoid antacids within 2 h of ATV dose • Caution with erectile dysfunction agents sildenafil (Viagra®), tadalafil (Cialis®) and vardenafil (Levitra®) – reduce initial dose (e.g. maximum dose sildenafil 25 mg in 48 h) • *If boosted, see ritonavir for full list of potential interactions*
Darunavir (TMC-114) Prezista® Janssen	600 mg bd (with ritonavir 100 mg bd) 800 mg od (with ritonavir 100 mg od) 400, 600 mg tablets	Take with food to improve bioavailability	Most common: – Nausea, vomiting diarrhoea, constipation, abdo pain – Headache, rash – Hyperlipidaemia Also – Raised LFTs. Caution in sulphonamide allergy – Other protease inhibitor 'class side effects', for example, lipodystrophy syndrome: metabolic/body shape changes (see BNF for more details)	• Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which may affect these enzymes – *rifampicin contraindicated, avoid St John's Wort* • Inhibits cytochrome P450 enzymes. Caution with other drugs metabolised by these enzymes as may get ↑ in levels. *Do NOT co-administer with ergotamines, antiarrhythmics* • *Increases* levels of midazolam – avoid or start with low dose and titrate and monitor carefully; do not use in outpatients, caution in day case attenders (*NB*: Manufacturer advises avoid.) • May increase levels of corticosteroids, including inhaled/intranasal steroids (avoid fluticasone and budesonide) • May require dose alteration of warfarin (monitor INR), methadone, bupropion (Zyban®) • *Caution with statins (including pravastatin) – start with lowest dose and titrate according to response. Simvastatin CONTRAINDICATED* • Caution with erectile dysfunction agents sildenafil (Viagra®), tadalafil (Cialis®) and vardenafil (Levitra®) – reduce initial dose (e.g. maximum dose sildenafil 25 mg in 48 h) • *See ritonavir for full list of potential interactions*

Table 41.3 General prescribing points for protease inhibitors—cont'd

Drug, names, manufacturer	Dose and formulation	Administration	Major/common side effects	Significant drug interactions and important pharmacokinetic information
Fosamprenavir (FAPV) Telzir® ViiV	700 mg bd (with 100 mg bd ritonavir) unlicensed doses: – 1400 mg od (with 200 mg od ritonavir) – 1400 mg bd (unboosted) 700 mg tablets 50 mg/mL oral solution	Can be taken with or without food	Most common: – Nausea and vomiting, diarrhoea – Rash – Fatigue Also – Raised LFTs – Hyperlipidaemia – Other protease inhibitor 'class side effects', for example, lipodystrophy syndrome: metabolic/lipid/body shape changes (see BNF for more details)	• Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which may affect these enzymes – *rifampicin contraindicated, avoid St John's Wort, carbamazepine* • Inhibits cytochrome P450 enzymes. Caution with other drugs metabolised by these enzymes as may get ↑ in levels. *Do NOT co-administer with simvastatin, ergotamines, antiarrhythmics* • *Increases levels of midazolam* – avoid or start with low dose and titrate and monitor carefully; do not use in outpatients, caution in day case attenders. (*NB*: Manufacturer advises avoid.) • May increase levels of corticosteroids, including inhaled/intranasal steroids *(avoid fluticasone and budesonide)* • May require dose alteration of warfarin (monitor INR), methadone, bupropion (Zyban®) • Caution with erectile dysfunction agents sildenafil (Viagra®), vardenafil (Levitra®) and tadalafil (Cialis®) – reduce initial dose (e.g. maximum dose sildenafil 25 mg in 48 h) • *If boosted, see ritonavir for full list of potential interactions.*
Indinavir (IDV) Crixivan® Merck Sharp and Dohme	800 mg every 8 h With ritonavir: 800 mg (with 100 mg ritonavir) bd or 400 mg (with 400 mg ritonavir) bd ↓ dose in hepatic insufficiency 200 and 400 mg capsules	Best on an empty stomach >1 h before food or >2 h after meals May take with light, low fat (<5 g fat) snacks. No food restrictions if with ritonavir. Store with desiccant. Drink >1.5 L water per day (even if taking with ritonavir)	– Nephrolithiasis – Hyperbilirubinaemia – Increases in AST and ALT – Rash, dry skin, pruritus, hair loss – Ingrown toenails – Taste perversion – Haemolytic anaemia – Other protease inhibitor 'class side effects', that is lipodystrophy syndrome: metabolic/lipid/body shape changes (see BNF for more details)	• Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which may affect these enzymes – *rifampicin contraindicated, avoid St John's Wort, carbamazepine*. Indinavir increased by ketoconazole and itraconazole • Inhibits cytochrome P450 enzymes. Caution with other drugs metabolised by these enzymes as may get – in levels. *Do NOT co-administer with simvastatin, ergotamines, antiarrhythmics* • *Increases levels of midazolam* – avoid or start with low dose and titrate and monitor carefully; do not use in outpatients, caution in day case attenders (*NB*: Manufacturer advises avoid.) • May increase levels of corticosteroids, including inhaled/intranasal steroids *(avoid fluticasone and budesonide)* • *May require dose alteration of warfarin (monitor INR), methadone, bupropion (Zyban®)* • Administer indinavir and didanosine *tablets* at least 1 h apart (ok to take with e-c caps) • Caution with erectile dysfunction agents sildenafil (Viagra®), vardenafil (Levitra®) and tadalafil (Cialis®) – reduce initial dose (maximum dose sildenafil 25 mg in 48 h) • *If boosted, see ritonavir for full list of potential interactions*

Drug	Dose	Administration	Side effects	Interactions
Kaletra® (LPV/r) (lopinavir + ritonavir) Abbott	2 tablets bd 5 ml bd (=400/100 mg bd) 4 tablets/10 ml od (not recommended if >3 protease inhibitor resistance mutations present) Tablets: 200 mg lopinavir with 50 mg ritonavir; 100 mg lopinavir with 25 mg ritonavir 400/100 mg lopinavir/ ritonavir in 5 ml oral solution	Tablets: No food restrictions Liquid: Take with or after food – Oral solution has high alcohol and propylene glycol content *Caution with disulfiram or metronidazole* *Tablets: store at room temperature Store liquid in refrigerator (stable at <25 °C for 6 weeks)*	Most common: – Diarrhoea, nausea, vomiting, headache, rash, dyslipidaemias – Raised LFTs (esp. AST and ALT) and GGT. More common if hepatitis B or C co-infected – Other protease inhibitor 'class side effects', that is, lipodystrophy syndrome: metabolic/lipid/body shape changes (see BNF for more details)	• Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which may affect these enzymes – *rifampicin contraindicated, avoid St John's Wort, carbamazepine* • Inhibits cytochrome P450 enzymes. Caution with other drugs metabolised by these enzymes as may get ↑ in levels. *Do NOT co-administer with simvastatin, ergotamines, antiarrhythmics* • *Increases* levels of midazolam – avoid or start with low dose and titrate and monitor carefully; do not use in outpatients, caution in day case attenders (*NB*: Manufacturer advises avoid.) • May increase levels of corticosteroids, including inhaled/intranasal steroids *(avoid fluticasone and budesonide)* • May require dose alteration of warfarin (monitor INR), methadone, bupropion (Zyban®) • Caution with erectile dysfunction agents sildenafil (Viagra®), tadalafil (Cialis®) and vardenafil (Levitra®) – reduce initial dose (e.g. maximum dose sildenafil 25 mg in 48 h) • *See ritonavir for full list of potential interactions*
Nelfinavir (NFV) Viracept® Roche	1250 mg bd 750 mg tds 250 mg tablets	*Take with or after food to increase bio availability (up to 2 h after full meal, or with small meal/snack)*	Most common: – Diarrhoea and flatulence, nausea Also – Hyperglycaemia/diabetes – Other protease inhibitor 'class side effects', that is, lipodystrophy syndrome: metabolic/lipid/body shape changes (see BNF for more details)	• Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which may affect these enzymes – *rifampicin contraindicated, avoid St John's Wort, carbamazepine* • Inhibits CYP450 enzymes. Caution with other drugs metabolised by these enzymes as may get ↑ in levels. *Do NOT co-administer with simvastatin, ergotamines, antiarrhythmics* • *Increases levels of midazolam* – avoid or start with low dose and titrate and monitor carefully; do not use in outpatients, caution in day case attenders (*NB*: Manufacturer advises avoid.) • May increase levels of corticosteroids, including inhaled/intranasal steroids *(avoid fluticasone and budesonide)* • *May require dose alteration of warfarin (monitor INR), methadone, bupropion (Zyban)* • Caution with erectile dysfunction agents sildenafil (Viagra), vardenafil (Levitra) and tadalafil (Cialis) – reduce initial dose (max dose sildenafil 25 mg in 48 h)
Ritonavir (RTV) Norvir ® Abbott	Usually used to 'boost' other protease inhibitors at doses of 100–200 mg od-bd 600 mg bd (antiretroviral dose) 100 mg tablets 400 mg/5 ml oral solution	*Do not administer liquid formulation with disulfiram or metronidazole due to high alcohol content (tablets ok with metronidazole)* Take with or after food if possible (to reduce GI intolerance) *Tablets and liquid stored at room temperature.*	– Asthenia, – Nausea, vomiting, – Diarrhoea, abdominal pain, – Anorexia, – Taste perversion, – Circumoral and peripheral paraesthesiae – Other protease inhibitor 'class side effects', that is, lipodystrophy syndrome: metabolic/lipid/body shape changes (see BNF for more details)	• Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which may affect these enzymes – rifampicin contraindicated, *avoid St John's Wort, carbamazepine* • Extremely potent inhibitor of cytochrome P450 enzymes. Caution with other drugs metabolised by these enzymes as may get ↑ in levels. *Do NOT co-administer with ergotamines, antiarrhythmics, pethidine, piroxicam, amphetamines (inc. ecstasy). Caution with diazepam, antifungals (e.g. ketoconazole), clarithromycin, and carbamazepine* • *Increases levels of midazolam* – avoid or start with low dose and titrate and monitor carefully; do not use in outpatients or day case attenders (*NB*: Manufacturer advises avoid.) • *Caution with statins – start with lowest dose and titrate according to response. Simvastatin CONTRAINDICATED.*

Continued

Table 41.3 General prescribing points for protease inhibitors—cont'd

Drug, names, manufacturer	Dose and formulation	Administration	Major/common side effects	Significant drug interactions and important pharmacokinetic information
				• May increase levels of corticosteroids, including inhaled/intranasal steroids *(avoid fluticasone and budesonide)* • *May require dose alteration of warfarin (monitor INR), methadone, bupropion (Zyban®)* • Caution with erectile dysfunction agents sildenafil (Viagra), tadalafil (Cialis) and vardenafil (Levitra) – reduce initial dose (e.g. maximum dose sildenafil 25 mg in 48 h) • *See BNF/data sheet for full list of contraindications and caution drugs before prescribing*
Saquinavir (SQV) Invirase® Roche	1000 mg (with 100 mg ritonavir) bd Unlicensed doses: – 400 mg (with 400 mg ritonavir) bd – 1600–2000 mg od (with 100 mg ritonavir od) 200 mg capsules, 500 mg tablets	Take with or after food (up to 2 h after a full meal)	– Diarrhoea – Nausea – Abdominal discomfort/wind – Raised LFTs – Prolonged QT interval – Other protease inhibitor 'class side effects', that is, lipodystrophy syndrome: metabolic/lipid/body shape changes (see BNF for more details)	• Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which may affect these enzymes – *rifampicin contraindicated, avoid St John's Wort, carbamazepine.* Co-administration of clarithromycin, ketoconazole, ranitidine or cimetidine may increase levels of saquinavir • Inhibits cytochrome P450 enzymes. Caution with other drugs metabolised by these enzymes as may get ↑ in levels. *Do NOT co-administer with simvastatin, ergotamines, antiarrhythmics* • *Increases levels of midazolam* – avoid or start with low dose and titrate and monitor carefully; do not use in outpatients, caution in day case attenders • May increase levels of corticosteroids, including inhaled/intranasal steroids *(avoid fluticasone and budesonide)* • *May require dose alteration of warfarin (monitor INR), methadone, bupropion (Zyban®)* • Caution with erectile dysfunction agents sildenafil (Viagra®), tadalafil (Cialis®) and vardenafil (Levitra) – reduce initial dose (e.g. max dose sildenafil 25 mg in 48 h) • *If boosted, see ritonavir for full list of potential interactions*
Tipranavir (TPV) Aptivus® *Boehringer Ingelheim*	500 mg bd: co-administer with 200 mg bd ritonavir 250 mg capsules	*Take with or after food to improve GI tolerance* Store in refrigerator (once opened, container may be stored below 30 °C for 60 days)	– Diarrhoea – Nausea, vomiting – Fatigue – Headache – Elevated LFTs – Other protease inhibitor 'class side effects', that is, lipodystrophy syndrome: metabolic/lipid/body shape changes (see BNF for more details)	• Metabolised by cytochrome P450 hepatic enzymes – caution with other drugs which may affect these enzymes – *rifampicin contraindicated, avoid St John's Wort, carbamazepine* • Inhibits cytochrome P450 enzymes. Caution with other drugs metabolised by these enzymes as may get ↑ in levels. *Do NOT co-administer with simvastatin, ergotamines, antiarrhythmics* • *Increases levels of midazolam* – avoid or start with low dose and titrate and monitor carefully; do not use in outpatients, caution in day case attenders (*NB*: Manufacturer advises avoid.) • May increase levels of corticosteroids, including inhaled/intranasal steroids *(avoid fluticasone and budesonide)* • *May require dose alteration of warfarin (monitor INR), methadone, bupropion (Zyban®)* • Caution with erectile dysfunction agents sildenafil (Viagra®), tadalafil (Cialis®) and vardenafil (Levitra®) – reduce initial dose (e.g. maximum dose sildenafil 25 mg in 48 h) • *See ritonavir for full list of potential interactions*

od, once daily; bd, twice daily; e-c, enteric coated; GI, gastro-intestinal; BNF, British National Formulary; LFTs, liver function tests; INR, International normalised ratio; AST, Aspartate transaminase; ALT, alanine transaminase; GGT, γ glutanyl transferase.

Table 41.4 General prescribing points for Integrase Inhibitors

Drug, names, manufacturer	Dose and formulation	Administration	Major/common side effects	Significant drug interactions and important pharmacokinetic information
Raltegravir Isentress® Merck Sharp and Dohme	400 mg bd 400 mg tablets	Can be taken with or without food	– Nausea, headache – Dizziness, vertigo – Abdominal pain, flatulence, constipation – Pruritus, arthralgia, fatigue – Raised creatine kinase – Myopathy and rhabdomyolysis reported but rare	• *Metabolised by glucuronidation* – caution with potent inducers of this pathway, for example, rifampicin. (No effect on cytochrome P450 enzymes) • Levels increased by proton pump inhibitors – clinical significance uncertain • Levels decreased by ritonavir, tipranavir, efavirenz, St John's Wort, nevirapine, no need for dose adjustment

bd, twice daily.

In addition, there are a number of combination formulations of NRTIs that may be used to reduce pill burden:

Abacavir + lamivudine (Kivexa®)
Tenofovir + emtricitabine (Truvada®)
Zidovudine + lamivudine (Combivir®)
Zidovudine + lamivudine plus abacavir (Trizivir®)

There is also one formulation combining two NRTIs with an NNRTI:
Tenofovir + emtricitabine + efavirenz (Atripla®)
 Other triple and quadruple mixed class co-formulations are in development.

 Most antiretroviral regimens will include two NRTIs, together with a PI and/or an NNRTI. In the UK, the most commonly prescribed NRTI combination as first-line therapy is tenofovir with emtricitabine (either as the combination formulation Truvada® or, with efavirenz, as Atripla®) which has the benefits of once daily administration and an improved toxicity profile compared to older therapies. A number of combinations should be avoided. These include: zidovudine and stavudine (intracellular competition resulting in antagonism); stavudine and didanosine (unacceptable toxicity); tenofovir and didanosine (unacceptable rates of virological failure and potential for CD4 decline).

Non-nucleoside reverse transcriptase inhibitors

NNRTIs inhibit the reverse transcriptase enzyme by binding to its active site. They do not require prior phosphorylation and can act on cell-free virions as well as infected cells. The NNRTIs available include:

Efavirenz (Sustiva®)
Nevirapine (Viramune®)
Etravirine (Intelence®)

Resistance to NNRTIs occurs rapidly in incompletely suppressive regimens and it is therefore essential that they are prescribed with at least two NRTIs or a combination of NRTIs and PIs. Cross-resistance between nevirapine and efavirenz, which are currently used as first-line NNRTIs, is high. The first of the second-generation NNRTIs, etravirine, is active against some viruses resistant to these agents. Rilpivirine (expected to be licensed in 2011) also has a different resistance profile, but is likely to be used as an alternative first-line NNRTI.

 The NNRTIs have much longer plasma half-lives than PIs and NRTIs, so when stopping an NNRTI-containing combination, consideration should be given to either continuing the other agents for a period after cessation of the NNRTI or switching to a boosted PI prior to regimen discontinuation.

Protease inhibitors

PIs bind to the active site of the HIV-1 protease enzyme, preventing the maturation of the newly produced virions so that they remain non-infectious. The following PIs are currently available:

Atazanavir (Reyataz®)
Darunavir (Prezista®)
Fosamprenavir (Telzir®)
Indinavir (Crixivan®)
Lopinavir co-formulated with ritonavir (Kaletra®)
Nelfinavir (Viracept®)
Ritonavir (Norvir®)
Saquinavir (Invirase®)
Tipranavir (Aptivus®)

The use of ritonavir-boosted PIs has superseded use of single PIs, due to better pharmacokinetic profiles, superior efficacy data and reduced likelihood of resistance development. Newer second-generation PIs such as tipranavir and darunavir are effective against many viruses resistant to the earlier PIs. Darunavir is used in first-line PI therapy as a once-daily boosted agent (800 mg with 100 mg of ritonavir); for patients with significant PI resistance a higher dose of 600 mg twice daily, each with ritonavir 100 mg, is used.

Table 41.5 General prescribing points for entry inhibitors

Drug, names, manufacturer, mode of action	Dose and formulation	Administration	Major/common side effects	Significant drug interactions and important pharmacokinetic information
Enfuvirtide (T-20) Fuzeon® Roche Fusion Inhibitor	90 mg bd Ideally every 12 h, but dosing interval of 8–16 h allowed (i.e. 4 h flexibility for each dose) 90 mg/mL powder and solvent for solution for s/c injection Each vial contains 108 mg enfuvirtide, 1 ml of reconstituted solution contains 90 mg enfuvirtide	Single use vials, reconstitute with 1.1 ml water for injection (may take up to 45 min to dissolve powder, DO NOT shake vial) Once reconstituted can be stored in fridge for 24 h (i.e. can make up more than 1 dose at once)	– Injection site reactions very common (pain/discomfort, erythema, nodules/cysts) but not usually requiring discontinuation – Other common side effects; insomnia, headache, lymphadenopathy, eosinophilia – Increased rate of bacterial infections (especially pneumonia) reported – Hypersensitivity reactions requiring discontinuation reported, but rare	• No clinically significant pharmacokinetic interactions expected
Maraviroc Celsentri® ViiV CCR5 Antagonist	Dose varies with co-administered medication: 300 mg bd if not with significant enzyme inhibitors/inducers 150 mg bd with significant enzyme inhibitors (e.g. protease inhibitors) 600 mg bd with significant enzyme inducers (e.g. NNRTIs, rifampicin) 150, 300 mg tablets	Can be taken with or without food. Must only be prescribed for patient with recently confirmed CCR5 tropic virus (i.e. not CXCR4 or dual/mixed tropic virus)	– Nausea most common – Vomiting, abdominal pain, constipation, bloating – Dizziness, paraesthesia, somnolence – Rash – Asthenia – Insomnia – Raised LFTs – Dose limiting adverse reaction in clinical trials, postural hypotension	• *Metabolised* by cytochrome P450 hepatic enzymes, caution with other drugs which may affect these enzymes as dose will *need to be adjusted. Do not co-administer with St John's Wort* • Does not inhibit or induce any cytochrome P450 enzymes • *See product literature for detailed information on dosing* • Adjust dose in renal impairment if co-administered with an enzyme inhibitor (see product literature) • *Contraindicated in patients with peanut or soya allergy (contains soya lecithin)*

bd, twice daily.

An alternative booster to ritonavir, cobicistat, is currently in development and is likely to be co-formulated with PIs as well as elvitegravir (see below).

Entry inhibitors

There are currently two types of entry inhibitors (fusion inhibitors and CCR5 inhibitors) with one agent available in each class. Fusion inhibitors block the structural rearrangement of HIV-1 gp41 and thus stop the fusion of the viral cell membrane with the target cell membrane, preventing viral RNA from entering the cell. CCR5 inhibitors selectively bind to the human chemokine receptor CCR5, preventing CCR5-tropic HIV-1 from entering cells.

Enfuvirtide (T-20, Fuzeon®), a fusion inhibitor, is administered subcutaneously and is largely used in heavily treatment experienced patients. The main side effect is injection site reactions. However, following the licensing of new agents from different antiretroviral classes, enfuvirtide is now rarely used.

Maraviroc (Celsentri®), a CCR5 inhibitor, is indicated for use in patients with only CCR5-tropic virus, which is determined by a tropism test just prior to commencing treatment. It is usually used in patients with resistance to one or more other antiretroviral classes.

Integrase inhibitors

Integrase inhibitors bind to the integrase enzyme, thus blocking the integration of viral DNA into host DNA. There is currently one licensed agent, raltegravir (Isentress). Whilst this was initially used in patients with resistant virus, it is increasingly being used either in first-line regimens or where tolerability issues arise with initial therapy. Other agents in development include elvitegravir and dolutegravir. Elvitegravir requires boosting and is being developed as a co-formulation with cobicistat.

Toxicity of antiretroviral therapies

As more antiretroviral agents have become available and the number of patient-years of exposure to them has increased, our understanding of their various toxicities has grown significantly.

Whilst there are many individual drug toxicities (see Tables 41.1–41.5), there are also a number of class-specific or therapy-related toxicities (Carr and Cooper, 2000).

Mitochondrial toxicity. Mitochondrial toxicity is increasingly recognised in patients with prolonged exposure to nucleoside analogue antiretrovirals, particularly stavudine, didanosine and, to a lesser extent, zidovudine, and is thought to explain such side effects as peripheral neuropathy, myopathy, pancreatitis and lactic acidosis. If these problems should arise, management is to switch the likely causative agent, if possible (McComsey and Lonergan, 2004).

Rash and hepatitis. These are both recognised side effects of the NNRTI class, although the incidence and severity appear greatest with nevirapine, particularly in patients with a higher CD4 count (>250 cells/mm^3 for women and >400 cells/mm^3 for men). Management is either close observation (in mild-to-moderate cases) or withdrawal of the causative agent (in severe cases). An abacavir hypersensitivity reaction is well characterised and historically occurs in approximately 6–8% of individuals who receive abacavir. It typically presents in the first 6 weeks of therapy as a progressive illness with fevers, rash and flu-like symptoms. Fatalities have been reported where the drug has subsequently been reintroduced in patients with a prior history of hypersensitivity reaction. Management has traditionally been to withdraw the agent and never reintroduce. However, the use of newer pharmacogenomic techniques, for example, HLA B*5701 testing, and subsequent prescription of abacavir only to those who are B*5701 negative have dramatically reduced the incidence of hypersensitivity reaction (Mallal et al., 2008).

Lipodystrophy. Lipodystrophy has been well reported in individuals on HAART. This is characterised by one or both of lipoatrophy (fat loss, particularly from the face, upper limbs and buttocks) and lipohypertrophy (abnormal fat deposition, particularly affecting the abdomen and neck). Whilst these body shape changes are associated with drug therapy, predominantly stavudine and zidovudine for lipoatrophy and possibly PIs for lipohypertrophy, it is likely that host and disease factors also play a role in aetiology (Carr, 2003; Lichtenstein, 2005). Management at present is to avoid or switch away from the causative agent(s) and/or to use cosmetic approaches (fillers or liposuction). Since the decline in use of the older NRTIs, the incidence of lipodystrophy has decreased dramatically.

Metabolic disturbances. Hypercholesterolaemia and hypertriglyceridaemia, in particular, are frequently seen in patients receiving HAART. Again, the aetiology of these toxicities is likely to represent a combination of drug and host factors. However, they are particularly associated with PIs, although the incidence appears lower with atazanavir. Whilst it is likely that this hyperlipidaemia contributes to an increased cardiovascular disease risk, this needs to be considered in the context of traditional risk factors, for example, smoking, which may be present in this patient group. Management is to reduce all modifiable risk factors and either switch away from the likely causative agent to one more metabolically favourable or consider adjunctive lipid-lowering therapy, taking into consideration potential drug–drug interactions (Schambelan et al., 2002).

Renal impairment and, rarely, Fanconi's syndrome have been reported with tenofovir. Creatinine clearance should be calculated and proteinuria quantified prior to starting therapy with this agent and should be monitored regularly.

Cardiovascular disease. Cohort studies have suggested an increased risk of cardiovascular disease with some PIs (Kaletra® and indinavir) and with the NRTI, abacavir (Sabin et al., 2008; Worm et al., 2010). This risk is independent of the effect on lipids and the mechanism has yet to be determined. As with lipid disturbances, the decision to start or continue these agents needs to be considered as part of a holistic approach to cardiovascular risk.

Opportunistic infections and malignancies

Detailed information on treatment guidelines can be obtained by consulting the relevant national guidelines, for example, British HIV Association guidelines for the management of opportunistic infections (Nelson et al., 2010),

tuberculosis (Pozniak et al., 2010), malignancies (Bower et al., 2008). Dosing schedules for the most commonly used drugs used to treat opportunistic infections are summarised in Table 41.6.

Fungal infections

***P. jiroveci* pneumonia.** This remains one of the most common causes of morbidity and mortality in HIV-positive individuals. Classically, patients present with an insidious onset of a non-productive cough, shortness of breath on exertion and an inability to take a deep breath. Fever, anorexia and weight loss are common accompanying symptoms. Patients are usually markedly immunosuppressed, with CD4 counts less than 200 cells/mm^3. Diagnosis is supported by the presence of exercise-induced oxygen desaturation and the typical chest radiographic appearance of bilateral interstitial shadowing, though in mild cases, the chest X-ray may be normal. *P. jiroveci* cannot be cultured in vitro, so the diagnosis is confirmed by demonstration of the organism by immunofluorescence or silver staining, or by nucleic acid amplification techniques (NAAT), of samples obtained by bronchoalveolar lavage. Sputum induction, by nebulisation of hypertonic sodium chloride, is not recommended for obtaining samples unless the procedure is being performed in the treatment centre sufficiently regularly to enable staff to maintain competence, as diagnostic sensitivity of the test is significantly affected by technique.

Treatment is instigated in patients with a proven diagnosis, or empirically where there is a suspicion prior to confirmation. Adequate samples may be obtained to make a diagnosis up to 7–10 days after starting treatment. Oxygen is essential for patients with compromised respiratory function. First-line therapy is high-dose co-trimoxazole for 21 days: oral for mild cases (1920 mg three times daily), and intravenous for moderate-to-severe disease (120 mg/kg/day in divided doses for 3 days, then 90 mg/kg/day for 18 days). Nausea and vomiting commonly occur and may be best managed pre-emptively by administration of a prophylactic antiemetic.

In cases of co-trimoxazole intolerance, several alternative therapies are available. For mild *P. jiroveci* pneumonia, a combination of oral trimethoprim (10–15 mg/kg/day in two divided doses) with dapsone (100 mg daily) may be effective. For moderate-to-severe disease, a combination of clindamycin (intravenous or oral) and primaquine is often used. Intravenous pentamidine is another alternative, though its use may be associated with more significant adverse reactions. Pentamidine should also be given in nebulised form (600 mg) via a suitable nebuliser, for example, Respirgard II, for the first 3 days, to ensure prompt attainment of adequate lung tissue levels. Oral atovaquone suspension can be used for mild-to-moderate *P. jiroveci* pneumonia but must be taken with food, particularly fatty food, to be effective. Glucose-6-phosphate dehydrogenase (G6PD) levels should be checked prior to (or as soon as possible after starting) treatment with co-trimoxazole, dapsone or primaquine.

For cases of moderate-to-severe *P. jiroveci* pneumonia (PaO$_2$ < 9.3 kPa or SpO$_2$ < 92%), adjunctive corticosteroid therapy is recommended, for example, prednisolone 75 mg daily for 5 days, 50 mg for 5 days, and then 25 mg for 5 days. Ventilatory support should be considered for patients in whom the underlying prognosis is good, for example, those presenting for the first time with *P. jiroveci* pneumonia, those without severe co-existing medical complications and those with remaining effective antiretroviral options.

It has been clearly demonstrated that prophylactic therapy reduces both the incidence and severity of *P. jiroveci* pneumonia in patients with either prior disease or those at risk of a first episode, and that this intervention significantly improves survival. Primary prophylaxis is recommended for those individuals with a previous AIDS-defining illness, markedly symptomatic disease (including oral candidiasis), a CD4 count < 200 cells/mm^3 or CD4 percentage <14%. Prophylaxis can be discontinued when CD4 is sustained above 200 cells/mm^3 for over 3 months on HAART.

Co-trimoxazole is the gold standard and also confers protection against toxoplasmosis and some other bacterial infections. Commonly used regimens with proven efficacy are 960 mg daily or three times a week or 480 mg daily. The incidence of adverse reactions to co-trimoxazole in HIV-positive individuals is higher than in the general population, although many patients who are intolerant of high-dose treatment do not experience problems at prophylactic doses. In cases of intolerance, several alternative approaches may be adopted. Desensitisation may be attempted or other agents may be used. Dapsone 100 mg daily, with or without pyrimethamine, according to *Toxoplasma* status, is effective but does not offer such broad protection against bacterial infections. Nebulised pentamidine at a dose of 300 mg every month via an appropriate nebuliser (with prior nebulised or inhaled β$_2$-agonist to prevent bronchospasm) can also be used but does not protect against extra-pulmonary *P. jiroveci* pneumonia.

Oropharyngeal candidiasis. Candidiasis is a frequent manifestation of HIV infection and may occur early in the disease. Clinically, it is usually characterised by white plaques on the oral mucosa, but may present as erythematous patches or as angular cheilitis. If swallowing is difficult (dysphagia) or painful (odynophagia), oesophageal involvement may be suspected.

First-line therapy for oral candidiasis is a systemic agent, usually fluconazole (50 mg daily for 7 days). An alternative is itraconazole (200 mg once daily); the solution has higher bioavailability than the capsule formulation and does not require an acid pH for absorption. Topical therapies are available where there is a clinical decision to avoid systemic antifungals (e.g. in patients with hepatic failure). They are as effective as oral azoles for oropharyngeal disease, but time to yeast clearance is longer and relapse rate is higher.

In cases of oesophageal candida, which is an AIDS-defining illness, systemic therapy is necessary using higher doses of the above agents for a longer duration, for example, fluconazole 100 mg once daily for 2 weeks. Continuous azole therapy or frequent courses of these drugs predispose to the development

Table 41.6 Selected drugs to treat opportunistic infections in HIV disease

Drug	Indication	Dosage: route, frequency, duration	Common or significant side effects include:	Significant interactions	Monitoring	Comments
Aciclovir	Herpes simplex Herpes zoster Prophylaxis/ suppression of herpes infections	5–10 mg/kg i.v. three times daily for 5–10 days, 200–400 mg p.o. five times daily for 5–10 days, 10 mg/kg i.v. three times daily for 5–10 days, 800 mg p.o. five times daily for 7 days. 200–400 mg p.o. twice daily	Nausea, vomiting, abdominal pain, diarrhoea, skin rash, abnormal LFTs extravasation (i.v.), renal impairment (i.v.). Confusion and other CNS effects (i.v.). Rapid increases in blood urea and creatinine levels related to peak plasma levels and the state of hydration of the patient	Ciclosporin, mycophenolate mofetil, tacrolimus, probenecid, lithium, theophyline, nephrotoxic drugs	Renal function (with i.v.)	Higher dose and longer duration for herpes encephalitis or varicella zoster. Patients on HAART with CD4 >300 cells/mm^3 may be treated as for immunocompetent. Intravenous infusion diluted to 0.5% (w/v) and infused over at least 1 h (reduces likelihood of renal toxicity)
Amphotericin 1. Sodium deoxycholate (Fungizone®) 2. Liposomal (AmBisome®) 3. Lipid complex (Abelcet®)	Cryptococcal meningitis and other severe fungal infections	Test dose of 1 mg i.v. (over 10–30 min, depending on product), followed by once daily i.v.: 1. 0.25–1.0 mg/kg (increased over 3–5 days as tolerated) 2. 1–3.0 mg/kg (increased over 2–3 days) 3. 5 mg/kg. Duration: 2–6 weeks (total induction period at least 6 weeks)	Fever, chills, nausea and vomiting, headache, anorexia, weight loss, malaise, myalgia, thrombophlebitis, epigastric pain, diarrhoea, renal impairment; hypokalaemia, hypomagnesaemia, anaemia hypotension, vasodilatation, flushing, liver function tests abnormal, hyperbilirubinaemia, alkaline phosphatase increased	Nephrotoxic drugs, antineoplastics, corticosteroids	Renal function, FBC, U+Es	Test dose required before first infusion with any parenteral amphotericin. All i.v. preparations administered in 5% glucose. Pre-and post-hydration with 0.9% sodium chloride may decrease nephrotoxicity. Liposomal and lipid complex formulations generally better tolerated
Atovaquone Suspension	Treatment of mild-moderate PCP Prophylaxis of PCP[a] Treatment of toxoplasmosis[a]	750 mg p.o. twice daily with food for 3 weeks 1.5 g p.o. twice daily for at least 6 weeks	Nausea, rash, diarrhoea, vomiting, headache, insomnia, fever, increased LFTs, decreased sodium, anaemia, neutropenia. Hyponatraemia, hypersensitivity reactions including angioedema, bronchospasm and throat tightness	Indinavir, metoclopramide, rifampicin, rifabutin, tetracycline	LFTs, U+Es, FBC	Absorption improved by taking with food (especially high fat food); reduced by diarrhoea
Azithromycin	Atypical *Mycobacterium* infections, toxoplasmosis and PCP (adjunctive therapy or part of combination regimen) MAC prophylaxis	500 mg oral daily for MAI treatment or PCP prophylaxis; 1250 mg oral once weekly for MAI prophylaxis[b]; 1250 mg daily for toxoplasmosis treatment[b]	Nausea, vomiting, abdominal discomfort, anorexia, dyspepsia, flatulence, diarrhoea, constipation, raised LFTs. (rare: ototoxicity)	Antacids, theophylline, coumarins, ciclosporin artemether/ lumefantrine, ergot derivatives, digoxin, bromocriptine, cabergoline, reboxetine, oestrogens	LFTs, hearing (if on long-term or high-dose therapy)	Less significant drug interactions than with the other macrolides For patients allergic to soya or peanut: risk of hypersensitivity reactions with some formulations and brands

Continued

Table 41.6 Selected drugs to treat opportunistic infections in HIV disease

Drug	Indication	Dosage: route, frequency, duration	Common or significant side effects include:	Significant interactions	Monitoring	Comments
Cidofovir	Cytomegalovirus retinitis	5 mg/kg weekly for two doses, then every 2 weeks thereafter	Renal impairment, neutropenia, ocular hypotony, iritis/uveitis, nausea, vomiting, alopecia, rash, asthenia, fever, chills, headache	Other nephrotoxic drugs, agents that are contraindicated with probenecid, tenofovir	Renal function (including urine protein) neutrophils	Must be co-administered with probenecid and intravenous fluids (see SPC/BNF for specific regimen). Caution with handling (potential carcinogen). Avoid if on tenofovir
Clindamycin	Treatment of PCP Toxoplasmosis treatment Toxoplasmosis maintenance	600 mg i.v./p.o. four times daily for 3 weeks 600 mg i.v./p.o. four times daily for at least 6 weeks 1.2 g p.o. daily in 3–4 divided doses	Diarrhoea, abdominal discomfort, oesophagitis, nausea, vomiting, rash, abnormal LFTs, thrombophlebitis (i.v.). Rarely pseudomembranous colitis, blood dyscrasias	Non-depolarising muscle relaxants, suxamethonium, oestrogens, pyrido-stigmine, neostigmine, erythromycin	LFTs, renal function, FBC, diarrhoea	Taken with primaquine for PCP. Taken with pyrimethamine for toxoplasmosis. Higher doses may be used if previous failure of co-trimoxazole (for PCP) or sulfadiazine (for toxoplasmosis)[b]
Co-trimoxazole (trimethoprim + sulpha-methoxazole)	Treatment of PCP Prophylaxis of PCP	Moderate–severe: 120 mg/kg i.v in 2–4 divided doses for 3 days, then 90 mg/kg for 18 days; mild: 1920 mg p.o. three times daily for 3 weeks. Prophylaxis: 480 or 960 mg p.o. daily or 960 mg three times per week (960 mg daily if on rifampicin)	Nausea, diarrhoea, headache, rash, hyperkalaemia, vomiting. (rare: drug fever, blood dyscrasias, serious skin reactions, e.g. Stevens-Johnson syndrome)	Amiodarone, oestrogens pyrimethamine, rifampicin, ciclosporin, lamivudine phenytoin, azathioprine, mercaptopurine, metho-trexate, sulphonylureas, warfarin	FBC, renal function, LFTs rash	For infusion, dilute each 480 mg with 125 ml of glucose 5% or sodium chloride 0.9% and infuse over 1.5–3 h. If fluid restricted, 480 mg in 75 ml of glucose 5%. Caution in G6PD deficiency
Dapsone	Prophylaxis of PCP Treatment of PCP[a]	100 mg p.o. daily (with trimethoprim 10–15 mg/kg/day in divided doses for 3 weeks for PCP treatment)	Anorexia, nausea, vomiting, rash. (rare: blood dyscrasias including methaemoglobinaemia; dapsone syndrome)	Rifamycins, probenecid, oestrogens, antacids	FBC, LFTs	Caution in G6PD deficiency
Famciclovir	Treatment of herpes zoster. Treatment of genital herpes	Doses for immunocompromised patients: zoster use 500 mg three times daily for 10 days; genital herpes all episodes use 500 mg twice daily for 7 days, for suppression 500 mg twice daily	Headache, nausea, diarrhoea, vomiting, abdominal pain, constipation, increased tendency to sweat, pruritus	Probenecid	Renal function	Patients on HAART with CD4 >300 cells/mm[3] may be treated as for immunocompetent
Fluconazole	Oesophageal candidiasis Oropharyngeal candidiasis Cryptococcal meningitis treatment Cryptococcal meningitis prophylaxis	100 mg p.o. daily for 2 weeks 50 mg p.o. daily for 7–14 days 400 mg i.v./p.o. daily for ≥8 weeks 200 mg p.o. daily	Headache, rash, abdominal pain, diarrhoea, flatulence, nausea, abnormal LFTs, hepatotoxicity	Coumarins, midazolam, sulphonylureas, rifabutin, rifampicin, phenytoin, tacrolimus, ciclosporin, theophylline, zidovudine, terfenadine	Renal function LFTs	Higher doses have been used for treatment and prophylaxis of candida and cryptococcus infections (depending on clinical response and antifungal sensitivities) i.v. route only necessary if patient nil by mouth.

Flucytosine	Cryptococcal meningitis treatment	100 mg/kg daily p.o./i.v. in four divided doses for 2 weeks (with i.v. amphotericin)	Nausea, vomiting, diarrhoea, rash (rare: blood dyscrasias, hepatotoxicity)	Cytarabine	Renal function FBC, LFTs	Oral formulation is no longer licensed in the UK but can be imported on named-patient basis
Foscarnet	Cytomegalovirus retinitis treatment Cytomegalovirus retinitis maintenance	180 mg/kg/day i.v. in 2–3 divided doses (adjust according to renal function) over 2h for 3 weeks 60, 120 mg/kg i.v. once daily over 2h for 5–7 days each week	Renal impairment, alterations in serum calcium, potassium, magnesium and other minerals, headache, rash, convulsions, thrombophlebitis, genital ulceration, anaemia, nausea, vomiting, diarrhoea, paraesthesia	Nephrotoxic drugs, drugs that inhibit renal tubular secretion (e.g. probenecid), i.v. pentamidine. When diuretics are indicated, thiazides are recommended	Renal function, LFTs, serum magnesium, potassium, calcium and phosphate, FBC, U+Es	Good hydration, prompt correction of electrolyte abnormalities and dose adjustment for renal function vital. Wash genital area after micturition to reduce risk of ulceration. Give centrally to prevent phlebitis. If infusion related side effects reduce rate. Adjust maintenance dose for disease state, drug tolerability and renal function
Ganciclovir	Cytomegalovirus induction treatment Cytomegalovirus retinitis maintenance	5 mg/kg i.v. twice daily for 3 weeks, 5 mg/kg i.v. once every day or 6 mg/kg once daily for 5 days each week	Blood dyscrasias, anorexia, renal impairment, abnormal LFTs, central nervous system effects, fatigue, nausea, vomiting, flatulence, abdominal pain, dysphagia, dysgeusia, dyspepsia, constipation, ear pain, injection site reactions, eye disorders and skin disorders	Zidovudine, didanosine, imipenem-cilastatin, probenecid, mycophenolate mofetil, nephrotoxic drugs, bone marrow suppressive agents	FBC renal function, LFTs	Give over 1h preferably via central venous access Caution with handling. Special dosage instructions for patients with renal impairment: Women of child bearing potential must be advised to use effective contraception during treatment. Men must be advised to practise barrier contraception during treatment, and for at least 90 days thereafter
Peginterferon alfa	Hepatitis C (in combination with ribavirin) Chronic hepatitis B	See product literature for dose and duration (varies by brand, genotype and initial response) weekly s.c. injection	Severe CNS and psychiatric effects, anorexia, nausea, influenza-like symptoms, lethargy, depression, ocular side effects, rash, myelosuppression, hypertriglyceridaemia	Theophylline	Lipids, renal function, LFTs, TFTs, U+Es, FBC, blood glucose	Longer duration of treatment in HIV-coinfected patients. Should be managed jointly by HIV and hepatology specialists
Pentamidine isetionate	PCP treatment Mild PCP treatment PCP prophylaxis	4 mg/kg i.v. once daily for 3 weeks (+600 mg nebulised for first 3 days) 600 mg nebulised daily for 3 weeks 300 mg nebulised every 4 weeks	Intravenous: renal impairment, postural hypotension, leucopenia, hypo/hyperglycaemia, pancreatitis, electrolyte disturbances, nausea, vomiting. Nebulised: cough, bronchospasm	Nephrotoxic drugs, foscarnet, drugs that prolong QT interval (e.g. quinolones, erythromycin)	Renal function, blood glucose, blood pressure, U+Es	Infuse over 1h with patient supine. Caution with handling. Pretreat with bronchodilator if nebulised and use special nebuliser
Primaquine	PCP treatment	15–30 mg p.o. daily for 3 weeks	Nausea, vomiting, anorexia, abdominal pain (rare: methaemoglobinaemia, haemolytic anaemia)	Bone marrow suppressive drugs, artemether/lumefantrine	FBC	Avoid in G6PD deficiency

Continued

Table 41.6 Selected drugs to treat opportunistic infections in HIV disease

Drug	Indication	Dosage: route, frequency, duration	Common or significant side effects include:	Significant interactions	Monitoring	Comments
Pyrimethamine	Toxoplasmosis treatment Toxoplasmosis maintenance	100 mg on day 1, then 50 mg p.o. once daily for at least 6 weeks Different in SPC 25 mg p.o. once daily	Anaemia, leucopenia, thrombocytopenia, rash	Bone marrow suppressive drugs, anti-malarials, methotrexate, antacids, lorazepam, kaolin, highly protein-bound drugs (e.g. coumarins)	FBC	Combined with sulfadiazine or clindamycin. Higher dose can be used if previous treatment failure Recommend folinic acid 15 mg od to reduce bone marrow suppression
Ribavirin	Hepatitis C treatment	Dose depends on product (Copegus or Rebetol), weight and hepatitis C genotype, see SPCs for specific details	Anaemia, neutropenia, thrombocytopenia. For other side effects reported in combination with peginterferon alfa, see earlier entry	Stavudine, zidovudine, didanosine, abacavir	FBC, LFTs, renal function	Given with peginterferon alfa Colony stimulating factor support may counteract haematological side effects without requiring dose reduction. Teratogenic
Rifabutin	MAI prophylaxis MAI treatment	300, 450 mg p.o. once daily with other drugs (consult SPC for specific details) 150 mg 3 times a week with Kaletra[b]	Abnormal LFTs, nausea, vomiting, bone marrow suppression, arthralgia, myalgia, jaundice (rare: uveitis, risk increased with concomitant administration of drugs that increase rifabutin levels)	Coumarins, aripiprazole, atovaquone, dapsone, efavirenz, erythromycin, clarithromycin, protease inhibitors, sirolimus, oral hypoglycaemics, azole and triazole antifungals, disopyramide, quinidine, carbamazepine, oestrogens, progestogens	LFTs, renal function	Combine with at least one other drug for MAI treatment. TDM of both agents may be useful when given with Kaletra
Sulfadiazine	Toxoplasmosis treatment[a] Toxoplasmosis maintenance[a]	1–1.5 g i.v./p.o. four times daily for at least 6 weeks. 2 g p.o. daily in divided doses	Nausea, vomiting, rash, bone marrow suppression, crystalluria (and see under co-tri moxazole)	Bone marrow suppressive drugs, ciclosporin, oestrogens, coumarins, methenamine	Renal function, LFTs, FBC	Use with pyrimethamine. Prevent crystalluria by ensuring good fluid input/output. Alkalinising urine with sodium bicarbonate may help if crystals formed
Valaciclovir	Herpes zoster treatment Herpes simplex treatment	1 g p.o. three times daily for 7 days. 500 mg p.o. twice daily for 5–10 days (initial) or 5 days (recurrent) episodes	Mild headache and nausea (more serious events reported in transplant patients on 8 g/day long term)	Ciclosporin mycophenolate mofetil tacrolimus probenecid	Renal function	Interactions more likely to be significant if renal impairment
Valganciclovir	CMV retinitis	Induction treatment: 900 mg twice a day with food for 3 weeks Maintenance: 900 mg once daily with food	See ganciclovir, similar potential side effects (except those associated with intravenous administration, e.g. injection site reactions)	As for ganciclovir	FBC, renal function, LFTs	

FBC, full blood count; U+Es, urea and electrolyte levels; LFTs, liver function tests; TFTs, thyroid function tests; MAI, *Mycobacterium avium intracellulare*; G6PD, glucose-6-phosphate dehydrogenase; PCP, *Pneumocystis jiroveci* pneumonia; CMV, cytomegalovirus; p.o., oral; i.v., intravenous; s.c., subcutaneous; SPC, Summary of product characteristics; BNF, British National Formulary; w/v, weight/volume; TDM, therapeutic drug monitoring; MAC, *Mycobacterium avium* complex.
[a]Unlicensed treatment indication in UK.
[b]Unlicensed dose in UK.

of azole resistance. In such instances, an alternative azole or an echinocandin may be used, or occasionally higher than usual doses of the original agent, for example, fluconazole 400 mg daily. In intractable cases, intravenous amphotericin may be required. With the use of HAART, such complications are rarely seen.

Cryptococcus neoformans. This causes a disseminated infection, usually with meningeal involvement, in individuals with HIV infection. Patients present with fever and headaches, often without the characteristic symptoms of meningism such as photophobia and neck stiffness. Diagnosis is normally made on the basis of CSF analysis, though serum cryptococcal antigen and blood cultures may also be indicative.

For patients who are moderately or severely unwell, intravenous amphotericin B deoxycholate (0.7–1 mg/kg/day) or a lipid complex/liposomal formulation, with or without flucytosine (100 mg/kg/day in divided doses, oral or intravenous) is the first-line therapy. The place of flucytosine in therapy remains uncertain, with the only clear benefit seen in patients not on HAART, in whom it speeds the rate of CSF sterilisation and reduces the relapse rate. However, it has not been shown to reduce mortality and can be associated with additional toxicity. Conventional amphotericin is associated with high rates of nephrotoxicity, leading in some cases to acute renal failure and death, although strategies can be employed to minimise adverse effects. However, despite the higher cost, the liposomal form (AmBisome®, 4 mg/kg/day) is now usually the agent of choice due to its more favourable toxicity profile. Many UK hospitals now only stock one intravenous amphotericin product, due to reports of errors following confusion between different formulations because doses, reconstitution procedures and administration vary. The usual duration of amphotericin (± flucytosine) treatment is 2 weeks, after which high-dose fluconazole (400 mg daily orally) should be continued for further 10 weeks. Subsequent maintenance therapy with fluconazole 200 mg daily has been shown to be effective in reducing the incidence of relapse and should be continued for life, or until immune function is restored (for example, CD4 > 100 cells/mm^3 in the presence of an undetectable viral load for at least 3 months). In milder cases fluconazole may be given for the entire duration of treatment. Itraconazole (400 mg/day) has been used but is less effective than fluconazole and should be used only if other agents are contraindicated.

Protozoal infections

Toxoplasmosis. *T. gondii* is a frequent cause of central nervous system disease in patients with AIDS. Individuals may present with headaches, fever, confusion, seizures or focal neurological symptoms and signs. Diagnosis is usually based on the appearance of ring-enhancing lesion(s) on computed tomography (CT scan). Definitive diagnosis is based on brain biopsy, which is rarely performed, but is generally made presumptively after response to therapy.

First-line treatment is sulphadiazine and pyrimethamine, with folinic acid to prevent myelosuppression, for 6 weeks, followed by maintenance therapy with lower doses of the same agents until CD4 count is consistently maintained above 200 cells/mm^3. The preferred alternative is clindamycin and pyrimethamine with folinic acid, with limited data for atovaquone, co-trimoxazole, clarithromycin and doxycycline. Adjunctive therapy with corticosteroids or anticonvulsants may be used in cases of severe oedema or seizures, respectively.

Cryptosporidiosis. *Cryptosporidium parvum* is a ubiquitous organism and a common cause of diarrhoea in immunocompetent individuals. In patients who are immunocompromised, persistent infection may occur characterised by abdominal pain, weight loss and severe diarrhoea. Diagnosis is generally based on stool analysis.

Although many agents have been investigated for the treatment of cryptosporidiosis, the majority of results have been disappointing. Nitazoxanide is possibly the most promising agent, but failed to demonstrate superiority over placebo in severely immunocompromised patients. The optimal treatment for cryptosporidiosis (and indeed the majority of chronic opportunistic infections) is to increase immunological function with HAART. The mainstay of management in patients who are not able or willing to take HAART remains symptomatic control with nutritional supplementation, adequate hydration and antidiarrhoeal agents.

Bacterial infections

Bacterial infections are common in the context of HIV infection. Recurrent bacterial pneumonia, particularly *Streptococcus pneumoniae,* and diarrhoeal illnesses associated with *Salmonella, Shigella* or *Campylobacter* are particularly common. In general, these are treated the same as in immunocompetent individuals, although recurrent infections and/or septicaemia occur more frequently.

Mycobacteria. In HIV-positive individuals, *M. tuberculosis* (TB) is characterised by increased likelihood of reactivation of latent disease; more rapid progression to clinical disease following acquisition; more frequent extrapulmonary manifestations of tuberculosis; and more rapid progression of HIV disease (if the individual is not receiving HAART). Overall, there is no increase in infectivity of tuberculosis compared with HIV-negative patients.

Definitive diagnosis is reliant on culture of the organism from biological specimens but may be complicated by atypical clinical features and reduced response to tuberculin testing; it is often necessary to initiate treatment empirically.

Treatment for pulmonary and extrapulmonary tuberculosis should follow conventional guidelines for immunocompetent individuals. Meningitis is an unusual but significant complication of tuberculosis. Treatment for all forms of CNS tuberculosis should consist of four drugs (isoniazid, rifampicin, pyrazinamide, ethambutol) for 2 months followed by two drugs (isoniazid, rifampicin) for at least 10 months. Adjunctive corticosteroids (either dexamethasone or prednisolone) should be given to all patients with tuberculous meningitis, regardless of disease severity (Thwaites et al., 2009).

The use of primary and secondary prophylaxis remains controversial but may be appropriate in high-incidence groups. The increased incidence of multidrug-resistant tuberculosis (MDRTB) and the emergence of extremely drug-resistant disease (XDRTB) is a cause for concern and raises many infection control issues. It also highlights the need for antibiotic therapy driven by bacteriological sensitivities.

Managing tuberculosis and HIV co-infection is further complicated by drug–drug interactions between anti-tuberculous and antiretroviral agents, overlapping toxicities and the risk of development of immune reconstitution disease (see later). This is a complex area and treatment should be guided by clinicians with the relevant specialist expertise (Pozniak et al., 2010). One of the most frequent concerns is when to initiate therapy for HIV in an individual receiving TB treatment. This decision is based upon the risk of developing other opportunistic infections in the medium term. HAART is usually started after 2 weeks of tuberculosis treatment in those with severe immunosuppression (CD4 <100 cells/mm^3), after 2 months if the CD4 is between 100 and 200 cells/mm^3, and on completion of tuberculosis treatment or at 6 months if the CD4 is greater than 200 cells/mm^3.

M. avium intracellulare (MAI) or *M. avium* complex (MAC) infection was historically a frequent manifestation of late-stage HIV disease, but is rarely seen now that HAART is widely used. Patients with disseminated infection classically present with fevers, weight loss, diarrhoea and hepatosplenomegaly. Diagnosis is sometimes made presumptively but is usually based on culture of the organism(s). *In vitro* sensitivities may not be good predictors of response to therapy. Therapy may need to be tailored to account for drug interactions with concomitant antiretrovirals, but usually includes azithromycin and ethambutol (ideally with rifabutin). Alternative agents include the quinolones and amikacin. Corticosteroids may be useful for symptomatic control. Although rifabutin, clarithromycin and azithromycin have all been demonstrated to be effective agents for primary prophylaxis against MAI, their cost–benefit remains controversial and use is not widespread in the UK. The strongest indications are for those patients with CD4 <50 cells/mm^3 who decline HAART, or who experience HAART failure (without further effective options) or who are receiving chemotherapy.

Viral infections

Cytomegalovirus. CMV is a herpes virus that is acquired by approximately 50% of the general population and over 90% of homosexual men. Like other herpes viruses, once infection has occurred, the virus remains dormant thereafter, but in individuals with advanced immunosuppression, reactivation may occur and cause disease. In the context of HIV infection, the most common sites of disease are the retina and gastro-intestinal tract, though neurological involvement and pneumonitis are well reported.

Diagnosis of CMV retinitis is based on clinical appearance; it may be detected in asymptomatic individuals but usually presents with symptoms of blurred vision, visual field defects or 'floaters'. Untreated CMV retinitis progresses rapidly to blindness and treatment substantially reduces the morbidity associated with this condition. Although previously lifelong treatment had been recommended, where immunological restoration occurs discontinuation may be possible. Conventional therapeutic approaches are based upon an initial induction period of high-dose therapy for 2–3 weeks, until the retinitis is quiescent, followed by lower dose maintenance treatment, with reinduction if disease progression occurs.

The most commonly used agent for induction therapy in the UK is ganciclovir, which can be given intravenously or orally, as the pro-drug valganciclovir. It is usually administered (5 mg/kg) via a central line over 1 h and should be handled as a cytotoxic agent. Valganciclovir is well absorbed and a dose of 900 mg twice daily has been shown to be as effective as intravenous ganciclovir for induction therapy. Significant side effects encountered with these agents include neutropenia, which may require colony-stimulating factor support, and thrombocytopenia. Maintenance treatment may also be given either intravenously (6 mg/kg on 5 days a week) or orally (valganciclovir 900 mg once daily).

Intravenous maintenance therapy requires the insertion of a permanent indwelling catheter and is therefore usually used only when oral administration is not possible. Intravitreal administration of ganciclovir is possible, but rarely used, as this does not confer any systemic protection.

An alternative agent to ganciclovir is foscarnet. It has a less favourable toxicity profile and is thus usually reserved for cases of therapeutic failure with ganciclovir. Its main adverse effects are electrolyte abnormalities, nephrotoxicity that requires dose adjustment or cessation of therapy, and ulceration, particularly of the genitals, which may be prevented by assiduous attention to personal hygiene after micturition. No effective oral formulation is currently available.

Cidofovir requires less frequent administration: two doses at weekly intervals for induction and fortnightly for maintenance, though intravenous administration is again required and nephrotoxicity and other metabolic disturbances are well recognised. A strict regimen of intravenous hydration and oral probenecid (2 g given 3 h prior to infusion and 1 g 2 and 8 h post-cidofovir) must be followed. The risk of nephrotoxicity is increased if cidofovir is co-administered with agents such as tenofovir that are excreted via the same renal tubular anion transporter.

CMV disease of the gastro-intestinal tract usually affects the oesophagus or colon, causing dysphagia and abdominal pain with diarrhoea, respectively. Diagnosis is based upon histological analysis of biopsy specimens. Treatment is as for CMV retinitis induction therapy; maintenance therapy is not usually given unless relapses occur. Neurological disease may present in a variety of ways, is difficult to diagnose and frequently carries a poor prognosis, even with treatment. The optimal agent, dosage and duration of therapy remain undetermined.

Impact of HAART on opportunistic infections

The widespread use of HAART has had a dramatic effect on the incidence, prognosis and clinical aspects of opportunistic infections.

Decreased incidence of opportunistic infections. HAART has resulted in a major reduction in the vast majority of opportunistic infections and a consequent reduction in mortality rates and requirement for hospital admissions.

Withdrawal of prophylaxis. The rise in CD4 count associated with HAART has led to an improvement in functional immunity. Clinical trials have suggested that the withdrawal of both primary and secondary prophylaxis against *P. jiroveci* pneumonia is safe, and similar results are thought to be likely for cryptococcosis, toxoplasmosis, MAI and CMV. Most would consider withdrawing prophylaxis in individuals on successful HAART if the CD4 count is consistently greater than 200 cells/mm³ (*P. jiroveci* pneumonia, toxoplasmosis, cryptococcosis) or 100 cells/mm³ (MAI and CMV).

Successful treatment of opportunistic infections. Some previously difficult to treat infections, notably cryptosporidiosis and microsporidiosis, appear to resolve with significant CD4 count improvements associated with HAART. However, in up to 30% of individuals, initiation of HAART can be associated with a clinical deterioration known as immune reconstitution inflammatory syndrome or IRIS. This typically occurs in the first 2–6 weeks after starting HAART and presents as fevers and localised symptoms pertaining to a recently treated or previously undiagnosed opportunistic pathogen. It is most frequently seen with mycobacteria (lymphadenitis with both *M. tuberculosis* and MAI) and CMV (vitritis, iritis and retinal oedema), but has been reported for most infections. Diagnosis is difficult as the signs and symptoms mimic those of resistant disease, non-adherence and co-morbidity. No management strategy is proven but corticosteroids, NSAIDs and immunomodulatory therapies (IL-2 and GM-CSF) have all been used.

Cancers

Although there are a number of malignancies associated with HIV infection, the most common are Kaposi's sarcoma and lymphoma.

Kaposi's sarcoma. This is the most common malignancy in people with HIV infection and may be triggered by infection with human herpes virus 8 (HHV-8). The majority of lesions affect the skin and appear as raised purple papules. These may be single or multiple and in severe cases may result in oedema, ulceration and infection. Visceral involvement is not uncommon but rarely causes clinically significant disease. In some cases, no therapeutic intervention is necessary and cosmetic camouflage may be sufficient. Indeed, treatment of HIV with antiretroviral therapy usually results in improvement, and in most cases, complete resolution, of Kaposi's sarcoma. When individual lesions are troublesome, local radiotherapy or intralesional vinblastine can be beneficial. Alitretinoin gel (0.1%) (9-*cis*-retinoic acid) is a topical, self-administered therapy approved for the treatment of KS in the USA but not licensed in Europe. In cases of widespread cutaneous disease or significant visceral involvement, systemic chemotherapy is used, though this is often withheld until the potential benefits of HAART have been established. The liposomal anthracyclines and taxanes are now the mainstay of systemic chemotherapy for Kaposi's sarcoma (Bower et al., 2008).

Lymphomas. The most common lymphomas in patients with HIV infection are high-grade B-cell (non-Hodgkin's) types. Primary central nervous system lymphomas, which are extremely rare in the general population, are more common in individuals with HIV infection but tend to occur only in those with severe immunosuppression. Diagnosis of lymphoma is usually based upon histological confirmation from biopsy specimens. This may not be possible for primary central nervous system disease. The advent of HAART has dramatically reduced the incidence of all lymphomas. However, whilst it has similarly improved the outcome for most cases, this is unfortunately not true for primary central nervous system lymphomas. Lymphoma of the central nervous system is associated with an extremely poor outcome, and in many cases, even palliative radiotherapy or corticosteroids confer little benefit.

The optimal therapy for HIV-associated lymphomas has yet to be determined, but the management plan should either be supervised by, or have input from, an oncologist with relevant specialist experience. The outcome for patients with relatively preserved immune function or those receiving HAART is comparable to that in the general population. However, many individuals are unable to tolerate treatment without dose modification. Drug interactions between antiretrovirals (particularly PIs) and chemotherapeutic agents need to be considered to minimise the risk of treatment-limiting toxicities, whilst the proactive use of colony-stimulating factors may enable optimal dosing.

Cervical intraepithelial neoplasia and anal intraepithelial neoplasia. These are both associated with human papillomavirus infection, are more common in individuals with HIV infection and may progress to cervical cancer and anal cancer, respectively. It is currently believed that HAART reduces the progression of cervical intraepithelial neoplasia (CIN) but this does not appear to be true of anal intraepithelial neoplasia (AIN), and there are concerns that the incidence of this malignancy may increase with improvements in HIV survival.

The optimal management is a combination of early diagnosis, surgery, chemotherapy and/or radiotherapy. It is possible that screening by smear tests and early treatment, for example, with imiquimod, may reduce the need for such aggressive treatment approaches.

Neurological manifestations

Neurological symptoms may be due to opportunistic infections, tumours or the primary neurological effects of HIV.

HIV encephalopathy or AIDS dementia complex (ADC) is believed to result from direct infection of the central nervous system with HIV itself. Individuals who may otherwise be physically well can be debilitated by profound cognitive dysfunction and amnesia. Although psychometric test results are

usually suggestive of the underlying aetiology, it is wise to rule out any other cause with brain scanning and CSF analysis.

The incidence of ADC has reduced dramatically with the use of HAART, and similarly, the use of HAART has been anecdotally associated with an improvement in outcome in many cases. Whilst it is known that the central nervous system penetration of some antiretroviral agents is better than others, the beneficial effects on ADC do not appear to be limited to those agents which penetrate well. Nonetheless, many clinicians would choose to include at least one agent with good penetration of the central nervous system in most HAART regimens, particularly in individuals with cognitive impairment. More recently, there have been increasing reports of more subtle cognitive impairment in patients with HIV receiving effective HAART therapy. The role of varying neuropenetrative agents in either the aetiology or the management of such patients is currently under investigation.

Progressive multifocal leucoencephalopathy (PML) is caused by JC virus and may, at presentation, appear similar to a cerebrovascular accident but will have characteristic white matter lesions on an MRI scan, with or without the presence of JC virus in the CSF. In many cases, the introduction of HAART prevents progression of disease, but it is unlikely to reverse the functional deficit at presentation. The role of adjunctive cidofovir in treatment remains controversial.

Hepatitis B co-infection

There are a number of ways in which HIV can impact on hepatitis B (HBV) infection:

- Hepatitis B vaccination is less successful
- Hepatitis B is less likely to be cleared and hence more likely to become chronic
- Hepatitis B infection is likely to be associated with higher hepatitis B DNA levels
- Progression to cirrhosis is more rapid
- Hepatocellular carcinoma is more common.

Although many individuals with HIV will have hepatitis B serological markers suggestive of previous infection, only 6–10% in most series have active hepatitis B infection.

Management requires an understanding of both viruses and is facilitated by the availability of drugs with dual HIV and hepatitis B activity (Brook et al., 2010). The HAART regimen should include two agents with anti-hepatitis B activity, usually tenofovir with either emtricitabine or lamivudine. If HIV develops resistance to these agents, they can still be continued for their anti-hepatitis B activity.

Hepatitis C co-infection

HIV also impacts on hepatitis C infection in a number of ways:

- Hepatitis C is less likely to be cleared spontaneously
- Higher levels of hepatitis C RNA are seen
- Hepatitis C progresses to cirrhosis more rapidly
- Hepatocellular carcinoma occurs more frequently
- Response to hepatitis C therapy is poor.

In the UK, approximately 5–10% of individuals are co-infected with hepatitis C; there are increasing reports of acute hepatitis C infection in gay men with HIV. In Eastern Europe, where the predominant route of HIV transmission is needle sharing, co-infection rates of over 50% are reported.

The management of hepatitis C/HIV co-infection is complicated (Brook et al., 2010). If treatment for hepatitis C is needed for someone on HAART, the antiretrovirals used must be compatible with hepatitis C therapy (pegylated α interferon and ribavirin). Didanosine, abacavir, stavudine and zidovudine should be avoided. It is commonplace to treat individuals with co-infection for a longer duration, for example, 48 weeks rather than 24 weeks for individuals with genotype 2 and 3 hepatitis C, and possibly 72 weeks for genotypes 1 and 4 – dependent upon early virological responses. Side effects of hepatitis C therapy tend to be more frequent and severe in the co-infected population. The proactive use of the colony-stimulating factors erythropoietin and G-CSF may enable optimal dosing of hepatitis C therapy and thereby improve outcome. The management of HCV is likely to be revolutionised by the availability of increasing numbers of Directly Acting Antivirals (DAAs) of which a large number are currently in development. The optimal way to use these and the potential drug-drug interactions with antiretrovirals have yet to be fully elucidated.

Women with HIV

In addition to the general points covered elsewhere in this chapter, specific issues for women with HIV include:

- Cervical screening should be carried out at least annually, to check for gynaecological manifestations of HIV
- Drug toxicity may manifest in different ways or occur with different frequencies, for example, nevirapine hypersensitivity reaction occurs at a lower CD4 count in women whilst lipodystrophy syndrome may also present differently, with breast hypertrophy commonly seen.

Pregnancy and contraception impact on the medicines prescribed for women of childbearing potential. The factors that need to be taken into account (where appropriate) may include:

- Interactions between many antiretrovirals and oral and injectable contraceptive agents (see Table 41.7). There are no interactions with the levonorgestrel-releasing intrauterine system, Mirena. (*Note*: barrier methods should also be recommended in addition to hormonal contraception, to prevent transmission of HIV and other sexually transmitted infections)
- Potential teratogenicity of the drugs prescribed
- Possible increased toxicity of the drugs prescribed to both mother and child
- The use of antiretroviral agents and other strategies to reduce vertical (mother-to-child) transmission of HIV.

The use of combination antiretroviral therapy, with or without caesarean section, with zidovudine as PEP to the neonate, together with a non-breast feeding strategy has reduced vertical transmission rates from 35% to less than 1% where HIV status is known and where antiretroviral therapies are widely available.

Table 41.7 Interactions between antiretroviral (ARVs) and contraceptive agents

	Combined oral contraceptive pill (COC)	Progesterone-only pill (POP)	Depot contraception-Depomedroxyprogesterone acetate (DMPA)	Implanon® Evra®
NNRTIs				
Efavirenz	C	C	A	C
Etravirine	A	A	B	B
Nevirapine	C	C	A	C
PIs				
Atazanavir/ritonavir	A Use COC with **at least** 30 µcg ethinyloestradiol. The increase in progestin exposure may lead to related side effects.	C	C	A
Atazanavir (unboosted)	A Use COC with **maximum** 30 µcg ethinyl estradiol	C	D	C
Darunavir/ritonavir	C	C	B	C
Foamprenavir/ritonavir	C	C	D	C
Indinavir (unboosted)	A	A	B	A
Lopinavir/ritonavir	C	C	B	C

Integrase inhibitors				
Raltegravir	A	A	A	A
CCR5 Antagonist				
Maraviroc	A	A	A	A
Entry inhibitors				
Enfuvirtide	A	A	A	A

A, combination can be used safely; B, no formal studies, but no clinically significant interactions expected; C, additional barrier contraceptive must be used or alternative method; D, avoid combination.

Nonetheless, questions remain regarding the optimal therapies to use, the risk of transmission of resistant virus to the neonate and the risk of toxicity from antiretroviral agents administered during pregnancy, particularly in the first trimester. Ideally, all HIV-positive women should be counselled regarding these issues before they become pregnant, so they can make informed decisions regarding both therapy and timing of pregnancy.

Guidelines are available that set out the management of HIV infection in pregnant women and the prevention of mother-to-child transmission (de Ruiter et al., 2008). In general, intervention reflects a risk/benefit evaluation between the efficacy of reducing transmission and the potential harmful effects to the mother and fetus. Where HAART is clinically indicated for the mother herself, this should utilise a regimen of optimal efficacy with a favourable safety profile. Where therapy

is initiated to reduce transmission, this is usually a HAART regimen but could be zidovudine monotherapy if the viral load is low (consistently <10,000 copies/mL). In the latter situation, the time of therapy initiation is guided by the viral load (Read et al., 2010):

if <10,000 copies/mL – start by 26 weeks;
if >10,000 copies/mL – start by 20 weeks;
if >32,000 copies/mL – start without delay.

Adjunctive caesarean section is recommended where monotherapy is used or there is a detectable viral load prior to delivery, but may not be essential if the mother is on fully suppressive HAART. Breastfeeding should be avoided and antiretroviral therapy is usually administered to the newborn for 4 weeks after birth. In the developing world, different strategies may be adopted. For example, single-dose nevirap-

ine monotherapy is effective in reducing transmission but may be associated with the development of resistance, and exclusive breast feeding, with or without antiretrovirals for the baby, may be recommended where water safety is poor.

Ethnicity

It is now recognised that ethnicity as well as gender can affect drug handling and response to treatment. This is due, in part, to epidemiological differences in gene expression. For example, reduced activity of cytochrome P450 2B6, one of the key enzymes involved in the metabolism of NNRTIs, appears to be more common amongst Africans than Caucasians. These drugs, therefore, have a significantly longer plasma half-life in those affected, which may impact on efficacy, toxicity and treatment interruptions. The prevalence of the HLA*B5701 gene, associated with abacavir hypersensitivity, also varies in different ethnic groups, though the clinical implications of this have yet to be fully researched.

As pharmacogenomics becomes more widely incorporated into clinical trials and routine patient care, it is hoped that a greater understanding will be gained of differences in response to treatment, enabling treatment strategies to be individualised and optimised.

Case studies

Case 41.1

Ms A is a 21-year-old UK-born pharmacy student who presented to her primary care doctor with a rash, swollen glands and flu-like illness. A presumptive diagnosis of swine flu was made. She was given a course of oseltamavir (Tamiflu®) and her symptoms largely resolved over the following 2 weeks. Two months later, her male partner attended his dentist for a routine check up and was found to have oral candidiasis. He had no obvious predisposing factors and his dentist thus suggested that he have an HIV test, which was positive. As a result of this, Ms A was advised to have a test and was subsequently found to be HIV positive too, with a CD4 count of 420 cells/mm³ and a plasma HIV RNA (viral load) of 610,000 copies/mL.

One year after her diagnosis, Ms A has had two consecutive CD4 counts below 350 cells/mm³ (the latest being 310) and a viral load of 50,000–95,000 copies/mL. She is advised to start antiretroviral therapy and plans to do this in a few weeks as soon as she has finished her final exams. She currently takes no medication and uses condoms for contraception/sexually transmitted infection prevention. You are part of the multidisciplinary team which will recommend the regimen to be offered/prescribed.

Questions

1. What is the most likely diagnosis for the illness Ms A initially presented with to her primary care doctor?
2. What baseline investigation results would you need to inform your choice of antiretroviral therapy?
3. What would you do if there was a need to start therapy urgently and these results were not available?
4. Assuming all results were normal, which antiretroviral therapy regimen would you suggest and why?
5. What are the main counselling points to discuss with Ms A when she starts antiretroviral therapy?

Answers

1. The most likely diagnosis is PHI, also known as seroconversion syndrome. Approximately 70% of people newly infected with HIV develop PHI symptoms, typically a flu-like illness, with fever, arthralgia, pharyngitis, rash and lymphadenopathy.
2. The most important HIV-specific investigation which must be performed prior to starting treatment is an HIV resistance test (usually a genotype). Failure to do this can result in premature treatment failure and rapid development of multiple class drug resistance. The presence of HIV resistance mutations is likely to affect the choice of regimen.

    Some clinicians would also perform tropism testing at this point, that is, immediately prior to starting therapy, but it would be unlikely to affect treatment choice at this stage, and hence antiretroviral therapy can be started before the result is available, which may be 6 weeks. The rationale for carrying out a tropism test now, even though a CCR5 inhibitor is not generally used first line, is that antiretroviral agents may subsequently need to be changed when the viral load is undetectable, due to toxicity or intolerance. In addition, the Trofile® test can only be reliably performed on samples with a viral load >1000 copies/mL. However, different tropism tests, which can be carried out on samples with low/undetectable viral load, are now available.

    HLA B*5701 testing might also be done at this stage. If negative, there is an extremely low probability of developing a hypersensitivity reaction on exposure to abacavir, should this drug be considered either at this stage or if treatment needs to be switched in future.

    Routine baseline blood tests (U&Es, eGFR, LFTs, etc.) should also be done to assist antiretroviral therapy choice and monitor for subsequent adverse effects. Some clinicians would also perform a urine protein creatinine ratio (UPCR) before starting a tenofovir-containing regimen.

    While CD4 count is a useful indicator of when to start treatment, and both CD4 and viral load are invaluable in monitoring antiretroviral therapy success, they do not usually influence the choice of agents.
3. Genotypic resistance test results usually take about 3 weeks to be reported, so if therapy needs to be started sooner (as in someone newly diagnosed with a CD4 count <200 cells/mm³), then a regimen must be selected that has at least one drug with a high genetic barrier to resistance and to which primary resistance is unlikely to be present. In this case, a ritonavir-boosted PI, such as darunavir 800 mg daily or atazanavir 300 mg daily, with ritonavir 100 mg daily, would usually be combined with two nucleoside/nucleotide reverse transcriptase inhibitors (e.g. Truvada® or Kivexa® 1 tablet daily). Non-nucleosides (NNRTIs) and integrase inhibitors should be avoided in this situation because they have a low genetic barrier to resistance, that is, the presence of a single resistance mutation is sufficient to render them ineffective.
4. If there was no baseline resistance and other blood results were within normal limits, a typical initial regimen would be two NRTIs and an NNRTI, such as Kivexa® (abacavir and lamivudine) and efavirenz or tenofovir, emtricitabine and efavirenz. The latter is available as a combination tablet (Atripla®, 1 tablet daily) which is widely prescribed as a first antiretroviral therapy combination. Although the UK licensed indication is currently only for adults whose viral load has been maintained at <50 copies/mL for >3 months on antiretroviral therapy (e.g. on the same drugs, but

taken as Truvada®, or tenofovir and emtricitabine, plus efavirenz), it is common practice to initiate therapy with Atripla.

5. Medication counselling should include:

- What the medication is and how to take it, as well as any specific storage conditions (eg tenofovir-containing preparations contain a desiccant)
- Potential side effects and how to prevent them, what to do and who to contact about them including out of hours. Check the Summary of Product Characteristics (www.medicines.org.uk) for the specific side effects of the drugs chosen. Generally, patients should be counselled on common/very common or serious potential effects which they may notice or those which will be monitored
- Relevant drug interactions, including with prescribed medicines, herbal and over-the-counter (OTC) preparations, recreational drugs and alcohol
- What to do if a dose is missed, administered late or the patient vomits soon after taking a dose
- The rationale for, and importance of, a high level of adherence for successful treatment, outlining services that are available to support her, such as provision of adherence aids.

Case 41.2

In 1995, Mr B, a 47-year-old man, presented with *P. jiroveci* pneumonia. He had a CD4 count of 123 cells/mm³, and plasma HIV RNA was unknown, as viral load testing was not routinely available in clinics at the time. He made a good response to treatment with high-dose co-trimoxazole and was subsequently commenced on dual combination therapy with zidovudine and zalcitabine (ddC, an NRTI, no longer marketed). He remained on this regimen for 18 months, until HIV RNA testing became available and he was found to have a viral load of 13,000 copies/mL and CD4 242 cells/mm³. His full antiretroviral therapy history, with reasons for switching, is detailed as follows (Table 41.8).

In September 2009 (now aged 62), his viral load remained <40 copies/mL, with CD4 670 cells/mm³. However, his creatinine clearance (calculated using Cockcroft-Gault equation) was 41 mL/min and urine protein:creatinine ratio was significantly raised, at 86 mg/mmol (normal <30 mg/mmol). Both were normal when last monitored 4 months previously. On questioning, he revealed that he had been taking regular ibuprofen (400 mg three times a day) for the past month, following a wrist fracture, as well as bendroflumethiazide 2.5 mg daily and tamsulosin 400 μcg daily, both of which he has been taking for more than 2 years.

Question

1. What are the possible drug-related causes of his renal dysfunction and what alterations, if any, to his drug therapy would you recommend?

Two weeks after stopping the ibuprofen, Mr B's creatinine clearance is now 52 mL/min and he is prescribed Atripla® 1 tablet daily. His repeat urine protein:creatinine ratio, 1 week after stopping ibuprofen was 42 mg/mmol (improving), with normal urine albumin:creatinine ratio. His serum phosphate was low and fractional excretion of phosphate was 35% (normal < 25%). Although his renal function was improving, it was decided to recommend changing his antiretroviral therapy to boosted darunavir (PI monotherapy), darunavir 800 mg daily and ritonavir 100 mg daily.

2. What information should Mr B be given about the proposed change of regimen?

Answer

1. Tenofovir use has been associated with renal dysfunction, the first sign of which may be a raised UPCR, although there are other causes. Mr B has a raised UPCR and reduced creatinine clearance, suggesting moderate renal dysfunction, which may be tenofovir related. However, regular concomitant NSAIDs and bendroflumethiazide may increase the risk of renal dysfunction. It is possible that the addition of regular ibuprofen has precipitated the renal dysfunction. Therefore, he would be advised to change to an alternative analgesic, if one is still required, starting with regular paracetamol.

Atripla is not recommended for patients with creatinine clearance <50 mL/min, as the doses of emtricitabine and tenofovir need to be adjusted. For creatinine clearance 30–49 mL/min, a dose of 200 mg emtricitabine and 300 mg tenofovir disoproxil fumarate (245 mg tenofovir disoproxil) every 48 h is required. The efavirenz dose remains 600 mg daily. However, Mr B's renal function must be closely monitored, for example, twice a week, to ensure that the doses are adjusted promptly to reflect any

Table 41.8 Mr B's ARV treatment history (Case 41.2)

Start date	Drug name, dose and frequency	Stop date	Viral load and CD4 at switch	Reason for changing
Nov 1995	Zidovudine 200 mg tds Zalcitabine 750 μgrams tds	May 1997	VL 13000 CD4 242	Virological failure
May 1997	Stavudine 40 mg bd Didanosine 200 mg bd Indinavir 800 mg tds	Apr 1999	VL <200 (lower limit of detection at that time) CD4 412	Renal stones (indinavir)
Apr 1999	Stavudine 40 mg bd Didanosine 200 mg bd Efavirenz 600 mg od	Jan 2002	VL <50 (lower limit of detection at that time) CD4 503 (stavudine and didanosine)	Lactic acidosis
Jan 2002	Tenofovir df 300 mg od Lamivudine 300 mg od Efavirenz 600 mg od	Mar 2008	VL <40 CD4 633	Simplification (Reduction in number of tablets)
Mar 2008	Atripla 1 tablet od			

change. This is to avoid over- or underdosing, and the associated risks of toxicity and antiretroviral therapy failure.

If the renal dysfunction continued or worsened, despite stopping the ibuprofen and dose adjusting his antiretroviral therapy, the choice of diuretic could be reviewed. If the problem still persists, then a change of antiretroviral therapy might be warranted.

2. Although the use of ritonavir-boosted darunavir monotherapy (darunavir/ritonavir) is an unlicensed indication, there are data from clinical trials, for example, Arribas et al. (2010), to support this approach. Mr B should be informed of this. Other discussion points should include:
   - How to take the new regimen: two darunavir 400 mg tablets, plus one ritonavir 100 mg tablet, taken together once daily, at the same time each day (±1 h), with or after food
   - How to switch from Atripla® to the new regimen. Atripla® is taken on an empty stomach, usually at night, to reduce CNS side effects and he may wish to take his new antiretroviral therapy at a different time. If he does this, he should ensure the interval between the last dose of Atripla® and the first dose of darunavir/ritonavir is no longer than 25 h
   - Storage conditions: Atripla® is supplied with a desiccant; darunavir and ritonavir tablets do not have any special storage requirements.

Case 41.3

Mr C is a 58-year-old homosexual man who was diagnosed HIV positive 25 years previously but has never had any AIDS-defining illnesses. He received 16 months of zidovudine monotherapy during 1993–1994 as part of a study but subsequently remained off therapy until 1996 when, following a fall in his CD4 count to 240 cells/mm³, he was commenced on stavudine, lamivudine and indinavir. His response was excellent, with a rise in his CD4 count to 520 cells/mm³ and a viral load below detection (<50 copies/mL), but in 1999, the indinavir was changed to Kaletra®, following an admission to hospital with indinavir-induced nephrolithiasis. In 2003, when his viral load was still undetectable, the stavudine was switched to abacavir because of marked facial and peripheral lipoatrophy. The facial wasting was successfully treated with a course of polylactic acid (New-Fill®) injections, and there has been a small, gradual natural recovery of subcutaneous limb fat. He has been on pravastatin 40 mg once daily and fenofibrate 160 mg once daily since 2000, when he also stopped smoking.

At his annual health review, his most recent surrogate markers remained excellent, with a CD4 count of 1100 cells/mm³ and a viral load of <40 copies/mL. However, his fasting lipids were total cholesterol 5.9 mmol/L, LDL cholesterol 4.5 mmol/L, HDL 1.0 mmol/L, triglycerides 3.3 mmol/L. His calculated creatinine clearance (Cockcroft and Gault equation) was 45 mL/min (it was >50 mL/min when last checked 4 months ago), he had a fasting glucose of 9 mmol/L and had a raised blood pressure (BP 140/95 mmHg confirmed on two separate occasions). His 10-year cardiovascular risk was calculated to be 21.5%.

Questions

1. What are the limitations of using this cardiovascular risk calculator in this situation? Is the calculated risk likely to be an over- or under-estimate and why?
2. Mr C is concerned about the implications of his annual health review results. What information and advice should he be given?
3. What changes to his drug therapy might you recommend?

Answers

1. The main limitation of using any cardiovascular risk calculator is that the population data underpinning it come from individuals whose HIV status was not recorded. HIV infection itself is thought likely to increase the risk of cardiovascular disease, but there is currently insufficient evidence of the extent of additional risk to be able to quantify this in any of the established cardiovascular disease risk calculations. In addition, some antiretrovirals, for example, abacavir, didanosine and Kaletra have been shown to be associated with an increased risk of cardiovascular disease. This is also not factored into any of the existing cardiovascular risk calculators. In addition, Mr C is already on lipid-lowering therapy, so his untreated lipid markers would be expected to be more abnormal. The calculated 10-year risk of 21.5% is therefore likely to be an underestimate.
2. Mr C should be given general lifestyle advice to follow a healthy balanced diet and take aerobic exercise at least three times a week. Specific lipid-lowering dietary advice could be given. It would be useful to establish if Mr C has changed his lifestyle in the last 4–6 months, for example, change in adherence to lipid-lowering therapy, change in diet, restarted smoking, taking any new medication, including non-prescription and herbal medicines. Any relevant cardiovascular risk factors should then be discussed/addressed. The possibility that two of his antiretrovirals may also be contributing to his cardiovascular risk should also be explained.
3. Given Mr C's high cardiovascular risk, a change of antiretroviral therapy should be considered. The risk associated with Kaletra® use appears to be cumulative, that is, related to length of time on treatment, whereas the data on the nature of the risk associated with abacavir are less clear. However, it would be appropriate to explore the options for changing his antiretroviral therapy. Currently, there are no data on the presence or absence of cardiovascular risk associated with the other two commonly used boosted PIs, atazanavir and darunavir. In the absence of any HIV resistance test results dating from soon after he stopped the zidovudine monotherapy, it should be presumed that some NRTI mutations may be 'archived'. Caution should therefore be exercised before prescribing combinations with a low genetic barrier to resistance, for example, those containing NNRTIs or integrase inhibitors, without PIs.

   Assuming Mr C's adherence to his lipid-lowering agents had been good, a change of therapy could be indicated, for example, pravastatin to atorvastatin. It would be reasonable to start with 20 mg atorvastatin, increasing to 40 mg if necessary and tolerated. However, if his antiretroviral therapy is going to be changed, it may be helpful to plan the changes in a stepwise fashion, so that the impact of each adjustment can be assessed. In this case, the lipid-lowering therapy alterations should be effected after the change of antiretroviral therapy. A change to simvastatin would be contraindicated if he remains on a PI.

Case 41.4

Ms D is a 50-year-old social worker who was referred to the hospital accident and emergency department by her primary care doctor following a 4-week history of worsening respiratory symptoms, despite treatment with amoxicillin, followed by clarithromycin. She has lost 3 kg in the last 2 months, has had a non-productive cough for 6 weeks and gets breathless climbing the stairs at home. Pulse oximetry showed desaturation to 91% on exercise and her arterial blood gas sample had a PaO₂ of 8.1 kPa. Chest X-ray showed bilateral interstitial infiltrates. Her past medical history includes irritable bowel syndrome (diagnosed

5 years ago), recurrent vaginal candidiasis for the past 7 years and allergic rhinitis for which she uses fluticasone nasal spray. She is divorced and has a 10-year-old son. She works in an inner city area and has no history of foreign travel outside mainland Europe. The hospital has recently introduced routine (opt out) HIV testing for all acute medical admissions, as a result of which Ms D was found to be HIV positive, with a CD4 count of 47 cells/mm³.

Questions

1. What are the most likely HIV-related differential diagnoses for her respiratory symptoms?
2. How should her respiratory symptoms be managed?
3. When should she start antiretroviral therapy?
4. What drug interactions would you need to consider when managing Ms D both in the first few weeks and also in the longer term?

Answers

1. The history, signs and symptoms (gradual onset, failure to respond to treatment for community acquired pneumonia, weight loss, non-productive cough, breathlessness on exertion, oxygen desaturation, low PaO_2 and chest X-ray appearance) are all suggestive of *P. jiroveci* pneumonia. However, some of them could also be consistent with TB which she may have been exposed to as a result of the nature and location of her job. TB would need to be excluded. As Ms D has a significant degree of immunesuppression, the possibility of more than one pathogen/diagnosis must always be considered.
2. Until TB has been excluded, Ms D should be nursed in a negative pressure room. A bronchoscopy should ideally be performed to assist diagnosis. She should be started on treatment for *P. jiroveci* pneumonia immediately with high-dose co-trimoxazole and systemic corticosteroid (see text and Table 41.8 for doses and administration details). Following induction treatment (usually 3 weeks' duration), she should receive secondary prophylaxis until her CD4 count on fully suppressive antiretroviral therapy is maintained above 200 cells/mm³.

    If she responds well to *P. jiroveci* pneumonia treatment and bronchial washings are negative for acid-fast bacilli, then it would be reasonable for her to be managed expectantly with regard to the possibility of TB, that is, not kept in isolation and not started on TB treatment unless relevant symptoms persist or worsen, or new ones develop.

    If TB treatment were required, the standard four-drug (rifampicin, isoniazid, pyrazinamide, ethambutol) 2-month induction regimen, followed by 4 months of rifampicin and isoniazid, plus pyridoxine would be recommended.
3. With a CD4 count of 47 cells/mm³, treatment with antiretroviral therapy would be recommended as soon as possible. Depending on how well she tolerated and responded to the *P. jiroveci* pneumonia treatment, and whether or not TB treatment was also needed, antiretroviral therapy would usually be started within 2–4 weeks of diagnosis. For more information, refer to British HIV Association guidelines for management of opportunistic infections (Nelson et al., 2010) and TB/HIV co-infection (Pozniak et al., 2010).
4. If Ms D did require TB treatment, the hepatic enzyme induction effect of rifampicin would need to be considered. For example, the dose of co-trimoxazole for *P. jiroveci* pneumonia prophylaxis should be a minimum of 960 mg once daily when co-administered with rifampicin.

    The choice and dose of antiretroviral therapy would also be affected if treatment was started after the HIV genotypic resistance test result was known; if no resistance had been found, then efavirenz-containing antiretroviral therapy would be possible. If co-administered with rifampicin, the efavirenz dose should be increased to 800 mg once daily. This would ideally be followed by TDM 2 weeks later, with further dose adjustment if necessary. Although the utility of antiretroviral therapy TDM remains controversial, this is a situation where it is commonly used.

    If PI-based antiretroviral therapy were initiated, either because of the presence of resistance mutations or whilst awaiting the HIV resistance test result, then TB therapy (if required) would need to be altered. Rifabutin (150–300 mg three times a week) would be used instead of rifampicin. PIs also interact with intranasal and inhaled fluticasone and budesonide, resulting in systemic absorption of these steroids, due to inhibition of cytochrome 450 3 A4 in the gut wall and the liver. Beclometasone nasal spray would be a suitable alternative preparation for Ms D's allergic rhinitis.

42 Fungal infections

M. Narayanan

Fungi are ubiquitous microorganisms that differ from bacteria in their cellular structure, and this makes them naturally resistant to antibacterial agents (Table 42.1). Fungi are broadly divided into yeasts and moulds. Yeasts are typically round or oval shaped microscopically, grow flat round colonies on culture plates and reproduce by forming buds from their cells. Moulds (e.g. *Aspergillus*, *Mucor*) appear as a collection or mass (mycelium) of individual tubular structures called hyphae that grow by branching and longitudinal extension. They appear as a fuzzy growth on appropriate conducive medium (e.g. *Penicillium* colonies on stale bread or Sabourauds agar). The most commonly seen yeast, *Candida*, occasionally produces pseudohyphae.

There are hundreds of species of fungi found in the environment, but only the important human fungal pathogens and their treatment will be discussed in this chapter. The fungi of medical importance can be divided into four groups (Table 42.2).

Some fungi like *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis* are known as dimorphic fungi (Table 42.2) because they are found in the infected host in yeast form at 35–37 °C temperature but grow as moulds, *in vitro*, at room temperatures (22 °C incubation).

Fungi mainly reproduce by forming spores through mitosis giving rise to two daughter cells. They are known by names given to this imperfect state (asexual reproduction), but the same fungus, for example, *Scedosporium apiospermum* (asexual form) is also known as *Pseudoallescheria boydii* (sexual form). However, for all practical purposes, only the oldest and best-established name for the fungi is used in diagnostic laboratories.

Fungal spore are spread by air, water and direct contact with infected source. Humans usually become infected by inhalation of airborne spores or by inoculation into traumatised skin and mucous membrane.

Laboratory diagnosis

Microscopical examination and culture of fungi is the mainstay of laboratory diagnosis. Appropriate staining of histological sections of affected tissue is helpful in making a

Table 42.1 Important characteristics of a fungal cell	
Fungi	**Bacteria**
Eukaryotes	Prokaryotes, eubacteria
Cell and cytoplasm	Cell and cytoplasm
Nucleus with multiple chromosomes enclosed in a nuclear membrane	No nucleus or nuclear membrane, has single chromosome
Contains endoplasmic reticulum, golgi apparatus, mitochondria and ribosomes	Other structures absent except ribosomes
Cytoplasmic membrane	Cytoplasmic membrane
Contains phospholipids and sterols	Contains phospholipids and no sterols
Cell wall	Cell wall
Contains chitins, mannans,+/- cellulose	Contains peptidoglycan, lipids and proteins

Table 42.2 Classification of fungi of medical importance

Group	Examples	Infections caused
Yeast	*Candida* spp.	Oral and vaginal thrush Deep seated: candidaemia, empyema
	Cryptococcus neoformans *Saccharomyces cervesiae* *Malassezia furfur*	Meningitis Rare systemic infection in immunocompromised host
Yeast-like	*Geotrichium candidium* *Trichosporon beigelii*	
Dimorphic fungi	*Blastomyces dermatitidis*	For first three: deep systemic organ involvement, more commonly in the immunocompromised host
	Coccidioides immitis *Histoplasma capsulatum* *Paracoccidioides brasiliensis* *Sporothrix schenckii*	Deep subcutaneous infection following trauma
Moulds 1. Hyaline a. Zygomyces	*Rhizopus* *Mucor* *Absidia*	Infections in neutropenic patients and those with diabetic ketoacidosis
b. Hyalohyphomycosis	*Aspergillus fumigatus* and other *Aspergillus* spp. *Fusarium* *Scedosporium apiospermum*	Systemic infection: invasive pulmonary or central nervous system involvement Fusarium keratitis Deep infection in immunocompromised host, for example, transplant patients
2. Dermatophytes	*Trichophyton* spp. *Microsporum* spp. *Epidermophyton*	For all three: various skin (ringworm) hair and nail infections
3. Dematiaceous	*Alternaria* spp. *Cladophialora* spp.	Deep tissue infection with granulomas Chromomycosis, mycetomas

diagnosis when culture growth may or may not be positive. Yeast colonies and moulds are characteristic in their appearance on culture plates and can be preliminarily identified by their shape, colour and temperatures at which they grow. For the genus and species identification of yeasts, microscopic examination and biochemical tests are necessary. Moulds are identified by their morphology and the nature of sporulation on agar medium.

Antifungal sensitivity testing for yeast is done by determining the minimum inhibitory concentration (MIC) of the antifungal agent in the E test® strip method which has now replaced the measurement of 'inhibition zone' by disc testing. E-test® strips are also available for determining sensitivity of antifungal agents against moulds. Molecular diagnosis utilising polymerase chain reaction (PCR) is not available for use in routine practice. Serological diagnosis to look for antibodies in patient's blood is of use only in *Coccidioides* infection. Enzyme-linked immunosorbent assay (ELISA) methods to look for galactomannan antigen in deep *Aspergillus* infection are available but not fully evaluated. A positive test needs to be interpreted in conjunction with other findings. Antigen detection is useful in disseminated *Histoplasmosis* and *Cryptococcosis*.

Fungal infection

It is important to distinguish harmless colonisation with fungi and significant infection, as only the latter would benefit from antifungal treatment.

More often, fungi are a cause of superficial infections of the skin and mucous membranes.

In some susceptible hosts whose immune system is heavily compromised, deep-seated infections involving organs like lungs and brain can manifest as 'difficult to cure' infections, for example, pulmonary aspergillosis or cryptococcal meningitis.

Antifungal agents

Topical and systemic antifungal agents are available to treat mucocutaneous candidiasis, various forms of tinea (ringworm) and other dermatophytosis, onychomycosis and deep-seated systemic infections (e.g. candidaemia, mucor mycoses, fungal endocarditis, osteomyelitis). Some infective conditions and their treatment are dealt with in the sections that follow. The side effects of a range of antifungal agents are set out in Table 42.3.

Table 42.3 Side effects of antifungal agents

Drug	Side effects
Griseofulvin	Mild: headache, gastro-intestinal side effects. Hypersensitivity reactions such as skin rashes, including photosensitivity Moderate: exacerbation of acute intermittent porphyria; rarely, precipitation of systemic lupus erythematosus. Contraindicated in both acute porphyria, systemic lupus erythematosus, pregnancy and severe liver disease
Terbinafine	Usually mild: nausea, abdominal pain; allergic skin reactions; loss and disturbance of sense of taste. Not recommended in patients with liver disease
Amphotericin	Immediate reactions (during infusion) include headache, pyrexia, rigors, nausea, vomiting, hypotension; occasionally, there can be severe thrombophlebitis after the infusion Nephrotoxicity and hypokalaemia Anaemia due to reduced erythropoiesis Peripheral neuropathy (rare) Cardiac failure (exacerbated by hypokalaemia due to nephrotoxicity) Immunomodulation (the drug can both enhance and inhibit some immunological functions)
Flucytosine	Mild: gastro-intestinal side effects (nausea, vomiting). Occasional skin rashes Moderate: myelosuppression (dose related), hepatotoxicity
Fluconazole	Mild: nausea, vomiting and occasional skin rashes; occasionally, elevated liver enzymes (reversible) Moderate or severe: rarely, hepatotoxicity and severe cutaneous reactions, especially in AIDS patients
Itraconazole	Mild: nausea and abdominal pain; occasional skin rashes Moderate or severe: rarely, hepatotoxicity
Voriconazole	Similar to fluconazole and itraconazole Mild: reversible visual disturbances occur in about 30% patients
Caspofungin	Mild: gastro-intestinal side effects; occasional skin rashes

Superficial infection

Candida infections

Epidemiology

Candida is a normal commensal of the human gastro-intestinal tract and skin. Loss of skin and mucosal integrity or use of broad-spectrum antibiotics which alter normal bacterial flora allow overgrowth of endogenous *Candida*. There are more than 100 species of *Candida*, but only a few are important as common human pathogens.

Thrush is candidal infection of the mucous membrane. It can manifest as oral infection, for example, oral thrush in various patient groups, vulvo vaginal thrush in females, balanitis in the uncircumcised man or intertrigo infection in moist skin surfaces in close proximity, for example, groin area. Patients with diabetes and steroid users, whether inhaled or oral, are also prone to infections. Dysphagia due to candidal oesophagitis presents in patients with AIDS and cancer.

Clinical presentation

Oral thrush typically presents as a sore mouth with white curd like patches on the tongue or oral mucosa which can bleed on scraping. Females with vaginal thrush present with itching and a creamy vaginal discharge. Skin infection in babies can present as pustular body rash or nappy rash in the moist perianal area. Candida folliculitis may present in unkempt, bearded men. Nail infection with C*andida* (onychomycosis), or subcutaneous tissue involvement under the nail (paronychia) is seen in people whose occupation involves prolonged hand immersion in water.

In severe oesophageal candidiasis, ulceration or formation of pseudomembranes and, rarely, perforation of lower third of the oesophagus may occur.

Candida can be a cause of hospital-acquired infection in patients as it is found in the hospital environment on inanimate objects or on skin of health care workers.

Treatment

Oral and vaginal candidiasis may be treated by either topical or systemic antifungal agents. The drugs currently available for topical use fall into two groups: the polyenes, of which only amphotericin and nystatin are used clinically, and the imidazoles such as econazole, clotrimazole, miconazole and fenticonazole. These agents are essentially identical in their antifungal activity and the only reasons to choose between them are price and differing preparations. The two systemic agents are both triazoles (fluconazole and itraconazole) and can be given by mouth. Skin infections may also be treated topically, but nail infections are unlikely to respond to a

topical antifungal agent alone and require systemic treatment. Oesophagitis will invariably require systemic treatment.

Topical treatment. The polyenes are broad-spectrum antifungal agents that are virtually insoluble in water and which are not absorbed from the gastro-intestinal tract or from skin or mucous membranes. Both nystatin and amphotericin (but particularly nystatin) are available in a wide range of formulations including pessaries, creams, gels, tablets, pastilles, etc. The choice of formulation clearly depends on the site of infection and patient preference.

Systemic treatment. Three triazole agents: fluconazole, itraconazole and voriconazole are available for systemic treatment of oral and vulvo vaginal candidiasis (VVC). A good source of advice on treatment is that from the Infectious Diseases Society of America (Pappas et al., 2009):

Vulvo vaginal candidiasis

- Several topical antifungal agents provide effective therapy; no agent is clearly superior
- A single 150-mg dose of fluconazole is recommended for the treatment of uncomplicated cases
- For recurring vulvo vaginal candidiasis, 10–14 days of induction therapy with a topical or oral azole, followed by fluconazole at a dosage of 150 mg once per week for 6 months, is recommended
- Complicated vulvo vaginal candidiasis requires topical therapy for 7 days or multiple doses of fluconazole (150 mg every 72 h for 3 doses). Recurrent infections with non-albicans *Candida*, for example, *C. glabrata,* may be more difficult to treat.

Candida balanitis

- Candida balanitis can be treated with topical polyenes or imidazoles, or with systemic fluconazole in the same dose as for vaginal infection.

It is sometimes stated that when treating a woman with vaginal candidiasis, the male partner should be treated simultaneously to prevent reinfection. Although there is no evidence to support this approach, it may be considered in women who suffer from repeated vaginal candidiasis.

Guidance on the treatment of topical and systemic therapy (Pappas et al., 2009) are also available for treatment of mild, moderate and severe oropharyngeal and oesophageal candidiasis and suppressive therapy for patients with HIV infection.

Dermatophytosis

Epidemiology

Dermatophytosis, or tinea, is a condition caused by three genera of dermatophyte fungi: *Trichophyton*, *Epidermophyton* and *Microsporum*. Unlike *Candida*, these are moulds which have a predilection for keratinised tissue such as skin, nail and hair. These fungi are very widely distributed throughout the world and may be acquired from the soil (anthrophilic, e.g. *Trichophyton rubrum*), from animals (zoophilic) or from humans (geophilic) infected with the fungus.

Some species are prevalent throughout the world, for example, *Microsporum canis,* while some are area specific, for example, *Trichophyton mentagrophyte* in Europe and New Zealand.

Clinical presentation

The classical clinical presentation of dermatophyte infection of the skin is ringworm (tinea), a circular, inflamed lesion with a raised edge and associated skin scaling. However, presentation is influenced by the site of infection, for example, tinea pedis (athlete's foot) between the toes, tinea cruris on the body, and by the actual species of fungus causing the infection. In general, less severe lesions are produced by human fungal strains, while those acquired from animals can produce quite intense inflammatory reactions.

Dermatophytosis of the nail results in thickened, discoloured nails, while in the scalp, infection presents with itching, skin scaling and inflammation, and patchy hair loss (alopecia).

Rarely, deep dermatophytosis may be seen in immunocompromised patients with involvement of subcutaneous tissue (granuloma).

Diagnosis

The diagnosis of dermatophyte infection is confirmed by collecting appropriate specimens such as material from infected nails and skin. The fungi can be seen microscopically and specimens may also be cultured, but antifungal susceptibility testing is not required.

Treatment

Small or medium areas of skin infection can be treated with topical therapy, but nail, hair and widespread skin infection should be systemically treated with oral antifungal agents.

The most commonly used topical agents are the imidazoles, of which a wide variety is available, including clotrimazole, ecoazole, miconazole, sulconazole and tioconazole. There is little to choose between these agents, all of which are usually applied two or three times daily, continuing for up to 2 weeks after the lesions have healed. Side effects are uncommon and usually consist of mild skin irritation. Other topical agents include amorolfine, terbinafine and tolnaftate.

The main oral antifungals used for dermatophytosis are terbinafine, itraconazole and fluconazole. Griseofulvin is an alternative treatment for tinea capitis.

Terbinafine. Terbinafine was the first member of a new class of antifungal agents, the allylamines, which became available for systemic use. These agents act by inhibition of the fungal enzyme squalene epoxidase, an enzyme involved in the synthesis of ergosterol, an essential component of the fungal cytoplasmic membrane. Although terbinafine has a very broad antifungal spectrum in the laboratory, its *in vivo* efficacy does not correspond to its *in vitro* activity, and it is used only for the treatment of dermatophyte infection.

Terbinafine is the treatment of choice for tinea infections at 250 mg/day for 2–4 weeks, 250 mg/day for 6 weeks for fingernail infection and 12 weeks for toenail infection.

About 70% of an oral dose of terbinafine is absorbed, and the drug appears in high concentrations in the skin. The half-life is about 16–17 h, and therefore the drug can be given once per day. Terbinafine is metabolised in the liver and the metabolites are excreted in the urine so that hepatic or renal dysfunction will prolong the elimination half-life.

Table 42.4 Conditions predisposing to systemic or deep-seated fungal infection

Infection	Predisposing conditions
Systemic candidiasis	Neutropenia from any cause (disease or treatment)
	Use of broad-spectrum antibiotics which eliminate the normal body flora
	Indwelling intravenous cannulae, especially when used for total parenteral nutrition
	Haematological malignancy and HSCT
	Solid organ transplantation
	AIDS (particularly associated with severe mucocutaneous infection)
	Intravenous drug abuse
	Cardiac surgery and heart valve replacement, leading to *Candida* endocarditis
	Gastro-intestinal tract surgery
	Oesophagectomy leak leading to pleural space infection (empyema)
Aspergillosis	Neutropenia from any cause, especially if severe and prolonged
	Acute leukaemia
	Solid organ transplantation (mainly lungs)
	Chronic granulomatous disease of childhood (defect in neutrophil function)
	Pre-existing lung disease (usually leads to aspergillomas; fungus balls form in the lung rather than invasive or disseminated infection)
Cryptococcosis	AIDS
	Systemic therapy with corticosteroids
	Renal transplantation
	Hodgkin's disease and other lymphomas
	Sarcoidosis
	Collagen vascular diseases
Zygomycosis	Diabetic hyperglycaemic ketoacidosis (leading to rhinocerebral infection)
	Severe, prolonged neutropenia
	Burns (leading to cutaneous infection)

HSCT, hematopoietic stem cell transplantation.

Itraconazole is the second preferred agent at 200 mg/day for 1–2 weeks and longer, with repeated courses for finger and toenail involvement.

Griseofulvin. The first orally administered treatment for dermatophytosis was griseofulvin, which has now been available for over 40 years. Griseofulvin is active only against dermatophyte fungi and is inactive against all other fungi and bacteria. In order to exert its antifungal effect, it must be incorporated into keratinous tissue, where levels are much greater than serum levels, and therefore it has no effect if used topically.

The usual adult dose is 10–20 mg/kg/day for 6 weeks for treatment of larger lesions in tinea corporis.

Griseofulvin is well absorbed and absorption is enhanced if taken with a high-fat meal. In children, it may be given with milk. A 1000-mg dose produces a peak serum level of about 1–2 mg/L after 4 h, with a half-life of at least 9 h. An ultra-fine preparation of griseofulvin exists which is almost totally absorbed and permits the use of lower doses (typically 330–660 mg daily). This preparation is not available in the UK. Elimination is mainly through the liver and inactive metabolites are excreted in the urine. Less than 1% of a dose is excreted in urine in the active form, but some active drug is excreted in the faeces.

The duration of treatment with griseofulvin is dependent entirely on clinical response. Skin or hair infection usually requires 4–12 weeks' therapy, but nail infections respond much more slowly; 6 months' treatment is often required for fingernails, a year or more for toenail infections. Unfortunately, the rate of treatment failure or relapse in nail infection is high, and may reach up to 60%. Hence, terbinafine and itraconazole may be preferred agents.

Pityriasis versicolor

This is a common superficial skin infection caused by a yeast-like fungus, *Malassezia furfur*. The organism is a member of the normal skin flora and lives only on the skin because it has a growth requirement for medium-chain fatty acids present in sebum.

Clinical presentation

The condition usually appears as patches scattered over the trunk, neck and shoulders. These patches produce scales and may be pigmented in light-skinned individuals, appearing light brown in colour. In dark-skinned patients, the lesions may lose pigment and appear lighter than normal skin.

In some patients, Malassezia yeast is also associated with dandruff and seborrhoeic dermatitis, although the exact role of the yeast in causing this condition remains uncertain. In AIDS patients, seborrhoeic dermatitis may be quite extensive and sudden in onset.

Malassezia folliculitis can appear as greasy papules or pustules on the trunk or face of an HIV-infected individual.

Diagnosis

The diagnosis is made by microscopy of scrapings from the lesion. The specimen is examined for the presence of yeast cells and short hyphae. Culture is not usually required for diagnosis and, since it requires special culture media, is not routinely attempted.

Treatment

Pityriasis versicolor is treated with topical terbinafine cream or a topical imidazole cream such as clotrimazole, econazole or miconazole. Cheaper topical alternatives are 2% selenium sulphide lotion or 20% sodium thiosulphate applied daily for 10–14 days. Relapses are common and treatment may need to be repeated. In severe cases, oral itraconazole (200 mg once daily for 7 days) may be given. Treatment of seborrhoeic dermatitis and folliculitis is undertaken with topical azole creams and 1% hydrocortisone. This condition can also often relapse.

Ear infection

Fungi sometimes infect the external auditory canal, causing otitis externa, the most common causative organisms being various species of *Aspergillus* (such as *A. niger* and *A. fumigatus*) and *Candida albicans* and other *Candida* species. A variety of other fungi found in the environment can also cause this condition. The use of topical antibacterial agents in the ear may predispose to local fungal infection.

Clinical presentation

Fungal infection of the ear usually presents as pain and itching in the auditory canal, sometimes with a reduction in hearing due to blockage of the canal. There may be an associated discharge from the ear. Clinical examination shows a swollen red canal, and the fungal mycelium is sometimes visible as an amorphous white or grey mass.

Diagnosis

The diagnosis of a fungal infection of the external canal can be made by microscopy and culture of material obtained from the ear.

Treatment

Aural toilet with removal of obstructing debris is very important in the management of fungal infections of the external auditory canal. A topical antifungal agent such as nystatin or amphotericin, or an imidazole can also be applied.

Infections with saprophytic fungi

Some saprophytic fungi (normally harmless human commensals) can cause significant infections. An example of such an infection in a host with a normal immune system is fusarium keratitis in contact lens wearers. *Penicillium marneffei* can cause skin infection and disseminated fatal infection in HIV-infected patients in South East Asia. *Scedospermium* pulmonary infections are seen in lung transplant recipients.

A large retrospective data from the USA revealed that the three most common non-Aspergillus moulds causing invasive fungal infection among patients receiving haemopoietic stem cell transplants (HSCT) were *Fusarium*, *Scedospermium* and *Zygomycetes*.

Deep-seated fungal infections

Most deep-seated or systemic fungal infections seen in the UK are the result of some breakdown in the normal body defences, which may be due to disease or medical treatment. Fungi that cause superficial infections can also cause deep-seated infection in immunocompromised patients with leukaemia and lymphoma and those in the post-transplant period of immunosuppression. There are, however, a group of fungi, often referred to rather misleadingly as the pathogenic fungi, which are able to cause systemic infection in a previously healthy person. These infections, which are usually due to dimorphic fungi, include diseases such as histoplasmosis, blastomycosis and coccidioidomycosis. They are rare in the UK but rather more common in the USA and other parts of the world.

Fungal infections in the compromised host

Common mycoses

Epidemiology and predisposing factors

There are a large number of conditions which may predispose the individual to systemic or deep-seated fungal infection. These are summarised in Table 42.4. A breach in the body's mechanical barriers may predispose to fungal infection. For example, fungal infection of the urinary tract occurs most commonly in catheterised patients who have received broad-spectrum antibiotics, while total parenteral nutrition (TPN) is strongly associated with fungaemia, sometimes with unusual fungi such as *Malassezia furfur*. This is due to the use of TPN infusions containing lipids, which are a growth requirement of this organism. Most cases of systemic fungal infection, however, are associated with a defect in the patient's immune system, and the nature of the organisms encountered is often related to the nature of the immunosuppression. Neutropenia, for example, is usually associated with *Candida* species, *Aspergillus* and mucormycosis, while defects of cell-mediated immunity, for example HIV infection, are strongly associated with infection by *Cryptococcus neoformans*. Prolonged diabetic ketoacidosis is a risk factor for developing rhinocerebral zygomycosis where mortality can be as high as 100% if there is significant underlying disease.

Many different fungi have been described as causing systemic fungal infection, but the most common organisms encountered and the conditions they cause are listed in Table 42.5. Of these, *Candida* and *Aspergillus* are by far the most common in the UK.

Table 42.5 Common causes of systemic and deep-seated fungal infection in the UK

Condition/organism	Common clinical presentations
Candidiasis (*Candida albicans*, *C. glabrata*, *C. krusei*, *C. tropicalis*, other *Candida* species)	Fungaemia Colonisation of intravenous cannulae Pneumonia Meningitis Bone and joint infections Endocarditis Endophthalmitis Peritonitis in chronic ambulatory peritoneal dialysis
Aspergillosis (*Aspergillus fumigatus*, *A. flavus*, other *Aspergillus* species)	Invasive pulmonary aspergillosis Disseminated aspergillosis Aspergilloma Endocarditis
Cryptococcosis (*Cryptococcus neoformans*)	Meningitis Pneumonia Cutaneous infection
Zygomycosis (various species of the genera *Rhizopus*, *Mucor*, *Absidia*)	Rhinocerebral infection Pulmonary mucormycosis Surgical wound and burns infection
Malassezia furfur	Cutaneous infection (especially in burns patients) Fungaemia associated with total parenteral nutrition

Clinical presentation

Symptoms can be non-specific like low-grade fever, night sweats, weight loss, cough, chest pain and septic shock in extreme cases (Table 42.6).

Diagnosis

Organ-specific radiological findings backed by laboratory tests, as discussed earlier in this chapter, are the mainstay of diagnosis.

Treatment

Compared to the vast array of antibacterial agents available to treat bacterial infections, there are very few systemic antifungal agents available and these comprise four major categories: the polyenes (conventional and lipid formulations of Amphotericin B), the triazoles (fluconazole, itraconazole, voriconazole and posaconazole), the echinocandins (caspofungin, anidulafungin and micafungin) and flucytosine. To provide optimal therapy to the patient, it is necessary to understand the profile, properties and toxicity of these agents. Table 42.7 details the antifungal spectrum of activity against common fungi.

Antifungal prophylaxis is commonly used to prevent invasive fungal infections in the 'at risk' group of patients.

Amphotericin B

Amphotericin, a member of the polyene group, is obtained from various species of *Streptomyces*. Chemically, it is a large carbon ring of 37 carbon atoms closed by a lactone bond. One

Table 42.6 Clinical presentation of systemic fungal infection

Condition	Clinical presentation
Fungaemia (the presence of fungi in the bloodstream), usually due to *Candida* species	Fever, low blood pressure and sometimes other features of septic shock, especially in neutropenic patients Relatively low-grade fungaemias such as those associated with colonised intravenous cannulae often present only with fever Disseminated infection to multiple organ systems is quite common with *Candida* species, leading to central nervous system disease, endocarditis, endophthalmitis, skin infections, renal disease, bone and joint infection
Pneumonia, most frequently due to *Aspergillus* species	Fever, chest pain and cough which may be non-productive. May progress rapidly, especially with *Aspergillus* infection, to severe respiratory distress, necrosis of the lung and pulmonary haemorrhage Formation of fungal balls in pre-existing lung cavities with or without invasion
Meningitis and other central nervous system infection	*Candida* infection may present as a typical meningitis, although it is often more insidious. Aspergillosis is associated with headache, confusion and focal neurological signs due to the presence of brain infarcts. Cryptococcosis most frequently presents as a chronic, insidious meningitis with headache and alteration in mental state
Mucormycosis	Angioinvasive. The most common presentation of mucormycosis is rhinocerebral infection. Initially an infection of the sinuses, it then spreads locally to the palate, orbit and eventually into the brain, leading to encephalitis Pulmonary disease can present as fungal balls radiologically with symptoms of haemoptysis

Table 42.7 Antifungal spectrum of activity against common fungi (adapted from Dodds Ashley et al., 2006)

Organism	Antifungal agent

Note: Plus signs (+) indicate that the antifungal agent has activity against the organism specified. Minus signs (−) indicate that the antifungal agent does not have activity against the organism specified. Plus-minus signs (±) indicate agent has variable activity against the organism specified. AmB, amphotericin B; Flu, fluconazole; Itr, itraconazole; Pos, posaconazole; Vor, voriconazole.
[a]Includes lipid formulations.
[b]*In vitro* data show that the echinocandins (specifically, micafungin) may have variable activity against the dimorphic fungi, depending on whether they are in the mycelial or yeast-like form.

side of the molecule contains seven carbon- to-carbon double bonds (polyene) and the other side contains seven hydroxyl groups. It dissolves in organic polar solvents but forms a colloidal suspension of micelles in water which is rendered stable by the addition of the surfactant sodium deoxycholate.

Mode of action. Amphotericin B binds to the ergosterol in fungal cell membrane affecting its integrity by forming pores

and therefore cell death. Nystatin, the other polyene, is only used topically because of toxicity associated with its systemic use.

Spectrum of activity. Amphotericin is active against a vast majority of fungi and this is the same for all formulations. Development of resistance is uncommon, although primary resistance has been identified for *Aspergillus terreus*, *Scedosporium* spp., *Trichosporon* spp. and *Candida lusitaniae*.

Pharmacodynamically, the ratio of the peak serum concentration to the MIC is important for its efficacy.

Amphotericin B deoxycholate (ABD). Released in 1950, colloidal in nature, amphotericin B deoxycholate is highly protein bound (99%) and insoluble in water. It penetrates poorly into cerebrospinal fluid. Initial elimination of the drug occurs with a half-life of 24–48 h, but this is followed by very slow elimination (half-life about 14 days). As a consequence, it may take 10 weeks for the drug to disappear from the circulation.

Amphotericin B deoxycholate is given by slow IV infusion in 5% dextrose with a dose range of 0.3–1 mg/kg increased to 1.5 mg/kg for serious invasive infections. The duration of treatment can vary from 1 to 2 weeks to longer, depending on the severity of the infection and the organ system involved.

Adverse effects. Nephrotoxicity is the most serious side effect of amphotericin. Renal failure should be monitored regularly at least every other day, and if the serum creatinine exceeds 250 μmol/L, the drug should be discontinued until the creatinine level falls below this limit. Hypokalaemia is also a problem and may be severe, necessitating replacement therapy.

Azotaemia may be seen in patients after the first few infusions of amphotericin B deoxycholate. Chills, fever and tachypnoea may occur but can be avoided by addition of hydrocortisone 25–50 mg to the infusion solution.

The manufacturer recommends that before commencing treatment, a 1 mg test dose should be given in 50 ml of 5% dextrose over a 1- to 2-h period and the patient monitored for fever, rigors and hypotension. True allergic reactions are rare.

Amphotericin B lipid formulations

The advantage of delivering amphotericin encapsulated in liposomes or as a complex with lipid molecules is that a higher unit dose can be given and there is reduction in toxic effects. Three such preparations are currently available: liposomal amphotericin B (AmBisome®), amphotericin B lipid complex (Abelcept®) and amphotericin B colloidal dispersion (Amphocil®).

Liposomal amphotericin B. In liposomal amphotericin B (AmBisome®), the drug is contained in small vesicles each consisting of a phospholipid bilayer enclosing an aqueous environment. This permits the delivery of higher doses (3 mg/kg is recommended, but doses up to 10 mg/kg have been used in some centres) compared to conventional amphotericin, with very little of the immediate toxicity which is such a problem with the conventional formulation. Higher peak serum concentrations are obtained with the liposomal formulation compared to equivalent doses of the conventional drug, although it is not certain if this is clinically relevant. Liposomal amphotericin is concentrated mainly in the liver and spleen, where it is taken up by cells of the reticuloendothelial system. Concentrations in the lung and kidneys are much lower, which may or may not be clinically important.

There is reduced nephrotoxicity with this formulation, and some of the renal dysfunction which has been described in clinical trials of liposomal amphotericin may have been due to concomitant drugs. Three randomised, comparative clinical trials of liposomal amphotericin versus conventional amphotericin B have shown reduced toxicity due to the liposomal preparation, and there is additional evidence for this from open studies. It is this comparative lack of toxicity which accounts for much of the popularity of this agent, despite its expense. These studies also indicate that this agent performs as well as the conventional preparation in febrile neutropenic patients.

Amphotericin B lipid complex and amphotericin B colloidal dispersion. Amphotericin B lipid complex (Abelcet®) is not a liposomal formulation, but consists of large sheets of amphotericin combined with phospholipids. This formulation gives lower peak serum levels compared to the conventional drug because it is rapidly taken up by tissue macrophages, while concentrations in the lungs and the liver are much higher. Patients seem to experience more immediate side effects than with liposomal amphotericin. There is less clinical trial evidence for the use of this agent compared to the liposomal preparation. Amphotericin B colloidal dispersion (Amphocil®) is a formulation consisting of tiny discs of amphotericin and cholesterylsulphate. Like the lipid complex, it too produces low peak serum levels but high liver concentrations compared to the conventional drug. There is less clinical experience with this preparation than with the liposomal preparation, and it appears to have a higher incidence of certain adverse reactions than conventional amphotericin.

Choosing a lipid preparation. Unfortunately, there are limited comparative trial data between the different lipid formulations. At present, the greatest clinical experience is with liposomal amphotericin B and by reason of this and the reduced incidence of side effects, it is the preferred agent of the three in many centres in the UK. In an ideal world, all patients requiring amphotericin would receive the conventional preparation initially, being changed to a lipid formulation only if they fail to respond to or cannot tolerate the side effects of the conventional form. However, the incidence of side effects and the difficulty in administration of conventional amphotericin have in practice led to its replacement in most centres with a lipid formulation.

Flucytosine

Amphotericin B and griseofulvin were the only systemic antifungal agents available until the early 1970s, when flucytosine became available for patient use.

Mode of action. Flucytosine (5-fluorocytosine) is a synthetic fluorinated nucleotide analogue. The mode of action is twofold. Following uptake by the cell, which is dependent on the presence of cytosine permease, flucytosine is deaminated to 5-fluorouracil by cytosine deaminase. This in turn is incorporated into fungal RNA in place of uracil, leading to impairment of protein synthesis. Further metabolism of 5-fluorouracil leads to a metabolite that inhibits the enzyme thymidylate synthetase, leading to inhibition of DNA synthesis. Mammalian cells have absent or weak cytosine deaminase activity which accounts for the selective toxicity of flucytosine.

For all practical purposes, flucytosine is only active against yeasts and yeast-like fungi. Inherent resistance occurs in approximately 10% of clinical isolates of *Candida* species, and acquired resistance develops rapidly if the drug is used alone.

There are several resistance mechanisms, some of which result from a single-step mutation giving a high frequency of acquired resistance in organisms exposed to the drug. For this reason, flucytosine should always be given in combination with another agent such as amphotericin, with which it is synergistic.

Pharmacokinetics. Flucytosine is highly soluble in water and over 90% of an oral dose is absorbed from the gastro-intestinal tract. Virtually all the absorbed dose is excreted unchanged in the urine by glomerular filtration. The elimination half-life is about 4 h, but this is greatly prolonged in renal failure and dosage modification is required in patients with renal dysfunction. The degree of protein binding is very low and flucytosine penetrates well into all tissues, including the aqueous humour of the eye, where about 10% of the serum level is achieved, and the CSF, where about 80% of the serum level is achieved.

Administrations. Flucytosine is given orally or by short intravenous infusion. The dose administered by either route in patients with normal renal function is 100–200 mg/kg/day in four divided doses. This must be reduced in renal failure, but the degree of reduction depends on the degree of renal impairment and it is obligatory to monitor the serum levels of flucytosine. Unfortunately, flucytosine assay is now rarely carried out routinely in UK laboratories. Flucytosine is usually given in conjunction with amphotericin which will probably cause some degree of renal dysfunction, so requiring modification of the flucytosine dose. To avoid dose-related marrow toxicity, the peak serum level, obtained at 1 h after an intravenous dose or 2 h after an oral dose, should be maintained in the range 70–80 mg/L and should not be allowed to exceed 100 mg/L.

Side effects. Some of the side effects of flucytosine are given in Table 42.3. The most important toxic effect is a dose-related myelosuppression with neutropenia and thrombocytopenia. This is usually reversible and can be avoided by monitoring serum levels of flucytosine and adjusting the dose accordingly. Hepatotoxicity is also probably a result of high serum levels, and liver function tests should be performed regularly. The drug is teratogenic in some animals and is not recommended in pregnant women for relatively trivial infections such as a fungal urinary tract infection. In cases of a life-threatening fungal infection, which is very rare in pregnancy, the potential benefits of flucytosine must be weighed against the possible risks.

Imidazoles

The imidazoles clotrimazole, econazole, fenticonazole, sulconazole and tioconazole are now principally used for the local treatment of vaginal candidiasis and for dermatophyte infections. Ketoconazole, which first became available in 1979, can be administered for systemic use, but even this agent has been superseded by the triazoles.

Triazoles

Three triazoles are licensed in the UK: fluconazole, itraconazole and voriconazole. They differ substantially from one another in their pharmacokinetic and antifungal activity (Table 42.8). Their main side effects are listed in Table 42.3.

The basic chemical structure of the triazoles is the azole ring, a five-membered ring containing three nitrogen atoms. Their principal mode of action involves one of the nitrogen atoms of the azole ring binding to fungal cytochrome P450 enzymes. This inhibits the demethylation of lansterol and leads to a reduced concentration of ergosterol necessary for a normal fungal cytoplasmic membrane. The propensity, in man, to also inhibit the metabolism of drugs by cytochrome P450 results in a considerable number of drug interactions.

Fluconazole

Clinical use. Fluconazole is available both orally and parenterally and is used only in the treatment and prophylaxis of infections due to yeasts and yeast-like fungi. It is not used for the treatment of infections due to moulds. It is highly effective in the treatment of *Cryptococcus* infection, but the first-line treatment of cryptococcosis of the central nervous system is the combination of amphotericin B plus flucytosine for CNS infection due to this organism. This may be followed by fluconazole, which in HIV-infected patients will be required life long as suppressive treatment to prevent relapse. In immunocompetent hosts, fluconazole may be used as the primary treatment for disease not involving the CNS, such as pulmonary infection.

In patients with candidaemia due to colonised intravenous cannulae, the most important treatment is removal of the infected cannula, but it is common practice to give a short course of antifungal therapy to prevent disseminated infection elsewhere. Although not proven in randomised clinical trials, changing potentially infected central-line catheters in candidaemia patients is probably the most important part of therapy.

In non-neutropenic patients, studies have shown fluconazole and caspofungin to be as efficacious as, and less toxic than, conventional amphotericin B. In such patients, where the infecting organism and its susceptibility to fluconazole are known, it would be reasonable to commence treatment with fluconazole; caspofungin is a potential alternative. In neutropenic patients, and in patients infected with fluconazole-resistant organisms, amphotericin continues to be the treatment of choice. Fluconazole has also been successfully used as prophylaxis against *Candida* infections in neutropenic patients and patients with AIDS, but this in turn has been associated with an increasing incidence of systemic infections with fluconazole-resistant strains.

Resistance. Some units that use fluconazole extensively have noted an increase in the isolation of yeasts resistant to the drug, with the prevalence of resistance related to the extent of use of fluconazole. Resistance in *Candida* species is mainly seen in patients who are given long-term prophylactic fluconazole. This selects out those *Candida* species such as *C. krusei* and *C. glabrata* that are inherently less susceptible to fluconazole. Resistance in *C. albicans*, the most common species infecting humans, is seen mainly in AIDS patients, partly due to the extensive use of fluconazole in treating severe oral and pharyngeal candidiasis in such patients and partly due to the very large numbers of yeasts in the oropharynx of AIDS patients with candidiasis, which increases the chance of resistance due to spontaneous mutation.

Table 42.8 Comparative pharmacokinetics of antifungal agents (adapted from Dodds Ashley et al., 2006)

Pharmacokinetic parameter	Antifungal agent

Itraconazole

Itraconazole is available for both oral and intravenous use. The drug was originally available in capsules, but a newer liquid formulation gives better absorption and pharmacokinetic profile than the original capsule preparation, leading to significantly greater bioavailability and higher serum levels. Systemic bioavailability of itraconazole oral solution is around 55% optimised under fasting conditions. Itraconazole is extensively metabolised by the liver, predominantly by the CYP 3A4 isoenzyme system and is known to undergo enterohepatic circulation. This is a broad-spectrum antifungal which is effective against yeasts, dermatophytes, the 'pathogenic' fungi and some filamentous fungi, such as *Aspergillus.*

Clinical use. In deep-seated infection, itraconazole is used to treat infections due to the 'pathogenic' fungi, but there is less published evidence of its use in the treatment of systemic candidiasis and it cannot be recommended for this purpose (Maertens and Boogaerts, 2005). However, it may be useful in patients who are infected with strains resistant to fluconazole, some of which may remain sensitive to itraconazole, and in patients who are for some reason unable to tolerate fluconazole. It has also been used to treat cryptococcosis, despite its poor penetration of cerebrospinal fluid, and in that condition, it is an alternative to fluconazole for patients who cannot take the latter drug. However, one study comparing fluconazole and itraconazole as maintenance treatment for cryptococcosis was discontinued due to the high rate of relapse in the itraconazole arm.

There is now considerable evidence to support the use of itraconazole as a prophylactic agent in immunocompromised patients. It has been shown to be effective in reducing the incidence of systemic fungal infection compared to placebo and to be more effective than fluconazole, although this is due to a greater reduction in infections due to filamentous fungi, including *Aspergillus*.

Voriconazole

Voriconazole is available for both oral and intravenous administration. It has advantages over itraconazole in that its absorption from the gastro-intestinal tract is significantly better and is not affected by reductions in gastric acidity due to disease or concomitant medication. Its spectrum of activity is similar to that of itraconazole, but it is more active against *Fusarium* species, a mould which causes superficial infection of the nails and cornea, and occasionally systemic infection in immunocompromised patients.

Pharmacokinetics. Voriconazole given orally is rapidly and almost fully absorbed (oral bioavailability > 90%) with a maximum serum concentration being achieved in about 2 h after administration under fasting conditions. It is extensively distributed into tissue and penetrates well into the CSF and into vitreous and aqueous humour. It is cleared by hepatic cytochrome P450 metabolism and is involved in many clinically relevant drug–drug interactions. Therapeutic drug monitoring may be indicated in some clinical settings.

Clinical use. The main clinical indication for the use of voriconazole is aspergillosis. Studies have shown improved efficacy compared to conventional amphotericin B in systemic *Aspergillus* infection. The largest randomised control trial demonstrates that voriconazole is superior to amphotericin B deoxycholate as primary therapy of Aspergillosis (Walsh et al., 2008). One particular indication is cerebral aspergillosis. Although rare, this carries a high mortality rate (90% or higher), and one study has shown this to be reduced by voriconazole, presumably due to its better penetration into the central nervous system. In addition to aspergillosis, voriconazole is also licensed for the treatment of *Fusarium* infection and for the management of patients infected with strains of *Candida* resistant to fluconazole. It has been shown to be as efficacious as amphotericin B followed by fluconazole in the treatment of candidaemia in patients who were not neutropenic, but it is not licensed for this indication.

Administration. For invasive pulmonary aspergillosis, a loading dose of 6 mg/kg IV every 12 h for 2 doses was given followed by 4 mg/kg every 12 h and converted to oral therapy 200 mg every 12 h depending on clinical review to decide duration of treatment.

Side effects. Voriconazole has a side-effect profile similar to that of other triazoles. Two adverse effects associated with voriconazole are visual disturbance (appearance of bright lights, colour changes or wavy lines) in 45% of patients and cutaneous phototoxicity (rash) in 8% patients. Both side effects are reversible after discontinuation of therapy.

Posaconazole

Posaconazole is the latest triazole to be licensed in the UK. Like itraconazole, it is absorbed slowly, is a highly protein bound (>98%) and reaches a steady state after a period of 7–10 days. Optimal absorption is achieved when taken with a high fatty meal.

Clinical use. Posaconazole is used 200 mg three times daily for prophylaxis of invasive fungal infection during neutropenia or moderate to severe graft versus host disease (GVHD).

Caspofungin

Caspofungin was the first of the echinocandins to become available for routine use, and others, such as micafungin and anidulafungin, have only recently become available. These agents interfere with the production of the fungal cell wall by inhibiting the synthesis of an important component, 1,3-ß-D-glucan. This is a target which does not exist in mammalian cells, providing selective toxicity against fungi. Caspofungin has a significant advantage over the triazoles in that it does not inhibit the cytochrome P450 system and therefore is not associated with such a wide range of drug interactions.

Susceptible fungi. The drug has a rather unusual spectrum of activity. It is active against most species of *Candida*, although some are less susceptible than others, but *Cryptococcus* is resistant. The commonly encountered species of *Aspergillus* are susceptible, but the drug is inactive against the dermatophytes and activity against other fungi is variable.

Clinical use. Caspofungin is only available for administration via the intravenous route and does not penetrate into the cerebrospinal fluid. Due to its spectrum of activity, caspofungin is indicated only for candidiasis and aspergillosis. A comparative study showed caspofungin to be as efficacious as conventional amphotericin B in invasive candidiasis. It has been shown to be effective in patients with aspergillosis who failed to respond to, or who could not tolerate, other antifungal agents. Finally, caspofungin was also shown to be as effective as liposomal amphotericin B in the empirical treatment of fungal infection in neutropenic patients and had a lower incidence of unwanted effects (Walsh et al., 2004). In the UK, the drug is licensed for this indication.

Choice of treatment

A recent development has been the use of combinations of antifungal agents to improve on the results of single agents. At the present time, there is little firm evidence to support the use of such combinations. Amphotericin B plus flucytosine in the treatment of cryptococcosis is the only combination where evidence exists of increased efficacy over either agent alone. However, faced with a seriously ill patient not responding to single agents, it is not surprising that many clinicians attempt the use of a combination of antifungals, even though the evidence is that the results are no better than monotherapy.

Practice points regarding the drug toxicity in systemic antifungal agents are detailed in Table 42.9.

Table 42.9 Practice points	
Drug toxicity in systemic antifungal agents	
Infusion-related side effects	• Particularly with conventional amphotericin B • Lipid-based preparations also show these, but to a lesser extent
Nephrotoxicity	• Particularly with conventional amphotericin B • Results in renal dysfunction • Cessation of treatment may be required • Drug-level monitoring is not helpful in prevention • Potassium loss and hypokalaemia are a serious complication • Renal toxicity may be potentiated by concomitant nephrotoxic agents
Hepatotoxicity	• Associated with the azole antifungals • Was particularly severe with ketoconazole • The newer triazoles may also cause serious liver damage
Bone marrow suppression	• Associated with flucytosine • Dose-related problem, so drug-level monitoring may help to prevent it • Tends to preclude the use of flucytosine in patients whose marrow is already damaged (e.g. in haematological malignancy or following bone marrow transplant)
Drug interactions	• Associated particularly with the azoles • Due to their mode of action in inhibiting the cytochrome P450 system • A wide range of drugs may be affected, some with serious interactions
Difficulties in drug administration	
Drug precipitation	• Amphotericin B will precipitate out if given in electrolyte-containing infusions • This may also happen in 5% dextrose due to acidity resulting from the manufacturing process
Need for a test dose	• Required for all amphotericin B preparations
Long infusion times and/or large infusion volumes	• A particular problem with conventional amphotericin • Long infusion times mean reduced access to intravenous cannulae for other purposes • Large infusion volumes may be undesirable in patients with renal or cardiac dysfunction
Variable absorption when taken by mouth	• A known problem with itraconazole • Absorption is reduced in the presence of raised gastric pH (e.g. following the use of antacids or drugs such as omeprazole) • Absorption is increased in the presence of food or if taken with a cola drink • Subtherapeutic levels may occur due to poor absorption • Therapeutic drug monitoring is recommended to avoid low levels

Continued

Table 42.9 Practice points—cont'd

Resistance to antifungal agents	

Amphotericin B	• Usually seen as a very broad-spectrum antifungal, but inherent resistance is seen in several clinically significant species:
	    Aspergillus terreus
	    Candida lusitaniae
	    Scedosporium apiospermum
	• Acquired resistance developing during treatment is very uncommon
	• Lipid preparations have identical *in vitro* antifungal activity to the conventional form

Flucytosine	• Acquired resistance during treatment is very common in *Candida* species • Monotherapy promotes the rapid development of resistance • Combination therapy with amphotericin will reduce the possibility of acquired resistance developing during treatment

Fluconazole	• Some species of *Candida* are inherently resistant or less susceptible to fluconazole:
	    C. krusei
	    C. glabrata
	• Long-term use of fluconazole may result in increased infections with these more resistant strains
	• Long-term use may also result in reduced susceptibility in strains of *C. albicans*

Case studies

Case 42.1

A 27-year-old woman visits her primary care doctor complaining that her toenails have become distorted and discoloured. Since it looks unattractive, she would like it corrected before her summer beach holiday. The primary care doctor makes the clinical diagnosis of tinea unguium (dermatophytosis of the nail) which is confirmed by laboratory culture of nail scrapings. The doctor knows that this condition is unlikely to respond to topical treatment and therefore consults the British National Formulary for a systemic agent. He finds that griseofulvin, terbinafine and itraconazole are all available for this condition. However, the situation is complicated by the fact that his patient tells him that she is trying to get pregnant and does not want to take anything which might harm a baby. At this point, the doctor seeks specialist advice.

Question

What is the most appropriate (and safe) treatment in this patient?

Answer

This is a difficult issue. Griseofulvin is contraindicated, due to its known teratogenicity in animals. In addition, this drug decreases the effectiveness of oral contraceptives, so it would not be appropriate to give it along with an oral contraceptive agent to prevent pregnancy during use. It is also recommended that oral contraception be continued for at least a month after discontinuing griseofulvin. Therefore, in this patient, it is not an appropriate choice.

The position of itraconazole is a little different. Like griseofulvin, it has the U.S. Food & Drugs Administration (FDA) category C (studies show fetal harm in animals, but evidence in human beings is lacking), but there is at least one report of almost 200 women given itraconazole in the first trimester of pregnancy without evidence of fetal harm. In the current state of knowledge, however, it would be difficult to recommend itraconazole to this patient.

Terbinafine carries FDA category B (no evidence in animal studies of fetal harm, but studies proving safety in pregnant women are not available). Therefore, it could be given to the patient if the benefit outweighs the risk, but since this is not a serious condition, this approach would be difficult to justify.

After some discussion, the patient decided that she wanted the condition treated more than she wanted to become pregnant, so she opted to take a course of terbinafine but return to using her oral contraception until the treatment course was complete.

Case 42.2

A 56-year-old diabetic male with carcinoma of the oesophagus undergoes sub-total oesophagectomy. He spends the early post-operative period on surgical ITU and is sent to the surgical ward for further management. On day 6, post-op, he begins to show signs of sepsis for which antibiotics are commenced. However, 48 h later, he has difficulty in breathing, takes a turn for the worse and is transferred to ITU. Imaging the chest revealed a leak from the oesophagectomy site and fluid collection in the pleural space. Gram stain of aspirated pleural fluid revealed budding yeast cells and sputum culture taken 2 days previously has grown *Aspergillus*.

Question

How should this patient's infection be managed?

Answer

The immediate management of this patient would involve drainage of pleural fluid through an intercostal drain and systemic antifungal therapy. The source is very likely to be oral thrush as the patient is diabetic and the candida has travelled from the mouth/oropharynx through the leak in the oesophagectomy wound into the pleural space. Fluconazole at 400 mg twice daily should be commenced awaiting full culture identification of the yeast and antifungal sensitivities. Urgent review is indicated for surgical intervention to close the leak. The duration of antifungal agent would be normally be 14–21 days.

Re-collection of yeasts in inadequately treated spaces can be a problem. It may be useful to add a second antifungal agent to fluconazole. The presence of *Aspergillus* in sputum may be an environmental contamination; therefore, a second specimen will be needed to confirm.

Aspergillus is not sensitive to fluconazole, in which case amphotericin B or voriconazole may be indicated.

Case 42.3

A 18-year-old boy with acute myeloblastic leukaemia sustained 20% accidental burns injury on face, upper body and right arm at a family barbecue. He had recently left hospital after successful antibiotic treatment for a febrile neutropenic episode post-chemotherapy.

Two weeks after admission to ITU for management of burns, he undergoes a septic episode with septic shock. A blood culture taken through a central line shows Gram-negative bacilli. He is commenced on broad-spectrum antibiotics. His peripheral blood count is 3×10^9/L and he has a markedly raised C-reactive protein (CRP). The patient has suffered a moderate degree of renal failure. Two days later, another blood culture is taken through an arterial line and shows yeast cells on Gram stain. Intravenous fluconazole is added to his treatment. Culture growth from the central line blood culture reveals *Pseudomonas aeruginosa* and *Candida albicans*. The arterial blood culture grows *Candida krusei*. Antifungal sensitivities are awaited.

Question

How should the patient be managed?

Answer

Treatment of infections in burns patients can be challenging as the loss in skin integrity increases the risk of being colonised with various endogenous and hospital-acquired bacteria and fungi. Patients with haematological malignancies and chemotherapy treatment are more vulnerable to opportunistic infections, and this case has an additional co-morbidity on top.

Ideally, antibiotics should be avoided in a patient who has an invasive fungal infection as it is believed that killing the bacterial flora helps fungi thrive in the absence of commensal competition. In this case, the patient has concomitant Gram-negative sepsis and lacks a strong bodily defence system because of his underlying disease condition.

Candida krusei is known to be resistant to fluconazole. It is difficult to treat intravenous catheter and other line infections with systemic antibiotics and antifungals alone. It is imperative that these lines are taken out, and treatment given through temporary peripheral lines for at least 48 h before a new central line is inserted. New lines are very likely to get colonised with the same microorganisms if inserted too early. Both *Candida albicans* and *Candida krusei* can be treated with a lipid formulation of amphotericin (use of non-lipid conventional formulations of amphotericin should be avoided as the patient has a moderate degree of renal failure and his present condition could deteriorate).

The duration of treatment can be decided based on daily clinical follow-up that includes imaging and echo cardiograms for up to 2 weeks to look for seeding of *Candida* in other organs. Choice of antifungals can be reviewed after antifungal sensitivity is made available and amphotericin can be switched to caspofungin if necessary.

Thyroid and parathyroid disorders

43

M.D. Page

Key points

- When diagnosing thyroid conditions, the possibility of drug-induced disease should always be considered.
- The treatment of hypothyroidism requires lifelong thyroxine therapy and monitoring.
- Thyroxine replacement therapy should be introduced cautiously in the elderly, particularly those with cardiac disease.
- Thyroxine replacement therapy can be given weekly in patients who forget their daily doses or who are unable to self-medicate.
- Thyrotoxicosis can be treated with thionamide therapy, radioiodine or surgery. The choice will largely be determined by the age of the patient, the cause of the thyrotoxicosis, the severity of the condition, co-morbidity and patient preference.
- Patients treated with thionamide therapy require careful counselling about the symptoms and management of agranulocytosis and should be given written guidance.
- Surgery for hyperparathyroidism is only required in a minority of patients.
- Hypoparathyroidism can occur after thyroid surgery. It is managed with vitamin D analogues and requires lifelong monitoring.
Fig. 43.1 Control of thyroid hormone secretion.

Thyroid physiology

The thyroid gland consists of two lobes and is situated in the lower neck. The gland synthesises, stores and releases two major metabolically active hormones: Tetra-iodothyronine (Thyroxine, T_4) and tri-iodothyronine (T_3). Regulation of hormone synthesis is by variable secretion of the glyco-protein hormone TSH from the anterior pituitary. In turn, TSH is regulated by hypothalamic secretion of the tripeptide thyrotrophin-releasing hormone (TRH) (Fig. 43.1). Low circulating levels of thyroid hormones initiate the release of TSH and probably also TRH. Rising levels of TSH promote increased iodide trapping by the gland and a subsequent increase in thyroid hormone synthesis. The increase in circulating hormone levels feeds back on the pituitary and hypothalamus, shutting off TRH, TSH and further hormone synthesis.

Both T_4 and T_3 are produced within the follicular cells in the thyroid. The stages in synthesis are shown in Fig. 43.2. In summary:

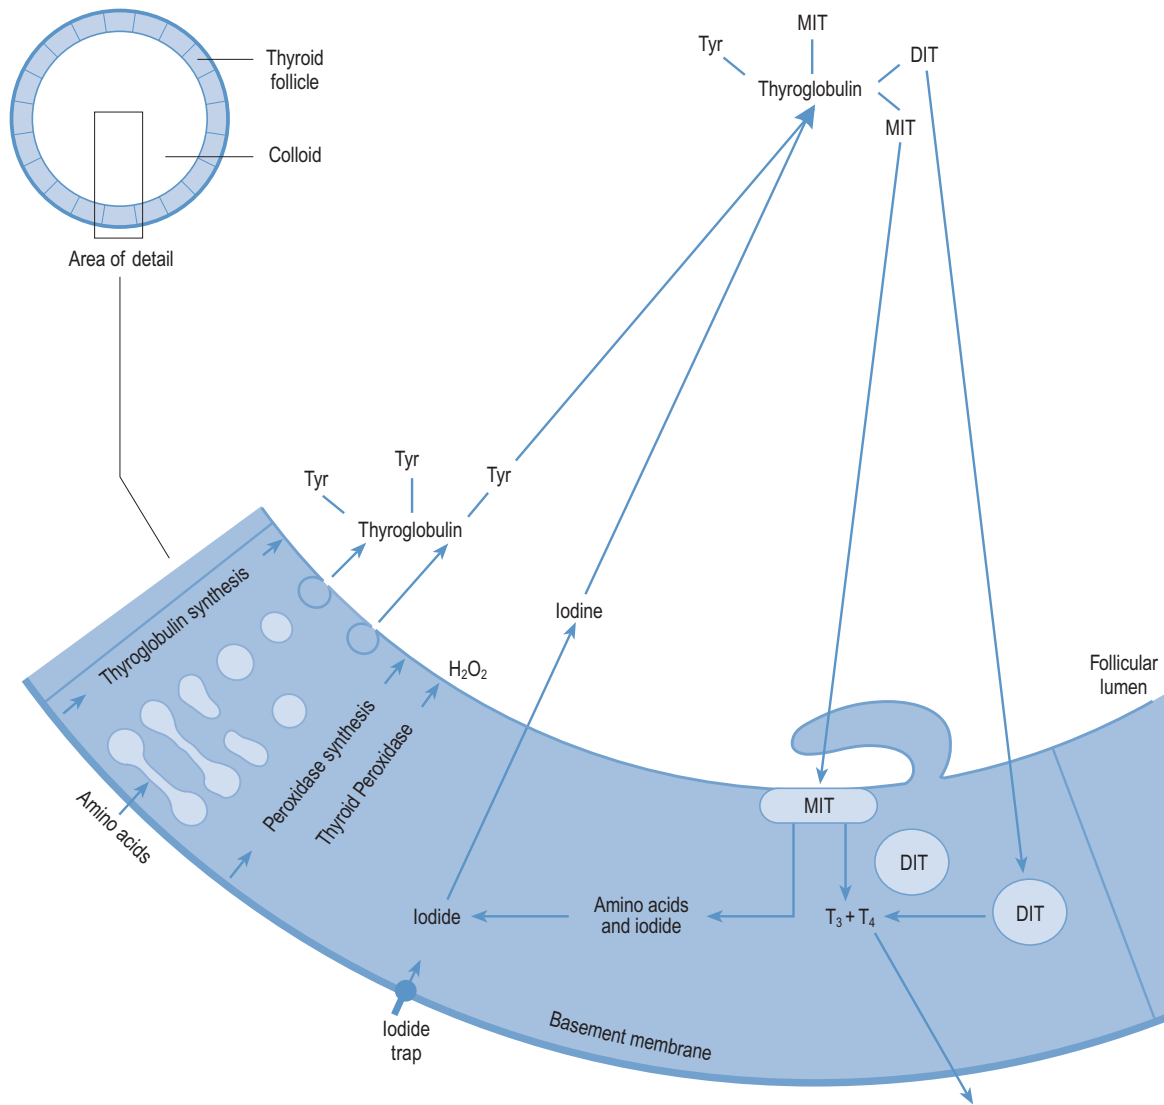
- Thyroglobulin and thyroid peroxidase (TPO) are synthesised by follicular cells.
- Hydrogen peroxide (H_2O_2) is synthesised at the luminal membrane.
- Dietary inorganic iodide is trapped from the circulation and transported to the follicular lumen where it is oxidised by H_2O_2.
- Iodine is then transferred onto the tyrosine residues in thyroglobulin by iodinase enzymes forming mono-iodotyrosine (MIT) and di-iodotyrosine (DIT).
- Subsequently, the formation of T_4 occurs as a result of the coupling of two DIT residues and of T_3 by coupling a DIT and an MIT residue. The hormones are then stored within the gland until their release into the circulation.
- Finally, thyroglobulin is resorbed into the follicular cell, hydrolysed and its amino acids and remaining iodine re-used.


Fig. 43.2 Synthesis of thyroid hormones.

The ratio of T_4:T_3 secreted by the thyroid gland is approximately 10:1. Consequently, the gland secretes approximately 80–100 μcg of T_4 and 10 μcg of T_3 per day. However, only 10% of circulating T_3 is derived from direct thyroidal secretion, the remaining 90% being produced by peripheral conversion from T_4. T_4 can therefore be considered a prohormone that is converted in the peripheral tissues (liver, kidney and brain) either to the active hormone T_3 or to the biologically inactive reverse T_3 (rT_3). In the circulation, the hormones exist in both the active free and inactive protein-bound forms. T_4 is 99.98% bound, with only 0.02% circulating free. T_3 is slightly less protein bound (99.8%), resulting in a considerably higher circulating free fraction (0.2%). Details of protein binding are shown in Table 43.1.

The hormones are metabolised in the periphery (kidney, liver and heart) by deiodination. T_4 and T_3 are also eliminated by biliary secretion of their glucuronide and sulphate conjugates (15–20%). The half-life of T_4 in plasma is about 6–7 days and that of T_3 24–36 h in euthyroid adults. The apparent volume of distribution for T_4 is about 10 L and for T_3 about 40 L.

Table 43.1 Plasma protein binding of thyroid hormones

Carrier protein	Plasma concentration	Proportion of T_4 and T_3 bound (%)
Thyroid-binding globulin (TBG)	15 mg/L	75
Transthyretin (formerly thyroid-binding prealbumin)	250 mg/L	10
Albumin	40 g/L	15

Hypothyroidism

Hypothyroidism is the clinical state resulting from decreased production of thyroid hormones or very rarely from tissue resistance.

Epidemiology

Accurate assessment of the prevalence and incidence of hypothyroidism is difficult due to variation in definitions and population samples. The prevalence of previously undiagnosed, spontaneous, overt hypothyroidism has been estimated to be between 2 and 4 per 1000 of the total population worldwide. However, if all cases of previously diagnosed hypothyroidism and the effects of previous thyroid surgery and radioiodine treatment are included, this prevalence rises to approximately 10 per 1000. In the UK, primary hypothyroidism is common with a prevalence of 14/1000 women (but <1/1000 men). Despite these data, population screening for autoimmune hypothyroidism is thought to be probably not cost-effective unless incorporated into a screening programme for other conditions. Although the disease may occur at any age, most patients present between 30 and 60 years of age.

Aetiology

Primary hypothyroidism accounts for more than 95% of adult cases. It is usually due to a failure of the thyroid gland itself as a result of autoimmune destruction, or the effects of treatment of thyrotoxicosis. Hypothyroidism may be drug induced. Amiodarone and lithium cause hypothyroidism in around 10% of patients treated (see later). Secondary disease is due to hypopituitarism, and tertiary disease due to failure of the hypothalamus. Peripheral hypothyroidism is due to tissue insensitivity to the action of thyroid hormones. A more extensive classification is shown in Box 43.1.

Iodides may produce hypothyroidism in patients who are particularly sensitive to their ability to block the active transport pump of the thyroid gland. Iodine absorption from topical iodine-containing antiseptics has been shown to cause hypothyroidism in neonates. This is potentially very dangerous at a critical time of neurological development in the newborn infant. Transient hypothyroidism may be seen in 25% of iodine-exposed infants.

Clinical manifestations

Hypothyroidism can affect multiple body systems, but symptoms are mainly non specific and gradual in onset (Box 43.2). Symptoms are frequently vague especially in the early stages. It is common for symptoms to be incorrectly attributed by patients and their relatives to increasing age. The reverse is also common in that patients who have read about, or have friends/family with, hypothyroidism will assume that it is responsible for symptoms of fatigue and weight gain. Thus, hypothyroidism is often confused with simple obesity and depression. Thyroid function tests give accurate diagnosis in all cases.

The most useful clinical signs are myotonic (slow-relaxing) tendon reflexes, bradycardia, hair loss and cool, dry skin. Effusions may occur into pericardial, pleural, peritoneal or joint spaces. Mild anaemia of a macrocytic type is quite common and responds to thyroxine replacement. Pernicious anaemia is a frequent concomitant finding in hypothyroidism. Other, organ-specific autoimmune diseases such as Addison's disease may be associated.

Myxoedema coma

Myxoedema coma is a rare but potentially fatal complication of severe, untreated hypothyroidism. Coma can be precipitated by hypothermia, stress, infection, trauma and certain

Box 43.1 Classification of hypothyroidism

Primary hypothyroidism
Congenital hypothyroidism
    Agenesis
    Inherited enzyme defects
Immune
    Hashimoto's thyroiditis
    Spontaneous hypothyroidism in Graves' disease
    Postpartum hypothyroidism
Iatrogenic
    Postoperative hypothyroidism
    Hypothyroidism after radioactive iodine
    External neck irradiation
    Drugs – antithyroid thionamides, amiodarone, lithium, elemental iodide
Iodine deficiency
Subacute (viral)

Secondary/tertiary hypothyroidism
Hypopituitarism – any cause
Hypothalamic disease

Peripheral hypothyroidism
Insensitivity to thyroid hormones

Box 43.2 Signs and symptoms of hypothyroidism

Skin and appendages	Dry, cool, flaking, thickened skin Reduced sweating Yellowish complexion. Puffy facies and eyes Sparse, coarse, dry hair Brittle nails
Neuromuscular system	Slow speech Poor memory and reduced cognitive function Somnolence Carpal tunnel syndrome Psychiatric disturbance Hearing loss Depression Muscle pain and weakness Delayed deep tendon reflexes
Metabolic abnormalities	Raised total and LDL cholesterol Macrocytic anaemia
Gastro-intestinal	Weight gain with decreased appetite Abdominal distension and ascites Constipation
Cardiovascular	Reduced cardiac output Bradycardia Cardiac enlargement

drugs, notably β-blockers and respiratory depressants, including anaesthetic agents, narcotics, phenothiazines and hypnotics. The condition is a medical emergency and should be treated rapidly and aggressively.

The term 'myxoedema' used to be synonymous with hypothyroidism. It is now reserved for advanced disease in which there is swelling of the skin and subcutaneous tissues.

Investigations

The laboratory investigation of hypothyroidism is extremely simple. Usually clinical assessment, combined with a single estimation of thyroid hormones and TSH, is sufficient to make the diagnosis. In primary disease, the levels of free T_4 and T_3 are low and the TSH level rises markedly. Some laboratories offer only TSH as a first-line test of thyroid function though this can result in delayed diagnosis of secondary or tertiary hypothyroidism, which should be suspected on the basis of a low free T_4 along with low TSH levels.

Elevation of the TSH level occurs early in the course of thyroid failure and may be present before overt clinical manifestations appear. It is important to appreciate that hypothyroidism is not one disease but a spectrum. Early hypothyroidism may be asymptomatic or the symptoms less obvious and non-specific, but a normal TSH with normal free T4 effectively excludes the diagnosis.

A chest radiograph may detect the presence of effusions, and an electrocardiogram (ECG) is useful, especially in patients with angina or coronary heart disease, in whom replacement therapy needs to be introduced gradually.

Testing thyroid function

As indicated earlier (and later in the section on thyrotoxicosis), a clinical assessment and measurement of free T_4 and TSH are usually all that are necessary to arrive at an accurate diagnosis of thyroid state. All modern TSH assays now employ double antibody immunometric techniques, which are robust and highly reliable. Moreover, these assays are now so sensitive that they are able to identify thyrotoxic patients with TSH levels below the normal euthyroid range. Commercial free T_4 and free T_3 assays, however, are all indirect methods and are subject to interference from drugs and other disease states. As such, both T_3 and T_4 can be decreased as a non-specific consequence of systemic illness ('sick euthyroid' syndrome) and depression along with a host of drugs (Surks and Sievert, 1995), which can interfere with thyroid hormone metabolism and free hormone assays (Table 43.2). Such patients require specialist assessment and collaboration with the local laboratory to rule out confounding disease and pituitary failure.

Treatment

The aims of treatment with thyroxine are to ensure that patients receive a dose that will restore well-being and that usually returns the TSH level to the lower end of the normal range (Vanderpump et al., 1996). All patients with symptomatic

Table 43.2 Drug effects on thyroid function

	Clinical/biochemical effects
Decrease TSH secretion

Increase thyroglobulin levels	
Oestrogen and tamoxifen Opiates and methadone	Increased total T_4
Others	
Cytokines – interferon and interleukin 2	Thyroiditis. Can produce hypothyroidism and thyrotoxicosis

hypothyroidism require replacement therapy. T_4 is usually the treatment of choice except in myxoedema coma where T_3 may be used in the first instance. Before commencing T_4 replacement, the diagnosis of glucocorticoid deficiency must be excluded to prevent precipitation of a hypoadrenal crisis. If in doubt, hydrocortisone replacement should be given concomitantly until cortisol deficiency is excluded.

The initial dose of T_4 will depend on the patient's age, severity and duration of disease and the coexistence of cardiac disease. In young, healthy patients with disease of short duration, T_4 may be commenced in a dose of 50–100 μcg daily. As

the drug has a long half-life, it should be given once daily. The most convenient time is usually in the morning. After 6 weeks on the same dose (not a shorter interval as TSH takes this time to stabilise after a dose change), thyroid function tests should be checked. The TSH concentration is the best indicator of the thyroid state, and this should be used for further dosage adjustment. A raised TSH concentration indicates inadequate treatment, poor adherence or both. The majority of patients will be controlled with doses of 100–200 μcg daily, with few patients requiring more than 200 μcg. In adults, the median dose required to suppress TSH to normal is 125 μcg daily. In the majority of patients, once the appropriate dose has been established, it remains constant. During pregnancy, an increase in the dose of thyroxine by 25–50% is needed to maintain normal TSH levels.

Exacerbation of myocardial ischaemia, infarction and sudden death are all well-recognised complications of T_4 replacement therapy. Patients with coronary heart disease may be unable to tolerate full replacement doses because of palpitations, angina or heart failure. Elderly patients may have undiagnosed ischemic heart disease. In these two groups of patients, treatment should therefore be started with 25 μcg daily and increased slowly by 25 μcg every 4–6 weeks. During this time, the patient's clinical progress should be carefully monitored. In some patients, T_4 may be better tolerated if a β-blocker such as propranolol is given concomitantly. Some authorities recommend starting with 5 μcg of T_3, the rationale being that if adverse effects occur, these can be alleviated more rapidly with a dose reduction due to the shorter half-life of T_3.

It is important to avoid both under- and overtreatment. Hypothyroidism is very rarely life threatening, but adverse effects may result from prolonged overtreatment (which is indicated by a TSH level suppressed below the normal range). Though T_4 exerts an effect on many organs and tissues, it is the effect on bone and the heart that give the greatest cause for concern. There is evidence that bone density is reduced in patients taking excessive T_4 replacement therapy (Faber and Galloe, 1994; Uzzan et al., 1996), and that atrial fibrillation is more common if TSH is suppressed (Sawin et al., 1994). In order to minimise the risk of development of these complications, the dose of T_4 should be carefully tailored to the needs of each individual patient. Some patients will have undetectable serum TSH levels while taking thyroxine and may complain of recurrent fatigue if the dose is reduced to permit the TSH to rise. In these patients, it may be permissible to leave the dose unchanged if levels of free T_4 and T_3 are normal, after a discussion of the relative risks and benefits with the patient (Vanderpump et al., 1996).

Patient care

Hypothyroidism requires lifelong treatment with T_4. Patients on long-term drug therapy are recognised to have a low adherence with their medication regimen. Treatment with T_4 is often terminated because patients feel well and think that treatment is no longer required. Patients should understand the effects of drug holidays on their health and thyroid

function tests and should know that a normal TSH indicates adequate dosage. Written advice should be provided and monitoring of dosage should continue annually. There are a series of excellent patient information leaflets available on the British Thyroid Association website at www.british-thyroid-association.org.

Despite adequate counselling, some patients persistently forget to take their tablets reliably, leading to variable thyroid state and wildly fluctuating test results. Other patients lack capacity to self-medicate reliably. There is evidence to show that weekly dosing with T_4 is a safe and acceptable way to manage this type of patient, in whom family members or community staff can supervise treatment (Grebe et al., 1997; Rangan et al., 2007). There are no guidelines yet published, but in practice, patients are normally started on 500–700 μcg T_4 weekly. Dose changes are made in exactly the same way by assessing TSH levels after 6 weeks of stable dosing.

Rarely, patients are seen in whom TSH levels fluctuate or remain elevated despite high doses of thyroxine and in whom adherence seems to be very good. There are a number of possible causes for this, including malabsorption of thyroxine which can be due to coeliac or inflammatory bowel disease or a number of commonly prescribed drugs (Table 43.2). Such patients will need a careful sequential assessment by an endocrine service (Morris, 2009).

Prevention

At present, nothing can be done to prevent autoimmune thyroid failure from developing; however, much can be done to ensure early detection and treatment. Careful follow-up of patients who have undergone radioiodine treatment, subtotal thyroidectomy or completed a course of treatment for thyrotoxicosis is essential along with monitoring of those prescribed amiodarone and lithium. An increase in TSH with normal concentrations of T_3 and T_4 will indicate the onset of hypothyroidism before the patient becomes symptomatic. Box 43.3 shows the prevalence of hypothyroidism after treatment for thyrotoxicosis.

Box 43.3 Prevalence of thyroid disturbance after treatment for thyrotoxicosis

Thyroidectomy
6–75% develop hypothyroidism over their lifetime, dependent on the amount of remnant tissue.
Risk highest during first year after surgery

Antithyroid drugs (>6 month course)
43% relapse with thyrotoxicosis in the first year
13–21% relapse with thyrotoxicosis in the next 4 years

[131]I therapy
24–90% develop hypothyroidism over their lifetime, depending on dose given

Hyperthyroidism/thyrotoxicosis

Hyperthyroidism is defined as the production by the thyroid gland of excessive amounts of thyroid hormones. Thyrotoxicosis refers to the clinical syndrome associated with prolonged exposure to elevated levels of thyroid hormone. This distinction is important when evaluating thyroid function tests (Table 43.3).

Epidemiology

Hyperthyroidism is a common condition. It has been estimated that there are 4.7/1000 women with active disease. When previously treated cases were included, the population prevalence rose to 20/1000 in women. As for hypothyroidism, it is much less common in men who have a lifetime prevalence of around 2/1000 (Tunbridge et al., 1977).

Aetiology

Hyperthyroidism is a disorder of various aetiologies. In clinical terms, thyrotoxicosis is the result of persistently elevated levels of thyroid hormones.

Graves' disease

Graves' disease is the commonest cause of thyrotoxicosis. It is an autoimmune condition and results from production of an abnormal IgG immunoglobulin which is able to occupy the TSH receptor on the thyroid follicular cell. Here, it mimics the effect of TSH, causing cell division and stimulating thyroid hormone secretion. These stimulatory imunoglobulins are known as thyroid receptor antibodies (TRABs). Very rarely, the TRABs are inhibitory to the TSH receptor, resulting in hypothyroidism.

Ninety per cent of patients with Graves' disease are young women often with a family history of the condition. In addition to the effects of thyrotoxicosis, around 30% of patients develop additional features including a congestive ophthalmopathy which is thought to result from antibody-mediated inflammation of orbital contents. Pretibial myxoedema, gynaecomastia and thyroid acropachy are rare manifestations.

In pregnancy, the maternal TRABs can pass across the placenta to the fetus resulting in transient neonatal thyrotoxicosis.

Nodular disease

Toxic multinodular goitre is also common but more often affects older women in whom an euthyroid nodular goitre may have been present for many years. Individual nodules become autonomous, producing T_3 and/or T_4. Clinically, the thyrotoxicosis is generally less severe and more gradual in onset. Often, only T_3 levels are elevated, though the TSH will be suppressed in all cases. Thyrotoxicosis may also be caused by single autonomous thyroid adenomas. These are benign well-differentiated tumours that secrete excessive amounts of thyroid hormones.

Table 43.3 Aetiology of hyperthyroidism

	Condition	Frequency	Clinical features	I^{131} uptake
Thyrotoxicosis (increased hormone synthesis)				
	Graves' disease	70%	Antibody mediated (TRABs) 90% are young women Diffuse goitre Ophthalmopathy (30%) Pretibial myxoedema Acropachy Transmissible to neonate	Increased
	Multinodular goitre	20%	Benign autonomous nodules Often secrete T_3 Older women Always relapse after withdrawal of thionamides	Increased
	Toxic single adenoma	5%		Increased
	Iodine induced	<1%	Increased urine iodine	Variable
	HCG induced	Rare	Molar pregnancy or choriocarcinoma	Increased
	TSH dependent	Rare	Pituitary tumour	Increased
Thyroiditis (thyroid destruction and leakage of stored thyroid hormones)				
	Acute	2%	Probably viral Neck pain – often severe	Absent
	Silent	2%	Viral Autoimmune	Absent
	Amiodarone induced	<1%	Increased urine iodine	Absent

TRABs, thyroid receptor antibodies.

Thyroiditis

If the thyroid is inflamed by viral or rapid autoimmune attack, the resulting follicular cell death will result in the release of pre-formed thyroid hormones. This usually presents as a painful mildly enlarged and tender thyroid. There is a brief period of hyperthyroidism before thyroid hormone levels fall to subnormal. Most often, this period of hyperthyroidism does not lead to clinically apparent thyrotoxicosis and in any event is brief, but it is common for these patients to be prescribed thionamides which compound the ensuing hypothyroidism. It is therefore necessary to be aware of these conditions. Neck pain with disturbed TFTs should prompt referral for specialist assessment which will usually include a request for an iodine uptake scan. Iodine uptake is absent in hyperthyroidism associated with thyroiditis.

Clinical manifestations

Thyrotoxicosis is characterised by increases in metabolic rate and activity of many systems due to excessive circulating quantities of thyroid hormones. There is a wide spectrum of clinical disturbances. The signs and symptoms reflect increased adrenergic activity, especially in the cardiovascular and neurological systems (Box 43.4). Not all manifestations will be seen in every patient. Additional clinical features will depend on the underlying cause of the thyrotoxicosis (Table 43.3).

The clinical features of thyrotoxicosis in the elderly may not be so obvious. Signs and symptoms of cardiovascular disturbance tend to predominate, atrial fibrillation is frequent and the patient may develop congestive cardiac failure.

Unexplained heart failure after middle age should always arouse suspicion of thyrotoxicosis.

The extrathyroidal manifestations of Graves' disease deserve separate mention. Most frequent is ophthalmopathy due to inflammation and expansion of the contents of the orbit. The eye is pushed forward (proposed) such that white sclera appears between the iris and the lower lid. Congestive changes develop including peri-orbital oedema, conjunctival swelling and redness. The extraocular muscles are swollen and become tethered leading to failure of movement of the globe of the eye and thus diplopia. Severe disease causes pressure in the orbit, which can compress the optic nerve leading to blindness. The cutaneous features of Graves' disease include thickening of the pretibial skin (myxoedema), onycholysis (separation of the nail from the nail bed) and acropachy (similar to finger clubbing).

Investigations

In those with suspected thyrotoxicosis, it is good practice to document the diagnosis with two sets of thyroid function tests. If the diagnosis is in doubt, treatment should be withheld because unless severe, thyrotoxicosis can usually be safely observed whilst awaiting the results of investigations. Plasma free T_4 (and/or T_3) levels are elevated. The TSH level is suppressed to subnormal levels in all causes of thyrotoxicosis, except the exceptionally rare cases of TSH secreting pituitary adenomas.

In the overwhelming majority of patients, the combination of the clinical findings and simple investigations is sufficient to make a firm diagnosis. Radioactive iodine uptake scans will differentiate those patients with thyroiditis. Measurement of TRABs will identify Graves' disease patients. If the diagnosis is still equivocal, the clinical findings should be reassessed and particular attention paid to the patient's drug history. There are a number of drugs that may modify the clinical features or interfere with the tests.

Treatment

A number of factors need to be considered when choosing the most appropriate form of therapy for an individual patient (Table 43.4). There are usually a number of therapeutic options available, and the patient should be involved in the deciding on treatment. The decision may also be influenced by physician preference, which in turn can depend on the facilities available. Three forms of therapy are available, including anti-thyroid drugs, surgery and radioactive iodine. There is no general agreement as to the specific indications for each form of therapy, and none of them is ideal, all being associated with both short- and long-term sequelae. Neither surgery nor radioactive iodine should be given until the patient has been rendered euthyroid due to the risk of inducing a thyroid crisis.

In children, surgery may be difficult and the complication rate is higher. Also, radioiodine has been avoided due to concern about the potential development of thyroid malignancy, though there are no data which suggest this to be a

Box 43.4	Signs and symptoms of thyrotoxicosis
Skin and appendages	Warm, moist skin Thinning or loss of hair Increased sweating Heat intolerance
Nervous system	Insomnia Irritability, nervousness Lid retraction – staring eyes Symptoms of an anxiety state Psychosis
Musculoskeletal	Fine motor tremor Proximal muscle weakness Rapid deep tendon reflexes Osteoporosis
Gastro-intestinal	Weight loss despite increased appetite Thirst Diarrhoea
Cardiovascular	Palpitations, tachycardia Shortness of breath on exertion Atrial fibrillation Congestive cardiac failure Worsening angina

Table 43.4 Treatments available for thyrotoxicosis

	Adverse effects (%)	Contraindications	Cautions
Thionamides Carbimazole Propylthiouracil	Rash/arthropathy (5%) Agranulocytosis (0.3%) Hepatitis (rare)	Previous severe allergy Cross reactivity in 10%	Pregnancy – PTU preferred. Do not use block/replace regimens
Radioiodine	Hypothyroidism requiring lifelong T_4	Pregnancy	Ensure euthyroid first Ophthalmopathy may deteriorate
Surgery	Hospital stay Neck scar Surgical/anaesthetic risk 10–75% require T_4		Ensure euthyroid first Ophthalmopathy may deteriorate

problem. In pregnancy, radioiodine is not used due to the likelihood of producing a hypothyroid neonate. Thyroid surgery during pregnancy should be deferred until the second trimester if possible and most patients can be controlled with drugs. Thionamide doses should be kept as low as possible, especially in the last 2 months of pregnancy, as excessive treatment may produce goitre in the fetus. Aplasia cutis is said to occur after carbimazole therapy, so propylthiouracil (PTU) is usually used in pregnancy. Pregnant patients with thyrotoxicosis should be under the care of a specialist endocrine unit.

Immediate treatment of thyrotoxicosis

Patients need to have their symptoms addressed and their thyrotoxicosis controlled. β-Blockers in standard antihypertensive doses are effective within a matter of hours and should be offered to all non-asthmatics with severe thyrotoxicosis. Carbimazole (40 mg once a day) or PTU (150 mg twice daily) will render most patients euthyroid within 6 weeks. Adjunctive treatment of cardiac disease and anxiety/sleeplessness may be required.

Graves' disease

A proportion (40–50%) of patients with Graves' disease will achieve a long-lasting remission after a period of euthyroidism on thionamides. The optimal duration of anti-thyroid treatment is unknown and remains a controversial issue (Maugendre et al., 1999), but in most units, the length of the treatment course has fallen to between 6 and 12 months. It is not appropriate to discuss complex treatment decisions with a thyrotoxic patient, so most are well into this period when discussions of their options occur. Remission of Graves' disease is much less likely in those with very large goitres, those who require high-dose thionamide treatment to maintain euthyroidism, those with high TRAB titres and patients who have relapsed once after a course of drug treatment. Such patients should therefore be rendered euthyroid and then have a discussion about either surgical or radioiodine thyroid ablation.

Nodular thyroid disease

As the nodules function autonomously and thyrotoxicosis will always recur when thionamides are stopped, there is no value in attempting to achieve a remission of nodular thyroid disease using prolonged medical treatment. Patients should be rendered euthyroid with drugs and then have a discussion about ablative therapy.

Anti-thyroid drugs

The thionamides, PTU, thiamazole (methimazole) and its precursor carbimazole are equally effective pharmacological therapies for thyrotoxicosis. In the UK, carbimazole is usually used. These drugs prevent thyroid hormone synthesis by inhibiting the oxidative binding of iodide and its coupling to tyrosine residues. PTU, but not carbimazole, inhibits the peripheral deiodination of T_4 to T_3. Thionamides may also have an immunosuppressive action.

Adverse effects. The most common adverse effect of anti-thyroid treatment is rash and arthropathy (5%) and less commonly agranulocytosis, hepatitis, aplastic anaemia and lupus-like syndromes (Table 43.5). Overall, serious effects such as these occur in approximately 0.3% of patients treated. These side effects usually occur during the first 6 weeks of treatment, but this is not invariable. Cross-sensitivity between carbimazole and PTU is around 10%, and the patient can often be safely changed to the alternative agent if an adverse event occurs.

Regular monitoring of white cell counts has been advocated, but is not warranted. Agranulocytosis is a rare event, and even if it does occur, it happens rapidly such that routine monitoring of white cell counts may miss it. At the time of prescription, all patients should be counselled about the possible implication of sore throat, mouth ulcers and pyrexia, and instructed to seek an urgent (within hours) full blood count. This verbal information should be backed up by written advice which should specify where the patient should go for the blood test. An abnormal white cell count should prompt urgent admission under a specialist endocrine team.

Table 43.5 Adverse effects of thionamides

	Adverse effect	Comments
Skin	Pruritic, maculopapular rash	Most common in first 6 weeks May disappear spontaneously with continued treatment Can be treated with an antihistamine Change to alternative agent Occurs in 5% of patients
	Urticarial rash with systemic symptoms, that is fever, arthralgia	Discontinue drug Alternative treatment required
Haematological	Agranulocytosis	Most common in first 6 weeks Incidence increases with age Discontinue drug Reversible Consider alternative treatment Occurs in 0.3% of patients
	Leucopoenia	Transient Continue treatment Does not predispose to agranulocytosis
Other	Hepatitis Vasculitis Hypoprothrombinaemia Aplastic anaemia Thrombocytopenia	Rare Discontinue drug

Treatment regimen

Carbimazole is usually given initially at a dose up to 40–60 mg daily, depending on the severity of the condition. It can be given as a single daily dose in multiples of 20 mg tablets to aid adherence. Although the plasma half-life is short (4–6 h), the biological effect lasts longer (up to 40 h). T_4 concentrations are checked at 6-week intervals until the patient is clinically euthyroid and the T_4 and T_3 levels are normalised. (TSH remains suppressed for at least 4 weeks after resolution of significant thyrotoxicosis, so TSH levels are unhelpful in the early stages of treatment.)

At this point, a decision is made about ongoing treatment. It is simplest to continue a high dose of carbimazole to suppress endogenous thyroid hormone production and to give a standard replacement dose of thyroxine to maintain euthyroidism, the 'block and replacement' regimen. This combination results in a steadier thyroid state, reduces the need for blood monitoring and requires fewer hospital attendances. Since adverse drug effects are allergic and not dose related, it is no more risky than tailored dose regimens.

Pregnancy is a specific situation, however, in which tailored dose PTU should be used. Both the immunoglobulins which cause Graves' disease and thionamide drugs cross the placenta and will affect the fetal thyroid, but maternal thyroxine is not able to reach the fetus. Thus, the lowest possible dose of PTU (preferred to carbimazole in pregnancy) should be used and the fetus closely monitored for heart rate and growth. Breast-feeding is considered to be safe when mothers are taking thionamides.

Patient counselling

Patients should be advised of the importance of regular clinic attendance. This is necessary to monitor both therapeutic outcome and the development of adverse effects. The development of skin rashes, mouth ulcers or a sore throat should be reported by the patient, immediately investigated and a full blood count performed (see Box 43.5). It may be dangerous to treat these symptoms with over-the-counter medication before carrying out further investigations.

It is important for the patient to understand the difference between specific anti-thyroid therapy and symptomatic treatment. The patient should also be advised about the timing of doses to aid adherence. Following completion of a course of treatment, the patient should understand relapse may occur, and medical help should be sought if the initial symptoms recur.

Thyroid ablative therapy

Thyroid ablation is required for all patients with toxic multinodular goitres, those who have relapsed or are likely to relapse after drug therapy for Graves' disease and those who are allergic to thionamides. Thyroid ablation can be achieved by radioiodine or surgery.

Radioactive iodine. Radioiodine therapy is extremely easy to administer by mouth and is very effective for a large majority of patients. It is contraindicated in pregnancy and breastfeeding and is usually avoided in children. It is known to make ophthalmopathy worse in some patients with Graves' disease, but giving prednisolone 0.5 mg/kg for 3 weeks and commencing thyroxine replacement early (3 weeks after radioiodine) can mitigate this. Despite public concern in relation to radioactivity, accumulated experience over more than 60 years has not demonstrated any discernible risk of genetic, leukaemic or lymphoma risk (Vanderpump et al., 1996).

Box 43.5 Counselling points for patients on anti-thyroid drugs

1. Carbimazole can be given as a single daily dose.
2. Identify anticipated duration of treatment.
3. Explain block and replacement regimens.
4. Explain use of adjuvant therapy, for example, β-blockers.
5. Encourage reporting of skin rashes, sore throat or mouth ulcers. Provide written guidance.
6. Ensure the patient understands the need for regular review.
7. Outline management of relapse.

The commonest complication is the development of hypothyroidism. Doses sufficient to cause thyrotoxicosis to remit will result in virtually 100% of patients given radioiodine for Graves' disease becoming hypothyroid and around 50% of those treated for multinodular disease. Patients should be counselled to expect to require lifelong thyroxine treatment after radioiodine therapy.

Anti-thyroid drugs must be withdrawn before radioiodine is given and should not be restarted for at least 3 days afterwards (otherwise, the isotope will not be trapped by the thyroid). The author conventionally recommends they be stopped 7 days before radioiodine. Since the ablative effect of radioiodine usually commences within 2–3 months, many patients with mild or moderate disease will not need to restart their drug treatments, though close patient monitoring is required. Patients with severe thyrotoxicosis should restart their anti-thyroid drugs on day 3. Treatment is then withdrawn periodically to assess the effects of the radioiodine.

The patient receiving radioiodine treatment is effectively radioactive for 6 weeks without ill effect. Since the patients are not at risk from this radioactivity, it seems inherently unlikely that the public faces any risk at all to health. Nevertheless, there are regulations governing exposure to radiation, which must be followed. After a standard 555-MBq dose, a patient must for 14 days avoid close continuous contact (2 m) with other persons for periods of more than 1 h, undertake to be careful in disposing of urine, and must not work. For 24 days, they must avoid close contact with children and pregnant women. In practice, it is these regulations and the concerns they engender in the patient that result in a proportion of patients preferring a surgical approach.

Surgery

Surgery is required for those patients with very large goitres, patients who cannot be persuaded of the safety of radioiodine and those who have reacted adversely to both thionamides in pregnancy. The hyperthyroid patient to be treated surgically should first be rendered biochemically euthyroid whenever possible, but occasionally surgery needs to be performed as a semi-urgent procedure. This may require urgent patient preparation with a combination of anti-thyroid drugs and β-blockers, and iodide given as Lugols solution. Iodide exerts a (usually) transient inhibitory effect on the ability of the gland to trap iodide, and it may also reduce the vascularity of the gland. In doses of 800–1200 mg/day, lithium is an effective anti-thyroid drug for patients who have reacted to thionamides. Lithium levels should be monitored to minimise toxicity. β-Blockers should be introduced and the dose titrated to reduce the pulse rate to below 80 beats/min. They are usually continued for 1 week postoperatively. It is imperative that treatment is given right up to the time of operation and the operation deferred if the pulse rate is not adequately controlled. Inadequate pre-treatment can result in the occurrence of thyroid crisis.

Complications of surgery include the generic ones of anaesthetic risk, bleeding, thromboembolic disease and infection. Specific risks of thyroid surgery include damage to recurrent laryngeal nerves (which may be particularly important to actors, singers and teachers) and hypoparathyroidism as a result of interference of the blood supply to the parathyroids or their inadvertent removal during surgery. If this occurs, tetany will begin within 48 h of the operation, and treatment should be initiated with intravenous calcium gluconate. All patients who have undergone partial thyroidectomy should have serum calcium estimation 3 months after operation since the development of hypoparathyroidism can be delayed. Later complications of thyroidectomy include hypothyroidism and recurrent thyrotoxicosis.

Treatment of complications

Ophthalmopathy

In most patients with Graves' disease, no specific treatment is required for the eyes. The commonest complaint is of 'grittiness', which can be treated with hypromellose eye drops or gel. If lid retraction is severe, inadequate lid closure can result in early morning soreness. This can be alleviated by the short-term use of 5% guanethidine eye drops instilled each night and morning. The eyes should be monitored for any signs of infection, and treated appropriately.

Fortunately, severe eye involvement occurs in less than 2% of patients with Graves' disease. Progressive ophthalmopathy producing severe complications from proptosis, diplopia or visual failure should be treated with high-dose steroid therapy (prednisolone, 60 mg daily) until symptoms resolve. Failure to respond is an indication for orbital irradiation or surgical decompression, but such patients should be under the care of a highly specialised ophthalmic surgeon.

Treatment of localised myxoedema

Myxoedema is usually localised to small areas and is asymptomatic. More extensive disease causes difficulty in walking and considerable discomfort. Probably the most effective therapy is the nightly topical application of steroid creams, such as betamethasone, under occlusive polythene dressings.

Thyroid crisis

This condition can develop in any patient with significant untreated thyrotoxicosis but is most common in those with severe Graves' disease. It is precipitated in such patients by infection, injury, trauma, anesthetics, surgery and radioiodine. There is rapidly progressive tachycardia, muscle weakness (including cardiomyopathy) hyperthermia, sweating and vomiting compounding hypotension with ensuing circulatory collapse. In addition, patients are extremely anxious and often psychotic. It should be managed as a medical emergency in a high-care area. In addition to supportive measures, specific anti-thyroid therapy is required along with drugs, which inhibit deiodination of T_4 to T_3. PTU (inhibits deiodinase) is given orally (or via NG tube) in high dose along with Lugols iodine. Glucocorticoids should be given i.v. as they also inhibit deiodinase. Effective β-blockade is required by i.v. infusion (propranolol preferred as it also inhibits deiodinase).

Drugs and the thyroid

From the previous pages, it will be evident that many commonly used drugs can affect the thyroid. This section draws together the most frequently encountered problems. In clinical practice, drug effects and interactions produce thyrotoxicosis, hypothyroidism or disturb thyroid function tests. It is worth specifically noting amiodarone, which contains large quantities of iodide which is released into the circulation during drug metabolism. The effects of amiodarone on the thyroid are extensive and complex.

Drugs and thyrotoxicosis

Table 43.2 indicates drug treatments associated with thyrotoxicosis. Amiodarone-induced thyrotoxicosis (AIT) is caused by two entirely different mechanisms. Type 1 AIT is similar to iodide-induced thyrotoxicosis and results from activation of nodular disease or of latent Graves' disease in patients with thyroid autoimmunity. In this condition, the thyroid is actively synthesising hormone and treatment is with thionamides. Type 2 AIT has features similar to thyroiditis with leakage of pre-formed thyroid hormone, low uptake of radiolabel on scanning and is treated with glucocorticoids. AIT is an extremely challenging condition to manage for multiple reasons. These include difficulty in discrimination between type 1 and type 2 disease, each of which have different treatments, and the facts that most patients are taking amiodarone for serious cardiac dysrhythmias and amiodarone has a very long tissue half-life. These patients should be under the care of a specialist endocrinology team.

A recent observation has been the increased frequency of Graves' disease in patients undergoing bone marrow transplantation, after administration of alemtuzumab (CAMPATH, a monoclonal antibody to CD52 cells), or alpha-interferon for multiple sclerosis and during Highly Active Anti-Retroviral Treatment (HAART) of HIV infection. It is thought that these cases all have immunological reconstitution as an underlying factor in their aetiology (Weetman, 2009).

Drugs and hypothyroidism

Amiodarone is frequently associated with the development of hypothyroidism, particularly in those patients with positive TPO antibodies, indicative of latent Hashimoto's disease. Such patients seem particularly sensitive to the high levels of iodine liberated by drug metabolism, and it is thought that hypothyroidism occurs because of a failure of the patient's thyroid to escape from the suppressive effect of iodine on thyroxine synthesis (the Wolff-Chaikoff effect). If amiodarone can be withdrawn, hypothyroidism will resolve over a period of months. More often, however, amiodarone is continued and thyroxine treatment is required.

Lithium inhibits T_4 and T_3 release from the thyroid (making it a useful adjunctive treatment for thyrotoxicosis in patients who react to thionamides) and causes a goitre in 40% of patients and hypothyroidism in 20%, again more commonly in those with positive TPO antibodies. Like amiodarone, lithium is usually continued and these patients are treated with thyroxine. Drug-related interference with absorption of thyroxine is one of the causes of hypothyroidism in patients treated with thyroxine. Table 43.2 indicates the agents which may be implicated.

Calcium and parathyroid hormone

Physiology

Most individuals possess four parathyroid glands situated posterior to the upper and lower lobes of the thyroid. These glands secrete parathyroid hormone (PTH). Calcium is approximately 50% ionically bound to albumin, and it is the unbound ionised plasma calcium levels which regulate the secretion of PTH, increased calcium concentration suppressing secretion and low levels stimulating it. PTH is an 84-amino acid straight-chain polypeptide which acts on hormone-specific receptors on target tissue cells. PTH acts on the renal tubular transport of calcium and phosphate and also stimulates the renal synthesis of 1,25-dihydroxycolecalciferol.

PTH and vitamin D act to maintain plasma calcium levels within the normal range. PTH increases distal tubular reabsorption of calcium and decreases proximal and distal tubular reabsorption of phosphate. The effects of PTH on bone are complex. The two major cell types in bone are osteoblasts and osteoclasts. Osteoblasts are responsible for the synthesis of extracellular bone matrix and priming of its subsequent mineralisation. Osteoclasts decalcify and digest the protein matrix of bone, liberating calcium. PTH stimulates osteoclast-mediated bone resorption but, in addition, has an anabolic effect on bone, with an increase in osteoblast number and function.

Hypoparathyroidism/hypocalcaemia

Hypoparathyroidism is the clinical state which may arise either from failure of the parathyroid glands to secrete PTH or from failure of its action at the tissue level.

Aetiology

Hypoparathyroidism most commonly occurs as a result of surgery for thyroid disease or after neck exploration and resection of adenoma causing hyperparathyroidism. In experienced hands, the incidence of permanent hypoparathyroidism is less than 1% for all thyroid and parathyroid surgery. Other causes include autoimmune parathyroid destruction either as an isolated idiopathic disorder or as part of a multiple endocrine deficiency characterised by hyposecretion of several endocrine glands. Transient hypoparathyroidism with symptomatic hypocalcaemia can occur in neonates. The condition pseudohypoparathyroidism occurs in patients with defects of the PTH receptor such that though PTH levels are normal (or raised), calcium is low. Increasingly, reports are identifying acute symptomatic hypocalcaemia and hypomagnesaemia complicating the use of omeprazole and other protein pump

inhibitors. These patients are severely magnesium depleted and have an acquired hypoparathyroidism which is reversible on stopping the offending drug (Cundy and Dissanayake, 2008).

Clinical manifestations

Most of the clinical features of hypoparathyroidism are due to hypocalcaemia. The decrease in ionised plasma calcium levels leads to increased neuromuscular excitability. The major signs and symptoms are shown in Box 43.6.

Investigations

Hypocalcaemia associated with undetectable or low plasma PTH levels is consistent with hypoparathyroidism. Total plasma calcium levels should always be corrected for any abnormality in the plasma albumin concentration using the following equation.

$$Corrected\ calcium = measured\ calcium + \{0.02 \times (40 - plasma\ albumin)\}$$

Hyperphosphataemia is often present. It should be noted that there are many other causes of hypocalcaemia (Box 43.7). Pseudohypoparathyroidism is easily distinguished as it is associated with excessive PTH secretion and reduced target organ responsiveness. Drugs that may produce hypocalcaemia include calcitonin, plicamycin (formerly mithramycin), phosphate, bisphosphonates, phenytoin, phenobarbital, colestyramine, cisplatin, 5-FU and high-dose i.v. citrate or lactate.

Treatment

Severe, acute hypocalcaemia with tetany should be treated with intravenous calcium gluconate. Initially, 10 mL of 10% calcium gluconate is given by slow intravenous injection,

Acute pancreatitis

---

preferably with ECG monitoring. If the patient can swallow, oral therapy should then be commenced. If further parenteral therapy is required, 20 mL of 10% injection should be added to each 500 mL of intravenous fluid and given over 6 h. The plasma magnesium level should always be measured in patients with hypocalcaemia, and if low, magnesium therapy instituted.

For chronic treatment, PTH therapy is not currently a practical option as the hormone has to be administered parenterally, and the current high cost is prohibitive. Maintenance treatment for hypoparathyroidism is easily achieved with a vitamin D preparation to increase intestinal calcium absorption, often in conjunction with calcium supplementation. Details of the preparations available are given in Table 43.6. Ergocalciferol (vitamin D_2) is difficult to use and is not recommended. It has a long pharmacological and biological half-life, takes 4–8 weeks to restore normocalcaemia and its effects can persist for up to 4 months following withdrawal. In contrast, calcitriol and its synthetic analogue alfacalcidol are much easier to use. Alfacalcidol restores normocalcaemia within 1 week and its effects only persist for 1 week following withdrawal, permitting greater flexibility in dosage manipulation. The usual daily dose is 0.5–2 μcg. Patients need close monitoring initially until stable normocalcaemia is achieved and thereafter at a minimum of 6-month intervals indefinitely.

Hyperparathyroidism

Hyperparathyroidism occurs when there is increased production of PTH by the parathyroid gland. Primary hyperparathyroidism causes hypercalcaemia. Secondary hyperparathyroidism reflects a physiological response to hypocalcaemia or hyperphosphataemia.

Epidemiology

Recent studies in the USA and Europe indicate an incidence rate for primary hyperparathyroidism of 25 cases per 100,000 of the population per year. The incidence is two to three times higher in women than in men, and the disease most commonly presents between the third and fifth decades.

Aetiology

Primary hyperparathyroidism is due to the development of either single parathyroid adenomas or rarely (<5%) hyperplasia of all four glands. It may occur as part of the dominantly inherited multiple endocrine neoplasia (MEN) syndromes.

There are several conditions associated with secondary hyperparathyroidism, including chronic renal failure and vitamin D deficiency. Chronic renal failure is the commonest cause. In the early stages of the disease, a rise in the plasma phosphate concentration causes stimulation of PTH release and, in more advanced renal impairment, reduced 1 α-hydroxylation of vitamin D results in reduced intestinal calcium absorption, hypocalcaemia and further stimulation

Table 43.6 Vitamin D preparations

Drug	Preparations	Activity
Ergocalciferol (calciferol, vitamin D$_2$)	Calciferol injection 7.5 mg (300,000 units/mL) Calciferol tablets 250 μcg (10,000 units) and 1.25 mg (50,000 units) Calcium and ergocalciferol tablets (2.4 mmol of calcium + 400 units of ergocalciferol)	Requires renal and hepatic activation
Colecalciferol (vitamin D$_3$)	A range of preparations containing calcium (500–600 mg) and colecalciferol (200–440 units)	Requires renal and hepatic activation
Alfacalcidol (1 α-hydroxycolecalciferol)	Alfacalcidol capsules, 250 ng, 500 ng and 1 μcg Alfacalcidol injection, 2 μcg/mL	Requires hepatic activation
Calcitriol (1,25-dihydroxycholecalciferol)	Calcitriol capsules, 250 ng and 500 ng Calcitriol injection, 1 μcg/mL	Active
Dihydrotachysterol	Dihydrotachysterol oral solution, 250 mg/ml	Requires hepatic activation

of the parathyroid glands. Tertiary hyperparathyroidism occurs in a minority of patients with end-stage renal failure when hyperplastic parathyroid glands become autonomous and secrete PTH in levels that raise calcium levels above normal.

Clinical manifestations

The clinical features of primary hyperparathyroidism are shown in Box 43.8. These are related to the effects of hypercalcaemia itself, plus the effects of mobilisation of calcium from the skeleton and excretion in the urine. With increasingly early recognition of the biochemical abnormalities of primary hyperparathyroidism largely due to automated measurement of plasma calcium, most patients are identified at an early stage with mild or asymptomatic disease. The classical presenting features of bone disease and renal stones are now relatively uncommon. Although radiological evidence of bone disease is now rare in these patients, measurement of bone mineral content by densitometry (DEXA) scanning usually indicates that bone loss is accelerated and the risk of osteoporotic fractures later in life is increased.

Box 43.8 Signs and symptoms in hyperparathyroidism

Anorexia, weight loss
Polydipsia, polyuria
Mental changes: poor concentration and memory
Fatigue
Nausea, dyspepsia and vomiting
Constipation
Hypertension
Renal stones
Conjunctival and corneal 'calcium' deposits
Bone pain and deformity
Pathological fractures

Investigations

Hypercalcaemia is the primary biochemical abnormality in primary hyperparathyroidism. Phosphate levels are often decreased and PTH levels are either inappropriately normal in the face of hypercalcaemia or elevated. In a patient with borderline elevation of calcium and a normal or only marginally elevated PTH, the benign condition familial hypocalciuric hypercalcaemia (FHH) must be excluded. Urine calcium excretion is increased in primary hyperparathyroidism and low in FHH.

There are many other causes of hypercalcaemia, including malignancy (including myeloma), drugs (thiazides, excess vitamin D), thyrotoxicosis, immobilisation and sarcoidosis. In all these situations, PTH levels are undetectable as the normal parathyroid glands appropriately switch off production of PTH in the face of hypercalcaemia. The most common cause of symptomatic hypercalcaemia in clinical practice is that associated with malignancy and this diagnosis must always be excluded.

Localisation of parathyroid tumours is only required in those listed for neck exploration. Most parathyroid surgeons request a neck ultrasound prior to performing a neck exploration. Isotope scanning, CT, MRI and selective venous sampling are reserved for those patients (around 1% in experienced hands) in whom the adenoma cannot be located at the first operation.

Treatment

Surgical removal of the adenoma or removal of all hyperplastic tissue is the only curative treatment for primary hyperparathyroidism; however, the natural history of hyperparathyroidism is not fully documented. Some studies have indicated that over 50% of untreated patients with primary hyperparathyroidism show no deterioration over 5 years, but the longer-term effects on renal function and bone mass

remain unknown. In practice, many patients are observed and their specific problems separately addressed. Thus, patients receive bisphosphonates for osteoporosis, anti-hypertensives, acid-lowering therapy and laxatives.

The main indications for surgical treatment are persistent hypercalcaemia > 2.85 mmol/L, symptomatic hypercalcaemia, renal impairment, renal stones and progression of osteoporosis. Postoperatively, temporary hypocalcaemia (hungry bones) is common. In patients with bone disease, treatment with alfacalcidol and calcium supplements should be started on the day before the operation. Approximately 10% of surgically treated patients develop permanent hyperparathyroidism.

Treatment of hypercalcaemia

Severe hypercalcaemia is a common medical emergency. It must be corrected whilst investigation continues to identify the cause. Table 43.7 shows the treatments available. In practice, rehydration and parenteral bisphosphonates, for example, pamidronate 60 mg in 250 mL normal saline over 30 min, will normalise calcium over 72 h in most patients.

Table 43.7 Treatment of hypercalcaemia

Mechanism	Treatment
Increase urinary calcium excretion	Normal saline plus loop diuretic
Reduce bone resorption	Bisphosphonates Calcitonin Gallium, mithramycin
Reduce gastro-intestinal absorption	Glucocorticoids in calcitriol dependent (vitamin D excess, sarcoid and some lymphoma patients)
Chelation Dialysis	Intravenous EDTA or phosphate

Case studies

Case 43.1

Mrs HP is a 49-year-old professional singer with Graves' disease. She was initially treated with carbimazole but developed a severe generalised rash, which necessitated withdrawal of the drug. A similar rash occurred within 2 weeks of starting PTU. She is overtly thyrotoxic with a blood pressure of 160/50 mmHg, a pulse of 110 beats/min and a large thyroid gland with a vascular bruit. Laboratory results show an elevated free T_4 and an undetectable TSH.

Questions

1. What are the options for treatment and what factors would you discuss with her that could influence her choice of treatment modality?

2. Mrs HP elects to have an ablative dose of radioactive iodine. What adjunctive therapy would you now consider?

Answers

1. This lady has experienced true allergic reactions to both available thionamide drugs and remains thyrotoxic. She should be counselled that thyroid ablation is required and that the treatment options include an ablative dose of radioactive iodine or thyroidectomy. It is necessary to consider features which would make surgery preferable. These would include concern about malignancy, features of local compression including difficulty swallowing or respiratory stridor, a large goitre causing cosmetic embarrassment or inability to receive radioiodine treatment (pregnancy, childhood). Radioactive iodine is more often an appropriate choice of treatment in patients who have either failed to achieve a remission with, or who have reacted adversely to, thionamides. It is known to be an entirely safe form of treatment though restrictions are placed on a patient for up to 1 month after the dose to reduce the public's exposure to radioactivity. Specific to this lady is her profession as a singer. She should be warned that surgery can rarely damage the recurrent laryngeal nerve leading to permanent hoarseness. This complication of surgery is often an important factor in choice of treatment for those who use their voice in their work (singers, actors, teachers, etc.).

2. To reduce the risk of inducing a thyroid crisis, attempts to render Mrs HP euthyroid before the dose of radioiodine should be made. If not asthmatic, she should be commenced on full doses of β-blockers. Propranolol-modified release is particularly useful as a once daily regimen will assist adherence and propranolol, unlike many other β-blockers, inhibits peripheral conversion of T_4 to T_3. Lithium should be commenced at 800 mg daily and will effectively reduce thyroid hormone secretion. Lithium has the useful added benefit of enhancing thyroidal retention of radioiodine and improving its efficacy in control of thyrotoxicosis in patients with large goitres.

Case 43.2

Mrs MG is a 66-year-old woman. She has a history of depression over many years and has recently been complaining of increased tiredness, lethargy and weight gain. Thyroid function tests have shown a TSH elevated at 12 mU/L (normal range, 0.3–5 U/L), but her free T4 is normal at 12.7 pmol/L (normal range, 10.5–25 pmol/L). Her TPO antibodies are positive at a dilution of 1:1600.

Questions

1. What is Mrs MG's thyroid state?
2. Should T_4 therapy be instituted, and if so, how should it be monitored?
3. What warnings should she receive about treatment?

Answers

1. Mrs MG has autoimmune thyroid disease and compensated hypothyroidism. The T_4 is being maintained in the normal range by virtue of increased TSH drive to the thyroid. Left alone, the disturbance is likely to get worse.

2. The British Thyroid Association has recommended that thyroxine treatment should be offered to patients with positive TPO antibodies whose TSH is above 10 mU/L and those whose TSH is between 5 and 10 who have symptoms which are compatible with hypothyroidism. Thyroxine should be commenced at 50 μcg daily and the dose adjusted along conventional lines by measurement of TSH at least 6 weeks after each dose change.

3. It is common for the non-specific symptoms of hypothyroidism to be mimicked by other conditions, notably depression. Mrs MG should be counselled that thyroxine treatment, though appropriate, may not reverse her symptoms and that if she remains symptomatic when her TSH has been normalised, alternative explanations for her symptoms will need to be considered.

Case 43.3

Mr DE is a 21-year-old man who has been treated for autoimmune hypothyroidism over 5 years. He is now prescribed thyroxine at 350 μcg daily, but his TSH has remained elevated varying between 24.4 and 68.2 mU/L. He also has alopecia areata which has had a very severe effect on his self-confidence and he has been seeing a private trichologist for advice.

Question

What are the possible causes of failure to satisfactorily treat his hypothyroidism?

Answer

The commonest cause of failure to suppress TSH is patient non-adherence with treatment. This is especially likely in a young patient with an irregular lifestyle and the elderly who are forgetful. Very few patients require as much as 350 μcg daily for an adequate replacement dose.

If assessment of the patient suggests that adherence is good, consideration must be given to malabsorption of thyroxine. This can be associated with inflammatory bowel disease or coeliac disease. A host of commonly prescribed drugs and medicines available over the counter may reduce thyroxine absorption. Amongst others, these include ferrous sulphate, some antacids and multivitamin preparations. In this patient, there may be other agents recommended by the trichologist which could affect thyroxine absorption.

Case 43.4

Mr JJ is 55 years old. Six years previously, he had a myocardial infarct complicated by ventricular tachycardia. He had an implantable defibrillator placed and has been taking amiodarone 200 mg daily. He is complaining of increasing exertional dyspnoea and weight loss. His free T_4 is returned at 99.1 pmol/L (normal range, 10.5–25 pmol/L) with a fully suppressed TSH confirming thyrotoxicosis.

Questions

1. How does amiodarone cause thyrotoxicosis?
2. What investigations should be considered?
3. How should he be managed?

Answers

1. Amiodarone-induced thyrotoxicosis (AIT) has two distinct causes. Type 1 AIT results from activation of latent autoimmune disease (Graves' disease) or nodular thyrotoxicosis, and is believed to be mediated by the high levels of iodine liberated through metabolism of the drug. Type 2 AIT is due to thyroiditis and results from release of pre-formed hormone. It is good practice to check a patient for thyroid autoantibodies and nodular disease prior to commencing amiodarone as patients with these markers are more likely to develop AIT.

2. It can be difficult to distinguish between type 1 and type 2 AIT. Patients should be referred urgently to a specialist endocrine unit. Thyroid autoantibodies should be requested along with an ultrasound of the thyroid, which will confirm nodular disease and will often show characteristic features of thyroiditis.

3. Type 1 AIT responds to thionamides. Type 2 AIT is treated with glucocorticoids. Amiodarone should be discontinued whenever possible, but since most patients have serious underlying coronary disease, this must only be done in conjunction with the patient's cardiologist. In practice, many patients are treated with both agents whilst awaiting the results of investigation and cardiology advice. For Type 2 AIT, if amiodarone can be discontinued, the thyroiditis usually resolves over a period of weeks. Otherwise, hypothyroidism will usually ensue and can be managed with thyroxine. For Type 1 AIT, if amiodarone cannot be stopped, thyroid ablation is required after control is achieved with thionamides. Since radioiodine uptake is characteristically low in patients receiving amiodarone, surgical removal may be necessary.

Case 43.5

Mrs BK is aged 76. During a routine assessment by her primary care doctor, her calcium is found to be 2.74 mmol/L (normal range, 2.25–2.60 mmol/L), her PTH is normal at 5.3 pmol/L (normal range, 1.5–6.5) and she has no symptoms. She has been taking weekly alendronate for osteoporosis over the past 4 years since sustaining a wrist fracture. Repeat DEXA scans have shown improved bone mineral density on this treatment. Review of her record discloses that her calcium was 2.67 at the time of her fracture, but at the time of her hysterectomy, when she was 45, her calcium was measured at 2.26 mmol/L.

Questions

1. Does she have primary hyperparathyroidism? Does she require any additional tests?
2. How should she be treated? What are the indications for neck exploration in primary hyperparathyroidism?

Answers

1. Yes, she has primary hyperparathyroidism. An elevated calcium with an inappropriately elevated PTH points to this diagnosis. If her parathyroid glands were normal, the PTH level would be undetectable in the face of the hypercalcaemia. It is very common for marginal hypercalcaemia to go unrecognised for many years in hyperparathyroidism. In the absence of the previous evidence of normocalcaemia from many years earlier, demonstration of an elevated urine calcium excretion would be required to provide reassurance that she does not have the inherited condition familial hypocalciuric hypercalcaemia (a benign and lifelong marginal elevation of calcium resulting from reduced sensitivity of the calcium sensing receptor in parathyroid cells). Since it is known that she once was normocalcaemic, no additional biochemical investigation is required though a renal scan should be arranged to rule out nephrocalcinosis.

2. Mrs BK can be reassured that no additional treatment is required at present. She should receive advice that her condition requires monitoring by annual calcium measurements and repeat DEXA scans to demonstrate continued response to alendronate. Absolute indications for neck exploration would include the presence of renal stone disease, progressive osteoporosis despite treatment, hypercalcaemic symptoms and calcium above 3.0 mmol/L. Relative indications include young age at diagnosis, a rising calcium over

2.8, osteoporosis or osteopaenia. A majority of patients with hyperparathyroidism can be satisfactorily treated medically.

Case 43.6

Ms JH is 22 years old when she is admitted to hospital after a grand mal convulsion. She is found to have a serum calcium of 1.15 mmol/L (normal range, 2.25–2.60) and an undetectable PTH.
She has been very well with no recent symptoms of paraesthesiae or tetany, and has no other biochemical abnormalities.

....

Questions

1. What is the likely cause of her hypocalcaemia? Does she require any other tests?
2. How should she be treated?
3. What monitoring does she require?

....

Answers

1. She has hypoparathyroidism which is most likely to be autoimmune. Hypoparathyroidism can be associated with neck surgery, neck malignancy and infiltrative disease. Very rarely, it is due to embryonic failure of development of branchial arches, is congenital and is associated with severe immunological failure. The absence of any previous history in a fit young woman makes other causes of hypoparathyroidism exceedingly unlikely. The absence of symptoms of hypocalcaemia indicates that her calcium has been low for a long time and supports a relatively slowly progressive pathology. Rapid falls to this level (e.g. after neck surgery) are invariably associated with hypocalcaemic symptoms. It is very likely that her magnesium level will also be low, and this should be tested as it may also require treatment in the short-term.

2. The emergency treatment of hypocalcaemia is by regular i.v. infusions of 10% calcium gluconate with magnesium sulphate by slow i.v. infusion in patients with significant hypomagnesaemia. Ms JH will then need oral vitamin D analogues plus calcium supplements to maintain her calcium in the normal range. 1-alpha cholecalciferol is an effective and convenient preparation and the dose required ranges from 0.5 to 2 μcg daily.

3. Once her calcium has been normalised, she will need biochemical monitoring at a minimum of 6-month intervals. She should never be discharged as in some patients the calcium can drift above the normal range. If this is not identified, renal stone disease and renal failure can develop.

Diabetes mellitus 44

Elizabeth A. Hackett and Stephen N. J. Jackson

Key points

- Diabetes is a chronic, incurable condition with an estimated 2.6 million individuals diagnosed in the UK, equivalent to over 4% of the population. An estimated 2.3 million have type 2 disease, 0.3 million type 1 disease and another 500,000 are probably undiagnosed.
- Up to 15% of hospital in-patients will have diabetes.
- The cost of treating diabetes and its related complications, around £9 billion, equates to 10% of the total NHS budget.
- Effective control of diabetes (glycaemic levels, blood pressure, dyslipidaemia) reduces the risk of developing long-term complications and saves both lives and money.
- Abdominal fat is metabolically different from subcutaneous fat and is implicated in the development of insulin resistance and type 2 diabetes.
- Extreme hyperglycaemia and hypoglycaemia may lead to diabetic emergencies, both of which carry mortality risks.
- There is a wide variety of insulins and delivery devices available, allowing regimens to be tailored to individual need.
- Dietary modifications and oral medicines may maintain adequate glycaemic control in type 2 diabetes, but in time many patients will eventually require insulin.
- People with diabetes require education and support to enable them to effectively manage their disease, diet and lifestyle.

Box 44.1	Aetiological classification of diabetes mellitus

Type 1 (β-cell destruction, usually leading to absolute insulin deficiency)
Autoimmune
Idiopathic

Type 2 (may range from predominantly insulin with relative insulin deficiency to a predominantly secretory defect with or without insulin resistance)

Other specific types
Genetic defects of β-cell function
Genetic defects in insulin action
Diseases of the exocrine pancreas
Endocrinopathies
Drug or chemical induced, for example, nicotinic acid, glucocorticoids, high-dose thiazides, pentamidine, interferon-α
Infections
Uncommon forms of immune-mediated diabetes
Other genetic syndromes sometimes associated with diabetes
Gestational diabetes

Diabetes mellitus is the most common of the endocrine disorders. It is a chronic condition, characterised by hyperglycaemia and due to impaired insulin secretion with or without insulin resistance. Diabetes mellitus may be classified according to aetiology, by far the most common types being type 1 and type 2 diabetes (Box 44.1). More than 2.6 million people in the UK have diabetes, and by the year 2025, this number is estimated to rise to 4 million.

Type 1 diabetes is a disease characterised by the destruction of the insulin-producing pancreatic β-cells, the development of which is either autoimmune T-cell mediated destruction (type 1A) or idiopathic (type 1B). In over 90% of cases, β-cell destruction is associated with autoimmune disease. Type 1 diabetes usually develops in the young (below the age of 30), although it can develop at any age and is usually associated with a faster onset of symptoms leading to dependency on extrinsic insulin for survival.

Type 2 diabetes is more common above the age of 40, with a peak age of onset in developed countries between 60 and 70 years, although it is being increasingly seen in younger people and even children. The prevalence of type 2 diabetes varies widely in different populations, being six times more common in those of South Asian origin compared with those of Northern European origin. It is caused by a relative insulin deficiency and insulin resistance. Symptoms are generally slower in onset and less marked than those of type 1. Type 2 diabetes may be an incidental finding, particularly when patients present with complications associated with the disease, for example, heart disease. Type 2 disease often progresses to the extent whereby extrinsic insulin is required to maintain blood glucose levels. The differences between type 1 and type 2 diabetes are highlighted in Table 44.1. It is sometimes difficult to distinguish clinically between type 1 and type 2 diabetes. The important thing to be aware of is that it is predominantly the degree of metabolic abnormality that is the key determinant of the form of treatment.

Two other varieties of non-typical diabetes that may be seen are latent autoimmune diabetes in adults (LADA) and maturity-onset diabetes of the young (MODY). LADA occurs in younger, leaner individuals who appear to have type 2 diabetes as they do not become ketotic and may manage without insulin for a time. Antiglutamic acid decarboxylase (GAD) antibodies may be present and the individual usually

685

Table 44.1 Differences between type 1 and type 2 diabetes

Type 1 diabetes	Type 2 diabetes
β-cell destruction	No β-cell destruction
Islet cell antibodies present	No islet cell antibodies present
Strong genetic link	Very strong genetic link
Age of onset usually below 30	Age of onset usually above 40
Faster onset of symptoms	Slower onset of symptoms
Insulin must be administered	Diet control and oral hypoglycaemic agents often sufficient control
Patients usually not overweight	Patients usually overweight
Extreme hyperglycaemia causes diabetic ketoacidosis	Extreme hyperglycaemia causes hyperosmolar hyperglycaemic state

progresses to insulin more rapidly than those with other varieties of type 2 diabetes. MODY was noted over 30 years ago and described a subset of type 2 diabetes of young onset, often with a positive family history. Genetic studies have now identified this to be a monogenic autosomal dominant form of diabetes. MODY related to the glucokinase gene typically causes a resetting of the glucose level with a 'mild' non-progressive hyperglycaemia in which diet treatment is usually sufficient. Other types of MODY are related to mutations in the hepatocyte nuclear factor genes and usually develop during adolescence or the early 20s. Pharmacological treatment is required, but sulphonylureas are extremely effective and insulin can usually be avoided.

Epidemiology

The incidence of type 1 diabetes is increasing worldwide, for unknown reasons. It is speculated that environmental changes may be causing modification to the diabetes-associated alleles. Also, since the introduction of insulin in the 1930s, an increasing number of people with type 1 diabetes have had children. There are major ethnic and geographical differences in the prevalence and incidence of type 1 diabetes. Figures are highest in Caucasians (especially Scandinavians), while the disorder is rare in Japan and the Pacific area. In northern Europe, the prevalence is approximately 0.3% in those under 30 years of age. Type 1 diabetes may present at any age, but there is a sharp increase around the time of puberty and a decline thereafter. Approximately 50–60% of patients with type 1 will present before 20 years of age.

Type 2 diabetes is much more common than type 1, accounting for 90% of people with diabetes. It usually occurs in those over the age of 40 years. Estimates in the UK suggest that type 2 diabetes currently affects approximately 2.3 million people, and up to another 500,000 are thought to be undiagnosed. The incidence of type 2 rises with age and with increasing obesity. As with type 1, there are major ethnic and geographical variations. In general, in non-obese populations, the prevalence is 1–3%. In the more obese societies, there is a sharp increase in prevalence with estimates of 6–8% in the USA, increasing to values as high as 50% in the Pima Indians of Arizona. Diabetes is six times more common among Asian immigrants in the UK than in the indigenous population. World studies of immigrants have suggested that the chances of developing type 2 are between two and 20 times higher in well-fed populations than in lean populations of the same race.

Aetiology

Both genetic and environmental factors are relevant in the development of type 1 diabetes, but the exact relationship between the two is still unknown. There is a strong immunological component to type 1 and a clear association with many organ-specific autoimmune diseases. Circulating islet cell antibodies (ICAs) are present in more than 70% of those with type 1 at the time of diagnosis. Family studies have shown that the appearance of ICAs often precedes the onset of clinical diabetes by as much as 3 years. Type 1 has been widely believed to be a disease of clinically rapid onset, but the development is related to a slow process of progressive immunological damage. However, it is not currently possible to use screening methods to reliably identify patients who will develop diabetes in the future. The final event that precipitates clinical diabetes may be caused by sudden stress such as an infection when the mass of β-cells in the pancreas falls below 5–10%.

Studies have been carried out in which patients with newly diagnosed type 1 were treated with immunosuppressive therapies such as ciclosporin, azathioprine, prednisolone and anti-thymocyte globulin. When started soon after diagnosis, these therapies showed transient improvements in clinical measures and increased the rate of remissions in which insulin was not required. However, their use is limited in an otherwise healthy and young population due to potential toxicity and the risks associated with immune suppression.

Studies have investigated the use of anti-CD3 monoclonal antibodies. When newly diagnosed type 1 patients are treated with short courses of anti-CD3 monoclonal antibodies, smaller insulin doses are required. This relates to better preservation of β-cell function.

Type 2 diabetes also has a strong genetic predisposition. Identical twins have a concordance rate approaching 100%, suggesting the relative importance of inheritance over environment. If a parent has type 2, the risk of a child eventually developing type 2 is 5–10% compared with 1–2% for type 1. Type 2 diabetes occurs because of the progressive development of insulin resistance and β-cell dysfunction, the latter leading to an inability of the pancreas to produce enough insulin to overcome the insulin resistance. About 85% of people with type 2 diabetes are obese. This highlights the clear association

between type 2 and obesity, with obesity causing insulin resistance. In particular, central obesity, where adipose tissue is deposited intra-abdominally rather than subcutaneously, is associated with the highest risk. Body mass index (BMI) has been used as an indicator for predicting type 2 risk; however, it does not take fat distribution into account, so waist circumference measurements are now being increasingly used.

Pathophysiology

The islets of Langerhans form the endocrine component of the pancreas, constituting 1% of the total pancreatic mass. Insulin is synthesised in the pancreatic β-cells, initially as a polypeptide precursor, preproinsulin. The latter is rapidly converted in the pancreas to proinsulin. This forms equal amounts of insulin and C-peptide through removal of four amino acid residues. Insulin consists of 51 amino acids in two chains (the A chain contains 21 amino acids and B chain contains 30), connected by two disulphide bridges. In the islets, insulin and C-peptide (and some proinsulin) are packaged into granules. Insulin associates spontaneously into a hexamer containing two zinc ions and one calcium ion.

Glucose is the major stimulant to insulin release. The response is triggered both by the intake of nutrients and the release of gastro-intestinal peptide hormones. Following an intravenous injection of glucose, there is a biphasic insulin response. There is an initial rapid response in the first 2 min, followed after 5–10 min by a second response which is smaller but sustained over 1 h. The initial response represents the release of stored insulin and the second phase reflects discharge of newly synthesised insulin. Glucose is unique; other agents, including sulphonylureas, do not result in insulin biosynthesis, only release. Once released from the pancreas, insulin enters the portal circulation. The liver rapidly degrades it and only 50% reaches the peripheral circulation. In the basal state, insulin secretion is at a rate of approximately 1 unit/h. The intake of food results in a prompt five- to tenfold increase. Total daily secretion is approximately 40 units.

Insulin circulates free as a monomer, has a half-life of 3–5 min and is primarily metabolised by the liver and kidneys. In the kidneys, insulin is filtered by the glomeruli and reabsorbed by the tubules and degraded. In both renal and hepatic disease, there is a decrease in the rate of insulin clearance, which may necessitate dosage reduction for those using exogenous insulin. Peripheral tissues such as muscle and fat also degrade insulin, but this is of minor quantitative significance.

The interaction of insulin with the receptor on the cell surface sets off a chain of messengers within the cell. This opens up transport processes for glucose, amino acids and electrolytes.

In type 1 diabetes, there is an acute deficiency of insulin that leads to unrestrained hepatic glycogenolysis and gluconeogenesis with a consequent increase in hepatic glucose output. Also, glucose uptake is decreased in insulin-sensitive tissues such as adipose tissue and muscle; hence, hyperglycaemia ensues. Either as a result of the metabolic disturbance itself or secondary to infection or other acute illness, there is increased secretion of the counter-regulatory hormones glucagon, cortisol, catecholamine and growth hormone. All of these will further increase hepatic glucose production.

In type 2 diabetes, the process is usually less acute, since insulin production decreases over a sustained period of time. Hyperinsulinaemia is able to maintain glucose levels for a period of time, but eventually β-cell function deteriorates and hyperglycaemia ensues. If this cycle is not interrupted, type 2 diabetes develops. Impaired glucose tolerance (IGT), impaired fasting glucose or hyperinsulinaemia may be detected before overt diabetes develops, and if so, a strict diet and exercise regimen leading to weight loss and improved insulin sensitivity may delay or even prevent the onset of diabetes. At the time of diagnosis, those with type 2 diabetes may have already lost about 50% of their β-cell function. Irrespective of treatment, β-cell function continues to decline with time, often leading to the need for regular insulin therapy.

Type 2 diabetes is also associated with the metabolic syndrome (or syndrome X), although the real relevance of this 'syndrome' continues to be debated in the literature (Khan et al., 2005). The metabolic syndrome is a group of risk factors commonly found in those with type 2 diabetes, including insulin resistance, glucose intolerance (type 2 diabetes or IGT), hyperinsulinaemia, hypertension, dyslipidaemia, central obesity, atherosclerosis and increased levels of procoagulant factors, for example, plasminogen activator inhibitor-1 and fibrinogen.

Pathophysiology of insulin resistance

Abdominal fat, found in abundance in the majority of those with type 2 diabetes, is metabolically different from subcutaneous fat and can cause 'lipotoxicity'. Abdominal fat is resistant to the antilipolytic effects of insulin, resulting in the release of excessive amounts of free fatty acids, which in turn lead to insulin resistance in the liver and muscle. The effect is an increase in gluconeogenesis in the liver and an inhibition of insulin-mediated glucose uptake in the muscle. Both these result in increased levels of circulating glucose. Further, excess fat itself may contribute to insulin resistance because when adipocytes become too large they are unable to store additional fat, resulting in fat storage in the muscles, liver and pancreas, causing insulin resistance in these organs.

Excess intra-cavity adipose tissue causes the oversecretion of some cytokines (adipokines or adipocytokines) associated with inflammation, endothelial dysfunction and thrombosis. Examples of such adipokines include plasminogen activator inhibitor-1 (which is prothrombotic), tumour necrosis factor-α and interleukin-6 (which are proinflammatory) and resistin (which causes insulin resistance). The atherosclerosis associated with insulin resistance is due to hypercoagulability, impaired fibrinolysis and the toxic combination of endothelial damage (caused by chronic, subclinical inflammation), oxidative stress and hyperglycaemia. Excess adipose tissue is also thought to cause undersecretion of a beneficial adipokine called adiponectin. Adiponectin suppresses the attachment of monocytes to endothelial cells, thereby protecting against vascular damage. People with type 2 diabetes have lower levels of adiponectin than those without diabetes and weight reduction increases adiponectin levels.

Clinical manifestations

The symptoms of both type 1 and type 2 diabetes are similar, but they usually vary in intensity. Those associated with type 1 diabetes are more severe and faster in onset. The symptoms are related to the osmotic effects of glucose and the abnormalities of energy partitioning. Common symptoms include polyuria (increased urine production, particularly noticeable at night) and polydipsia (increased thirst). These are a consequence of osmotic diuresis secondary to hyperglycaemia. These symptoms are frequently accompanied by fatigue due to an inability to utilise glucose and marked weight loss because of the breakdown of body protein and fat as an alternative energy source to glucose. Blurred vision caused by a change in lens refraction may also occur and patients should be advised that as glucose levels are normalised, vision normally improves and new spectacles should be avoided for the first 3 months of effective treatment of the hyperglycaemia. Patients may also experience a higher infection rate, especially Candida, and urinary tract infections due to increased urinary glucose levels.

Type 1 diabetes

The metabolic abnormality at presentation of an individual with type 1 diabetes is often profound. The symptoms mentioned earlier are usually extreme and of recent (days or weeks) onset. In a significant proportion, the presenting symptoms are those of diabetic ketoacidosis, nausea, vomiting, dehydration, shortness of breath secondary to an attempt by the respiratory system to neutralise the metabolic acidosis caused by the ketones and, in extreme cases, coma.

Type 2 diabetes

Many patients with type 2 diabetes have an insidious onset of hyperglycaemia, with few or no classic symptoms. This is particularly true in obese individuals, whose diabetes may be detected only after glycosuria or hyperglycaemia is found serendipitously. Some patients are unaware of the disease even with marked classic symptoms as they begin so gradually and over such a long period of time. Recurring infections, for example, urinary tract, chest, soft tissue, are common because sustained hyperglycaemia can result in severe impairment of phagocyte function, and raised glucose levels provide a growth medium for bacteria.

Generalised pruritus and symptoms of vaginitis, which may be due to candidal infection, are frequently the initial complaints of women with type 2 diabetes. Patients often present when the complications of sustained hyperglycaemia have already developed, for example, cardiovascular disease or renal disease. Retinopathy may be detected on routine ophthalmological examination. Alternatively, a combination of neuropathy, peripheral vascular disease (PVD) and infection may manifest as foot ulceration or gangrene. In some cases, patients present with hyperosmolar hyperglycaemic state (HHS) where glucose levels in excess of 35 mmol/L are found and excessive dehydration has occurred. Occasionally, patients with type 2 diabetes present with diabetic ketoacidosis, especially in severe infection or in those of African/Caribbean descent.

Diagnosis

In June 2000, the UK formally adopted the World Health Organization criteria for diagnosing diabetes mellitus that was initially published in 1999. It has since been updated and the diagnostic criteria have been reiterated (World Health Organization, 2006).

1. Diabetes symptoms (i.e. polyuria, polydipsia and unexplained weight loss) plus:
   - a fasting serum glucose concentration ≥7.0 mmol/L
   - or serum glucose concentration ≥11.1 mmol/L 2 h after 75 g anhydrous glucose in an oral glucose tolerance test (see later).
2. With no symptoms, diagnosis should not be based on a single glucose determination but requires confirmatory serum venous determination. At least one additional glucose test result, on another day with the value in the diabetic range, is essential, either fasting or from the 2-h post-glucose load. If the fasting value is not diagnostic, the 2-h value should be used.

Current recommendations are that the diagnosis is confirmed by a glucose measurement performed in an accredited laboratory on a venous serum sample. A diagnosis should never be made on the basis of glycosuria or a stick reading of a finger prick blood glucose alone, although such tests are being examined for screening purposes. Glycated haemoglobin (HbA$_{1c}$) is also not currently recommended for diagnostic purposes, although this is currently being considered.

Glucose tolerance test

The patient should not be taking any drugs which interfere with glucose handling. A normal diet with at least 150 g of carbohydrate per day should be consumed for the 3 days before the test, but the patient should be fasted from 8 pm (except for water) on the day before the test. The test should commence at around 9 am with a venous serum glucose test, followed by the administration of 75 g of glucose by mouth over a 5-min period. This is often given in the form of 394 mL of Lucozade® original. The second venous serum glucose sample is then taken 2 h after the drink. The patient should be seated and is not permitted to smoke, eat or drink anything other than water until the test is complete. As there is a risk of later-onset hypoglycaemia in some individuals, it is advisable to suggest that the patient has something to eat immediately upon completion of the test, especially if he/she is planning to drive.

Diabetic emergencies

Hypoglycaemia and extreme hyperglycaemia, causing diabetic ketoacidosis or hyperosmolar hyperglycaemic state, constitute the three acute emergencies associated with diabetes.

Hypoglycaemia

Hypoglycaemia can occur both with insulin treatment and in those taking some oral agents, especially the longer-acting sulphonylureas, for example, chlorpropamide and glibenclamide. Definitions of hypoglycaemia vary, and in particular, there is no WHO definition. However, symptoms caused by the release of counter-regulatory hormones predominantly adrenaline (epinephrine), noradrenaline (norepinephrine) and glucagon tend to occur when the venous serum glucose drops below 3.0 mmol/L in healthy individuals. These symptoms described in Box 44.2 are a normal physiological response to hypoglycaemia and should alert the person to consume carbohydrates. Individuals may not respond appropriately to hypoglycaemia of this degree for several reasons, termed hypoglycaemia unawareness. First, the relevance of the symptoms has not been explained to them. This is an educational failing. It is imperative, therefore, that

Box 44.2 Symptoms of hypoglycaemia
Autonomic
Sweating
Trembling
Tachycardia
Palpitations
Pallor
Neuroglycopaenic
Faintness
Loss of concentration
Drowsiness
Visual disturbances
Abnormal behaviour (agitation, aggressiveness)
Confusion
Coma
Other
Hunger
Headache
Perioral tingling/numbness

people with diabetes who are prescribed medication which is known to cause hypoglycaemia should be educated about the autonomic symptoms so that they may take action to avoid further decline of serum glucose. Second, the symptoms simply may not occur because of autonomic neuropathy. One of the commonest complications of diabetes is neuropathy, and when this includes the autonomic nervous system, there are no reliable symptoms to warn the individual that they are hypoglycaemic. A similar situation may occur as a consequence of drugs which suppress autonomic symptoms, such as β-blockers. Third, the patient may have recurrent hypoglycaemia. In those individuals who suffer frequent hypoglycaemic episodes, the autonomic symptoms may cease to occur. There is some evidence that the symptoms can be regained if, for a period of a few weeks, the serum glucose level can be maintained out of the hypoglycaemic range. Finally, the individual may be hypoglycaemia unaware because of alcohol intoxication.

If the serum glucose is allowed to drop to around 2 mmol/L, there are acute changes in cerebral function which lead initially to confusion. This is followed by coma, seizures and death if the glucose drops below about 0.5 mmol/L. Any cerebral malfunction is termed neuroglycopaenia.

Causes of hypoglycaemia

The most common causes of hypoglycaemia are either a decrease in carbohydrate consumption, excess carbohydrate utilisation from unexpected exercise or increase in circulating insulin (Table 44.2).

Nocturnal hypoglycaemia

Sometimes, hypoglycaemia occurs throughout the night. Symptoms may include restlessness, although this may not be identified unless observed by another person. When nocturnal hypoglycaemia occurs, the person often wakes feeling unrested, unwell or with a headache. Contrary to what might be expected, morning blood glucose readings may be high because

Table 44.2 Causes of hypoglycaemia	
Cause	Comment
Missed meals or delays in eating	Reduced carbohydrate intake, therefore reduction in glucose levels
Not eating the usual amount of carbohydrates	Reduced carbohydrate intake, therefore reduction in glucose levels
Increased doses of insulin	Increased uptake of glucose into cells and increased storage of glucose as glycogen
Increased doses of oral insulin secretagogues	Increased levels of insulin therefore increased uptake of glucose into cells and increased storage of glucose as glycogen
Introduction of other blood glucose-lowering agents to oral insulin secretagogues	Enhanced hypoglycaemic effects
Increase in exercise	Increased uptake of glucose into cells
Excessive alcohol consumption	Impaired gluconeogenesis
Liver disease	Impaired gluconeogenesis and glycogenolysis

a sustained hypoglycaemic episode leads counter-regulatory hormones to raise blood glucose levels. This could present a confusing picture as the obvious solution to a raised blood glucose level in the morning would be to increase the evening/night-time dose of insulin. However, in the case of nocturnal hypoglycaemia, this would make the problem worse. If nocturnal hypoglycaemia is suspected, then blood glucose should be measured at night, for example, 2.00–3.00 am. If confirmed, the patient should either have a snack before bedtime, reduce the evening/night-time dose of insulin, alter the timing of administration of the evening dose of intermediate- or long-acting insulin in order to delay the peak of bioavailability or change the intermediate-acting insulin to a peakless analogue as appropriate. It is important to discuss nocturnal hypoglycaemia with patients as there is often a fear of dying from unrecognised hypoglycaemia in sleep. This fear is unfounded because of the protection from hypoglycaemia severe enough to cause death afforded by the counter-regulatory hormones. This occurs even in those individuals with autonomic neuropathy.

Treatment of hypoglycaemia

If the patient is able to swallow safely without the risk of aspiration, then glucose should be taken orally. However, if unable to swallow or if there is a risk of aspiration because, for example, of a decreased level of consciousness, parenteral treatment should be given, either intravenous glucose or intramuscular glucagon.

The most effective oral treatments are pure sources of glucose, for example, five glucose tablets or glucose drinks such as 150 mL of Lucozade®. In an emergency, hot drinks should be avoided as they might burn and drinks containing milk are not suitable as the fat in milk slows down sugar absorption. Blood glucose levels should be measured about 10–15 min after treating hypoglycaemia. If below 3.5 mmol/L, more glucose should be consumed. If above 3.5 mmol/L and the next meal will be over 1 h, then a long-acting carbohydrate is also required, for example, bread or biscuits. However, if the person is taking an α-glucosidase inhibitor such as acarbose, then monosaccharide carbohydrates must be given because disaccharides and polysaccharides will not be absorbed due to inhibition of the enzymes cleaving carbohydrate into absorbable monosaccharide units.

Should parenteral treatment be required, 25 g of intravenous glucose or 1 mg of intramuscular glucagon is recommended. Glucagon takes approximately 15–20 min to work, but if the person has liver disease (cirrhosis) or is malnourished, then glucagon may not work because glucagon acts by mobilising glucose stores from the liver. In such cases, intravenous glucose must be given. A number of serious extravasation injuries, some necessitating amputation of the affected limb, have been caused by 50% glucose. As a consequence, many hospitals now use 20% glucose.

Diabetic ketoacidosis

Diabetic ketoacidosis is serious, and in developed countries, it has a mortality rate of 5–10%. It occurs because absence of insulin causes extreme hyperglycaemia. At the same time, the normal restraining effect of insulin on lipolysis is removed. Non-esterified fatty acids are released into the circulation and taken up by the liver, which produces acetyl coenzyme A (acetyl CoA). The capacity of the tricarboxylic acid cycle to metabolise acetyl CoA is rapidly exceeded. Ketone bodies, acetoacetate and hydroxybutyrate are formed in increased amounts and released into the circulation. Further, osmotic diuresis, caused by hyperglycaemia, lowers serum volume, causing dizziness and weakness due to postural hypotension. Weakness is increased by potassium loss, caused by urinary excretion and vomiting due to stimulation of the vomiting centre by ketones, and catabolism of muscle protein. When insulin deficiency is severe and of acute onset, all of these symptoms are accelerated. Ketoacidosis exacerbates the dehydration and hyperosmolarity by producing anorexia, nausea and vomiting. As serum osmolarity rises, impaired consciousness ensues with coma developing in approximately 10% of cases. Metabolic acidosis causes stimulation of the medullary respiratory centre, giving rise to Kussmaul respiration (deep and rapid breathing) in an attempt to correct the acidosis. The patient's breath may have the fruity odour of acetone (ketones) commonly described as smelling like pear drops or nail varnish remover.

Precipitating factors for diabetic ketoacidosis in type 1 disease are usually omission of insulin dose, acute infection, trauma or myocardial infarction. Although diabetic ketoacidosis is normally associated with type 1 diabetes, it may rarely occur in people with type 2.

Diagnosis of diabetic ketoacidosis

Diagnosis requires demonstration of hyperglycaemia and metabolic acidosis with the presence of ketones. The biochemical diagnosis of ketoacidosis is usually made at the bedside and confirmed in the laboratory. Urinalysis will show marked glycosuria and ketonuria. A blood glucose test strip usually shows a blood glucose level of more than 22 mmol/L. Formal laboratory measurement of glucose, urea, creatinine, electrolytes and venous bicarbonate should be carried out. Two potentially misleading laboratory results are the white blood cell count and serum sodium. The former will always be raised but correlates with the ketone body level and is not therefore a guide to infection. The serum sodium level will often be low due to the osmotic effect of glucose draining water from the cells and diluting the sodium. The sodium concentration will also be spuriously low if there is marked dyslipidaemia.

Treatment of diabetic ketoacidosis

Treatment comprises fluid volume expansion (initially with 0.9% sodium chloride), correction of hyperglycaemia and the presence of ketones (by infusion of insulin), prevention of hypokalaemia, and identification and treatment of any associated infection. Once the patient is better, they should be reviewed by the diabetes team in order to discuss how to avoid future episodes of diabetic ketoacidosis.

Hyperosmolar hyperglycaemic state

HHS is associated with type 2 disease and has a higher mortality rate (15%) than diabetic ketoacidosis. HHS usually occurs in middle-aged or elderly people, about 25% of whom have previously undiagnosed type 2 diabetes.

In HHS, unlike diabetic ketoacidosis, there is no significant ketone production and therefore no severe acidosis. Hyperglycaemia occurs gradually over a sustained period of time, leading to dehydration due to osmotic diuresis which, if severe, results in hyperosmolarity. Hyperosmolarity may increase blood viscosity and the risk of thromboembolism. Factors precipitating HHS are infection, myocardial infarction, poor adherence with medication regimens or medicines which cause diuresis or impair glucose tolerance, for example, glucocorticoids.

Diagnosis of HHS

The diagnostic features of HHS are hyperglycaemia (often in the region of 55 mmol/L, which is generally much higher than for diabetic ketoacidosis), dehydration and hyperosmolarity. There may be a mild metabolic acidosis but without marked ketone production. Conscious levels on presentation range from slight confusion to coma. In some cases, seizures occur. Serum sodium and potassium levels are usually normal, but creatinine is high. The average fluid deficit is 10 L, so circulatory collapse is common.

Treatment of HHS

Treatment requires fluid replacement to stabilise blood pressure and improve circulation and urine output. Sodium chloride 0.9% or 0.45% (if serum sodium is greater than 150 mmol/L) is given and monitoring of blood pressure and cardiovascular status undertaken. Potassium may be added if required. Insulin treatment is started via intravenous infusion but is not aggressive, since fluid replacement also lowers serum glucose levels. Prophylaxis or treatment for thromboembolism may also be required.

Long-term diabetic complications

Diabetes and its long-term complications cost the NHS substantial amounts of money – approximately 10% of the total budget (£173 million/week).

Although all long-term complications may occur in each type of diabetes, the spectrum of incidence is different. Many patients with type 2 diabetes have had their disease a long time before the diagnosis, by which time many have developed diabetic complications (Figs. 44.1 and 44.2). However, diabetic complications can be limited and sometimes prevented altogether if good management occurs from an early stage. Hyperglycaemia and hypertension are the two major modifiable risk factors that influence the development of diabetic complications.

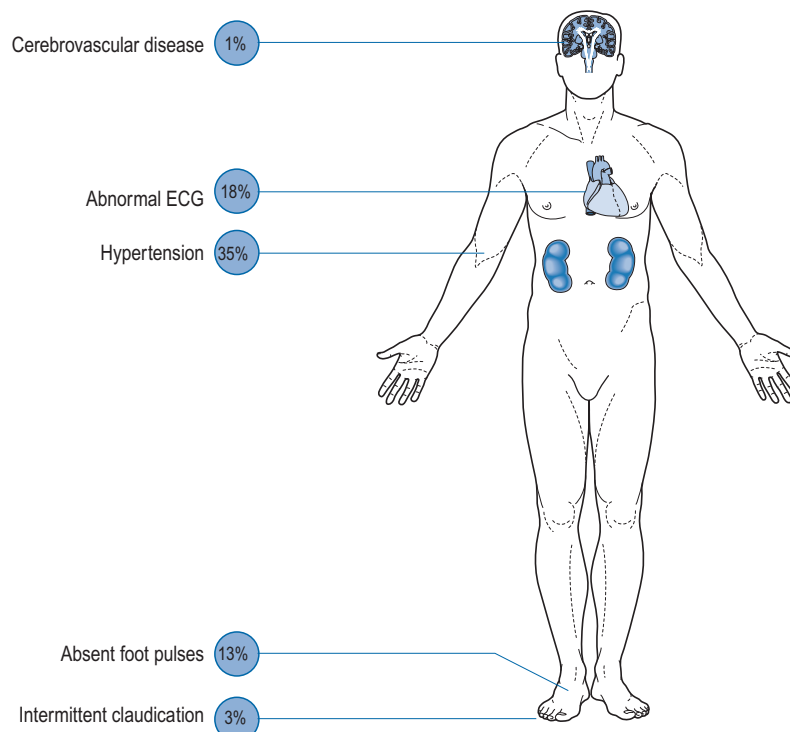
Patients with diabetes should undergo regular review of their disease management for early signs of associated complications and review of these risk factors and their management. Diabetic complications are frequently divided into macrovascular and microvascular complications. Macrovascular complications arise from damage to large blood vessels and microvascular complications occur from damage to smaller vessels. The general aetiology of macro- and microvascular


Fig. 44.1 Incidence of macrovascular complications at diagnosis in type 2 diabetes.

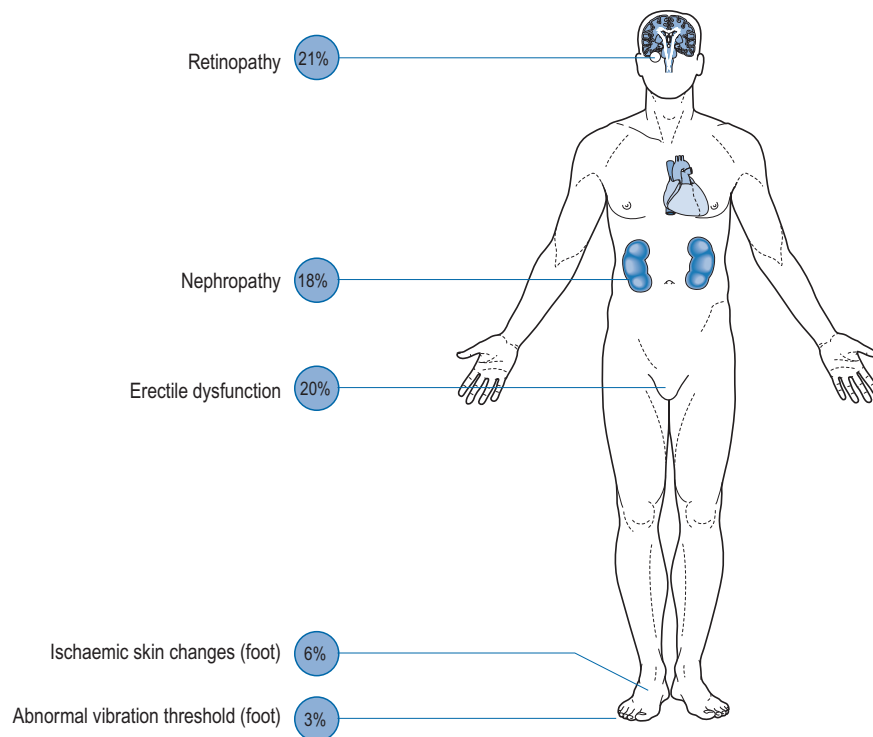
- Cerebrovascular disease 1%
- Abnormal ECG 18%
- Hypertension 35%
- Absent foot pulses 13%
- Intermittent claudication 3%


Fig. 44.2 Incidence of microvascular complications at diagnosis in type 2 diabetes.

complications is the same and results from atherosclerosis of the vessels, which may lead to occlusion. The main aims of treatment are, first, to prevent the immediate symptoms associated with diabetes, for example, polyuria, polydipsia, etc., and second, to prevent development, or slow the progression of the long-term disease complications.

Macrovascular disease

The risk of macrovascular complications, including cardiovascular disease (coronary heart disease and stroke) and PVD, is 2–4 times higher for people with diabetes.

Cardiovascular disease

The most common cause of death in people with type 2 diabetes is cardiovascular disease which accounts for an estimated 80% of deaths in this patient group. The risk of a person with diabetes having a myocardial infarction (MI) is the same as someone without diabetes having a second myocardial infarction. The risk of cardiovascular disease is increased further if nephropathy is present. Other cardiovascular disease risk factors are the same as in the non-diabetic population and include smoking, hypertension and dyslipidaemia. However, these risk factors are enhanced in the presence of diabetes, and therefore smokers are encouraged to stop, and individuals with hypertension and lipid disorders are actively reviewed and treated. Silent myocardial infarction (infarction with no symptoms) is more common in those with diabetes and may be due to cardiac autonomic neuropathy. Cerebrovascular disease is also more commonly associated with diabetes, and

patients have a greater mortality and morbidity compared to the general population.

Hypertension. Hypertension is twice as common amongst the diabetic population compared to the general population. It affects over 80% of those with type 2 diabetes. The treatment target ranges for people with diabetes are generally lower than for people without diabetes, as hypertension is associated with the development of macro- and microvascular complications. For people with type 2 diabetes, hypertension is a feature of the metabolic syndrome and is associated with insulin resistance. For those with type 1 disease, it is closely associated with renal disease.

Peripheral vascular disease

PVD affects the blood vessels outside the heart. In people with diabetes, it often affects the arteries of the legs and may give rise to intermittent claudication, a cramping pain experienced on walking, due to reversible muscle ischaemia secondary to atherosclerosis. The iliac vessels can be affected, causing buttock pain and also erectile dysfunction. If PVD is present, the risk of cardiovascular disease increases. About 20% of people with PVD die from myocardial infarction within 2 years of symptom onset.

PVD is also responsible for much of the morbidity associated with diabetic foot problems.

Microvascular disease

Microvascular complications include retinopathy, nephropathy and neuropathy.

Retinopathy

Diabetic retinopathy is the leading cause of blindness in people under the age of 60 in industrialised countries. Twenty years from the onset of diabetes, over 90% of people with type 1, and over 60% of people with type 2, will have diabetic retinopathy. The main problem with diagnosing retinopathy is that it is symptomless until the disease is far advanced. Therefore, if regular screening is not undertaken, diagnosis may not be made early enough for successful treatment intervention. Tight glycaemic control has been shown to prevent and delay the progression of retinopathy in patients with type 1 disease. Likewise, for patients with type 2 diabetes, both tight glycaemic control and tight blood pressure control reduce the risk of developing retinopathy. When retinopathy is detected early, sight may be saved by laser photocoagulation. In advanced cases, surgery may be required.

Pregnancy may worsen moderate-to-severe retinopathy, particularly if there is poor or sudden improvement in glycaemic control. However, tight glycaemic control during pregnancy reduces the long-term risks of retinopathy.

Nephropathy

In diabetic renal disease, the kidneys become enlarged and the glomerular filtration rate (GFR) initially increases. However, if the nephropathy progresses, the GFR starts to decline. Serum creatinine used alone to estimate renal function has limitations. The GFR can be estimated (eGFR). The most popular method is the modified Modification of Diet in Renal Disease (MDRD) formula, which requires serum creatinine, age, sex and ethnicity:

$$eGFR = 175 \times [\text{plasma creatinine} (\mu mol / L) \times 0.011312]^{1.154} \times$$
$$[\text{age in years}]^{0.203} \times [1.212 \text{ if black}] \times [0.742 \text{ if female}]$$
$$eGFR = \text{glomerular filtration rate} (mL / min per 1.73 m^2)$$

The presence of nephropathy is indicated by the detection of microalbuminuria (small amounts of albumin present in urine). If higher amounts of albumin are detected, this is termed proteinuria (or macroalbuminuria) and signifies more severe renal damage. Microalbuminuria is defined as an albumin:creatinine ratio (ACR) greater or equal to 2.5 mg/mmol (men) and 3.5 mg/mmol (women). Proteinuria may be defined as an albumin:creatinine ratio greater than 30 mg/mmol or albumin concentration greater than 200 mg/L. Proteinuria may progress to end-stage renal disease and require dialysis. Albumin in the urine increases the risk of cardiovascular disease, with microalbuminuria associated with 2–4 times the risk, proteinuria with nine times the risk and end-stage renal disease increasing risk by 50 times.

Tight control of both glycaemic levels and blood pressure reduces the risk of developing nephropathy. Angiotensin-converting enzyme (ACE) inhibitors and/or angiotensin receptor blockers (ARBs) are the treatments of choice, since both have been demonstrated to provide renal protective effects additional to their antihypertensive effects. ACE inhibitors and ARBs have been shown to delay the progression to proteinuria in patients with microalbuminuria. Although not proven for all individual drugs in these classes, it is considered to be a class effect. However, these drugs should be used with care if there is a risk of renovascular disease.

Peripheral neuropathy

Peripheral neuropathy is the progressive loss of peripheral nerve fibres resulting in nerve dysfunction. Diabetic neuropathies can lead to a wide variety of sensory, motor and autonomic symptoms. The most common is the symmetrical distal sensory type, which is particularly evident in the feet and may slowly progress to a complete loss of feeling. It is most prevalent in elderly patients with type 2 diabetes but may be found with any type of diabetes, at any age beyond childhood. Painful diabetic neuropathy is another manifestation of sensory neuropathy; it can be extremely disabling and may cause considerable morbidity. Guidance on the treatment of painful neuropathy is available (National Institute for Health and Clinical Excellence, 2010). Diabetic proximal motor neuropathy is rapid in onset and involves weakness and wasting, principally of the thigh muscles. Muscle pain is common and may require opiate analgesia. Distal motor neuropathy can lead to symptoms of impaired fine co-ordination of the hands and/or foot slapping.

Autonomic neuropathy may affect any part of the sympathetic or parasympathetic nervous systems. The most common manifestation is diabetic impotence. Bladder dysfunction usually manifests as loss of bladder tone with a large increase in volume. Diabetic diarrhoea is uncommon, but can be troublesome as it tends to occur at night. Gastroparesis may cause vomiting and delayed gastro-intestinal transit and variable food absorption, causing difficulty in the insulin-treated patient. Postural hypotension due to autonomic neuropathy is uncommon but can be severe and disabling. Disorders of the efferent and afferent nerves controlling cardiac and respiratory function are more common, but rarely symptomatic. Autonomic neuropathy may also cause dry skin and lack of sweating, both of which may contribute to diabetic foot problems.

Macro- and microvascular disease combined

Diabetic foot problems

Infected diabetic foot ulcers account for the largest number of diabetes-related hospital bed-days and are the most common non-trauma cause of amputations. The rate of lower-limb amputation in people with diabetes is 15 times higher than in the general population. The lifetime risk of a person with diabetes developing a foot ulcer is around 15%. Diabetic foot ulcers are a costly problem and are associated with considerable morbidity. Foot problems often develop as a result of a combination of specific problems associated with having diabetes, that is sensory and autonomic neuropathy, PVD and hyperglycaemia. Poor foot care and poorly controlled diabetes are also contributory factors. Development of foot

ulcers may be partly preventable by patient education. People with diabetes learn that their feet are particularly vulnerable, and if problems arise, they must seek immediate professional advice.

There are three main types of foot ulcers: neuropathic, ischaemic and neuroischaemic. Neuropathic ulcers occur when peripheral neuropathy causes loss of pain sensation. The ulcers can be deep but are usually painless and are caused by trauma to the foot which is not noticed until after significant damage has occurred. Ischaemic ulcers result from PVD and poor blood supply causing a reduction in available nutrients and oxygen required for healing. Ischaemic ulcers are painful and usually occur on the distal ends of the toes. Most ulcers have elements of both neuropathy and ischaemia and are termed neuroischaemic.

Diabetic foot ulcers are prone to infection, the most common pathogens being staphylococci and streptococci. Wounds with an ischaemic component are commonly infected with anaerobic organisms.

Charcot arthropathy. This is an uncommon foot complication caused by severe neuropathy. It results in chronic, progressive destruction of joints with marked inflammation. Reduced bone density leads to bone fractures, altered foot shape and gross deformity. Owing to the deformity which occurs, excess pressure over protruding bone frequently leads to ulceration unless footwear is extensively modified.

Treatment

Treatment for people with diabetes includes advice on nutrition, physical activity, weight loss and smoking cessation if appropriate. Drug therapy is prescribed where necessary.

Structured education programmes

It is now considered standard care to offer people with diabetes education to help them manage their diabetes themselves on a day-to-day basis. This should be offered in a structured way and based upon theories of adult learning. Group education is now invariably offered as it offers economic advantages over one-to-one education as well as peer support. Examples of such programmes include DAFNE (Dose Adjustment For Normal Eating) in type 1 diabetes and DESMOND (Diabetes Education for Self Management in the Ongoing and Newly Diagnosed) in type 2 diabetes.

Diet

Dietary control is the mainstay of treatment for type 2 diabetes and plays an integral part in the management of type 1. Dietary recommendations have undergone extensive review in recent years and considerable changes have been made. Generally speaking, healthy eating advice for people with diabetes is the same as for the general population. Some of the general dietary advice that patients should be given is shown in Box 44.3.

Box 44.3   General dietary advice for people with diabetes

- Eat regular meals based on starchy foods such as bread, pasta, potatoes, rice and cereals. Whenever possible, choose high-fibre varieties of these foods, for example, wholemeal bread and wholemeal cereals which have a lower glycaemic index.
- Try to cut down on fat, particularly saturated (animal) fats. Monounsaturated fats such as olive oil are preferred. Use less butter, margarine, cheese and eat fewer fatty meals. Choose low-fat dairy foods, for example, skimmed milk and low-fat yoghurt. Grill, steam or oven bake instead of frying or cooking with oil or other fats.
- Try to eat at least five portions of fruit and vegetables every day. This provides vitamins and fibre as well as helping to balance the overall diet.
- Cut down on sugar and sugary foods. Sugar can still be used as an ingredient in foods and baking as part of a healthy diet. Use sugar-free, low-sugar or diet squashes and fizzy drinks, as sugary drinks cause blood glucose levels to rise quickly.
- Use less salt as high intake can raise blood pressure. Food can be flavoured with herbs and spices instead of salt.
- Drink alcohol in moderation. Two units/day for a woman and three for a man. A small glass of wine or half a pint of normal strength beer is one unit. Never drink on an empty stomach as alcohol can exacerbate hypoglycaemia.

Carbohydrates and sweeteners

The blood glucose level is closely affected by carbohydrate intake. Previous guidance for people with diabetes recommended eating about the same amount of carbohydrate at approximately the same time each day and generally advised restriction of carbohydrates. As a consequence of this advice, a number of people tended to eat more fat. Current guidance for carbohydrate consumption still emphasises the importance of total carbohydrate intake, but it focuses on selecting carbohydrates with a lower glycaemic index, that is carbohydrates which give sustained release of sugars over time, as opposed to carbohydrates with a high glycaemic index that give high peaks in blood glucose concentration. Examples of carbohydrates with a low glycaemic index include beans, pulses and starchy foods like wholemeal pasta and wholegrain bread. Total carbohydrate consumption should not exceed 45–60% of energy intake, with monounsaturated fat and carbohydrate combined making up 60–70% of energy intake.

Sucrose or 'sugar' may be included in the diet, according to the new guidance, but sucrose should account for no more than 10% of total energy and should be spaced throughout the day, rather than being consumed all in one go. Sugar alcohols, for example, sorbitol, maltitol and xylitol, often used as sugar substitutes in diabetic foods, are expensive and may cause diarrhoea. They are therefore considered to confer little advantage over sucrose. Non-nutritive or intense sweeteners such as aspartame, saccharin, acesulphame K, cyclamate and sucralose may be useful, especially for those who are overweight.

Alcohol. Alcohol contains carbohydrates and, if consumed in excess, may cause hyperglycaemia. However, more dangerously, it is also associated with later-onset (up to 16 h postalcohol) hypoglycaemia and hypoglycaemia unawareness.

Alcohol must be restricted to the same maximum weekly quantities as for the general population, that is, 14 units (women) and 21 units (men), with 1–2 alcohol-free days per week. In these quantities, alcohol has cardioprotective effects.

Fats

Since obesity is a major problem in type 2 diabetes and fats contain more than twice the energy content per unit mass than either carbohydrate or protein, consumption of fats should be limited. Monounsaturated fats have a lower atherogenic potential and are therefore recommended as the main source of dietary fat. Intake of fat should be less than 35% of total energy consumption, with saturated and trans-unsaturated fats accounting for less than 10% of energy intake and mono-unsaturated fats providing 10–20%.

Examples of monounsaturated fats are olive oil and rapeseed (also known as canola) oil. Saturated fats are chiefly of animal origin, for example, beef, pork, lamb, whole milk products with some found in plants, for example, cocoa butter, coconut oil and palm oil. Trans-unsaturated fats are found in hydrogenated vegetable oils and hard margarines. N-6 polyunsaturated fats such as cornflower, sunflower, safflower, soyabean oil and seed oils should account for less than 10% of energy intake, and n-3 polyunsaturated fats (fish oils) should be eaten as fish, rather than fish oil supplements, once or twice a week.

Protein

For adults without nephropathy, protein intake is recommended as less than 1 g/kg of body weight, equivalent to about 10–20% of total energy intake. For those with nephropathy, protein intake may need to be further restricted, but this requires expert dietetic advice and supervision.

Fibre

There is no quantitative dietary recommendation for fibre intake. Dietary fibre has useful properties in that it is physically bulky, and it delays the digestion and absorption of complex carbohydrates, thereby minimising hyperglycaemia. For the average person with type 2 diabetes, 15 g of soluble fibre from fruit, vegetables or pulses is likely to produce a 10% improvement in fasting blood glucose, glycated haemoglobin and low-density lipoprotein cholesterol (LDL-C). Insoluble fibre from cereals, wholemeal bread, rice and pasta has no direct effect on glycaemia or dyslipidaemia, but it has an overall benefit on gastro-intestinal health and may help in weight loss by promoting satiety.

Salt

Sodium chloride should be limited to a maximum of 6 g/day. A reduction in salt intake from 12 to 6 g/day has been shown to produce a reduction in systolic blood pressure of 5 mmHg and a reduction of 2–3 mmHg in diastolic pressure.

Obesity management in type 2 diabetes

Obesity management is a very important issue in type 2 diabetes owing to the insulin resistance which occurs as a consequence of excess adipose tissue. Whilst any loss of weight in those who are overweight or obese is of benefit in diabetes in that it is associated with an improvement in dyslipidaemia, hypertension and glycaemic control, bariatric surgery can lead to profound improvements. Recent studies have shown that laparoscopic banding can induce remission of type 2 diabetes in 48% of individuals and Roux-en-y bypass procedures can induce remission in 84%. More importantly, bariatric surgery is associated with a 92% relative risk reduction in diabetes-specific mortality and consequently should be offered to those with diabetes who have a BMI of 35 kg/m^2 or higher (National Institute for Health and Clinical Excellence, 2006). For those with a BMI of 28 kg/m^2 or greater, it is recommended that the pancreatic and gastric lipase inhibitor, orlistat, be considered as the modest weight reduction which can be achieved with this agent yields benefits in diabetes control.

Insulin therapy in type 1 diabetes

All patients with type 1 diabetes require treatment with insulin in order to survive. Exogenous insulin is used to mimic the normal physiological pattern of insulin secretion as closely as possible for each individual patient. However, a balance is required between tight glycaemic control and hypoglycaemia risk. If the risk of hypoglycaemia is high, then it may be necessary to aim for less tight glycaemic control. There is a wide variety of insulin preparations available which differ in species of origin, onset of action, time to peak effect and duration of action (Table 44.3).

Species of origin

Until the 1980s, insulin was obtained and purified from the pancreas of pigs and cows. Human sequence insulins have subsequently been developed using recombinant DNA technology and are now the most common insulins in use. Many of the animal-derived products have been withdrawn, but some animal insulins continue to be available. Porcine insulin only differs from human insulin in one amino acid at the end of the B chain (position B30). Human insulin may be produced semi-synthetically by enzymatic modification of porcine insulin (emp). However, most human insulin is manufactured using genetic engineering and recombinant DNA technology. This is done by inserting either synthetic genes for the insulin A chain and B chain, or the proinsulin gene, or a proinsulin-like precursor into *Escherichia coli* (crb, prb) or yeast cells (pyr). The cells are fermented, resulting in large amounts of the recombinant protein, which is then converted into insulin and purified. More recently, human insulin analogues have been developed through genetic and protein engineering, to produce insulin molecules with differing pharmacokinetic properties.

It is now standard practice to commence all patients requiring insulin on human insulin. In those who have been changed from animal to human insulin, there has been concern that

Table 44.3 Insulin preparations

Preparation	Origin	Onset (h)	Peak (h)	Duration (h)
Soluble insulin				
Human Actrapid (pyr)	H	0.5	2–5	8
Humulin S (prb)	H	0.5	1–3	5–7
Hypurin Bovine Neutral	B	0.5/1	2–5	6–8
Apidra (insulin glulisine)	H	0.25	1	3–4
Humalog (insulin lispro)	H	0.25	1–1.5	2–5
Novorapid (insulin aspart)	H	0.25	1–3	3–5
Hypurin Porcine Neutral	P	0.5/1	2–5	6–8
Insuman Rapid (crb)	H	0.5	1–3	7–9
Biphasic insulin				
Humulin M3 (prb)	H	0.5	1–8.5	14–15
NovoMix 30	H	0.25	1–4	Up to 24h
Humalog Mix 25	H	0.25	1–2	22
Humalog Mix 50	H	0.25	1–2	22
Hypurin Porcine 30/70	P	0.5	4–12	24
Insuman Comb 15 (prb)	H	0.5	2–4	12–20
Insuman Comb 25 (prb)	H	0.5	2–4	12–19
Insuman Comb 50 (prb)	H	0.5	1–4	12–16
Isophane insulin				
Hypurin Porcine Isophane	P	2	6–12	24
Insuman Basal (crb)	H	1	3–4	12–20
Human Insulatard (pyr)	H	2	4–12	24
Humulin I (prb)	H	0.5	2–8	18–20
Hypurin Bovine Isophane	B	2	6–12	24
Insulin zinc suspension (mixed)				
Hypurin Bovine Lente	B	2	8–12	30
Protamine zinc				
Hypurin Bovine PZI	B	4	10–20	36
Long-acting analogues				
Lantus (insulin glargine)	H	2–4	No peak	20–24
Levemir (insulin detemir)	H	2–4	6–14	16–20

Insulin preparations classified as being of human (H), beef (B) or pork (P) origin; prb, proinsulin recombinant bacteria; crb, chain recombinant bacteria; pyr, precursor yeast recombinant.

human insulin may be associated with an increased risk of hypoglycaemic unawareness, although current evidence suggests that this is unlikely if the switch is done appropriately. Human insulin may be more potent dose for dose than animal insulin due to the formation of antibodies. Conventionally, doses are reduced by 25% or more when changing from animal to either human or analogue insulin.

Insulin preparations

The onset of action, peak effect and duration of action are determined by the insulin type and by the physical and chemical form of the insulin.

Fast-acting insulins. Conventional fast-acting insulins are soluble insulins (also known as neutral insulins). After subcutaneous injection, soluble insulin appears in the circulation within 10 min. The concentration rises to a peak after about 2 h and then declines over a further 4–8 h. This absorption curve can be contrasted with the physiological insulin concentration curve, where peak concentrations are reached 30–40 min after a meal and decline rapidly to 10–20% of peak levels after about 2 h.

The fast-acting recombinant insulin analogues (insulin lispro, insulin aspart and insulin glulisine) are more rapidly absorbed than the non-analogue soluble insulins and have a shorter duration of action. The analogues therefore offer more flexibility. They are more convenient for some patients as they can be given immediately before a meal rather than the 30 min before recommended for human soluble insulin. Another benefit is a reduced risk of hypoglycaemia because of the shorter duration of action. These pharmacokinetic differences arise as the short-acting analogues remain as monomers (single units) unlike regular soluble human insulins which self-associate into a hexameric (6-unit) form. Hexamers need to

dissociate into dimers and monomers to be readily absorbed from subcutaneous tissue, which causes delayed absorption.

Intermediate-acting insulins. Conventional intermediate-acting insulins are insoluble, cloudy suspensions of insulin complexed with either protamine (also known as isophane or NPH insulin) or zinc (lente insulin).

Over time, insulin dissociates from the protamine, which gives the preparation its extended activity. The onset of action is usually 1–2 h with the peak effect being seen at 4–8 h. There is considerable inter-patient variation in the duration of action, but it usually requires twice-daily administration to adequately cover a 24-h period. Protamine insulin and soluble insulin do not interact when mixed together. Therefore, ready-mixed (biphasic) preparations are available containing both isophane and soluble insulin.

Long-acting insulins. More recently, long-acting insulin analogues such as insulin glargine and insulin detemir have been developed using recombinant DNA technology. They both have a duration of action of about 24 h, a more predictable, flat profile of action with no pronounced peaks and less inter- and intra-subject dosing variability.

Insulin glargine differs from human insulin as two arginine molecules have been added to the B chain at the C-terminal end. This alters the isoelectric point from pH 5.4 to 6.7. Also, the neutral amino acid glycine replaces the asparagine residue at position A21. The changes mean that insulin glargine remains soluble at a slightly acidic pH. The product is buffered at a pH of 4. Once it is injected into subcutaneous tissue, it forms a microprecipitate in the more neutral surrounding pH. This allows slow absorption from the injection site.

Insulin detemir has a long duration of action and is formulated at neutral pH. It differs from human insulin by omission of the amino acid threonine at position B30 and the attachment of a fatty acid chain (myristic acid) to lysine at position B29. The modification allows the insulin molecule to reversibly bind to albumin, via the fatty acid chain, following absorption from subcutaneous injection. This reduces the amount of free, active insulin detemir (bound insulin is inactive). The long duration of action is produced by dissociation of the insulin molecule from albumin.

Insulin delivery

All the currently licensed insulin products are available only by injection. An inhaled insulin product available for a short period of time is no longer obtainable. The subcutaneous route is routinely used for maintenance therapy, as opposed to the intravenous route which is sometimes used in hospital. Insulin can be injected subcutaneously into the outer aspect of the thigh, abdominal wall, buttocks or upper arm. However, injecting into the arm is incredibly difficult and is therefore not usually a site of choice. The main advantages associated with subcutaneous injection are accessibility, which allows most patients to administer their own insulin. However, this route cannot be regarded as physiological as it delivers insulin to the systemic rather than portal circulation.

A small number of patients still use disposable plastic syringes with insulin from a vial as their means of insulin administration, although the vast majority now use pen injection devices. Insulin pens may either be refillable or disposable. Although not in themselves improving diabetic control, they are popular amongst users since they are compact and more convenient as they remove the need to draw up insulin from a vial.

Intravenous insulin delivery should be used in the management of ketoacidosis and hyperosmolar states. The intravenous route is also preferable for diabetic patients due to have major surgery and who may be 'nil by mouth' after surgery. The short half-life of insulin (3–5 min) means that changes in infusion rate have a rapid effect on insulin action and glycaemic control. Intravenous insulin is commonly delivered as either a continuous insulin infusion at a variable rate or an infusion made with a fixed amount of insulin, with glucose and potassium in the same bag. The former is also commonly referred to as a 'sliding scale' insulin regimen, in which the rate of infusion is adjusted according to frequent blood glucose readings, usually hourly. It is administered with a co-infusion of glucose (with potassium, unless patient is hyperkalaemic). The latter type of insulin infusion is known as GKI (glucose, potassium, insulin), GIK or the Alberti regimen. Intravenous insulin regimens are not routinely recommended for patients who are eating and drinking.

Insulin regimens

Standard insulin regimens for managing type 1 disease vary between two to five injections daily. They must be tailored to the individual patient and will depend on lifestyle, willingness to achieve the best control and ability to cope with both injecting insulin and subsequent monitoring of blood glucose. The chosen insulin regimen is negotiated between patient and health care professional and may change throughout life according to priorities and patient preference. Starting doses of insulin and the ratio of short- to intermediate-acting insulin are very variable. In patients who are very active, such as manual workers and those who exercise regularly, the starting dose should be kept low to reduce the risk of significant hypoglycaemia.

Mealtime plus basal regimens. The best control for type 1 diabetes may be attained using a mealtime plus basal regimen, also referred to as a basal-bolus regimen. This mimics normal physiological insulin release more closely than other regimens. A mealtime plus basal regimen requires mealtime injections of insulin with a fast-acting preparation, preferably with an analogue, plus one or two injections of a basal (intermediate- or long-acting) insulin. This may require up to five injections a day. As a general rule, with this regimen, the soluble insulin injections given before each meal usually comprise 40–60% of the total daily dosage. Some individuals may benefit from exogenous insulin delivery via a continuous subcutaneous insulin infusion administered via a pump worn on their person. The pump can be programmed to give a different basal rate of infusion at different times of day, and boluses are then provided by the pump at mealtimes. There are specific indications for pump therapy (National Institute for Health and Clinical Excellence, 2008).

These regimens offer the most flexibility of dosing and eating habits, and often better blood glucose control. A number of patients have been taught to count mealtime carbohydrates and calculate their own insulin dose on the basis of the pre-prandial blood glucose concentration, which allows greater scope for 'normal eating'. An example is the DAFNE (dose adjusted for normal eating) programme (DAFNE Study Group, 2002), in which patients are required to attend structured, group education on five consecutive days.

The disadvantage of mealtime plus basal regimens is that they require multiple injections, unless a pump is *in situ*, and require regular blood glucose monitoring and the ability of the patient to match insulin doses according to carbohydrate intake, exercise levels and prevailing glucose levels. For some people, this is either too difficult or unsuitable.

Twice-daily regimens. The mealtime plus basal regimen may be too hard for some, for example, school-age children, to manage. In this type of situation, a twice-daily regimen may be more suitable. The simplest and most effective twice-daily regimens use premixed insulin, comprising a short- or rapid-acting plus an intermediate-acting insulin. Regular human insulin mixes and analogue mixes are available. The regular human insulin mixes should be given 30 min before breakfast and 30 min before the evening meal, whereas analogue mixes may be given immediately before these meals. The longer-acting component of the insulin mix given at breakfast time must span the lunchtime meal and the evening dose must bridge the night time. Twice-daily regimens using intermediate- or long-acting insulins alone are not sufficient for maintenance control of type 1 diabetes. Occasionally, they are used in newly diagnosed patients who are not acutely ill, adding the short-acting preparation if and when indicated by self-monitoring.

Adjusting the insulin dose

The information on which insulin dosage adjustment is based should be derived from blood glucose self-monitoring and the incidence and timing of hypoglycaemia. On twice-daily fast- and intermediate-acting insulin regimens, the soluble insulin may be considered as acting up to the next meal or to bedtime, while the extended-acting insulins act up to the next injection. The glucose concentration at the end of the period can be taken as a measure of the appropriateness of the relevant dose.

Adjustments to a dose of insulin should depend on the degree of insulin resistance present. In order to determine a suitable adjustment dose, the effect of other dosage adjustments in the same patient should be taken into consideration, as should the total insulin dose. For example, a 2-unit dose increase in someone taking 6 units of insulin would be a 33% dosage increase; however, a 2-unit dose increase in someone taking 60 units of insulin would be proportionately much less and make less impact.

Storage of insulin

Insulin formulations are stable if kept out of light, and they are not subject to freezing or extremes of heat. Loss of potency of 5–10% occurs in vials kept at high ambient room temperatures for 2–3 months. Insulin should therefore be stored in a domestic refrigerator except for the vial(s), cartridge(s) or pens in current use which, depending on the individual preparation, may be stable for 4–6 weeks (see manufacturers' recommendations). When pen injector devices are in use, they should never be stored in a refrigerator as there have been reports of devices 'seizing up' when stored in the cold. Also, the injecting of cold or refrigerated insulin is undesirable because it is more painful and the insulin absorption profile is altered.

Adverse effects of insulin

Hypoglycaemia is a common physiological complication of insulin therapy and is often a source of great anxiety to patients and carers. The symptoms (see Box 44.2) may occur at different blood glucose levels in different individuals.

Thickening of subcutaneous tissues can occur at injection sites because of recurrent injection in the same area, known as lipohypertrophy. As well as looking unsightly, it can result in impaired and erratic insulin absorption, leading to poor glycaemic control. The solution is to rotate injection sites. Bruising is usually a sign of superficial injections. Localised skin reactions occasionally occur but resolve even with continued use of the same insulin preparation.

Systemic allergic reactions rarely occur with the current universal use of highly purified insulins. Though not usually species specific, it is worthwhile trying insulin of a different species if allergy occurs. Also, some patients may experience allergy to the excipients within the insulin product or to the needle used for administration. If this is suspected, it is helpful to seek the advice of an immunologist and try an insulin product with different excipients.

Management of type 2 diabetes

About 80% of patients with type 2 diabetes are overweight at diagnosis, and this is known to cause insulin resistance. This means that higher doses of medication may be required to control blood glucose levels. Advice on weight loss through increased physical exercise and calorie restriction, in addition to education about general healthy eating, is required. Targets for weight should be to maintain a normal BMI of between 20 and 25 kg/m^2 or a waist circumference of less than 88 cm in women and 102 cm in men, which lowers the risk of developing insulin resistance. In those who are already overweight or obese, however, an achievable target of 10–15% body weight loss should be discussed as, if achieved, this will have significant benefits in overall diabetes control.

Some people are able to normalise their glycaemic control by weight loss and attention to diet (diet controlled). Nevertheless, such individuals still invariably have diabetes and are at risk of developing diabetic complications. Hyperglycaemia may still occur, especially in times of stress or if dietary control is lost, and consequently they should be monitored regularly.

For over 75% of people with type 2 diabetes, dietary measures and exercise alone do not produce adequate glycaemic control and oral hypoglycaemic therapy is required. Within

3 years of diagnosis, a large majority of patients will require oral drug therapy. In the UK, there are six classes of oral agents currently available: a biguanide (metformin), sulphonylureas (glibenclamide, gliclazide, glimepiride, glipizide, tolbutamide), meglitinides (repaglinide and nateglinide), a thiazolidinedione (pioglitazone), an α-glucosidase inhibitor (acarbose) and the dipeptidyl peptidase-4 inhibitors (saxagliptin, sitagliptin and vildagliptin).

Acarbose has been poorly tolerated in trials, with only 39% of those receiving the drug still taking it after 3 years. The main reason for non-adherence appears to be flatulence. Acarbose is rarely prescribed in the UK but is popular in other countries such as Germany. Metformin remains the cornerstone of oral treatment for type 2 diabetes. The sulphonylureas and meglitinides are known as insulin secretagogues, since they both enhance secretion of insulin from the pancreatic β-cells. The relatively recent introduction of the dipeptidyl peptidase inhibitors (DPP-4 inhibitors) has been welcomed and is a useful new class of drug, particularly for those in whom weight is a problem, since they do not cause weight gain like many of the other drug treatments. Likewise, the incretin mimetics, another new class of injectable drugs, are often helpful for the obese population since they are associated with weight reduction.

In type 2 diabetes, the progressive decline in β-cell function with time and increasing insulin resistance means people with this disease show a progressive loss of glycaemic control and usually require two or three drugs to maintain control before ultimately requiring insulin.

The factors used to select a particular treatment include the patient's clinical characteristics, such as their degree of hyperglycaemia, weight and renal function (Fig. 44.3). In acutely ill people with significant hyperglycaemia, insulin therapy may well be required, albeit transiently because acute illness leads to an increase in stress hormones, all of which are anti-insulin.

Biguanides

Metformin is the only biguanide available in the UK. The mechanism of action of biguanides is still not completely understood. However, the principal mode of action is via potentiation of insulin action at an unknown intracellular locus, resulting in decreased hepatic glucose production by both gluconeogenesis and glycogenolysis. Metformin also stimulates tissue uptake of glucose, particularly in muscle, and is thought to reduce gastro-intestinal absorption of carbohydrate. The action of metformin does not involve stimulation of pancreatic insulin secretion and therefore it is still a beneficial agent when β-cell function has declined. Another advantage of metformin over insulin secretagogues, and sulphonylureas, in particular, is that it does not cause hypoglycaemia and is not associated with weight gain. Metformin has a short duration of action, with a half-life of between 1.3 and 4.5 h, and does not bind to serum proteins. It is not metabolised and is totally renally eliminated.

It has been shown that diabetes-related death was reduced by 42% in overweight subjects who took metformin for 10 years, compared to those who took conventional therapies such as a sulphonylurea or insulin. Myocardial infarction was also reduced by 39% over the 10-year follow-up period. Consequently, metformin has become the first-line therapy for glycaemic control when oral agents are indicated especially in overweight and obese patients.

Adverse effects. The most common adverse effects of metformin, affecting about a third of patients, result from gastro-intestinal disturbances including anorexia, nausea, abdominal discomfort and diarrhoea. In some patients, diarrhoea can be extreme and can preclude metformin use. However, the gastro-intestinal side effects are usually transient and can be minimised by starting with a low dose, increasing the dose slowly and administering the drug with or after food. A suggested regimen is to start with 500 mg daily for 1 week, then 500 mg twice daily for 1 week, increasing the dosage at weekly intervals until the desired glycaemic response is achieved or intolerance occurs. The maximum licensed dose is 3 g/day, but doses of more than 2 g/day often cause intolerance. If the initial dose of 500 mg daily causes side effects, then some prescribers reduce the starting dose to 250 mg daily for a week. This may be difficult for some patients as the 500 mg strength tablets are not scored and are not easy to halve.

Two modified-release metformin preparations are now available and permit once-daily dosing. Clinical evidence suggests that these formulations cause fewer problems with gastro-intestinal side effects. The maximum licensed dose of the modified-release preparations (2 g daily) differs from the standard preparation.

The two previously available biguanides, phenformin and buformin, were withdrawn due to deaths associated with lactic acidosis. Lactic acidosis is a rare complication with metformin, with an estimated incidence of five cases per 100,000 patient-years. However, it is potentially life threatening. Patients at most risk are those with renal insufficiency in whom the drug accumulates, individuals with co-existing conditions where lactate accumulates, and those who are unable to metabolise lactate. In practice, metformin should not be prescribed for patients who have renal impairment (eGFR <45 mL/min/1.73 m^2) and should be stopped in anyone with an eGFR <30 mL/min/1.73 m^2. Metformin should also be stopped in severe liver disease, uncontrolled cardiac failure or severe pulmonary insufficiency. It should be withdrawn in patients with severe intercurrent illness, for example, acute myocardial infarction or septicaemia, or those undergoing major surgery or requiring investigation using radiographic contrast media and should only be restarted once renal function has been evaluated and determined as within acceptable limits.

Role of metformin. Metformin is useful in obese patients with diabetes as it does not cause weight gain. If there are no contraindications, it can be used in conjunction with diet as second-line therapy in patients not adequately controlled on diet alone. As it has a different mode of action to the sulphonylureas, meglitinides, thiazolidinediones, α-glucosidase inhibitors and DPP-4 inhibitors, it can be valuable when prescribed in combination.

HbA$_{1c}$ ≥ 6.5%[1] after trial of lifestyle interventions

Metformin[2]

HbA$_{1c}$ ≥ 6.5%[1]

HbA$_{1c}$ < 6.5%[1] Monitor for deterioration

Metformin + sulphonylurea[4]

HbA$_{1c}$ ≥ 7.5%[1]

HbA$_{1c}$ < 7.5%[1] Monitor for deterioration

Add insulin[2,8], particularly if the person is markedly hyperglycaemic

Insulin + metformin + sulphonylurea[4]

HbA$_{1c}$ ≥ 7.5%[1]

HbA$_{1c}$ < 7.5%[1] Monitor for deterioration

Consider sulphonylurea[4] here if:
- not overweight (tailor the assessment of body-weight-associated risk according to ethnic group[3]), or
- metformin is not tolerated or is contraindicated, or
- a rapid therapeutic response is required because of hyperglycaemic symptoms

Consider a rapid-acting insulin secretagogue for people with erratic lifestyles

Consider substituting a DPP-4 inhibitor[9] or a thiazolididedione[10] for the sulphonylurea if there is a significant risk of hypoglycaemia (or its consequences), or a sulfonylurea is contraindicated or not tolerated

Consider adding sitagliptin or a thiazolidinedione[10] instead of insulin if insulin is unacceptable (because of employment, social, recreational or other personal issues, or obesity)
Consider adding exenatide[6] to metformin and a sulfonylurea if:
- BMI ≥ 35kg/m^2 in people of European descent[7] and there are problems associated with high weight, or
- BMI < 35kg/m^2 and insulin is unacceptable because of occupational implications or weight loss would benefit other comorbidities

Increase insulin dose and intensity regimen over time

Consider pioglitazone with insulin if:
- a thiazolidinedione has previously had a marked glucose-lowering effect, or
- Blood glucose control is inadequate with high-dose insulin

Metformin[2] + DPP-4 inhibitor[5,9] or a thiazolidinedione[5,10]

HbA$_{1c}$ ≥ 7.5%[1]

HbA$_{1c}$ < 7.5%[1] Monitor for deterioration

Metformin[2] + sulphonylurea[4] + sitagliptin[5], or Metformin[2] + sulphonylurea[4] + a thiazolidinedione[5,10], or Metformin[2] + sulphonylurea[4] + exenatide[6]

HbA$_{1c}$ < 7.5%[1] Monitor for deterioration

HbA$_{1c}$ ≥ 7.5%[1]

Start insulin[2,8]

Sulphonylurea[4]

HbA$_{1c}$ ≥ 6.5%[1]

HbA$_{1c}$ < 6.5%[1] Monitor for deterioration

Consider adding a DPP-4 inhibitor[9] or a thiazolidinedione[10] if metformin is not contraindicated or not tolerated

Sulphonylurea[4] + DPP-4 inhibitor[5,9] or a thiazolidinedione[5,10]

HbA$_{1c}$ ≥ 7.5%[1]

HbA$_{1c}$ < 7.5%[1] Monitor for deterioration

HbA$_{1c}$ ≥ 7.5%[1]

HbA$_{1c}$ < 7.5%[1] Monitor for deterioration

Fig. 44.3 Algorithm for the treatment of glycaemic control in type 2 diabetes. (1) or individually agreed target, (2) with active dose titration (3) see the NICE clinical guideline on obesity (www.nice.org.uk/CG43), (4) offer once-daily sulphonylurea if adherence is a problem, (5) only continue DPP-4 inhibitor or thiazolidinedione if reduction in HbA$_{1c}$ of at least 0.5 percentage points in 6 months, (6) only continue exenatide if reduction in HbA$_{1c}$ of at least 1 percentage point and weight loss of at least 3% of initial body weight in 6 months, (7) with adjustment for other ethnic groups, (8) continue with metformin and sulfylurea (and acarbose if used), but only continue other drugs that are licensed for use with insulin. Review the use of sulphonylurea if hypoglycaemia occurs, (9) DPP-4 inhibitor refers to saxagliptin, sitagliptin or vidagliptin, (10) thiazolidinedione refers to ploglitazone.

Sulphonylureas

Mode of action. The major action of this class of drug relies on the ability of the pancreas to secrete insulin and hence requires functioning β-cells to exert a beneficial effect. Sulphonylureas lower blood sugar by increasing pancreatic β-cell sensitivity to glucose, allowing more insulin to be released from storage granules for a given glucose load. Sulphonylurea therapy is also associated with increased tissue sensitivity to insulin, resulting in improved insulin action. Studies also suggest that sulphonylureas may promote an increased systemic bioavailability of insulin due to reduced hepatic extraction of the insulin secreted from the pancreas.

Pharmacokinetics. The pharmacokinetic parameters of oral hypoglycaemic agents are shown in Table 44.4. Chlorpropamide is the slowest and longest acting agent, but it is now very rarely used. Although glibenclamide has been shown to

have a short elimination half-life, it has a prolonged biological effect, which may be explained by slower distribution and the existence of a deep compartment, possibly the islet cells. All sulphonylureas are metabolised by the liver to some degree and some may have active metabolites.

Choice of drug. There are many factors which influence the choice of sulphonylurea. These may relate to the drug itself, the patient or the prescriber. There are few well-controlled long-term clinical comparisons between sulphonylureas. It would appear that, when dosage is individualised and governed by the effect on fasting blood glucose, there is little or no difference in clinical efficacy between different agents. In general, if a patient is not well controlled on the maximum dosage of one sulphonylurea, it is not worthwhile changing to another one.

Adverse effects. The frequency of adverse effects from sulphonylureas is low. They are usually mild and reversible on

Table 44.4 Pharmacokinetic properties of oral hypoglycaemic agents

Drug	Main route of elimination	Elimination half-life (h)	Duration of action (h)	Daily dose range	Doses per day
Sulphonylureas					
First generation					
Tolbutamide	Hepatic	4–24	6–10	0.5–2 g	1–3
Chlorpropamide	Hepatic (80%) Renal (20%)	24–48	24–72	100–500 mg	1
Second generation					
Glibenclamide	Hepatic (40%) Biliary (60%)	2–4	16–24	2.5–15 mg	1–2
Glipizide	Hepatic	2–4	6–24	2.5–40 mg	1–3
Gliclazide	Hepatic	10–12	10–24	40–320 mg	1–2
Glimepiride	Renal (60%) Biliary (40%)	5–8	12–24	1–6 mg	1
Biguanides					
Metformin	Renal	1–5	5–8	1–3 g	2–3
Meglitinides					
Repaglinide	Hepatic	1	4–6	1–16 mg	3 (with each main meal)
Nateglinide	Hepatic	1	3–4	180–540 mg	3 (with each main meal)
Thiazolidinediones					
Pioglitazone	Hepatic	5–6	16–24	15–30 mg	1
Dipeptidyl pepidase-4 inhibitors					
Sitagliptin	Renal	10–12	12–24	100 mg	1
Vildagliptin	Renal	3	10–12	50 mg	1–2
Saxagliptin	Renal and hepatic	2–3	At least 24 h	5 mg	1
Incretin mimetics					
Exenatide	Renal	2–3	Data not available	5–10 mcg	2
Liraglutide	No main organ identified	13	Data not available	0.6–1.8 mg	1

drug withdrawal (Table 44.5). The most common adverse effect is hypoglycaemia, which may be profound and long lasting. Hypoglycaemia due to sulphonylureas is often misdiagnosed, particularly in the elderly. The major risk factors for the development of hypoglycaemia include use of a long-acting agent, increasing age, renal or hepatic dysfunction and inadequate carbohydrate intake. The major side effect is, however, weight gain.

Other adverse effects are rare; blood dyscrasias occur in 0.1% of patients and rashes in up to 3%. Chlorpropamide can produce troublesome flushing after ingestion of alcohol, and about 5% of patients develop hyponatraemia due to its effect on increasing renal sensitivity to antidiuretic hormone (ADH). Most patients are asymptomatic with this problem, but occasionally severe hyponatraemia is observed. However, as mentioned earlier, this agent is no longer used in routine practice.

Sulphonylurea dosage. The dosage should be individualised for each patient. The lowest possible dose required to attain the desired levels of blood glucose, without producing hypoglycaemia, should be used. Treatment should start with a low dose and be increased if necessary approximately every 2 weeks. For many agents, the maximum effect is seen if the dose is taken half an hour before a meal, rather than with or after food. The number of daily doses required will depend on the agent used and the total daily dose. For several drugs, it becomes necessary to administer the drug two or three times daily when the dose is increased.

A modified-release preparation of gliclazide is available. A dose of 30 mg of the modified-release product is equivalent to 80 mg of the standard-release preparation.

Drug interactions. Several drugs can interfere with the efficacy of sulphonylureas by influencing either their pharmacokinetics or pharmacodynamics, or both. Despite much literature about displacement interactions with sulphonylureas, the clinical significance is doubtful. Many reported cases involve first-generation agents, which have a different protein-binding site from the second-generation agents, which bind in a non-ionic fashion and are not readily displaced. Ingestion of alcohol can cause hypoglycaemia in itself and can also prolong the hypoglycaemic effect of sulphonylureas.

Table 44.5 Adverse effects of sulphonylureas

Adverse effect	Comments
Gastro-intestinal	Affects approximately 2% Most commonly nausea and vomiting Dose related Advise patient to take with or after food
Dermatological	Affects 1–3% Usually occur within the first 2–6 weeks Most commonly: generalised photosensitivity, pruritus, maculopapular rash May require discontinuation of drug Cross-sensitivity between sulphonylureas is common Rare cases of severe allergic reactions, for example, erythema multiforme Stevens–Johnson syndrome
Haematological	Rare cases of fatal agranulocytosis or pancytopenia Other haematological effects usually reversible on discontinuing drug Some reports of reversible haemolytic anaemia
Hepatic	Mild, reversible elevation of liver function tests Cholestatic jaundice Usually a hypersensitivity reaction associated with fever, rash and eosinophilia
Cardiovascular	Possible excess of cardiovascular mortality in patients treated with tolbutamide (not proven)
Hypothyroidism	Association not proven May be rare cases
Alcohol flush	Rarely seen with sulphonylureas other than chlorpropamide Change to another agent
Syndrome of inappropriate antidiuretic hormone (SIADH)	Chlorpropamide and, to a lesser extent, tolbutamide enhance the effect of ADH on the kidney Results in hyponatraemia Risk factors are increasing age, congestive cardiac failure and diuretic therapy
Hypoglycaemia	The most common adverse effect and may be severe and prolonged Highest incidence with chlorpropamide and glibenclamide All sulphonylureas and meglitinides have been implicated Risk factors include increasing age, impaired renal or hepatic function, reduced food intake, weight loss Decrease dose, change to a shorter-acting agent or discontinue sulphonylurea therapy

Meglitinides

The meglitinides are insulin-releasing agents (insulin secret-agogues), also called 'post-prandial glucose regulators'. They are characterised by a more rapid onset and shorter duration of action than sulphonylureas. Their site of action is pharmacologically distinct from that of the sulphonylureas. Repaglinide, a benzoic acid derivative, was the first member of the class. It is licensed for use as a single agent when diet control, weight reduction and exercise have failed to regulate glucose levels, or in combination with metformin. Nateglinide was introduced later and is a derivative of the amino acid d-phenylalanine. Nateglinide is only licensed for combination therapy with metformin when metformin alone is inadequate.

Mode of action. Like the sulphonylureas, the meglitinides stimulate first-phase insulin secretion by inhibiting ATP-sensitive potassium channels in the membrane of the pancreatic β-cells. This causes depolarisation and gating of the calcium channels (which are voltage sensitive), increasing the intracellular concentration of calcium and stimulating insulin release. The release of insulin only occurs in the presence of glucose. As glucose levels drop, less insulin is secreted. Conversely, if carbohydrates are consumed and glucose levels rise, insulin secretion is enhanced.

Pharmacokinetics. The pharmacokinetic properties of the meglitinides confer a rapid onset and a short duration of action. The individual parameters are shown in Table 44.4. The meglitinides are extensively metabolised in the liver, repaglinide by oxidative biotransformation and direct conjugation with glucuronic acid. The cytochrome P450 enzymes CYP2C8 and CYP3A4 have been shown *in vitro* to be involved its metabolism. Nateglinide is metabolised predominantly by cytochrome P450 enzyme CYP2C9 and to a lesser extent by CYP3A4. Repaglinide has no active metabolites, but nateglinide has partially active metabolites, one-third to one-sixth the potency of the parent compound. The meglitinides should be taken immediately before main meals, although the time can

vary up to 30 min before a meal. The pharmacokinetic profile of meglitinides offers some advantages in patients with poor renal function or irregular eating habits.

Adverse effects. The meglitinides may cause a range of side effects, most commonly hypoglycaemia, visual disturbances, abdominal pain, diarrhoea, constipation, nausea and vomiting. More rarely, hypersensitivity reactions can occur as well as elevation of liver enzymes. The meglitinides may also cause weight gain.

Dosage. The recommended starting dose for repaglinide is 500 μcg before or with each meal, increasing as necessary (depending on blood glucose measurements) every 1–2 weeks to a maximum single dose of 4 mg and a maximum daily dose of 16 mg. When patients are transferred from other therapies, the recommended starting dose is 1 mg preprandially. The recommended starting dose of nateglinide is 60 mg three times a day before meals, which may be subsequently increased to 120 mg three times a day. The maximum single dose is 180 mg, which may be given with the three main meals of the day.

Drug interactions. Drugs which induce or inhibit the cytochrome P450 enzymes CYP2C8 and CYP3A4 interact with repaglinide. Examples of drugs which enhance or prolong the hypoglycaemic effect include gemfibrozil, clarithromycin, ketoconazole, itraconazole, trimethoprim, other hypoglycaemic drugs, monoamine oxidase inhibitors, non-selective β-blockers, ACE inhibitors, salicylates, NSAIDs, octreotide, alcohol and anabolic steroids. Drugs which induce cytochrome P450 enzymes may also interact, for example, rifampicin and phenytoin, and may decrease repaglinide serum levels. Drugs that inhibit CYP2C9 may interact with nateglinide. Drugs that may enhance or prolong the hypoglycaemic effect include ACE inhibitors, gemfibrozil and fluconazole. The hypoglycaemic effects of nateglinide may be reduced by diuretics, corticosteroids and β-blockers.

Role of meglitinides. The meglitinides are an effective hypoglycaemic therapy in type 2 diabetes. They may be most beneficial in patients who experience problems with post-prandial glucose elevation and as single therapy in patients who eat at unpredictable times or have a tendency to miss meals. However, no outcome studies have been undertaken, and so their long-term use has not been proven to be more effective than the less expensive sulphonylureas. Therefore, their exact place in therapy is currently unclear.

Thiazolidinediones

Research into the action of the thiazolidinediones, also known as glitazones, has led to greater understanding of the development of type 2 diabetes. Only one glitazone, pioglitazone, is currently available following the removal of rosiglitazone from the UK market in 2010. Pioglitazone has been shown to have a significant benefit on macrovascular morbidity and mortality, demonstrating the benefit of a glucose-lowering agent on macrovascular disease (Dormandy et al., 2005).

Mode of action. The glitazones act as agonists of the nuclear peroxisome proliferator-activated receptor-γ (PPAR-γ). PPAR-γ is mostly expressed in adipose tissue but is also found in pancreatic β-cells, vascular endothelium and macrophages. It is also expressed weakly in those tissues that express predominantly PPAR-α, for example, skeletal muscle, liver and heart. The thiazolidinediones lower fasting and post-prandial glucose levels in addition to lowering free fatty acid and insulin concentrations. They enhance insulin sensitivity and promote glucose uptake and utilisation in peripheral tissues. They also suppress gluconeogenesis in the liver and, by increasing insulin sensitivity in adipose tissue, suppress free fatty acid concentrations. In addition, patients with IGT have shown increased insulin secretory responses. However, they do not have a direct effect on insulin secretion. The indirect effects of glitazones on adipose tissue are due to alterations in the regulation of gene expression. Various adipokines (adiponectin, tumour necrosis factor-α, resistin and 11β-hydroxysteroid dehydrogenase 1) are regulated by PPAR-γ agonists in animal studies. Other effects of glitazones on the vasculature include antiatherogenic effects thought to be caused by a reduction in the inflammatory response, decrease in vasoconstriction and an increase in plaque stability.

Pharmacokinetics. Pioglitazone is metabolised extensively in the liver to both active and inactive metabolites (see Table 44.4).

Adverse effects. Pioglitazone has been associated with weight gain and oedema, particularly in patients with hypertension and congestive cardiac failure. Since the thiazolidinediones can lead to a worsening of heart failure that may be fatal, pioglitazone should not be used in patients with a previous history of or pre-existing heart failure. Combination therapy with insulin and thiazolidinediones has been found to result in a higher incidence of oedema. There is also an increased risk of bone fracture with pioglitazone, and it should be used with caution in post-menopausal women. Anaemia occurs in about 1% of patients and is seen as a small decrease in the haemoglobin concentration during the first 4–12 weeks of therapy. However, it is suggested this decrease is due to dilutional effects caused by an increase in serum volume. Pioglitazone caused weight gain of around 3.5 kg during clinical trials. Some patients also experience headache, abdominal pain, myalgia and upper respiratory infection. Pioglitazone may also elevate liver transaminases.

Rosiglitazone was withdrawn from the UK market because use was associated with an increased risk of cardiovascular disorders, including heart attacks and heart failure. Another thiazolidinedione, troglitazone, was withdrawn from the UK market in 1997 because of liver failure linked to a toxic metabolite of troglitazone.

Dosage. Pioglitazone is started at a dose of 15 mg or 30 mg and may be increased to 45 mg once daily. In combination with metformin or a sulphonylurea, the current dose can be continued. Administration of pioglitazone may be either with or without food. Dosage adjustment is not necessary in patients with mild or moderate renal impairment or in the elderly. However, neither agent should be used in patients with severe renal impairment or in those with hepatic impairment.

Drug interactions. Pioglitazone is metabolised by cytochrome P450 CYP3A4. Therefore, drugs which induce or

inhibit this enzyme interact with pioglitazone. Ketoconazole, itraconazole, erythromycin and fluconazole increase serum concentrations, while rifampicin and phenytoin decrease serum levels of pioglitazone.

Role of thiazolidinediones. Thiazolidinediones improve glycaemic control in patients, especially in those with insulin resistance, by reducing HbA_{1c} levels up to 1.5% compared to sulphonylurea or metformin alone.

Glitazones should be used as third-line therapy after life style modification and the use of metformin or a sulphonylurea as monotherapy. However, if glycaemic control remains poor, pioglitazone can be used either with metformin if treatment with a sulphonylurea is unsuitable, with a sulphonylurea if treatment with metformin is unsuitable, or with metformin and a sulphonylurea if insulin is unsuitable (National Institute for Health and Clinical Excellence, 2009). Treatment should only be continued if, after 6 months of treatment, the HbA_{1c} has reduced by 0.5% of its starting value.

Monotherapy with a thiazolidinedione may be a valuable treatment option for patients who are known to be insulin resistant. Triple therapy can be an alternative to transferring a patient to insulin, but the modest reduction in HbA_{1c} usually means that many patients will eventually require insulin. It is important to be aware that owing to their mode of action involving changes in gene transcription, thiazolidinediones take up to 3 months to have their maximum effect on glycaemic control.

α-glucosidase inhibitors

Acarbose reduces carbohydrate digestion by interfering with gastro-intestinal glucosidase activity. Although overall carbohydrate absorption is not significantly altered, the post-prandial hyperglycaemic peaks are markedly reduced. Acarbose is minimally absorbed in unchanged form from the gastro-intestinal tract.

Adverse effects. The most common adverse effect of acarbose is abdominal discomfort associated with flatulence and diarrhoea. These symptoms usually improve with continued treatment but can be minimised by starting with a low dose and titrating slowly.

Systemic adverse effects are rare but high doses have been associated with idiosyncratic elevations of serum hepatic transaminase levels. Patients titrated to the maximum dose of 200 mg three times daily should be closely monitored, preferably at monthly intervals for the first 6 months. If elevated transaminase levels are observed, reduction in dose or withdrawal of therapy should be considered.

Role of acarbose. Acarbose is a therapeutic option in type 2 patients inadequately controlled by diet alone, or by diet and other oral hypoglycaemic agents. However, the gastro-intestinal side effects do limit the use of acarbose in clinical practice.

Dipeptidyl peptidase-4 inhibitors

The DPP-4 inhibitors are a new class of drugs that work on the incretin system. They are also commonly referred to as the 'gliptins'.

Mode of action. DPP-4 inhibitors block the normal inactivation of incretins (glucagon like peptide-1 [GLP-1] and glucose-dependent insulinotropic peptide [GIP]). Incretins play a role in increasing endogenous insulin in response to a high glucose load, that is, post-prandially. They also reduce the amount of glucose produced by the liver when glucose levels are sufficiently high. By blocking DPP-4, these drugs prolong incretin activity and inhibit glucagon release. This in turn causes a decrease in blood glucose and an increase in insulin secretion.

Pharmacokinetics. DPP-4 inhibitors are predominantly renally excreted. However, there is also a degree of hepatic metabolism involved in the elimination process, which varies with each drug. Sitagliptin is mainly excreted as unchanged drug in the urine, with a small metabolic contribution from the liver via the cytochrome P450 system. The kidney is thought to be mainly responsible for metabolic hydrolysis of vildagliptin to an inactive compound. Although saxagliptin is mainly eliminated renally, some hepatic biotransformation does occur via the cytochrome P450 system (CYP3A4/5), which results in a metabolite with half the potency of the parent compound. The pharmacokinetic parameters of the DPP-4 inhibitors are detailed in Table 44.4.

Adverse effects. All three DPP-4 inhibitors have been linked to gastro-intestinal side effects and upper respiratory tract infection. DPP-4 inhibitors do not cause hypoglycaemia, but they have the potential to cause hypoglycaemia when prescribed with other agents that can produce this effect. Vildagliptin has been associated with rare reports of liver dysfunction. Therefore, it is recommended liver function tests are performed prior to starting treatment, at 3-monthly intervals for the first year and then periodically thereafter.

Drug interactions. DPP-4 inhibitors have a low potential for interaction with other medicines. However, as both sitagliptin and saxagliptin are metabolised by cytochrome P450 3A4/5 (and CYP2C8 for sitagliptin), they have the potential to interact with potent inducers or inhibitors of these enzyme. In practice, few drugs have been formally assessed. Therefore, general advice is to monitor blood glucose levels carefully if one of these drugs is co-prescribed with sitagliptin or saxagliptin.

Role of dipeptidyl peptidase-4 inhibitors. DPP-4 inhibitors are licensed for use as dual therapy with metformin, a sulphonylurea or a thiazolidinedione. Sitagliptin is also licensed as both mono- and triple therapy with metformin and a sulphonlyurea or a thiazolidinedione. Similar to the thiazolidinediones, it is recommended that a DPP-4 inhibitor is used as third-line therapy typically in those who still do not have adequate control or cannot tolerate treatment with metformin and/or a sulphonylurea. DPP-4 inhibitors are also useful if further weight gain is likely. However, if insulin resistance is a key factor, then treating with a thiazolidinedione may be a better choice.

Incretin mimetics

The incretin mimetics, as the name suggests, mimic the effects of incretins. The two currently licensed in the UK, exenatide and liraglutide, are only available as subcutaneously injectable

products. Incretin mimetics have both been demonstrated to cause weight loss, which is a particularly beneficial effect in many patients with type 2 diabetes.

Mode of action. The incretin mimetics bind to and activate the glucagon-like peptide-1 (GLP-1) receptor, hence increasing insulin secretion, suppressing glucagon secretion, increasing satiety and slowing gastric emptying. All of these effects help to lower blood glucose levels.

Pharmacokinetics. Incretin mimetics have a longer duration of action than endogenous GLP-1. Exenatide is eliminated primarily by renal clearance. However, the specific organ responsible for liraglutide elimination has not been identified. Table 44.4 details additional pharmacokinetic parameters of the incretin mimetics.

Adverse effects. Both incretin mimetics have been associated with nausea, and other gastro-intestinal disturbances. However, once therapy has been established, the incidence of these side effects decreases. Acute pancreatitis has also been rarely reported. For this reason, both patients and their carers should be advised of the signs and symptoms of this complication and advised to stop taking the drug and seek medical attention immediately if they occur. Since the incretin mimetics cause glucose-dependent insulin release, hypoglycaemia is uncommon and in most cases can be attributed to other agents taken concurrently

Drug interactions. The potential for drug interactions with the incretin mimetics is low. However, as they can cause a delay in gastric emptying, they may influence the absorption of other medicines administered at the same time. For this reason, it is advised that any narrow therapeutic index drugs taken concomitantly are monitored carefully. Also, if other oral medicines are being taken where the threshold concentration is important (e.g. antibiotics), it is advised that these should be taken at least 1 h before exenatide. This may be assumed for liraglutide, although this is not specifically stated in the summary of product characteristics.

Role of incretin mimetics. It is recommended that exenatide be added to metformin and a sulphonylurea as third-line therapy (as an alternative to insulin, thiazolidinediones or DPP-4 inhibitors) for patients who have either a BMI of $\geq 35\,kg/m^2$, are of European decent (adjustments to this threshold may be made for other ethnic groups at greater risk of cardiac disease) and have other medical problems associated with increased body weight. Alternatively, exenatide may be used in patients with a BMI $<35\,kg/m^2$ who are not able to take insulin, for example, for occupational reasons, or who have other conditions that would benefit from weight loss. Treatment should only be continued if there has been an HbA_{1c} reduction of at least 1% and a weight loss of at least 3% from starting treatment, over a 6-month period.

Insulin therapy in type 2 diabetes

The younger age of onset of type 2 diabetes and tighter glycaemic targets mean that the majority of patients with type 2 diabetes progress to insulin therapy, since recent evidence confirms that long-term glycaemic improvement reduces the risk of both microvascular (Holman et al., 2008) and macrovascular (Turnbull et al., 2009) complications.

It is currently common practice to introduce insulin to an oral medication schedule, although if hypoglycaemia becomes a problem, then the oral medications may be reduced or stopped. A number of different insulin regimens for use in patients with type 2 diabetes are available, the most common of which include once-daily basal insulin, twice-daily biphasic (pre-mixed) insulin, or prandial insulin, using a rapid/short-acting insulin with meals. Until recently, there have not been any trial data to determine which insulin regimen is most effective in controlling blood glucose levels and minimising hypoglycaemia in patients with type 2 diabetes. However, recent work suggests that patients who have basal insulin or prandial insulin added to their oral therapy have better HbA_{1c} control than those who receive biphasic insulin. In addition, the basal insulin regimen is associated with fewer hypoglycaemic episodes and less weight gain than the other two regimens (Holman et al., 2009). Basal insulin should be titrated to achieve normal fasting glucose levels, and the patient may be taught this self-titration protocol (Davies et al., 2005).

In a lean patient (BMI $<25\,kg/m^2$), significant insulin deficiency is more likely and therefore from the outset of insulin treatment either a basal-bolus or twice-daily regimen may be preferred.

In type 2 patients who require temporary insulin during intercurrent illness, a soluble preparation such as Humulin S or Human Actrapid can be given two or three times daily with a small dose of isophane insulin at bedtime to control blood glucose quickly and eliminate symptoms. The dose is selected initially according to the patient's previous insulin requirements, if any, and adjusted according to four times daily blood glucose measurements.

Treating hypertension

The co-existence of hypertension and diabetes dramatically increases the risk of microvascular and macrovascular complications. Most important is the increased risk of cardiovascular disease. Tight control of blood pressure may be a more effective method of preventing complications in patients with type 2 diabetes than tight glycaemic control. It is recommended that, for patients with type 2 diabetes, the target blood pressure should be <140/80 mmHg, or for those with pre-existing kidney, eye or cerebrovascular damage the target should be reduced to <130/80 (National Institute for Health and Clinical Excellence, 2009). First-line blood-pressure-lowering therapy should be a once-daily, generically prescribed angiotensin-converting enzyme (ACE) inhibitor. Exceptions to this are people of African-Caribbean descent, in whom first-line therapy should be an ACE inhibitor plus either a diuretic or a generic calcium-channel blocker.

In young patients with type 1 diabetes, the blood pressure target is <135/80 mmHg. However, if there is abnormal albumin excretion (renal disease) or two features of the metabolic syndrome are present, then the blood pressure target should be lowered to 130/80 mmHg with maximal doses of either an ACE inhibitor or ARB as first-line therapy.

Treating obesity

Obesity is a significant risk factor in the development of type 2 diabetes. Evidence suggests that for each kilogram increase in body weight, the risk of diabetes increases by 4.5%. It is estimated that almost one-fifth of the population has a BMI of over 30 kg/m² and is therefore obese.

Treatment of obesity may require modification of lifestyle (diet and exercise regimens) to reduce calorie intake and increase calorie utilisation, pharmacological intervention and/or surgery. Currently orlistat, a lipase inhibitor, is the only drug available on prescription for the treating of obesity. Orlistat can also be purchased in community pharmacies as a branded over-the-counter product. Both sibutramine and rimonabant were withdrawn because of unwanted side effects.

Orlistat is licensed for use with a 'mildly hypocalorific diet' to treat obese people (BMI >30 kg/m²) or overweight patients with a BMI >28 kg/m² and associated risk factors. It should be discontinued after 12 weeks if a 5% weight reduction since the start of treatment has not been achieved. Orlistat increases the amount of faecal fat excretion but is associated with a number of gastro-intestinal side effects such as oily leakage from the rectum, flatulence, faecal urgency and incontinence. A greater reduction in the incidence of type 2 diabetes has been observed in patients treated with both orlistat and lifestyle modification (Torgerson et al., 2004).

Over recent years, the use of bariatric surgery has increased in popularity, which is another treatment option for those who are seriously struggling with their weight with a BMI over 35–40 kg/m², who have other conditions caused by being overweight such as diabetes.

Patient care

Patient education

Patient involvement is paramount for the successful care of diabetes. This is highlighted in the national service standards for diabetes (Department of Health, 2002) which state that all patients, and carers, where appropriate, will be encouraged to develop a partnership with their clinicians to enable them to manage their diabetes and maintain a healthy lifestyle, often through shared care plans. Structured education for patients with type 2 diabetes is important and should be offered to every patient and/or their carer around the time of diagnosis. It is considered to be an integral part of diabetes care (National Institute for Health and Clinical Excellence, 2009).

Education will depend upon the individual patient and the availability of local resources. Individual tuition is preferable in the early stages after diagnosis and is usually delivered by a diabetes specialist nurse. The educational aspect of care is a gradual and ongoing process. At a later stage, group education can be effective and many patients appreciate and find support in meeting others who have the same disease. Many such programmes are multidisciplinary and involve doctors, nurses, dieticians, pharmacists and chiropodists. It is essential to involve the patient's family and carers in the educational process. Patients can also obtain support and information from specialist organisations such as Diabetes UK (available at www.diabetes.org.uk/home.htm).

Patients require education and information about many subjects, ranging from general lifestyle advice through to knowledge about the medicines they are prescribed (Box 44.4).

Advice about the use of over-the-counter medications, diet, foot care products and diabetic food products is frequently requested.

Annual review

People with diabetes should attend their hospital clinic or primary care practice (if this service is offered locally) for an annual review to screen for diabetic complications. Monitoring and optimising glycaemic control are also undertaken although this should be done on a more regular basis, as should review of patients with known complications. The annual review is increasingly taking place in primary care, with referral to secondary care if required. The typical assessments undertaken at an annual review are described in Box 44.5.

is, therefore, a difficult balance between the use of aggressive treatment with its associated risk of hypoglycaemia and the benefits of reducing complications to maintain an acceptable quality of life. Box 44.6 sets out some of the common therapeutic problems in diabetes.

Glycaemic management targets

The theoretical ideal for all patients with diabetes is to achieve normoglycaemia. As this is not always possible, the aim is to achieve the best possible control compatible with an acceptable lifestyle for the patient. In some patients, this may mean only symptomatic control, in others this may be tight control. In making this decision, the following factors should be considered: the patient's age, motivation, intelligence, understanding, likely adherence, co-existing diseases, ability to recognise hypoglycaemia, duration of their diabetes and the presence/absence/severity of diabetic complications.

Targets for pre-meal blood glucose of between 4 and 7 mmol/L and post-meal values of <10 mmol/L may be set for most patients, provided there is no significant hypoglycaemia risk. An optimal HbA$_{1c}$ target of 6.5% for most of those with type 2 diabetes has been suggested (National Institute for Health and Clinical Excellence, 2009). However, it is recommended that targets should be individualised and that for some a higher target would be more appropriate especially if there is a risk of hypoglycaemia at the lower target. For those with type 1 diabetes, the recommended target is less than 7.5% (National Institute for Health and Clinical Excellence, 2004).

The diabetes treatment goals in older people may be different and more conservative than in younger adults. For example, some elderly patients may have poor vision and limited manual dexterity, which may or may not be linked to a degree of cognitive impairment. Others may have multiple pathology and take a number of other medications. Therefore, the goals of therapy need to be both individual and realistic. In some people, they will involve only the optimisation of body weight, control of symptoms and avoidance of hypoglycaemia which has an increased risk of severe brain damage and may occur without the usual warning signs in the elderly. In others, reasonably tight control may be appropriate. There

Monitoring glycaemic control

Clinic monitoring

There are several ways in which glycaemic control can be monitored in primary and secondary care. Estimates of average control are often useful. Glycation of minor haemoglobin components occurs in the blood, with the extent depending on both the amount of glucose present and the duration of exposure of the haemoglobin to glucose. Estimates of glycated haemoglobin (HbA$_{1c}$) provide an index of average diabetes control over the preceding 2–3 months, that is, the lifespan of a red blood cell. HbA$_{1c}$ can be measured at any time, the patient does not need to be fasted, and levels are not normally affected by acute changes in therapy, diet or exercise. However, they may be lower in those with reduced red cell lifespan, for example, pregnancy or advanced renal failure. Serum fructosamine represents the glycation of all serum proteins and gives information about control over the preceding 3 weeks. As albumin is the major serum protein, hypoalbuminaemia may affect fructosamine levels. However, HbA$_{1c}$ is the preferred marker for average glycaemic control.

Home monitoring

Type 1 diabetes. All patients treated with insulin should be offered home blood glucose monitoring (HBGM). Capillary blood is applied to a reagent strip which has been impregnated with enzymes, for example, glucose oxidase. Some home blood glucose monitoring methods require visual comparison of colour changes which correspond to various blood glucose concentrations. More commonly, meters may be used to give readings and are more convenient for people who are colour blind or who have poor eyesight. Home blood glucose monitoring enables patients and carers to make a direct assessment

of the effect of changes in medicines, dietary habits, exercise and patterns of illness. It has the additional benefit that it can detect hypoglycaemia and, unlike urine testing in which glycosuria may only be detected some time after changes in blood glucose have occurred, it enables more accurate calculations of insulin doses.

Patients with type 1, who are by definition ketosis prone, should also know how and when to test their urine for ketones. This test need not be carried out as part of routine monitoring but is essential at times of intercurrent illness, especially when the blood glucose is ≥17 mmol/L.

Type 2 diabetes. Many people with type 2 diabetes are treated with diet alone or with oral hypoglycaemic agents, and unless they have problems with hypoglycaemia, urine glucose monitoring should be adequate. This is a simple non-invasive test that can detect hyperglycaemia but not hypoglycaemia. Home blood glucose monitoring is used by some patients with type 2, particularly if control is poor, if they are undergoing medication dose titration, if they are being treated with insulin or if they are prone to hypoglycaemia. It is also recommended that blood glucose monitoring be undertaken before driving and at times of intercurrent illness, when blood glucose levels may be particularly erratic.

Regardless of whether individuals with type 1 or type 2 diabetes are using home blood glucose monitoring or urine testing, it is important they are educated about what to do with the results; otherwise, there is little point in testing.

Case studies

Case 44.1

Mrs TM is a 36-year-old married lady who has type 1 diabetes. She undertook a home pregnancy test because she was feeling particularly nauseated in the mornings and her period was late. The test was positive confirming that she was pregnant. However, at 8 weeks, she experienced vaginal bleeding and abdominal pain. She attended the Accident & Emergency department, where a miscarriage was confirmed. Upon questioning, it was discovered that she had been taking folic acid 400 μcg daily for the previous 6 months but had not received any pre-conception diabetes care. Her most recent HbA$_{1c}$ was 7.3% (56 mmol/mol). Her regular medications are ramipril 10 mg daily, simvastatin 40 mg daily, insulin glargine at night and insulin aspart three times daily with meals.

Questions

1. Why should women of childbearing age be offered advice about pregnancy?
2. What blood glucose targets should Mrs TM have been advised to aim for before and after conceiving?
3. Was she taking appropriate dietary supplements prior to conception?
4. What advice should she be given with respect to her regular medication?

Answers

1. Mrs TM should have been offered preconception advice prior to becoming pregnant because glucose control needs to be optimal to reduce the risks of miscarriage, congenital malformation, stillbirth and neonatal death associated with diabetes in early pregnancy. Preconception advice should also include information for the patient on how diabetes affects pregnancy and how pregnancy affects diabetes, what dietary supplements to take and advice on diabetes-related medicines that are unsafe to take during pregnancy.
2. Mrs TM should aim for an HbA$_{1c}$ target of below 6.1% (43 mmol/mol) before conceiving. During pregnancy, she should aim for fasting blood glucose levels of 3.5–5.9 mmol/L and 1-h postprandial levels of below 7.8 mmol/L.
3. Mrs TM was taking the appropriate dietary supplement; however, the recommended dose for women with diabetes is 5 mg daily, rather than 400 μcg daily. The 5-mg strength tablets are available on prescription.
4. Mrs TM should have been advised to stop her ramipril and simvastatin since both have been associated with an increased risk of birth defects.

Case 44.2

Mr LG is a 47-year-old man with type 2 diabetes. He has recently had basal insulin (insulin detemir) added into his other diabetes medicines: metformin modified release 1 g twice a day and gliclazide 80 mg twice a day. He complains of waking with a headache and feeling 'groggy' and unrested in the morning. His recent blood glucose readings have generally been very good although his before breakfast readings are 10–13 mmol/L. He is worried because he is feeling worse since he started insulin, even though his blood glucose levels are much improved. He has made an appointment with his primary care doctor. His primary care doctor suspects nocturnal hypoglycaemia may be causing his recent symptoms.

Questions

1. What is nocturnal hypoglycaemia?
2. Why might nocturnal hypoglycaemia cause raised blood glucose levels in the mornings?
3. How can the diagnosis of nocturnal hypoglycaemia be confirmed?
4. How should it be treated?

Answers

1. Nocturnal hypoglycaemia is a low blood glucose reading that occurs during the night. Definitions vary but it is generally accepted that a reading of less than 3.5 mmol/L is 'hypoglycaemia'. The normal symptoms of hypoglycaemia may be missed if the patient does not wake. However, signs noticed (often by partners) might include restlessness, sweating and nightmares. Symptoms experienced by the patient in the mornings commonly include headache, lethargy and raised blood glucose levels.
2. Nocturnal hypoglycaemia may be caused by a rebound rise in blood glucose levels due to the 'somogyi effect'. This is the effect of the counter-regulatory hormones, glucagon, cortisol, adrenaline (epinephrine) and growth hormone, which all increase glucose in response to low levels.

3. Commonly, nocturnal hypoglycaemia can be confirmed by undertaking a blood glucose reading in the early hours of the morning, that is, between 2 and 4 am. This may require the patient to set their alarm to be woken at this time.
4. Nocturnal hypoglycaemia once confirmed may be treated by either having a bed-time snack, or by reducing the dose of night-time insulin. In the case of Mr LG, stopping his sulphonylurea may also help resolve the problem. Care must be taken when interpreting raised blood glucose levels in the morning, since the obvious intervention would be to increase the dose of night-time insulin. However when nocturnal hypoglycaemia is the cause, increasing the insulin dose would only make the problem worse and more dangerous for the patient.

Case 44.3

Mr PT is a 69-year-old man with longstanding type 2 diabetes. He has recently noticed that his right shoe has been rubbing his foot, which he finds confusing since he has been wearing these shoes for 6 months with no problems. His whole left foot now looks red and swollen and when Mr PT inspected it closely, he noticed that there was a weeping sore. However, his foot is not painful, so he does not feel too concerned.

Questions

1. What is the most likely reason that Mr PT did not feel any pain associated with the sore?
2. Why might Mr PT's shoe suddenly have started to rub his foot?
3. Should he be more concerned?

Answers

1. Mr PT has probably developed sensory neuropathy in his feet. This usually begins with the loss of the sensation of vibration and then may progressively lead onto the loss of sensation altogether.
2. The shape of the feet of people with diabetes has been observed to change over time. This may be due to the development of neuropathy which can weaken muscles causing alterations to the shape of the arch of the foot and toes. In this case, we know that Mr PT has sensory neuropathy since he is unable to feel the pain of the weeping sore. It is likely that Mr PT may also have motor neuropathy.
3. Mr PT should be concerned because his lack of sensation does not indicate that the foot injury is not serious. He is at risk of developing an infected ulcer and needs prompt treatment to prevent the problem from becoming severe. If he does not seek treatment, he may even risk losing his foot through amputation.

Case 44.4

Miss IL is a 17-year-old teenager with recently diagnosed type 1 diabetes. She has been admitted to hospital with diabetic ketoacidosis (DKA), which was precipitated by a diarrhoea and vomiting bug. As she was vomiting she was not eating, and hence she temporarily stopped injecting her insulin.

She is normally well controlled on a basal bolus insulin regimen comprising insulin glargine (Lantus) at night and insulin glulisine (Apidra) three times daily with meals.

Questions

1. Why was it a mistake for Miss IL not to inject her insulin whilst she was not feeling well enough to eat?
2. What advice should patients on insulin be given regarding glucose management when they are feeling unwell and not able to eat normally?
3. What are the initial management priorities for patients admitted with diabetic ketoacidosis?
4. What is the correct way for subcutaneous insulin to be re-introduced after a patient has been on a continuous intravenous insulin infusion?

Answers

1. This is a common misunderstanding amongst patients and sometimes even health care professionals. When a person is unwell, their basal insulin requirements can often increase, despite not eating. This is because of the stress involved and the increase in the production of counter-regulatory hormones which increase glucose levels.
2. Patients should be counselled on what are commonly referred to as 'sick day rules' and should be given contact numbers for advice if they are unclear or struggling with management. Generally patients need to increase the frequency of glucose monitoring to 4-hourly or more and test urine for ketones on a regular basis. Carbohydrate intake should be maintained as much as possible using sugary drinks or fruit juice, soups, jelly or snack foods if they are having difficulty in eating. Fluid intake is important and patients should be advised to have a glass of water every hour, aiming for 3 L in 24 h. If the blood glucose level is less than 12 mmol/L and ketone result is negative-small, patients should continue their normal insulin dose. If the blood glucose level is between 12 and 18 mmol/L and the ketone result is negative-small, the patient should re-test within 4 h or at the next meal and add 4 extra units of insulin to doses of up to 20 units and 8 extra units to doses greater than 20 units. If the blood glucose level is more than 18 mmol/L and ketones are moderate or large, patients should take 50% extra insulin. If blood glucose is more than 20 mmol/L and ketones are moderate or large, the dose of insulin should be doubled. If the patient is vomiting and blood glucose levels are over 16 mmol/L, then medical help should be sought, especially if there is no improvement after the second test or the next insulin injection.
3. Intravenous sodium chloride 0.9% should be started as soon as possible. A fixed rate intravenous insulin infusion should then be started. Current recommendations are to begin at a rate of 0.1 units/kg. Regular hourly monitoring of blood glucose and ketones should be undertaken and 2-hourly monitoring of serum potassium for the first 6 h.
4. When the patient is biochemically stable, they may be converted back to subcutaneous insulin. The current national guidelines from the Joint British Societies Inpatient Care Group (2010) recommend that long-acting subcutaneous insulin analogues are continued throughout treatment of diabetic ketoacidosis in order to prevent rebound hyperglycaemia when the intravenous infusion is stopped. Therefore, Miss IL's glargine should have been continued. Her rapid-acting insulin (Apidra®) should be re-introduced at the next meal and the intravenous insulin infusion should be stopped 30 min afterwards.

Menstrual cycle disorders 45

K. Marshall and S. Calvert

Key points

- Girls can begin experiencing menstrual disorders once ovulatory cycles are established.
- Up to 95% of women experience changes premenstrually, but severe premenstrual syndrome is more common in the 30–40 year age group.
- The aetiology of premenstrual syndrome is multifactorial, the symptomatology complex and treatment options diverse.
- It has been estimated that 50–80% of women of child-bearing age will suffer from dysmenorrhoea at some time.
- Treatment options vary according to the type of dysmenorrhoea (primary or secondary) but include non-steroidal anti-inflammatory drugs, combined oral contraceptive pills, and progestogen-only preparations.
- Menorrhagia (excessive menstrual blood loss) affects up to 30% of menstruating women. The management of the condition depends upon the cause and can be either surgical or medical.
- Endometriosis (the presence of extrauterine endometrial tissue) can give rise to an array of symptoms including subfertility. Treatment may be designed to improve fertility and manage symptoms. Medical and surgical treatments are available.

Once a girl reaches puberty, various physiological events occur, leading to the onset of menstruation, or the menarche. The average age of the menarche has decreased to around 12.5 years and a halt in this trend towards earlier menarche is not evident. This decline has been attributed to an improvement in nutrition and overall health. Body weight is linked to menarchal age and it is possible that as body fat increases so does serum leptin (hormone which influences calorie intake) which in turn may increase the pulsatile release of gonadotrophin-releasing hormone (GnRH).

Menstruation is an event that occurs relatively late in puberty and 95% of girls reach the menarche between the ages of 11 and 15 years. One UK study has shown that one girl in eight begins to menstruate whilst still at primary school. Even before the first ovulatory cycle has taken place, childhood ovarian activity will have gradually increased the production of oestrogen, leading to the development of the secondary sexual characteristics. These events are probably initiated by the central nervous system (CNS) which ultimately triggers the necessary gonadal changes that will eventually lead to the establishment of the menstrual cycle. It may take up to 2 years

for the hypothalamic–pituitary–gonadal axis to mature and for regular ovulation to take place. In girls who only start to menstruate when they are older, it may take even longer. This should be considered when taking a patient's medical history.

Menstruation itself occurs as a result of cyclic hormonal variations (Fig. 45.1). During the first half or follicular phase of the menstrual cycle, the endometrium thickens under the influence of increasing levels of oestrogen (most notably estradiol, which at the peak of its preovulatory surge reaches around 2000 pmol/L) secreted from the developing ovarian follicles. Once the serum oestrogen level has surpassed a critical point it triggers, by positive feedback, the anterior pituitary to release, about 24 h later, a surge of luteinising hormone (LH; up to 50 iu/L) and after 30–36 h, ovulation follows.

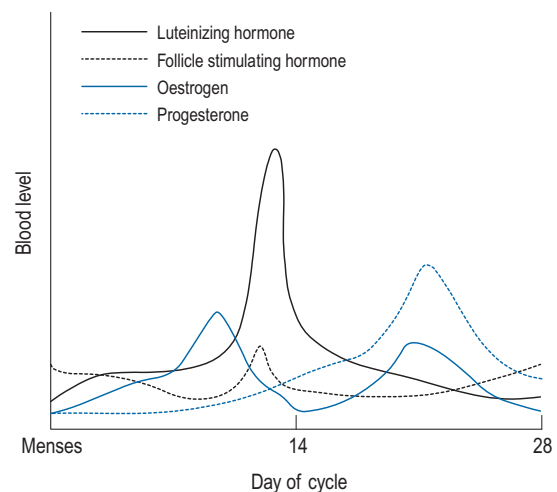
After ovulation, which occurs around day 14 of a 28-day menstrual cycle, and as the luteal phase progresses, the endometrium begins to respond to increasing levels of progesterone. Both progesterone and oestrogen are secreted from the corpus luteum which is formed from the remains of the ovarian follicle after ovulation. The lifespan of the corpus luteum is remarkably constant and lasts between 12 and 14 days; hence, the length of the second half or the luteal phase of the menstrual cycle is between 12 and 14 days. Between days 18 and 22 of a 28-day cycle, both sex steroids peak, with levels of progesterone reaching around 30 nmol/L. As progesterone has a thermogenic effect upon the hypothalamus, basal body temperature


Fig. 45.1 The hormonal events that occur during the menstrual cycle in women.
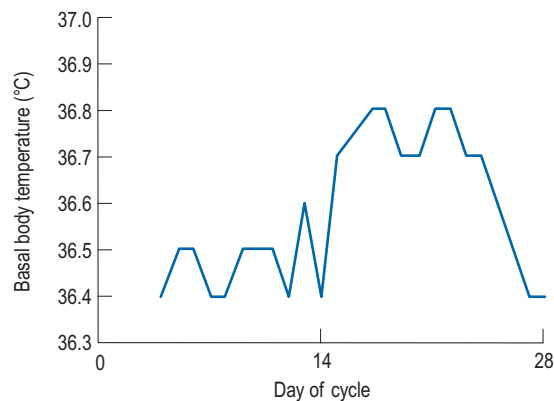

Fig. 45.2 Typical temperature chart from a 28-day ovulatory menstrual cycle.

Fig. 45.3 Eicosanoid biosynthesis and inhibition.

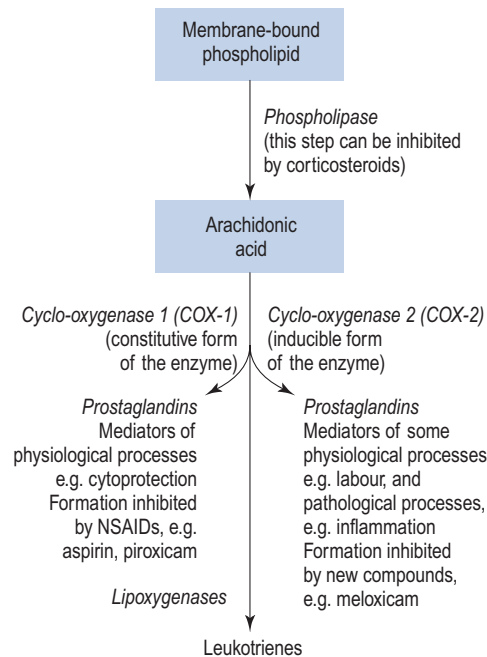
increases by about 1 °C in the second half of an ovulatory cycle (Fig. 45.2). Most ovulatory cycles range from 21 to 34 days.

These synchronised changes mean that about a week after ovulation, the endometrium is prepared for implantation, providing fertilisation has taken place. If conception does not occur, then luteolysis begins and steroid levels fall. This means that the endometrium cannot be maintained, there is a loss of stromal fluid, leucocyte infiltration begins and there is intraglandular extravasation of blood. Finally, endometrial blood flow is reduced and this leads to necrosis and sloughing, that is menstruation. Initially, the blood vessels that remain intact after sloughing are sealed by fibrin and platelet plugs; subsequent haemostasis is probably achieved as a result of vasoconstriction of the remaining basal arteries. Nitric oxide may be involved in the initiation and maintenance of menstrual bleeding by promoting vasodilation and inhibiting platelet aggregation. The myometrium is the muscular layers of the uterus that contract spontaneously throughout the menstrual cycle, the frequency of these contractions being influenced by the hormonal milieu. The myometrium is also more active during menstruation. The average blood loss per period is between 30 and 40 mL.

There is evidence which suggests a physiological and pathological role for the local hormones, known as prostaglandins, in the process of menstruation. Prostaglandins are 20-carbon oxygenated, polyunsaturated bioactive lipids, which are cyclooxygenase-derived products of arachidonic acid. Indeed, both the myometrium and the endometrium are capable of synthesising and responding to prostaglandins. A potential role for another family of autocoids, the leukotrienes, in the regulation of uterine function remains uncertain, although it is known that leukotrienes can also be synthesised from arachidonic acid by lipoxygenase enzymes (Fig. 45.3).

Disorders associated with menstruation are a major medical and social problem for women which also impact upon their families.

Premenstrual syndrome (PMS)

PMS encompasses both mood changes and physical symptoms. Symptoms may start up to 14 days before menstruation, although more usually they begin just a few days before


and disappear at the onset of, or shortly after, menstruation. However, for some women, the beginning of menstruation may not signal the complete resolution of symptoms. Numerous studies have demonstrated that this condition can cause substantial impairment of normal daily activity, including reduced occupational activity and significant levels of work absenteeism. Severity varies from cycle to cycle and may be influenced by other life factors such as stress and tiredness. The most severe form of PMS may be referred to as premenstrual dysphoric disorder (PMDD) as defined by the Modified Diagnostic and Statistical Manual of Mental Disorders appendix IV, or DSM-IV (American Psychiatric Association, 2000) and for which the criteria are set out in Box 45.1. Other bodies (American College of Obstetricians and Gynecologists, 2000) have published diagnostic criteria for PMS (Box 45.2). There is considerable overlap between PMS and PMDD.

Epidemiology

Up to 95% of menstruating women experience some changes premenstrually. Clinically relevant PMS occurs in about 15–20% of these women and PMDD has an estimated incidence of 3–8%. It has been estimated that PMS may account for over 17 million disability-adjusted life years (DALYS) in the European Union. PMS affects young and older women alike and does not appear to be influenced by parity. Severe PMS is more common in the 30–40 year age range, and married women with young children commonly seek help. Certain events may be linked with the onset of PMS, including childbirth, cessation of oral contraceptive use (incidence of reported PMS is lower in pill users), sterilisation, hysterectomy or even increasing age.

Box 45.1 Summary of DSM-IV diagnostic criteria for premenstrual dysphoric disorder (PMDD)

One-year duration of symptoms which are present for the majority of cycles (occur luteal/remit follicular)

Five of the following symptoms (with at least one of these*) must occur during the week before menses and remit within days of menses.
- Irritability*
- Depressed mood or hopelessness*
- Affective lability* (sudden mood swings)
- Tension or anxiety*
- Decreased interest in activities
- Change in sleep patterns
- Difficulty concentrating
- Feeling out of control or overwhelmed
- Lack of energy
- Other physical symptoms, for example, breast tenderness, bloating
- Change in appetite, for example, food cravings

Seriously interferes with work, social activities, relationships

Not an exacerbation of another disorder

Confirmed by prospective daily ratings during at least two consecutive symptomatic cycles

---

Box 45.2 Diagnostic criteria for premenstrual syndrome (PMS)

Patient reports ≥1 of the following affective and somatic symptoms during the 5 days before menses in each of three prior menstrual cycles:

Affective	Somatic
Depression	Breast tenderness
Angry outbursts	Abdominal bloating
Irritability	Headache
Anxiety	Swelling of extremities
Confusion	
Social withdrawal	

Symptoms relieved within 4 days of menses onset without recurrence until at least cycle day 13

Symptoms present in absence of any pharmacological therapy, hormone ingestion, or drug or alcohol abuse

Symptoms occur reproducibly during two cycles of prospective recording

Patient suffers from identifiable dysfunction in social or economic performance

---

PMS may be exacerbated by other stresses, typically those associated with family life. Women with a body mass index over 30 are more likely to suffer from PMS. There is also some evidence that crimes, accidents, examination failure, absenteeism and marital disturbances may be more common premenstrually.

Aetiology

PMS is not seen before puberty, during pregnancy or in post-menopausal women, and therefore, the ovarian hormones have been implicated. The mineralocorticoids, prolactin, androgens, prostaglandins, endorphins, nutritional factors (e.g. pyridoxine, calcium and essential fatty acids) and hypoglycaemia may be involved. In addition, changes in CNS function have been implicated as cerebral blood flow in the temporal lobes is decreased premenstrually in PMS sufferers, and noradrenergic cyclicity is disrupted. As symptoms vary so much from cycle to cycle, and from individual to individual, it is likely that different aetiological factors apply to different women, all of which may be affected by extenuating emotional circumstances. There is some evidence that predisposition to PMDD may be familial.

Hormones

The cyclicity of PMS suggests an ovarian involvement. This is substantiated by the fact that it is still experienced after hysterectomy if the ovaries are left intact and that it disappears during pregnancy and after the menopause. One theory attributes PMS to luteal phase progesterone deficiency leading to a progesterone/estradiol imbalance, but there is no direct clinical evidence to support this in terms of serum progesterone levels. However, the problem could lie at the cellular level, that is, a paucity of functional steroid receptors leading to differential sensitivity to hormones. Alternatively, it could be a central control defect, as ovarian suppression by GnRH analogues can alleviate symptoms in some women; however, the use of these drugs is generally not recommended because of their unwanted effects associated with production of a hypo-oestrogenic state.

The central actions of the sex steroids or their neuroactive metabolites are important. Research into the complex relationship between the steroids and the CNS is ongoing, and progressing with the advent of new tools such as the progesterone receptor modulators. Estradiol increases neuronal excitability possibly via increasing the activity of glutamate (an important excitatory neurotransmitter). Progesterone, and its metabolites, can bind to the γ-aminobutyric acid A ($GABA_A$) receptor, and this interaction would induce an effect similar to that evoked by benzodiazepines. The mineralocorticoid, aldosterone, may be associated with the increase in fluid retention as serum levels of this hormone are elevated in the luteal phase. However, no significant difference in blood levels of this mineralocorticoid has been found between PMS sufferers and non-sufferers. In contrast, one study has found that baseline levels of cortisol were elevated during the luteal phase in PMS sufferers.

Prolactin is secreted from the decidual cells at the end of the luteal phase of the menstrual cycle as well as from the anterior pituitary. This hormone has a direct effect upon breast tissue and hence may be associated with breast tenderness. Prolactin is also associated with stress and has an indirect relationship with dopamine metabolism and release in the CNS. It promotes sodium, potassium and water retention.

However, there are no consistent differences in hormone blood levels of prolactin between PMS sufferers and non-sufferers. Again, the differences could lie at the receptor level. Local hormones such as the prostaglandins may also be implicated in the aetiology of PMS as synthesis of these autocoids can be affected by the sex hormones as well as substrate availability. Prostaglandin imbalance is implicated in PMS as increased synthesis of certain prostaglandins, for example, PGE_2, have antidiuretic and central sedative effects as well as promoting capillary permeability and vasodilation. Deficiencies of others, for example, PGE_1, which can attenuate some of the actions of prolactin, may also contribute to the syndrome.

Vitamins and minerals

Pyridoxine phosphate is a co-factor in a number of enzyme reactions, particularly those leading to production of dopamine and serotonin (5-hydroxytryptamine). It has been suggested that disturbances of the oestrogen/progesterone balance could cause a relative deficiency of pyridoxine, and supplementation with this vitamin appears to ease the depression sometimes associated with the oral contraceptive pill. Decreased dopamine levels would tend to increase serum prolactin, and decreased serotonin levels could be a factor in emotional disturbances, particularly depression. There is some evidence that premenstrual mood changes are linked to cycle-related alterations in serotonergic activity within the CNS and, therefore, serotonin may be important in the pathogenesis of PMS. There are also data to suggest that a variety of nutrients may play a role in the aetiology of PMS, specifically calcium and vitamin D. Further hydroxylation of 25-hydroxyvitamin D_3 ($25(OH)D_3$) takes place in target tissues which include the breast and the endometrium. In the Nurses' Health Study II (NHSII), high total vitamin D intake lowered risk of PMS by almost a third (Bertone-Johnson et al., 2005). Oestrogen influences calcium metabolism by affecting intestinal absorption, and parathyroid gene expression and secretion, so triggering fluctuations throughout the menstrual cycle. Disruption of calcium homeostasis has been associated with affective disorders.

Essential fatty acids

Essential fatty acids, such as γ-linolenic (or gamolenic acid/ GLA), provide a substrate for prostaglandin synthesis. γ-Linolenic is converted into dihomo-γ-linolenic acid, which forms the starting point for the synthesis of prostaglandins of the 1 series (e.g. PGE_1). It has been suggested that women with PMS are abnormally sensitive to normal levels of prolactin and that PGE_1 is able to attenuate the biological effects of this hormone. Hence, if there is a γ-linolenic deficiency, then there is less substrate for PGE_1 synthesis. Therefore, the effect of prolactin with respect to breast tenderness, fluid retention and mood disturbances may be exaggerated. Numerous other dietary factors may also be involved, including excess saturated fats and cholesterol, moderate-to-high alcohol consumption, zinc and magnesium deficiencies, diabetes, ageing

and viral infections, all of which hinder the conversion of cis-linolenic acid to γ-linolenic. Pyridoxine, ascorbic acid and niacin also increase conversion of γ-linolenic to PGE_1, while there is some evidence to suggest that linolenic acid metabolite levels are reduced in women with PMS.

Psychological factors

PMS may not be wholly explicable in pathophysiological terms, but it should not be regarded as a psychosomatic disorder as there is no simple relationship between its existence, severity and personality. It is not strictly confined to particular types of women, although there is no doubt that PMS interacts with many aspects of life, especially difficult or stressful times. The latter has been termed the 'vulnerability factor' which, although not a function of the menstrual cycle, can affect the way a woman reacts.

Symptoms

Symptoms occur 1–14 days before menstruation begins and disappear at the onset or shortly after menstruation begins. For the rest of the cycle, the woman feels well. Symptoms are cyclical, although they may not be experienced every cycle, and can be either physical and/or psychological (see Boxes 45.1. and 45.2 for symptomatology). The lives of the 5% or so of women who are severely affected may be completely disrupted in the second half of the menstrual cycle. The symptoms of PMS tend to decrease as a woman gets closer to the menopause as her ovulatory cycles become less frequent.

Management

The first step in the management of PMS is recognition of the problem and realisation that many other women also suffer. Keeping a menstrual diary is useful and will establish any link between symptoms and menstruation, and this will provide a cornerstone for diagnosis. After a few months, it will allow the patient to make predictions and help her deal with changes when they arrive. The effectiveness of medical intervention depends upon which symptoms are being experienced, underlining the importance of a menstrual diary and experimentation. In terms of treatment, self-help and perseverance will be required in the management of PMS. The wide variety of symptoms may require exploring a number of treatment options before optimal relief can be achieved.

Non-pharmacological strategies

Maintenance of good general health is important, especially with respect to diet and possible deficiencies. Dietary modifications that may be helpful include restricting caffeine and alcohol intake. Smoking can also exacerbate symptoms. Exercise may help, as may learning simple relaxation techniques. If fluid retention is a problem, then reducing fluid and salt intake may be of value. Increasing the intake of natural diuretics such as prunes, figs, celery, cucumber, parsley and foods high in potassium such as bananas, oranges, dried fruits, nuts, soya beans

and tomatoes may all be useful. Hypoglycaemia may also be involved in premenstrual tiredness, so eating small protein-rich meals more frequently may help.

Results from clinical trials involving pyridoxine (vitamin B_6) have shown conflicting results. However, some women do respond to pyridoxine and show improvement, particularly with respect to mood change, breast discomfort and headache. A typical dosage regimen would be 50 mg twice daily after meals or 100 mg after breakfast. The dose should not exceed 100 mg a day. Gastric upset and headaches have been reported at doses greater than 200 mg. High doses over long periods have also been associated with peripheral neuropathies. Pyridoxine should be commenced 3 days before symptom onset and continued for 2 days after menstruation has started.

Calcium supplementation has shown some activity in reducing emotional, behavioural and physical symptoms. Likewise, there is limited evidence that supplementation with γ-linolenic acid, found in evening primrose oil, gives relief from physical symptoms, especially breast tenderness.

Pharmacological management

Progestogens. Synthetic progestogens, in preparations such as Cyclogest® and Duphaston®, have been used in the past. However, because of the lack of convincing trial evidence and the risk of side effects, the use of progestogens is no longer recommended. Possible side effects include weight gain, nausea, breast discomfort, breakthrough bleeding and changes in cycle length. Problems arise because some synthetic progestogens, especially 19-nor compounds such as norethisterone and levonorgestrel, also display some affinity for glucocorticoid, mineralocorticoid and androgen receptors. The specificity of these synthetic agents is influenced by the substituents present on the steroid nucleus, particularly at C13. For example, the third-generation progestogens that have an ethyl group at C13 (gestodene, desogestrel and norgestimate) have the least androgenic activity of all the 19-nor compounds but are still orally active.

Combined oral contraceptives (COC). Some women are helped by the COC pill because it prevents ovulation from taking place. However, the use of exogenous oestrogen may be contraindicated because it can increase the risk of venous thromboembolism. This occurs because oestrogen decreases blood levels of the potent natural anticoagulant antithrombin III and at the same time increases serum levels of some clotting factors. Women with other risk factors for thromboembolic disease should also avoid this form of therapy. The incidence of venous thromboembolism in healthy, non-pregnant women who are not taking an oral contraceptive is about five to ten cases per 100,000 women per year. For those using COCs containing second-generation progestogens, for example, levonorgestrel, this incidence is about 15 per 100,000 women per year of use. Some studies have reported a greater risk of venous thromboembolism in women using preparations containing the third-generation progestogens desogestrel and gestodene. The incidence in these women is about 25 per 100,000 women per year of use. However, it should be noted that the absolute risk of venous thromboembolism in women using COCs containing these third-generation progestogens remains very small and well below the venous thromboembolism risk associated with pregnancy.

It is thought that use of third-generation progestogens is associated with increased resistance to the anticoagulant action of activated protein C. Oral contraceptive treatment diminishes the efficacy with which activated protein C down regulates *in vitro* thrombin formation. This is known as activated protein C resistance and is more pronounced in women using the COC pills containing desogestrel than in women using those containing levonorgestrel. However, it has also been recognised that women who do react to third-generation progestogens with venous thromboembolism may be revealing a latent thrombophilia. There are several conditions, congenital or acquired, that can cause thrombophilic alterations. A genetic factor known as factor V Leiden mutation is the most common inherited cause of thrombophilia, and this mutation results in resistance to the effects of activated protein C. Carriers of this mutation have more than a 30-fold increase in risk of thrombotic complications during oral contraceptive use, although this has been disputed (Farmer et al., 2000) because no increase in risk of venous thromboembolism was found with the third-generation progestogens. In conclusion, if there is a history of thromboembolic disease at a young age in the immediate family, then disturbances of the coagulation system must be ruled out.

The combination of ethinylestradiol with drospirenone is also available as an oral contraceptive and appears to be useful in the management of PMS. Drospirenone is a derivative of spironolactone, with affinity for progesterone receptors, but it also acts as a mineralocorticoid antagonist. This progestogen, therefore, alleviates some of the salt-retaining effects of the ethinylestradiol.

Bromocriptine. Bromocriptine stimulates central dopamine receptors and thus inhibits the release of prolactin. It may be useful for breast tenderness and occasionally has beneficial effects upon fluid retention and mood changes. It should be used in small doses, for example, 1–1.25 mg at bedtime with food, to avoid the side effects of nausea and faintness due to hypotension. The dose can be slowly increased to 2.5 mg twice a day if required. It is advised that ergot-derived dopamine receptor agonists, such as bromocriptine, have been associated with pulmonary, retroperitoneal and pericardial fibrotic reactions (Anon, 2002). Excessive daytime sleepiness and sudden onset of sleep can also occur with dopaminergic drugs.

Danazol. Danazol is a synthetic steroid derived from ethisterone. It is weakly androgenic and has been described as an attenuated androgen. Danazol interacts with androgen receptors, but it also has some affinity for the progesterone receptor. It inhibits the pulsatile release of gonadotrophins from the anterior pituitary and so abolishes cyclical ovarian activity, leading to amenorrhoea in the majority of women and a subsequent fall in serum oestrogen levels. However, because of the high incidence of side effects, it tends to be used as a last resort for relief of severe mastalgia and mood changes. These side effects relate to the androgenicity of the compound and include nausea, giddiness, muscular pain, weight gain, acne and virilisation. These can be minimised by using low doses of 200 mg a day.

Gonadotrophin-releasing hormone analogues. GnRH analogues, sometimes referred to as gonadorelin analogues, are useful for managing the physical symptoms, but are less effective with respect to emotional symptoms. These agents inhibit the hypothalamic–pituitary–gonadal axis. However, they can only be used for short periods of time, no more than 6 months, because they induce a hypo-oestrogenic state, and therefore bone loss becomes significant after 6 months' treatment. Should a patient respond well to GnRH analogues for PMS following hysterectomy, because of underlying pelvic pathology, bilateral oophorectomy may also be of benefit.

Prostaglandin synthesis inhibitors. Improvements in tension, irritability, depression, headache and general aches and pains can be seen in some women who take prostaglandin synthesis inhibitors. Most of the information available centres upon the use of mefenamic acid at doses of 250 mg three times a day 12 days before a period is due, increasing to 500 mg three times a day 9 days before the period and continuing until the third day of menstruation. Other inhibitors of prostaglandin synthesis are likely to be just as effective and may be associated with fewer side effects. Some experimental evidence, however, suggests that, in addition to being a cyclo-oxygenase inhibitor, mefenamic acid also has activity as an antagonist at prostaglandin E receptors, and therefore this may be useful if heavy menstrual bleeding is also a problem. For optimum effectiveness, this form of therapy should be started 24 h before the onset of symptoms. However, this starting point may be difficult to predict for women with irregular cycles.

Antidepressants. The selective serotonin reuptake inhibitors (SSRIs) are becoming more popular in the treatment of PMS-related depression because they are effective and well tolerated (Brown et al., 2009). Several randomised controlled trials using fluoxetine, sertraline, citalopram, fluvoxamine or paroxetine concluded that SSRIs are an effective first-line therapy for severe PMS and the side effects at low doses are generally acceptable. Two studies also found that not only do SSRIs improve behavioural symptoms, but some improvement in physical symptoms was also noted. Common side effects experienced include headache, nervousness, drowsiness and fatigue, sexual dysfunction and gastro-intestinal disturbances. Other agents such as tricyclic antidepressants and anxiolytics such as buspirone have been used. However, they appear to improve fewer PMS symptoms than the SSRIs.

St John's Wort has been used to reduce the severity of PMS, but the available evidence is limited.

Dysmenorrhoea

Dysmenorrhoea is usually subdivided into primary and secondary dysmenorrhoea. The former may also be referred to as spasmodic dysmenorrhoea, which is a uterine problem and is predominantly a complaint of young women. Secondary dysmenorrhoea is so called because it occurs secondary to some underlying pelvic pathology such as endometriosis or pelvic inflammatory disease (PID).

Epidemiology

The estimates vary but epidemiological studies suggest that between 50% and 80% of women will suffer from dysmenorrhoea at some time during their reproductive life, and up to 15% of these women will be seriously debilitated by the condition, with social and economic consequences. In the USA, it has been estimated that dysmenorrhoea accounts for the loss of 600 million working hours which equates to >2 billion dollars. Women in Western countries now have fewer pregnancies and this may be a contributory factor in the increasing prevalence of dysmenorrhoea.

Primary dysmenorrhoea

Aetiology and symptoms

The incidence of primary dysmenorrhoea peaks in women in their late teens and early 20s, the pain coinciding with establishment of ovulatory cycles. A typical sufferer will usually complain of lower abdominal pain (cramping), which may radiate down into the thighs, and backache. Some women also suffer gastro-intestinal symptoms (nausea, vomiting, diarrhoea), headaches and faintness. Symptoms are intense on the first day of menses but rarely continue beyond day 1 or 2 of the cycle. Factors that appear to increase the severity include young age at menarche, extended duration of menstrual flow (pain can be most severe when the flow is lighter), smoking and parity (the prevalence and severity of dysmenorrhoea is decreased in parous women). Other factors such as weight, length of menstrual cycle or frequency of physical exercise do not influence the condition.

In terms of aetiology, studies carried out in the 1950s and 1960s first drew attention to the possible role of the prostaglandins. This was followed by many *in vivo* studies which showed that women suffering from primary dysmenorrhoea do have greater concentrations of prostaglandins, predominantly $PGF_{2\alpha}$, and to some extent PGE_2, in their menstrual fluid compared with matched control subjects. Such a prostaglandin imbalance would favour increased myometrial contractility. The effects of the prostaglandins on human myometrium are now well documented, and increased biosynthesis of prostaglandins may also account for the gastro-intestinal problems encountered by some sufferers. A role for the prostaglandins is substantiated by the fact that women whose diet contains more omega-3 fatty acids tend to suffer less. When eicosapentaenoic acid (EPA) is the substrate for prostaglandin biosynthesis, prostaglandins of the three series are produced (e.g. PGE_3 and TXA_3). Such local hormones are less potent stimulators of the myometrium and less effective vasoconstrictors. Other potential mediators are the endothelins, vasoactive peptides produced in the endometrium that may play a role in the local regulation of prostaglandin synthesis, and vasopressin, a posterior pituitary hormone that stimulates uterine activity and decreases uterine blood flow. The smaller branches of the uterine arteries are very sensitive to the vasoconstrictor actions of these mediators, and it is these resistance vessels that are important in the control of uterine blood flow. The interrelationship between blood flow and myometrial activity is summarised in Fig. 45.4.
Fig. 45.4 The interactive role of myometrial stimulants and vasoconstrictive agents in the pathway leading to pain in dysmenorrhoea.

Measurements of intrauterine pressure and myometrial activity have been made for research purposes, but there are no simple objective measurements for dysmenorrhoea.

Secondary dysmenorrhoea

Aetiology and symptoms

Secondary dysmenorrhoea tends to afflict women in their 30s and 40s, and usually occurs as a consequence of some other pelvic pathology such as endometriosis or pelvic inflammation. In terms of symptoms, it differs from primary dysmenorrhoea in that the pain may actually start before menstruation begins, continue for the duration of menses and be associated with abdominal bloating, backache and a general feeling of 'heaviness' in the pelvic area. The intrauterine contraceptive device may also exacerbate menstrual pain, since it causes localised inflammation that triggers the release of prostaglandins. The prostaglandins may also be implicated in the chain of events that lead to pain associated with secondary dysmenorrhoea. For example, if the cause is endometriosis, in which endometrial tissue is found outside the uterine cavity, then this extrauterine tissue can also synthesise prostaglandins, which may in turn disrupt normal uterine function.

Treatment

In terms of analgesia, the most rational choice would be a non-steroidal anti-inflammatory drug (NSAID) (Zahradnik et al., 2010), as these compounds decrease prostaglandin biosynthesis by inhibiting cyclo-oxygenase. Differences in anti-inflammatory activity between different NSAIDs are small. However, there is considerable variation in individual patient tolerance and response, and a lack of response to one particular agent does not mean that a patient would not respond to a different NSAID.

Mefenamic acid is frequently used to manage pain due to dysmenorrhoea. As previously stated, this compound not only inhibits prostaglandin production but also appears to possess some prostaglandin E receptor blocking activity which may serve to augment its effect. However, these preparations are not suitable for all women and some, about 30% of women, will not respond. There is substantive evidence (Marjoribanks et al., 2010) that NSAIDs are effective in the treatment of dysmenorrhoea and are more effective than paracetamol. However, there is insufficient evidence regarding the comparative efficacy of individual agents in terms of superiority of analgesia or side-effect profile.

The lack of an effect with an NSAID may be explained by pathway diversion, since the arachidonic acid that was to be converted to a prostaglandin via the action of cyclo-oxygenase can be utilised by an alternative biosynthetic route, leading to increased formation of leukotrienes. Alternatively, the second cyclo-oxygenase enzyme (COX-2), which is generally induced under pathological conditions, may be involved. Many of the currently available NSAIDs are relatively poor inhibitors of COX-2, and if some of the prostaglandins in these uterine disorders are produced via the action of this form of cyclo-oxygenase, then it is not surprising that the NSAIDs are not 100% effective. Celecoxib and etoricoxib have been shown to be effective, although none is currently licensed for use in dysmenorrhoea.

A small study has investigated the use of the leukotriene receptor antagonist montelukast (Singulair®) in the treatment of dysmenorrhoea (Fujiwara et al., 2010). The results suggest blockade of leukotriene receptors alleviate pain and reduce NSAID usage, and this appears to be most effective in women without endometriosis.

It has been estimated that approximately 50% of primary dysmenorrhoea sufferers will gain relief from taking the oral contraceptive pill, although, as this is a condition afflicting young girls, there may be attitudinal problems to the use of these products either in the patient or her parents. The oral contraceptive pill inhibits ovulation and thereby prevents increased luteal phase prostaglandin synthesis and so decreases uterine contractility. However, not all women are suitable candidates for COC use because of the potential problems associated with exogenous oestrogen. Contraindications include high blood pressure, obesity and a significant personal or family history of venous thromboembolism. Progestogenic preparations (e.g. dydrogesterone 10 mg twice daily from day 5 to 25 of cycle, norethisterone 5 mg three times daily from day 5 to 24 of the cycle) or progestogen-only pills may be useful if they inhibit ovulation. For pain relief, there appears to be no significant difference between the various formulations. Antispasmodics such as hyoscine butylbromide and propantheline bromide have a very limited role in the treatment of dysmenorrhoea, not least because of their poor oral bioavailability. Related compounds such as atropine also have negligible effects upon the human uterus. A summary of the treatment options for dysmenorrhoea is presented in Table 45.1. Future therapy may involve use of vasopressin antagonists. Clinical trials have shown these compounds to be effective and well tolerated and they do not affect bleeding patterns.

For secondary dysmenorrhoea, the best treatment lies in finding the underlying cause and then taking an appropriate therapeutic route. For example, if some form of PID is diagnosed that can be attributed to a causative organism, then antimicrobial therapy is appropriate. PID is most commonly caused by the presence of a sexually transmitted infection. The most frequent causative organisms are *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. In addition, any procedure that may compromise the mucus barrier of the cervix, for example, insertion of an intrauterine device, may also

Table 45.1 Summary of treatment options for dysmenorrhoea

Drug	Side effects
NSAIDs	Gastric irritation, which can be minimised by taking with or after food or selecting an agent with less gastrotoxicity, for example, ibuprofen. Hypersensitivity reactions, particularly bronchospasm. Headache, dizziness, vertigo, hearing problems (e.g. tinnitus) and haematuria. NSAIDs may adversely affect renal function and provoke acute renal failure
Combined oral contraceptives	Many side effects are dose related and so the development of the ultra-low-dose preparations (i.e. those containing 20 µcg ethinylestradiol) is beneficial. An alternative to the oral preparations is the low-dose transdermal combined contraceptive which releases 20 µcg ethinylestradiol and 150 µcg of norelgestromin (active metabolite of the third-generation progestogen, norgestimate). The most serious potential adverse effect is the increased risk of thromboembolism due to a decrease in circulating levels of antithrombin III while increasing serum levels of some clotting factors. This risk increases with age and smoking. Analysis of current data suggests that the risk of breast cancer is not increased for most women who use the combined oral contraceptive for the major portion of their reproductive years. Use of the combined oral contraceptive also conveys several health benefits besides being an effective contraceptive. The progestogenic side effects are discussed as follows
Progestogen-only preparations	Use of these agents may cause menstrual disturbances, for example, breakthrough bleeding. Other adverse effects relate to the selectivity of the synthetic hormone, for example, norethisterone is a first-generation progestogen and has some affinity for steroid receptors other than progesterone and so possesses androgenic, oestrogenic and antioestrogenic activity. The third-generation progestogens (gestodene, norgestimate and desogestrel) have the least androgenic activity. This should be advantageous as it is the androgenicity of the compounds that correlates with the decrease in high-density lipoproteins

increase the risk of contracting PID. Treatment of endometriosis will often reduce symptoms of dysmenorrhoea. Surgical treatment for secondary dysmenorrhoea such as hysterectomy is also possible for those women who do not want to become pregnant.

Non-pharmacological management options have recently been reviewed and include high-frequency transcutaneous nerve stimulation (TENS) and acupuncture (Proctor et al., 2002). Both of these therapies showed some potential benefit. There is limited evidence to support the use of uterine nerve ablation and presacral neurectomy, to interrupt the sensory nerve fibres near the cervix blocking the pain pathway. Dietary therapies such as vitamin and mineral supplementation have also been investigated. One study identified that vitamin B_1 100 mg daily may be effective in relieving pain (Proctor et al., 2002). Magnesium supplementation also shows promising results. Unfortunately, evidence is still lacking to support use of other herbal and dietary therapies, for example, omega-3 fatty acids. Some Chinese herbal medicines have shown interesting results but trial quality is poor.

Menorrhagia

Blood loss is considered to be excessive if it exceeds 80 mL per period, although both women themselves and clinicians find it difficult to objectively quantify blood loss. In practice, it is defined by the woman's subjective assessment of blood loss. Any change in menstruation, whether real or perceived, may be disturbing with respect to social, occupational or sexual activities and can lead to other problems including depression and concern about an undiagnosed problem such as cancer. Physically excessive blood loss will precipitate

iron deficiency anaemia (haemoglobin <12 g/dL) which, if left undiagnosed and untreated, will compound the problems outlined earlier.

If a patient has any intermenstrual or postcoital bleeding, then referral to a gynaecologist for endometrial biopsy is essential to exclude intrauterine pathology. Up-to-date cervical cytology is also required. It should also be noted that hormonal contraceptives may cause some irregular spotting or breakthrough bleeding, but this is generally a tolerance effect. Non-oral methods, particularly implants, depots and intrauterine systems decrease bleeding with continued use (see later). WHO recommends a 90-day reference period for reporting vaginal bleeding.

Epidemiology

In the UK, about 30% of women complain of heavy menstrual bleeding, and about 1 in 20 women aged 25–44 years consult their primary care doctor about this problem. Historically, once referred to a gynaecologist, 60% of women could expect to have a hysterectomy within 5 years. Recent changes in the management of women with menorrhagia and new treatment options, particularly endometrial ablations and the levonorgestrel intrauterine contraceptive devices (LNG-IUS), have significantly reduced hysterectomy rates for menorrhagia to a third of the number 10 years ago.

Aetiology and investigation

The aetiology of menorrhagia can be divided into three categories: underlying pelvic pathology, systemic disease and dysfunctional uterine bleeding (Box 45.3). The typical symptoms suggestive of underlying pelvic pathology are presented in Box 45.4. Pelvic pathologies associated with menorrhagia

---

Box 45.3 Causes of menorrhagia (percentage frequency)

Dysfunctional uterine bleeding (60%), that is cause is unknown

Other gynaecological causes (30%):
    Uterine or ovarian tumours
    Endometriosis
    Pelvic inflammatory disease
    Intrauterine contraceptive devices
    Early pregnancy complications

Endocrine and haematological causes (<5%)
    Thyroid disorders, for example hypothyroidism
    Platelet problems and clotting abnormalities

Box 45.4 Symptoms suggestive of underlying pelvic pathology

Irregular bleeding

Sudden change in blood loss

Intermenstrual bleeding

Postcoital bleeding

Dyspareunia

Pelvic pain

Premenstrual pain

include myomas (fibroids, common benign tumours of the myometrium), endometriosis, adenomyosis (penetration of endometrial tissue into the myometrium), endometrial polyps, polycystic ovarian disease and endometrial carcinoma. Although endometrial cancer is more typically seen in postmenopausal women, approximately 50% of those patients diagnosed with it premenopausally will have associated menorrhagia. Systemic diseases from which menorrhagia may stem include hypothyroidism, disorders involving the coagulation system such as elevated endometrial levels of plasminogen activator and systemic lupus erythematosus. Very few women fall into this group. About 60% of menorrhagia sufferers have no underlying systemic or pelvic pathology and have ovulatory cycles. These patients are said to have dysfunctional uterine bleeding and local uterine mechanisms appear to be important in the control of menstrual blood loss. Occasionally, cycles may be anovulatory, with heavy blood loss because the endometrium has become hyperplastic under the influence of oestrogen. In addition, use of an intrauterine contraceptive device may also increase menstrual blood loss.

Prostaglandins appear to play a role in the aforementioned local mechanisms and have been implicated in menorrhagia. Studies have suggested an association between the type and quantity of endometrial prostaglandin synthesis and the degree of menstrual blood loss. In the mid-1970s, it was discovered that women with heavy periods had raised endometrial levels of $PGF_2\alpha$ and PGE_2 and that blood loss could be reduced by the use of drugs inhibiting prostaglandin formation. More studies suggested that, in menorrhagic women, there is a shift towards increased biosynthesis of PGE_2, which is known to dilate uterine vasculature and/or increase the number of membrane receptors for this prostanoid. The availability of arachidonic acid, a substrate for prostaglandin synthesis, is also greater in women with menorrhagia. Levels of the vasodilators or their metabolites, PGI_2 and nitric oxide (NO), are also increased in the menstrual blood collected from women with excessive blood loss. It has been suggested that menorrhagia is an angiogenesis-related disease associated with changes in the pattern of vascular fragility involving the upregulation of various vascular endothelial growth factors.

Excessive menstrual blood loss is the most common cause of iron deficiency anaemia in women of reproductive age. In an otherwise healthy, well-nourished woman, it has been estimated that menstrual blood loss would have to exceed 120 mL to precipitate iron deficiency anaemia. Objective measurement of menstrual blood loss is difficult, so measurement of full blood count (including red blood cell indices and serum ferritin levels), and in particular, haemoglobin concentration, gives some indication of blood loss. Thyroid function should also be assessed. If fibroids are suspected, then pelvic ultrasound may be required. Endometrial biopsy is needed if there is an associated irregularity of menstruation or if intermenstrual or postcoital bleeding is present. In the case of regular menses, however, investigation of the uterine cavity would usually only be required in women over the age of 35 years or if medical treatment fails to alleviate symptoms. Young women presenting with dysfunctional uterine bleeding may have underlying coagulopathies such as von Willebrand's disease or Christmas disease, which should be excluded.

Treatment

The management of menorrhagia depends upon the cause of the condition and a woman's desire to conceive. Treatment can be either surgical or medical (Table 45.2). The effectiveness of drug therapy is obviously influenced by the accuracy of the diagnosis. Drug treatment is also influenced by a woman's contraceptive needs; for example, COCs can reduce menstrual blood loss by up to 50%, but in women over 35 years of age who smoke, this form of therapy would need careful consideration. Low-dose luteal phase progestogens are no longer recommended for treatment of heavy but regular periods as they increase menstrual blood loss in this situation. However, they may be of value in women with an irregular cycle. Long-term, long-acting progestogens, however, may render a woman amenorrhoeic. Other hormonally based therapies include the GnRH analogues, although their propensity to induce a hypo-oestrogenic state with long-term use may be problematic (a 6-month course would reduce trabecular bone density by 5–6%). Danazol can reduce menstrual blood loss but its use is generally prohibited by its side-effect profile. However, in 2009, a local vaginal treatment of 200 mg a day was investigated in 55 women (Luisi et al., 2009). Results showed danazol to be effective in reducing blood loss and few

Table 45.2 Summary of drug treatment options for menorrhagia

Drug	Comments
Combined oral contraceptive	See Table 45.1. These preparations are taken for 21 days with a 7-day pill-free (or placebo) period to allow for a withdrawal bleed
Progestogen-only preparations	See Table 45.1. Compounds such as norethisterone can be used, for example, 5 mg three times daily or 10 mg twice daily for the latter half of the cycle. Ten days of therapy should be sufficient from day 15 of the cycle in ovulatory cycles. However, if the cycles are anovulatory, then a minimum of 12 days' therapy is more appropriate. Progestogens for 12 days are also required to prevent endometrial hyperplasia in peri- and postmenopausal women taking oestrogen. When progestogens such as norethisterone are used, the dosage required is higher than that used in the combined oral contraceptive pill, and the adverse effects associated with the synthetic progestogens, particularly the 19-nortestosterone derivatives, may be more pronounced
Intrauterine progestogen-only contraceptive	The levonorgestrel-releasing intrauterine device (LNG-IUS) typically releases 20 µcg of levonorgestrel/24 h. Unlike non-medicated IUCDs, which may increase menstrual blood loss, this device appears to reduce it, as a result of the local endometrial actions of the progestogen. The device also offers contraceptive cover without many of the side effects associated with the non-medicated IUCDs. Progestogen-related side effects should be minimised because of the low dose of levonorgestrel employed. Initially, bleeding patterns may be disrupted, but menstrual blood loss should become lighter within three menstrual cycles
Danazol	Danazol suppress the pituitary–ovarian axis. Side effects include amenorrhoea, hot flushes, sweating, changes in libido, vaginitis and emotional lability. Danazol also causes androgenic side effects such as acne, oily skin and hair, hirsutism, oedema, weight gain, voice deepening and decreasing breast size. Danazol has to be taken daily
GnRH analogues (gonadorelin)	After an initial period of stimulation, these agents suppress the pituitary–ovarian axis. As result of inducing a hypo-oestrogenic state, these compounds should only be used for 6 months because they may decrease trabecular bone density
NSAIDs	These agents only need to be taken for the first 3–4 days of menses
Tranexamic acid	This drug appears well tolerated, but can produce dose-related gastro-intestinal disturbances. Patients who may be predisposed to thrombosis are at risk if given antifibrinolytic therapy. This compound is usually only taken for the first 3 days of menses

IUCDs, intrauterine contraceptive devices; GnRH, gonadotrophin-releasing hormone.

adverse effects were reported. A trial of ormeloxifene, a selective estrogen receptor modulator (similar to raloxifene), 60 mg twice weekly has been used successfully to reduce blood loss with relatively few side effects (Kriplani et al., 2009).

Prostaglandins have been implicated in the aetiology of several forms of menorrhagia. Therefore, NSAIDs may be of use in some patients, especially if there is pain associated with menstruation. The NSAIDs appear to be most effective in women with the heaviest blood loss, for example, mefenamic acid 500 mg three times daily from day 1 until heavy flow ceases.

Women with menorrhagia have greater endometrial fibrinolytic activity, hence the use of antifibrinolytic drugs, which are plasminogen activator inhibitors. Tranexamic acid became available for purchase over the counter in UK pharmacies in 2010 as Cyklo-F®. This can be sold to women aged 18–45 years old with a history of regular heavy menstrual bleeding over several consecutive menstrual cycles. Tranexamic acid reduces menstrual blood loss by up to 50% (Lethaby et al., 2000), the recommended dose being 1 g three times daily

starting on the first day of menses for up to 4 days. Agents such as tranexamic acid carry a risk of unwanted thrombogenesis, but this does not appear to be translated into practice as increased numbers of deep vein thromboses. This class of drugs decreases menstrual blood loss better than NSAIDs and oral luteal phase progestogen (Lethaby et al., 2005). However, tranexamic acid should be stopped if it has produced no benefit after three cycles.

The levonorgestrel intrauterine contraceptive devices (also known as intrauterine systems or LNG-IUS) can be left in place for up to 5 years following insertion. They reduce menstrual blood loss by up to 90% after 12 months of use. The levonorgestrel-releasing intrauterine system provides relief from dysmenorrhoea, effective contraception and long-term control of menorrhagia. A study showed that the levonorgestrel-releasing intrauterine device was the most cost-effective treatment followed by ablation surgery (Clegg et al., 2007). In addition, other slow-release progestogenic devices such as nesterone implants and vaginal rings also reduce menstrual blood loss and promote amenorrhoea.

Hysterectomy has been the traditional surgical treatment for menorrhagia, with either an abdominal or vaginal approach used (Marjoribanks et al., 2006). Newer alternatives to hysterectomy include endometrial ablation, which can be done by electrosurgical, laser, microwave or thermal techniques. Endometrial ablation is less invasive than hysterectomy, but recurrence of menorrhagia can occur and amenorrhoea cannot be guaranteed. There is evidence that pretreatment with a single dose of a GnRH agonist before the ablation procedure gives a better result. These preparations cause an initial stimulation of gonadotrophin release which then suppresses the hypothalamic–pituitary axis, producing a hypo-oestrogenic state. If circulating levels of oestrogen are low, then endometrial growth will not be stimulated; thus, it will be thinner, making the surgical endometrial destruction more effective. With GnRH pretreatment, modern techniques such as microwave ablation have achieved amenorrhoea rates of about 50% and patient satisfaction rates of 90%.

Endometriosis

Endometriosis is a condition in which endometrial tissue is found outside the uterus. These so-called ectopic endometrial foci have been found outside the reproductive tract in the gastro-intestinal tract, the urinary tract and even the lungs.

Aetiology

Aetiology remains unclear, although retrograde menstruation, when shed endometrial cells migrate up through the fallopian tubes, would appear to be involved. This may occur because abnormalities in uterine innervation cause disruption in the usual patterns of myometrial contractility with consequent loss of the usual fundocervical polarity. Endometriosis is found in women in whom the normal route for the menstrual flow is disrupted, such as when there is some genital tract abnormality. Women who have frequent and heavier periods also seem to be more likely to suffer from endometriosis. Familial predisposition may also be a factor and several gene polymorphisms have been identified.

Studies suggest that endometrium from endometriosis sufferers tends to be more invasive. This may reflect either biological or genetic differences in the peritoneal milieu and may be explained by the upregulation of certain types of metalloproteinase responsible for the degradation of basement membrane. Endometrial tissue from women with endometriosis has aromatase activity which can be stimulated by PGE_2. Therefore, ostensibly the endometriotic lesions have their own oestrogen supply as aromatase converts androgenic precursors into oestrogen and oestrogen stimulates biosynthesis of PGE_2; thus, the cycle is self-perpetuating. *In vitro* studies have shown that eutopic and ectopic endometrial explants have different lipidomic profiles in terms of their prostaglandin release and the myometrium from endometriosis suffers is more acontractile during menses. Pilot studies in the USA using aromatase inhibitors, such as anastrozole and letrozole, are ongoing.

Epidemiology

Endometriosis was previously considered to be a disease affecting women in their 30s onwards, but increasing use of laparoscopy has revealed that it can occur at any time throughout a woman's reproductive life. The condition is dependent upon oestrogen stimulation, and as such, it does not occur before the menarche or after the menopause. The exact incidence of the disease is unknown, but it is believed to be about 10% in the general female population of reproductive age. One study has found a positive correlation between a menarche before 13 years and increased risk of developing endometriosis.

Symptoms

Although not all women with endometriosis are symptomatic, the pelvis is the most commonly affected site. Consequently, most of the symptoms of endometriosis relate to this region. Symptoms take the form of dysmenorrhoea and pelvic pain. However, the severity of the pain does not necessarily reflect the extent of the disease because women with severe pain may have few lesions, and vice versa. Dyspareunia often with postcoital discomfort is also common. There may also be menstrual irregularities.

The link between endometriosis and infertility is recognised, but the mechanisms involved have not been established. If the ovaries or fallopian tubes themselves are directly affected by the endometriotic lesions, then fertility may be compromised by purely mechanical means. However, the situation is less clear when the endometriosis does not cause any anatomical distortions. In this case, some of the postulated causes of infertility associated with endometriosis include ovulation disorders such as luteinised unruptured follicle syndrome, anovulation, premature ovulation; hyperprolactinaemia; and changes in the peritoneal environment such as extrauterine endometrial material which, like normal endometrium, is subject to control by the ovarian steroids and like its uterine counterpart is also capable of producing prostaglandins. Prostaglandin levels, along with macrophage concentrations, are raised in the peritoneal fluid of women with endometriotic explants, and these may alter tubular and uterine motility within the abdomen.

Outside the reproductive tract, endometrial deposits can be found along the urinary and gastro-intestinal tracts. If the former is involved, then the patient may suffer from cyclical haematuria, dysuria or even ureteric obstruction. If there is gastro-intestinal tract involvement, then symptoms could include dyschezia, cyclical tenesmus and rectal bleeding or even obstruction. Very occasionally, the lesions are found at more distant sites such as the lungs, where they could cause cyclical haemoptysis. A reduction in bone mass in women with endometriosis has also been reported.

Treatment

The aims of treatment in endometriosis are to relieve symptoms and improve fertility if pregnancy is desired. Treatment can be either surgical or medical. Surgery is increasingly

performed laparoscopically and can be employed to restore normal pelvic anatomy, divide adhesions or ablate endometriotic tissue using either laser treatment or electrodiathermy. Medical treatment utilises the fact that endometriotic tissue is oestrogen dependent, and any drug therapy that will oppose the effects of oestrogen should, among other things, inhibit the growth of the endometriotic tissue. Hence, the choices of drug treatment are as follows.

- GnRH analogues such as buserelin, goserelin, leuprorelin and nafarelin. These initially stimulate the hypothalamic–pituitary–ovarian axis but thereafter induce a hypo-oestrogenic state by paradoxically inhibiting follicle-stimulating hormone (FSH) and LH release.
- Low-dose COC (20–30 μcg of ethinylestradiol) monophasic preparations have been found to be as effective as GnRH analogues, and they may slow down disease progression in young women and preserve future fertility.
- Compounds with androgenic activity such as danazol also inhibit pituitary gonadotrophin release by interfering with the negative feedback and cause atrophy of endometrial tissue.
- Progestogens such as dydrogesterone, medroxyprogesterone acetate and norethisterone initially cause decidualisation of the endometrial tissue followed by glandular atrophy.

None of the aforementioned drug therapies are free from side effects. Use of the GnRH analogues may evoke menopausal symptoms such as hot flushes, decreased libido, vaginal dryness (topical vaginal lubricants may be helpful), mood changes and headache. The problems associated with the hypo-oestrogenic state limit the long-term use of GnRH analogues. Although lipoprotein levels are not affected adversely, bone mass is, and this loss of bone density may not be entirely reversible after cessation of therapy. Various 'add-back' hormone replacement therapies have been successfully used to minimise bone demineralisation, for example, low-dose oestrogen/progestogen combinations used continuously. Such regimens protect against osteoporosis and other hypo-oestrogenic side effects without apparently affecting clinical efficacy. Pain associated with endometriosis was relieved similarly by gosarelin and a low-dose oral contraceptive (Prentice et al., 1999). However, side-effect profiles differed, for example, hot flushes and vaginal dryness with the former agent and headache and weight gain with the latter.

The androgenic compounds, because of their very nature, are associated with hirsutism, weight gain and acne. Side effects associated with synthetic progestogens relate again to androgenicity, although dydrogesterone is free from virilisation. However, using a levonorgestrel-releasing intrauterine device ensures the low dose of levonorgestrel is delivered locally and the more direct pelvic distribution may be useful in the management of endometriosis. Recent results suggest this device causes the downregulation of endometrial cell proliferation and increased apoptotic activity. Longer-term studies, over 5 years, need to be undertaken to determine how long this effect is maintained and also effectiveness on symptoms such as dyspareunia and dyschezia.

Researchers have also found that certain dietary changes may be beneficial and reduce symptoms. A decreased intake of glycaemic carbohydrates such as sugar, rice and potatoes in addition to reducing/eliminating caffeine and increasing the intake of omega-3 oils such as flax seed oil may also be helpful. In addition, one study found that women with endometriosis tended to have a lower body mass index than those without the condition.

Total pelvic clearance, including the removal of the ovaries, is practical in women who have completed their family. This tends to be a last resort treatment but it is usually effective. However, surgery may be difficult if multiple lesions are present. There is no evidence that hormonal suppression improves surgical outcome.

Neither surgical nor medical management is effective in all cases. Studies suggest that pain associated with endometriosis responds well to both surgical and medical treatment, but symptoms of recurrence occur in about 50% of patients within 5 years of stopping treatment. Fertility may be increased by the use of surgery to remove endometriotic foci causing anatomical distortion. The same benefit is not associated with medical treatment.

Case studies

Case 45.1

A 13-year-old girl is brought to her primary care doctor by her mother. She has been struggling with long, heavy periods for 6 months and as a result is missing time at school.

Questions

1. What non-hormonal treatment options would be considered?
2. What other treatments might be an option?

Answers

1. In young girls, it is worthwhile trying non-hormonal treatment options first as they will tend to have a lower side-effect profile than hormonal treatment. Tranexamic acid at a dose of 1 g three times a day should be taken while bleeding. This is a very simple and effective option with few side effects and a reported 50% reduction in menstrual blood loss. Another option would be to try a non-steroidal preparation such as mefanamic acid (500 mg three times daily from first day of bleeding until period ends), especially if associated dysmenorrhoea is a significant problem. Tranexamic acid and an NSAID can be taken together if required.
2. Cyclical norethisterone (5 mg three times daily from day 5 to day 25 of cycle) can be helpful if the periods are irregular, but it is not recommended for heavy regular periods. Progestogenic side effects such as nausea and bloating can limit use. The COC pill can be very effective at relieving menorrhagia and dysmenorrhoea, provided that there are no contraindications. Sometimes, parents can raise concerns about the use of a contraceptive agent, some parents perhaps believing that it may promote promiscuity.

Case 45.2

A 33-year-old woman has been diagnosed with endometriosis having presented with severe dysmenorrhoea. She has visited the gynaecology clinic to discuss treatment options but is very concerned about her fertility. She does not wish to conceive at the present time but would certainly plan to try for a baby in the next couple of years.

Questions

1. What effect does endometriosis and its treatment have on fertility?
2. What treatment options could be considered?

Answers

1. Severe endometriosis with significant distortion of the pelvic anatomy can cause tubal blockage and hence cause tubal factor infertility. Most patients will have much less severe endometriosis which, although not causing any anatomical abnormality, is associated with a reduction in fertility. Such couples tend to take longer to conceive perhaps because the endometrial deposits create an unfavourable milieu for the egg and sperm. Surgical treatment such as diathermy or laser destruction or excision of endometriotic deposits may improve fertility, although such surgery can be complicated. Medical treatments are not associated with an improvement in fertility rates as many treatment options are contraceptive in themselves and should not be used if women wish to try to conceive. In this situation, symptom control with analgesia may be the best option.
2. As this patient is not wishing to conceive, a trial of medical therapy should be considered. Surgery for endometriosis is a highly skilled procedure which has a significant risk of complications. Medical treatment options include GnRH analogues, the COC pill or a prolonged course of progestogens such as medroxyprogesterone acetate. All have different side effects and contraindications but are all equally effective at reducing symptoms of endometriosis. Currently, the most popular option is a 6-month course of a GnRH analogue which is generally well tolerated. Vasomotor symptoms can be treated with add-back hormone replacement therapy with a continuous combined preparation or tibolone. Treatment is limited to a 6-month course because of the bone loss associated with the GnRH-induced hypo-oestrogenism. The COC pill can be taken in a conventional way, but anecdotal experience supports tricycling, that is, taking 3 packets back to back and only having a withdrawal bleed after the third packet. Clearly, the usual contraindications to taking a COC pill apply. Progestogens are often poorly tolerated with side effects such as bloating and nausea.

Case 45.3

A 33-year-old with very heavy and prolonged periods presents to her primary care doctor requesting hysterectomy. Her mother had a hysterectomy at age 38 and this patient feels that it is her only option.

Questions

1. What treatment options would you offer this patient before considering hysterectomy?
2. What investigations are necessary?

Answers

1. Before considering treatment, the patient should have a pelvic examination, primarily to exclude large fibroids which are unlikely to respond to medical therapy. Current advice is to recommend a levonorgestrel-releasing intrauterine device as first line for heavy menstrual bleeding (NICE, 2007). If the patient declines this, other options would include tranexamic acid and/or a non-steroidal NSAID such as mefenamic acid taken at the onset of the period. The COC pill could be considered if not contraindicated. Cyclical norethisterone may be of benefit if the menstrual cycle is irregular. Hysterectomy should be reserved as the last option and if medical therapy fails. Consideration should be given to an endometrial ablative procedure before resorting to major surgery.
2. If pelvic examination is normal, the only investigation recommended for this lady is a full blood count to exclude anaemia. If examination suggests the possibility of a pelvic mass, an ultrasound scan should be organised. Further endometrium investigation, by hysteroscopy or endometrial biopsy, in women under 45 with heavy menstrual bleeding and no intermenstrual bleeding, is not indicated unless medical treatment options fail.

Menopause 46

K. Marshall and S. Calvert

Key points

- Menopause is signalled by the last menstrual period; this cessation of menstruation results from a loss of ovarian follicular activity.
- The problems associated with menopause result from the ensuing loss of the female sex steroid oestrogen.
- On average, 35% of a woman's life is spent in a peri-menopausal or post-menopausal state.
- Declining oestrogen levels can give rise to vasomotor symptoms, localised atrophy of the genitalia, psychological problems, osteoporosis and coronary heart disease.
- In the UK, only about 50% of women seek help for their symptoms.
- The hormonal content of a particular hormone replacement therapy (HRT) regimen is important, as is the route of delivery, in determining the side effects observed.
- Contraindications to HRT include undiagnosed vaginal bleeding in post-menopausal women or the presence of an oestrogen-dependent tumour.
- For women with an intact uterus, hormone replacement regimens must include a progestogenic component to prevent overstimulation of the endometrium.
- Alternative options to traditional HRT regimens include the use of tibolone, raloxifene and the bisphosphonates.

Menopause

The UK, like many countries in the developed world, has an ageing population, life expectancy is increasing and women continue to live longer than men, whilst birth rates are declining. Currently, a woman can expect to live about 35% of her life in a post-menopausal state.

Menopause is signalled by a woman's last menstrual period and is defined as the permanent cessation of menstruation resulting from loss of ovarian follicular activity. The occurrence of the last menstruation can only be diagnosed retrospectively and is usually taken as being final if it is followed by a 12-month bleed-free interval; such women are defined as being post-menopausal. The mean age of menopause in the UK is 51 years, and by the age of 54 years, around 80% of women will be post-menopausal. If menopause occurs before 40 years, it would be classed as a premature menopause. Many women will experience erratic periods before the final cessation due to inadequate ovarian oestrogen secretion; these women are described as being peri-menopausal. This transitional phase usually lasts around 4–5 years. The problems associated with menopause result from oestrogen deprivation. Hormone replacement therapy (HRT) reduces the effects of this deprivation and overcomes the associated symptoms.

Menopause is a natural event in the anatomical, physiological and psychological changes which form the female climacteric. Some women will go from the transition of being pre-menopausal to post-menopausal with no symptoms at all. Many will experience the symptoms associated with oestrogen lack, whether in the peri-menopausal or post-menopausal phase, which include:

- vasomotor symptoms
- localised atrophy of urogenital tissues
- osteoporosis
- psychological problems
- coronary heart disease.

Initially, the symptoms are more likely to include vasomotor symptoms such as hot flushes, night sweats and palpitations, and psychological problems such as mood changes, irritability, sleep disturbance, depression and decreased libido. Many women suffer from vaginal dryness and dyspareunia, which serve to enhance the loss of libido, and this in turn can adversely affect psychological well-being. The urethral mucosa may become atrophied, leading to an increased incidence of urinary tract infections or urinary incontinence. In some women, the urethra may eventually become fibrosed, leading to dysuria, frequency and urgency (urethral syndrome). The long-term consequences of oestrogen deprivation are often symptomless. There is a significant loss of calcium from the bones, which may give rise to frequent fractures, and there is a change in the blood lipid profile, which is associated with a rise in coronary heart disease.

Physiological changes

Ovarian

The approaching menopause is associated with loss of ovarian follicular activity. Human ovaries contain approximately 700,000 follicles at birth, but these cells have a high mortality rate and fewer than 500 of them will be ovulated. This number falls progressively with increasing age so that by the time the woman approaches 50 years of age, the number of follicles has fallen to zero or very few. The rate of follicle loss is highest during the decade between 40 and 50 years of age, possibly

due to an increase in the rate of degeneration (atresia) of the earliest follicles. Women over the age of 45 years who are menstruating regularly have been shown to have 10 times as many follicles as those with irregular cycles; those who have not had a period for 12 months have few follicles remaining. Thus, the size of the follicular pool is an important determinant in ovarian function.

Ovarian function includes two major roles: the production of eggs (gametogenesis) and the synthesis and secretion of hormones (hormonogenesis). Both of these functions undergo subtle changes with ageing so that fewer ova are produced and they are less readily fertilised, and the hormone levels become irregular. It is the granulosa cells in the developing follicle that normally secrete estradiol, and lack of this follicular activity results in diminishing oestrogen secretion. The diminution in the number of active follicles is followed by an increase in follicle-stimulating hormone (FSH) secretion from the anterior pituitary gland as the normal feedback mechanisms between ovarian estradiol secretion and the hypothalamus–pituitary axis become disrupted. It may be that there is an age-related decrease in sensitivity to feedback inhibition that exacerbates this increase in FSH levels. In women who are still bleeding, an FSH level exceeding 10–12 iu/L on day 2 or 3 of the bleed is indicative of a diminished ovarian response. A high FSH level (above 30 iu/L) and a low estradiol level (below 100 pmol/L) in the plasma characterise menopause. The low oestrogen level fails to stimulate growth of the uterine endometrium. As endometrial growth has not occurred, there can be no menstruation (shedding of the endometrium) and this signifies that menopause has arrived. Since ova are not being released, the production of progesterone from the ovary also ceases and the levels of luteinising hormone (LH) eventually rise. Thus, peri-menopausal and menopausal women are subjected to an increasing ovarian hormone deficiency, as shown in Table 46.1.

When the ovaries are conserved after hysterectomy they will usually continue to produce some estradiol, but the levels of this hormone will decline up to the age of the natural menopause. Post-menopausally, in all women, androstenedione (secreted from the adrenal cortex) is converted in adipose tissue and muscle (peripheral conversion) to estrone, which becomes the major circulating oestrogen (but estrone is about 10 times less potent than estradiol). The levels of FSH and LH remain elevated for many years if no HRT is given, but these elevated levels have no effect on the ovary since the follicles are atretic.

The cessation of reproductive function in the woman and the declining oestrogen production from the ovary are not the only physiological events associated with menopause. For many years, oestrogen was considered to be associated only with the genitourinary system, but its effects are more wide ranging and the major tissues affected include blood vessels, bones and the brain.

Urogenital system

With the failure in ovarian oestrogen production, the number of uterine endometrial oestrogen receptors occupied falls and endometrial growth is not sustained. Thus, in the post-menopausal woman, the endometrium becomes thin and atrophic. Likewise, in the other target tissues containing oestrogen receptors, the basal layers of the vaginal epithelium are no longer stimulated to maintain the vaginal epithelium and produce natural lubricants from the vaginal glands. The result is vaginal atrophy and a thin, dry vagina may result in dyspareunia. Because the lower urinary tract and the lower genital tract share common embryological origin, deprivation of oestrogen can result in urethral and bladder problems. Often, peri-menopausal and post-menopausal women report an increase in urinary frequency, nocturia and urge incontinence. For some women, these changes may become manifest as long as 10 years after menopause.

Bone

Osteoporosis is defined by WHO as a systemic skeletal disease characterised by low bone mass and microarchitectural deterioration of bone tissue leading to enhanced bone fragility and a consequent increase in fracture risk. In 2006, WHO estimated that it affects 200 million women worldwide. In addition, approximately 30% of women over the age of 50 have one or more vertebral fractures compared with one in five men over the age of 50 who will have an osteoporosis-related fracture in their remaining lifetime. The total number of hip fractures in 1950 was 1.66 million, and by 2050, this figure could reach 6.26 million. Twenty percent of people die within 1 year of a hip fracture (Cooper, 1997). Typical morbidities after a vertebral fracture include:

- back pain
- loss of height
- deformity (kyphosis, protuberant abdomen)
- reduced pulmonary function
- diminished quality of life: loss of self-esteem, distorted body image, dependence on narcotic analgesics, sleep disorder, depression, loss of independence.

To contextualise risk, the remaining lifetime probability in women at menopause of a fracture at any one of these sites exceeds that of breast cancer (~12%). Also, the likelihood of a fracture at any of these sites is 40% or more in developed countries (Kanis et al., 2000), a figure close to the probability of

Table 46.1 Ovarian hormone secretion after the onset of the normal menstrual cycle

	Pre-menopausal (normal cyclic)	Peri-menopausal (irregular cycles)	Post-menopausal (cessation of cycle)
Oestrogens	+++	++	+→ −
Progesterone	+++	+	−
Androgens	+	+	+→ −

coronary heart disease. Risk factors for osteoporosis include low body mass index (<19 kg/m^2), smoking, early menopause, family history of maternal hip fracture, long-term systemic corticosteroid use and conditions affecting bone metabolism, especially those causing prolonged immobility. Osteoporosis is most common in white women. People with osteoporosis are at risk of fragility fractures, occurring as a result of mechanical forces which would not ordinarily cause fracture. The clinically relevant outcome in evaluating treatments for osteoporosis is the incidence of fragility fracture as otherwise this condition is asymptomatic and therefore undiagnosed. The most common sites for these fractures are the hip, vertebrae and wrist. In the UK, the combined cost of hospital and social care for patients with a hip fracture amounts to more than £1.73 billion per year (Torgerson et al., 2001). This is very similar to the annual £1.75 billion health care system costs of coronary heart disease costs. The cost of treating all osteoporotic fractures in post-menopausal women has been predicted to increase to more than £2.1 billion by 2020 (Burge, 2001).

Cardiovascular system

Young adult women are protected against the development of hypertension and its deleterious consequences in the cardiovascular system. Levels of low-density lipoprotein cholesterol (LDL-C) and very-low-density lipoprotein cholesterol (VLDL-C) are decreased by oestrogen, and the levels of high-density lipoprotein cholesterol (HDL-C) are increased, thereby giving some protection against atherosclerosis. HDL-C is known to promote cholesterol efflux from macrophages in the arterial wall, thereby reducing atheromatous plaque and conferring a protective effect against heart disease. However, after menopause, this protection is lost and the incidence of high blood pressure and associated cardiovascular disease increases to levels similar to those found in age-matched men.

Oestrogen has direct beneficial effects in the control of blood pressure, possibly via regulating endothelium-mediated control of arteriolar tone. In women deprived of oestrogen, endothelium-dependent vasodilation is impaired. This dysfunction is largely associated with a reduction in nitric oxide availability. Oestrogen increases nitric oxide availability by stimulating endothelial nitric oxide synthase (eNOS). Oestrogen also stimulates the production of other endothelium-derived relaxing factors such as prostacyclin (prostaglandin I$_2$). Research suggests that the oestrogen receptor (ER)α is important in mediating the vascular effects of oestrogen. Studies using selective ERα agonists are being undertaken. However, many pathways are stimulated by oestrogen receptor activation and the relative importance of these different pathways varies from tissue to tissue.

Miscellaneous

Thinning of the skin, brittle nails, hair loss and generalised aches and pains are also associated with reduced oestrogen levels (Hall and Phillips, 2005). The skin is the largest non-reproductive target on which oestrogen acts. Oestrogen receptors, predominantly of the ERβ type, are widely distributed within the skin. Both types of oestrogen receptor (ERα and ERβ) are expressed within the hair follicle and associated structures. Thus, epidermal thinning, declining terminal collagen content, diminished skin moisture, decreased laxity and impaired wound healing (selective ERα ligands are being investigated for their wound-healing properties) have been reported in post-menopausal women.

In addition, women also show increasing body weight associated with ageing. This weight gain tends to increase or begin near menopause. Body fat redistribution to the abdomen also occurs independent of weight gain. This type of centralised abdominal fat distribution is widely recognised as an independent risk factor for cardiovascular disease in women.

Psychological changes

Older age at menarche and younger age at menopause are associated with poorer cognitive functioning during ageing. Recent studies have demonstrated that sex steroids have a multifarious and complex relationship with the central nervous system (Hogervorst et al., 2009). For example, there may be a positive correlation between increasing parity and improved executive functioning in response to oestrogen. This temporal relationship between oestrogen deprivation and response to exogenous oestrogen was clearly exemplified in the memory study arm of the WHI (Coker et al., 2010) and MWS studies (Hogervorst and Bandelow, 2010) at the turn of the twenty-first century.

Depression is twice as common in women as in men and may increase during times of changing hormonal levels such as at menopause. Some aspects of decreased central nervous system function have been related to falling oestrogen levels. Preclinical studies have shown oestrogen to have several positive effects on central nervous system function. Perhaps the most important is promotion of acetylcholine synthesis and increased synaptogenesis in the hippocampus. ERβ is expressed in this area of the brain as well as the entorhinal cortex and thalamus, areas crucially involved in explicit memory. Human neuroimaging studies have also indicated that oestrogen influences regional cerebral blood flow in women.

Management

Hormone replacement therapy

HRT is a complicated clinical issue requiring an in-depth risk/benefit assessment. The vast amount of study data are often conflicting, and careful analysis is required. Many factors need to be reviewed before it is prescribed. One important factor is age, as data have shown that if a woman aged less than 35 has a hysterectomy and a bilateral oophorectomy, her risk of non-fatal myocardial infarction is nearly eight times that of her age-matched counterpart who has retained her ovaries. Age at time of HRT prescription in relation to menopausal age, that is, number of years of oestrogen deprivation before

replacement, is also of importance when considering outcomes. Individual differences in hormone metabolism (both endogenous and exogenous) are also likely to be important as several different cytochrome enzymes metabolise oestrogen and may be affected by inherited polymorphisms. Therefore, some women may produce oestrogenic metabolites possessing considerable oestrogenic activity, whilst others produce metabolites which are relatively non-oestrogenic. Body mass index (BMI) also influences response to HRT, with increased plasma estradiol levels observed in women with higher BMIs.

HRT is effective for symptomatic relief of menopausal symptoms, and its use is justified when symptoms adversely affect quality of life. Current advice is that the lowest effective dose for a particular woman should be used for the shortest period of time. Local oestrogen replacement may be used to reverse the symptoms of urogenital atrophy as it appears to be more effective than systemic therapy. There is no evidence to suggest that local oestrogen treatment is associated with significant risks.

Treatment with HRT should be reviewed at least annually, with alternative therapies considered for the management of osteoporosis. In the treatment of menopausal symptoms, the benefits of short-term HRT outweigh the risks in the majority of women, but in healthy women without symptoms, the risks outweigh the benefits.

Contraindications to the use of HRT include undiagnosed vaginal bleeding in post-menopausal women, the presence of an oestrogen-dependent tumour, liver disease (where liver function tests have failed to return to normal), active thrombophlebitis, and active or recent arterial thromboembolic disease, for example, angina or myocardial infarction. A history of deep vein thrombosis and pulmonary embolism requires careful evaluation before the use of oestrogen therapy. Use in patients with Dubin–Johnson and Rotor syndromes may also be contraindicated.

Oestrogen therapy

Since the symptoms and long-term effects of menopause are due to oestrogen deprivation, the mainstay of HRT is oestrogen. This may be administered orally or parenterally but, in either case, the oestrogens used are naturally occurring and include:

- estradiol
- estriol
- estrone
- estropipate
- conjugated equine oestrogen (estrone sulphate 40%, equilin sulphate 60%)
- estradiol valerate.

The use of 'natural' oestrogens reduces the risk of the potentially dangerous oestrogenic effects such as raised blood pressure, alteration in coagulation factors and an undesirable lipid profile, which sometimes occur with the more potent synthetic oestrogens used in the oral contraceptive agents. A 'natural' oestrogen is defined as one that is normally found in the human female and has a physiological effect. Natural

oestrogens are less potent (up to 200 times) than synthetic oestrogens. As they are naturally occurring compounds, the plasma half-life of these oestrogens is similar to that of the ovarian-secreted oestrogens and the duration of action is shorter than the synthetic oestrogens, such as ethinylestradiol, used in many formulations of the contraceptive pill. The plasma ratio of estradiol to estrone is normally about 1:1 to 2:1, and the aim of HRT should be to preserve this ratio.

There are four main routes of administration for oestrogens in HRT:

- oral
- transdermal (patches/gels/cream)
- subcutaneous (implants)
- vaginal (creams and medicated rings).

The use of oral oestrogen therapy, while convenient for the patient, does mean that the oestrogen will be subjected to conversion to estrone by the liver and the gut, thereby altering the estradiol:estrone ratio in favour of the less active oestrogen, estrone. The oral preparations have different metabolic effects due to first-pass hepatic metabolism. Smoking stimulates metabolism of oestrogens by cytochrome P450 and decreases plasma oestrogen levels by 40–70% in oral oestrogen users. Smoking has no significant effect on plasma oestrogen levels in users of transdermal preparations. Oral delivery compared to transdermal delivery (Table 46.2) also has different effects on lipid levels (Vrablik et al., 2008). In addition, orally administered oestrogens undergo first-pass hepatic metabolism, which may result in some reduction in anti-thrombin III, a potent inhibitor of coagulation. Implants and patches show smaller changes in coagulation, platelet function or fibrinolysis.

More constant levels of oestrogen result from the use of transdermal patches containing estradiol, and these have the added advantage of a more physiological estradiol:estrone ratio (Delmas et al., 1999). However, the adhesive used in these transdermal patches and the alcohol base can cause skin irritation. The patch is applied to the non-hairy skin of the lower body, and care should be taken to ensure that it is placed away from breast tissue. The patch is changed either once or twice a week, thus providing a constant reservoir of estradiol to provide a controlled release into the circulation. Estradiol is also available in a gel formulation, applied daily to the skin over the area of a template (to ensure correct dosage), but

Table 46.2	Effect of HRT administration route on lipid profile
Oral	**Transdermal**
↓ Low-density lipoprotein	↓ Low-density lipoprotein
↓ Total cholesterol	↓ Total cholesterol
↑ High-density lipoprotein	↔ High-density lipoprotein
↑ Triglycerides	↓ Triglycerides
↑ Bile cholesterol	↔ Bile cholesterol

this formulation may give erratic absorption. The intranasal preparation, administered as a nasal spray, also avoids hepatic first-pass metabolism.

The oestrogen implant gives a constant level of oestrogen from a few days after insertion for up to 6 months. This formulation maintains the best estradiol:estrone ratio and is a convenient method of administration, requiring repeat implants only every 6 months. However, because the levels of oestrogen are constantly raised, there will be some increase in oestrogen receptor numbers, and this can lead to a recurrence of symptoms of oestrogen deficiency due to the presence of unoccupied oestrogen receptors, even in the presence of normal or even high oestrogen levels. This phenomenon, called tachyphylaxis, results in patients becoming symptomatic and requesting repeat implants earlier and earlier. In such cases, it is unwise to treat with additional oestrogen; the patient should receive counselling and perhaps a change of preparation. The disadvantage of the implant is that, once inserted, it cannot be removed readily and even if it is removed, the oestrogen level will take at least a month to fall. There is also evidence that the uterine endometrium, if present, remains stimulated for some time after removal of the implant.

Both the transdermal and implant preparations avoid the first-pass hepatic effects of oral oestrogens and are less likely to affect liver enzyme systems and clotting factors. Some studies show an increase in the incidence of venous thromboembolism (VTE) in women taking HRT. Therefore, patients who have a history of deep vein thrombosis or pulmonary embolism will need careful guidance, with each woman being considered individually, and the relative risks evaluated. Other risk factors include severe varicose veins, obesity or a family history of deep vein thrombosis (DVT). If HRT is justified in such patients, transdermal preparations are a better alternative than oral preparations.

Vaginal creams containing oestrogen are available but generally fail to produce the reliable plasma levels required to protect against the long-term effects of oestrogen deprivation. They provide short-term relief from menopausal symptoms, in particular, atrophic vaginitis. A vaginal ring which releases estradiol at a controlled rate in physiological levels for up to 3 months is an alternative for women who cannot tolerate transdermal patches.

The dose of oestrogen used in HRT sufficient to preserve bone density is usually higher than that necessary to alleviate vasomotor symptoms. The doses suggested to protect bone density are estradiol 2 mg/day orally, 50 µg/day transdermally and 50 mg every 6 months by implant. If the conjugated equine oestrogens are used, the oral dose should be 0.625 mg/day. The lower doses found in vaginal creams may alleviate the vasomotor symptoms but will not protect against osteoporosis. Current guidelines advise the use of the lowest possible dose of HRT to relieve vasomotor symptoms and recommend alternative treatment to prevent and treat osteoporosis.

Oestrogens should be used alone only in women who have undergone a hysterectomy; if the uterus is present, the endometrium will be stimulated and this increase in endometrial growth may be a precursor to development of a malignant condition. Current practice is to administer progestogens with oestrogen. In the early 1970s, when oestrogen was used alone, HRT received a bad press because in women who had not undergone hysterectomy, there was an increased incidence of endometrial carcinoma. In women who have undergone hysterectomy, oestrogens are usually administered continuously.

Progestogen therapy

The only proven reason for adding a progestogen to oestrogen therapy for HRT in women with an intact uterus is to protect the endometrium from hyperplasia and possible neoplasia. There are many preparations which contain progestogens added to oestrogen for a number of days per month. However, to effectively prevent endometrial hyperplasia, the progestogen must be taken for a minimum of 12 days. The minimum dose of progestogen required to protect against hyperplasia depends on the potency of the compound used.

The progestogens commonly available in HRT preparations are either derivatives of progesterone, such as medroxyprogesterone and dydrogesterone, or 19-nortestosterone substitutes such as norethisterone or levonorgestrel. All these synthetic progestogens are active following oral administration and provide adequate protection of the endometrium against oestrogen stimulation. Some transdermal preparations also incorporate a progestogenic compound in the regimen. As with all semisynthetic or synthetic hormones, these compounds may act on receptors other than the progesterone receptor, and the long-term consequence of this is not predictable.

Progesterone is the only progestogen to act solely on the progesterone receptor, but it has poor oral bioavailability and so it is difficult to achieve satisfactory plasma concentrations. However, the micronised preparations are better absorbed. Progesterone may also be administered at night in the form of a pessary or suppository, or by injection in the form of a long-lasting subdermal implant. The progestogen in HRT is most commonly administered orally or transdermally and usually one of the synthetic progestogens is used.

Oestrogen and progestogen regimens

The monthly withdrawal bleed is perceived by some postmenopausal patients to be an unacceptable side effect of HRT, and this has resulted in the development of a number of regimens in an effort to minimise this effect (Box 46.1). Formulations have been produced with which bleeding only occurs every 3 months instead of every 4 weeks, or it does not occur at all.

Box 46.1 Regimens of combined oestrogen and progestogen therapy for use in HRT

- Oestrogen 28 days + progestogen 12 or 14 days, then repeat without interval (bleed every 4 weeks)
- Oestrogen 70 days + progestogen 14 days followed by 7 days placebo tablets (bleed every 3 months)
- Oestrogen + progesterone continuously (no bleed)
- Oestrogen continuously + Mirena IUS (bleed variable but levonorgestrel likely to reduce bleed and can provoke amenorrhoea)

The use of the 70-day oestrogen preparation, while being more popular with women because bleeding only occurs every 3 months, needs further evaluation as regards endometrial protection. Bleeding can be avoided altogether if a combination of oestrogen and progestogen is given continuously throughout the treatment (continuous combined HRT). Such a preparation should only be given to women who are at least 12 months post-menopausal and have an atrophied endometrium; otherwise, breakthrough bleeding may occur. Bleeding in the first 6 months (usually just spotting) is not uncommon but bleeding after this time should be investigated, although the incidence of endometrial hyperplasia is low with this continuous regimen. Others recommend a 28-day interval between courses of treatment to allow the endometrium to become atrophic in patients who are changing from the cyclical therapy to the continuous combined therapy. Patients who commence cyclical HRT prior to ceasing menstruation should change to a continuous combined preparation only after the age of 54 (when there is an 80% chance that they will be post- rather than peri-menopausal) to reduce the risk of breakthrough bleeding. An alternative option is to use the levonorgestrol-loaded intrauterine system (IUS or Mirena) in conjunction with oral oestrogen. This option can be particularly useful for women intolerant of progestogenic side effects.

Not all progestogens have the same pharmacological profile and these differences have implications for their usage. Two of the most widely used synthetic progestogens are medroxyprogesterone acetate and norethisterone. These are used as the progestogenic component of an HRT regimen in combination with oestrogen but have been shown to increase the risk of breast cancer in long-term HRT users (Million Women Study Collaborators, 2003; Women's Health Initiative, 2002). Structurally, medroxyprogesterone acetate is more similar to natural progesterone than norethisterone. The metabolism of these two compounds is also different, as medroxyprogesterone acetate is the major progestogenic compound rather than one of its metabolites. In contrast, the metabolites of norethisterone exhibit significant activity in addition to a wide range of non-progestogenic actions. Norethisterone also binds to sex hormone–binding globulin, whereas medroxyprogesterone acetate does not.

The most notable difference in steroid receptor-binding affinity between the two synthetic progestogens and endogenous progesterone is that although all the compounds have affinity for the mineralocorticoid receptor, only the natural compound has antagonist activity. As a consequence, the synthetic compounds may be unable to counteract the sodium-retaining and blood pressure–raising effects of the oestrogens used in HRT. Endogenous progesterone affinity for the glucocorticoid receptor is also different, with medroxyprogesterone acetate a more potent antagonist than norethisterone. This may influence their side-effect profiles and impact on inflammation, immune response, adrenal function and bone metabolism.

Tibolone

Tibolone is a synthetic steroid that has oestrogenic, progestogenic and androgenic effects that alleviate menopausal symptoms without a monthly bleed. The oestrogenic effects are weak and should not promote endometrial hyperplasia, but 10–15% of women on this treatment experience breakthrough bleeding. The drug is given continuously but is not suitable for women within 1 year of menopause or immediately after oestrogen therapy because in such cases breakthrough bleeding is most likely to occur. The evidence suggests that this drug is protective against osteoporosis, but the long-term cardioprotective effects remain unclear as there is some evidence of a lowering of HDL-C. It should also be withdrawn if signs of thromboembolic disease occur. The androgenic action of tibolone tends to increase libido. It has been reported that tibolone does have fewer breast-related adverse effects than oestrogenic or oestrogenic–progestogenic HRT regimens.

Raloxifene

Raloxifene is a non-steroidal benzothiophene that binds to some oestrogen receptors and belongs to a class of drugs referred to as selective oestrogen receptor modulators (SERMs). These compounds act selectively on some oestrogen receptors to increase bone mineral density and antagonise oestrogen-dependent effects on breast and endometrial tissues in post-menopausal women. However, there is a reported increased risk of thromboembolism, particularly in the first 4 months of use. Raloxifene cannot be used to treat vasomotor symptoms in peri-menopausal women. In fact, it is reported to induce hot flushes. It has little or no stimulatory effect on the uterine endometrium and is not associated with uterine bleeding.

In summary, raloxifene is a compound that selectively stimulates one group of oestrogen receptors and may be considered a curative treatment for osteoporosis and a preventive agent in the development of oestrogen-dependent breast tumours.

Clinical monitoring

Before initiating HRT, a detailed patient history and physical examination are essential to eliminate medical disorders and genital malignancy. Bone mineral densitometry can also be helpful to establish a baseline for subsequent measurements. Blood tests should include serum electrolytes and creatinine, liver function tests, haemoglobin, lipids and a full blood count. Urine analysis should also be performed. The history and findings from the physical examination may indicate other tests. The patient should have undergone routine cervical smear examination and, preferably, mammography. In women with an intact uterus, any irregular vaginal bleeding should be investigated to exclude endometrial pathology.

After starting therapy, the woman should be seen within 3 months in the first instance and then at intervals between 6 and 12 months so that symptoms may be assessed and any side effects of therapy can be reported. Blood pressure

measurements are undertaken on these routine visits; HRT is usually associated with a fall in blood pressure due to a vasodilator action of oestrogen. Hypertension is not a contraindication to treatment with HRT but does need treatment before starting on oestrogen therapy. Some women may have an elevated blood pressure on oral oestrogen but show no such effect with the non-oral route. Weight gain may occur some months after treatment has been initiated, and the patient should be advised to reduce calorie intake accordingly.

Stopping HRT

Guidelines (see Section 7.3.1 British National Formulary) indicate that there are a number of signs and symptoms which suggest that women should be advised to immediately stop taking HRT and these include:

- sudden severe chest pain
- sudden breathlessness or cough with blood-stained sputum
- unexplained severe pain in calf of one leg
- severe stomach pain
- serious neurological effects
- hepatitis, jaundice, liver enlargement
- blood pressure above systolic 160 mmHg and diastolic 100 mmHg
- detection of a risk factor, for example, prolonged immobility after surgery or leg injury.

Once HRT has been stopped, investigation and treatment should be undertaken as appropriate.

Examples of serious neurological effects include unusual severe, prolonged headache. This is especially important if the headache occurs for the first time or it becomes progressively worse. Marked numbness, especially if it suddenly affects one side or part of the body, is important. Other neurological effects are sudden partial or complete loss of vision or disturbance of hearing or other perceptual disorders. HRT should also be stopped if the following occur: dysphasia, bad fainting attack or collapse, a first unexplained epileptic seizure/weakness and motor disturbances.

Alternatives to HRT

HRT remains the most effective treatment for vasomotor symptoms, resulting in 80–90% reduction in hot flushes. Of the non-hormonal agents, serotonin–norepinephrine reuptake inhibitors (SNRIs) such as venlafaxine and its active metabolite desvenlafaxine appear to be the next most useful treatments; gabapentin may be equally effective, whilst clonidine is only modestly effective in reducing hot flushes. Generally, there is a lack of safety information and trial data regarding alternative therapies. Trials with black cohosh, red clover and soy foods, all of which contain phytoestrogens, have yielded conflicting results and have raised concerns about hepatoxicity (black cohosh) and interactions with anti-coagulants (red clover).

Bisphosphonates such as alendronate, etidronate and risedronate are inhibitors of bone resorption and increase bone mineral density by altering osteoclast activation and function. Bisphosphonates are used with care in women with upper gastro-intestinal problems and their posology is complex. They are contraindicated in patients with hypocalcaemia. Etidronate is also contraindicated in patients with severe renal impairment.

Teriparatide, a recombinant human parathyroid hormone, is licensed to treat osteoporosis in post-menopausal women. It stimulates new formation of bone and may increase resistance to fracture. However, it has several contraindications including hypercalcaemia, severe renal impairment, metabolic bone diseases and unexplained elevations of alkaline phosphatase.

A Cochrane review supports the efficacy of strontium ranelate for the reduction of fractures in post-menopausal osteoporotic women (O'Donnell et al., 2006). The main side effect reported was diarrhoea, but the potential vascular and neurological side effects should be explored further. National guidance (NICE, 2010) details the role of alendronate, etidronate, risedronate, raloxifene and strontium ranelate for the primary prevention of osteoporotic fragility fractures in post-menopausal women.

Advances in bone biology may lead to the design of more elegant therapies to deal with osteoporosis. An example would be denosumab, a human monoclonal antibody which binds to the receptor activator of nuclear factor-κβ ligand (RANKL), which is responsible for osteoclast differentiation, activation and survival. Denosumab therefore mimics the function of osteoprotegerin limiting bone resorption.

Some small studies have shown that aerobic exercise can improve cardiovascular parameters and reduce menopausal symptoms in addition to reducing BMI.

Treatment with HRT

Vasomotor symptoms

Vasomotor symptoms include hot flushes, headaches, insomnia, giddiness and faintness. They occur in about 70–80% of women and result in physical distress in about 50%, lasting for up to 5 years in around one-quarter of the women. Flushes and sweats, particularly night sweats, indicate vasomotor instability and probably result from unoccupied oestrogen receptors on blood vessels. Oestrogens cause a rapid rise in blood flow through the blood vessels, and lack of oestrogen will render the oestrogen receptors in these vessels supersensitive to any subsequent rise in oestrogen level. During the perimenopause and menopause, oestrogen levels tend to fluctuate and it is suggested that it is these fluctuations that result in vasomotor symptoms. The extreme sensitivity of blood vessel oestrogen receptors tends to mean that a clinical response to vasomotor symptoms is achieved with low doses of oestrogen. There is also likely to be central control via a supra-pituitary mechanism incorporating several chemical pathways involving serotonin, noradrenaline and dopamine. General advice

regarding diet, for example, avoiding certain foods and drinks that cause vasodilation such as hot spicy foods and alcohol, may be helpful to some women. There is some evidence that regular exercise, which stimulates the production of hypothalamic β-endorphins, may reduce the risk of hot flushes.

Urogenital tract

These symptoms include:

- vaginal dryness and dyspareunia (painful sexual intercourse)
- vaginal discharge and bleeding
- urinary incontinence, urgency of micturition, recurrent symptoms of cystitis.

Symptoms result from oestrogen deficiency in menopausal woman and may be treated either with systemic HRT preparations or with topical applications of oestrogen incorporated into vaginal creams, pessaries and silicone vaginal rings. Such topical routes of administration do result in some systemic absorption of oestrogen through the vaginal mucosa and since this may be erratic, vasomotor symptoms may ensue. Absorption of oestrogen from these topical applications may also stimulate uterine endometrial development, if present. Consequently, it is recommended that these treatments should not be used for more than 6 months. The dose of oestrogen required to stimulate the oestrogen receptors in the vagina and the lower urethra is about 10 μcg/day, and the efficiency of such low doses has been demonstrated in a number of clinical trials. The effect of oestrogen on vaginal symptoms is more marked than its effect on urinary symptoms, but the incidence of urinary sensory dysfunction may be improved. Menopausal atrophic vaginitis may respond to a short course of a topical vaginal oestrogen preparation used for a few weeks and repeated if necessary. Current guidance is that the minimum effective dose should be used for the shortest duration.

Initial treatment with local oestrogen may result in a reaction to the presence of oestrogen in tissues containing oestrogen receptors, such as the breast and vagina. The longer the time between starting HRT and menopause, the greater these effects. During initial treatment, other effects observed include headache, appetite increase and calf muscle cramps, but these side effects usually resolve without intervention. HRT with small doses of an oestrogen (together with a progestogen in women with an intact uterus) is appropriate for alleviating menopausal symptoms such as vaginal atrophy or vasomotor instability.

Bone

In a woman not treated with HRT, approximately 15% of bone mass is lost within 10 years of menopause, resulting in an increased incidence of fracture, typically of the hip. Such fractures take up at least 10% of orthopaedic beds, and the total cost in terms of morbidity and mortality is high. The effect of oestrogen lack is to increase osteoclastic bone resorption. There is an overall increase in bone turnover, more bone is resorbed than replaced and there is an associated increase in the rate of bone loss which may continue for 5–10 years.

Oestrogens may exert effects on bone through the calcium-regulating hormones such as calcitonin and parathyroid-regulating hormones. Evidence also exists for the effect of oestrogens on the local production of bone growth factors, cytokines, in particular osteoprotegerin, which blocks osteoclastogenesis and prostaglandin E_2.

The greatest effect of oestrogen on bone is seen with implants, where an approximately 8% increase in vertebral bone density is seen within 1 year of treatment. Estradiol patches are the next most effective route of administration (Fig. 46.1), while oral therapy only achieves an increase in bone density of about 2% per annum. However, 5 years of oral oestrogen therapy will still achieve a lifetime reduction in femoral neck fracture of as much as 50%.

Oestrogen improves the quality and quantity of bone in the post-menopausal woman. It may be started at any time after menopause, and the benefit will continue for the duration of treatment. Bone loss will continue after treatment ceases, which leads into the difficult area of how long treatment should continue. It was previously recommended that to obtain maximum benefit from treatment with oestrogen, the duration of the course should be at least 10 years. However, studies have identified some potential adverse effects of HRT (Million Women Study Collaborators, 2003; Women's Health Initiative, 2002). Therefore, this recommendation is controversial, particularly in women with an intact uterus, where a combined HRT preparation is required as there is probably a greater risk of adverse outcome. Oestrogen given systemically in the peri-menopausal and post-menopausal period or tibolone given in the post-menopausal period also diminishes post-menopausal osteoporosis, but other drugs are preferred.

Raloxifene is licensed for the prevention and treatment of osteoporosis as an alternative to HRT. Raloxifene reduces bone loss and increases bone density at the spine and hip in post-menopausal women. With its oestrogen antagonist effect on breast and endometrium, raloxifene may prove to be an advance over oestrogen treatment in osteoporosis prevention and treatment in post-menopausal women. It does, however, cause hot flushes which may be unacceptable for some.
Fig. 46.1 Percentage of change from baseline (mean ± SEM) in lumbar spine bone mineral density in patients receiving placebo (open circles) or transdermal 17β-estradio 50 μcg/day (filled circles), 75 μcg/day (squares) or 100 μcg/day (filled triangles) (from Delmas et al., 1999).

Cardiovascular system

The estimated influence of HRT on the incidence of coronary heart disease, venous thromboembolism and stroke is summarised in Table 46.3.

Coronary heart disease

Women at 45 years are significantly less likely than men to die of coronary heart disease, but by the age of 60 years, the death rate from the disease is similar in both sexes. Oestrogen is probably central to this gender difference as women who experience early loss of endogenous estradiol have an accelerated risk of developing coronary heart disease. Intuitively, it would appear logical that post-menopausal women would gain benefit from receiving exogenous oestrogen. However, there are conflicting views as to whether this is, or is not, the case. A 4-year study of women with coronary heart disease in the USA (Heart and Estrogen-Progestin Replacement Study, HERS) who were also receiving HRT (conjugated equine oestrogen and medroxyprogesterone acetate) demonstrated no significant reduction in stroke (Simon et al., 2001). This was in contrast to the increased risk of myocardial infarction in the first year of starting HRT in the original HERS report (Hulley et al., 1998). The Women's Health Initiative (2002), another US-based study, also reported an increase in coronary events in the first year of receiving HRT.

The relevance of both studies to UK practice has been challenged as both involved use of conjugated equine oestrogen/medroxyprogesterone acetate regimens. In the UK, natural progesterone is preferred, and this differs from medroxyprogesterone acetate in that it does not attenuate the beneficial effects of oestrogen in reducing the development of coronary artery atherosclerosis and protecting against coronary vasospasm. A study (De Vries et al., 2006) using the UK General Practice Research Database found HRT was associated with a decrease in risk of acute myocardial infarction, and there was no difference between the different oestrogen–progestogen combinations. A recent study found that transdermal but not oral oestrogen replacement therapy significantly reduced atherogenic index of plasma (Vrablik et al., 2008). This occurred by increasing HDL particle size and therefore improving the antiatherogenic properties.

The International Menopause Society consensus statement (2009) states that HRT can be given to women around the age of natural menopause without increasing the risk of coronary heart disease and may even decrease the risk in this age group. HRT is not contraindicated in women with hypertension, and in some cases, HRT may even reduce blood pressure. HRT is contraindicated in women with a history of myocardial infarction, stroke or pulmonary embolism.

Venous thromboembolism

It is known that the oestrogen in the combined oral contraceptive pill contributes to thromboembolic disorders. Whether the same applies to the oestrogen in HRT is unclear as the dose of oestrogen found in HRT is much lower and more physiological than that in the oral contraceptive pill. Analysis of the results from the Women's Health Initiative (2002) has confirmed that there is an increased risk of pulmonary embolism with HRT and the risk is greater with oral HRT than transdermal oestrogen.

Table 46.3 Estimated influence of HRT on incidence of gynaecological cancers, venous thromboembolism, stroke and CHD (MHRA/CHM, 2007)

Risk	Age range (years)	Background incidence per 1000 women in Europe not using HRT		Additional cases per 1000 women using oestrogen only HRT (estimated)		Additional cases per 1000 women using combined (oestrogen-progestogen) HRT (estimated)	
		Over 5 years	Over 10 years	For 5 years' use	For 10 years' use	For 5 years' use	For 10 years' use
Breast cancer	50–59	10	20	2	6	6	24
	60–69	15	30	3	9	9	36
Endometrial cancer	50–59	2	4	4	32	NS	NS
	60–69	3	6	6	48	NS	NS
Ovarian cancer	50–59	2	4	<1	1	<1	1
	60–69	3	6	<1	2	<1	2
Venous thromboembolism	50–59	5		2		7	
	60–69	8		2		10	
	60–69	9		3		3	
Coronary heart disease	70–79	29–44		NS		15	

Note: Where background incidence or additional cases have not been included in the table, this indicates a lack of available data. NS indicates a non-significant difference.

Oral oestrogen, in contrast to the transdermal route, undergoes extensive first-pass metabolism. This increases the production of prothrombotic factors in the liver and is associated with a reduction in fibrinogen and factor VII activation, such as von Willebrand's factor and anti-thrombin, and enhanced fibrinolysis (RCOG, 2004). HRT is also associated with increased resistance to activated protein C.

Whilst oestrogen exposure and age increase the risk of venous thromboembolism, they do not explain the increased risk seen in the first year of HRT use. An underlying thrombophilia, a known risk in hyperoestrogenic situations, is thought to be the additional factor that makes certain women susceptible to venous thromboembolism. Guidelines (RCOG, 2004) to manage the risk of venous thromboembolism have been produced for women starting or continuing HRT (Box 46.2). The selective oestrogen receptor modulators (SERMS) such as raloxifene are considered to carry the same risk of thrombosis as oestrogen-containing HRT.

Overall, minimising cardiovascular risk whilst obtaining the benefits of HRT is influenced by the age of the women treated, their body mass index, cardiovascular health and menopausal history, the timing of initiation of HRT, the formulation of the product used, and polymorphism.

Cancer

Details of the estimated influence of HRT on the incidence of cancer are presented in Table 46.3.

Colorectal cancer

Colorectal cancers tend to occur in women over 50, and several studies have indicated that HRT can reduce the risk by around 35%. The exact mechanism for this protective effect on the colon is unclear, although it has been suggested that oestrogen may decrease the formation of potentially carcinogenic bile acids.

Ovarian cancer

The risk of ovarian cancer risk is known to be affected by exogenous hormones, with a reduced incidence consistently reported in users of oral contraceptives. The relationship between the hormones used in HRT and ovarian cancer is, however, less clear. Women who use oestrogen plus a progestogen do not appear to be at increased risk of ovarian cancer, perhaps because the progestogenic component has an apoptotic effect on the ovarian epithelium. This has been supported

Table 46.4 Properties of progestogens and their link to breast cancer (adapted from Campagnoli et al., 2005)

Progestogen	Action
19-Nortestosterone derivatives, medroxyprogesterone acetate	Oestrogenic activity Influence on 17β-hydroxysteroid dehydrogenase
19-Nortestosterone derivatives, medroxyprogesterone acetate	Metabolic effects, opposing those of oestrogen, on insulin sensitivity. Hepatic effects, opposing those of oestrogen, that is increasing IGF-1 (insulin-like growth factor), decrease in sex hormone-binding globulin
19-Nortestosterone derivatives	Binding to sex hormone-binding globulin with consequent reduction in capacity to bind oestrogen

Box 46.2 Summary of guidelines for dealing with the risk of venous thromboembolism (VTE) in women receiving HRT (adapted from RCOG, 2004)

Women starting or continuing HRT
- Women starting or continuing HRT should be counselled with regard to perceived benefits and possible risks for their individual situations, including consideration of alternative therapies.
- All women commencing HRT should be counselled about the risk of VTE, should be aware of the signs and symptoms of VTE and should be able to access medical help rapidly if they suspect that they have developed a thrombus.
- Universal screening of women for thrombophilic defects prior to or continuing the prescription of HRT is inappropriate.
- Prior to commencing HRT, a personal history and a family history assessing the presence of VTE in a first- or second-degree relative should be obtained.
- HRT should be avoided in women with multiple pre-existing risk factors for VTE.

Women with a personal or family history of VTE
- Testing for thrombophilia should be discussed with, and available for, women with a personal or family history of VTE.
- In women with a previous VTE, with or without underlying heritable thrombophilia, oral HRT should be usually avoided in view of the relatively high risk of recurrent VTE.
- In women with a personal history of VTE but with an underlying thrombophilic trait identified through screening, HRT is not recommended in high-risk situations such as anti-thrombin deficiency or with combinations of defects.
- In women over 50 years with a history of VTE within the previous year, a full clinical history and examination with appropriate investigations is warranted for underlying disease.
- If a woman who is on HRT develops VTE, HRT should be discontinued.
- If a woman wants to continue on HRT after VTE, long-term anti-coagulation should be considered.

by studies in small groups of women with a mutation in either the *BRCA1* or *BRCA2* gene (point mutations associated with breast and ovarian cancer) which demonstrated that HRT did not adversely influence the risk of developing ovarian cancer. In contrast, other large HRT trials have suggested a possible increase in risk of ovarian cancer, particularly in women who have had a hysterectomy and are receiving long-term oestrogen-only HRT.

Endometrial cancer

Unopposed oestrogen therapy at least doubles the risk of endometrial cancer, but the addition of a progestogen, either in continuous combined or sequential regimens, reduces this risk. Of the two regimens, continuous combined administration is more effective than sequential therapy in reducing the risk of endometrial hyperplasia.

Breast cancer

Breast cancer is the most common cause of disease and death in middle-aged women, affecting around one in 11 women before the age of 75 in developed countries. Over the past 20 years, there has been a growing body of evidence to suggest that progesterone contributes to the development of breast cancer. Evidence to support this came from trials in which use of combined regimens increased breast cancer risk more than oestrogen alone. This is thought to have occurred because the synthetic progestogens possessed some non-progesterone like effects that potentiated the proliferating action of oestrogen. In the USA, the most commonly used progestogen in HRT was medroxyprogesterone acetate combined with conjugated equine oestrogen and administered orally. In contrast, in central and southern Europe, a wider range of progestogens is used, particularly the 19-nortestosterone derivatives. Studies investigating the use of natural micronised progesterone to improve bioavailability in HRT regimens have demonstrated no increased risk of breast cancer. *In vitro* studies with medroxyprogesterone have found it promotes the reproductive transformation of estrone into estradiol by influencing the activity of 17β-hydroxysteroid dehydrogenase. The properties of the synthetic progestogens are outlined in Table 46.4.

The relationship between different HRT regimens and breast cancer is complex (Table 46.4). There are many potential confounders to be considered when interpreting trial data, for example, time of initiation of therapy, in relation to menopausal status, body mass index, prior hormone use, etc. Chlebowski et al. (2009) reported on the decline in breast cancer in the USA after a reduction in HRT usage following publication of the WHI trial (2002). This prompted a response from the President of the International Menopause Society (Sturdee, 2009) summarised as follows:

- Decline in breast cancer rates started at least 3 years before the WHI study was halted (which led to a dramatic drop in HRT use). This implies that decline in breast cancer rates must be independent of the reduction in HRT use.

- Breast cancer takes years to develop and at least a decade to reach the detectable stage. If HRT use causes breast cancer, then the drop in breast cancer rates would not be seen for some time.
- The drop in breast cancer rates could be due to other factors, for example, changes in screening.

Notwithstanding these arguments, the problem on what to advise women contemplating HRT can be problematic. Current advice recommends that the minimum effective dose of HRT should be used for the shortest duration, but for the treatment of menopausal symptoms the benefits of short-term HRT outweigh the risks in the majority of women, especially in those aged under 60 years (Joint Formulary Committee, 2010).

Psychological symptoms

Psychological symptoms include:

- depression
- mood changes and irritability, which may also be associated with other life changes occurring at this time
- exhaustion
- poor concentration and memory
- panic attacks
- lowered libido, which may be exacerbated by the above symptoms together with dyspareunia linked to lack of oestrogen and falling androgen levels.

The role of HRT in this area has not been clearly defined, although in several studies, surgical menopause has been associated with depression, indicating a correlation with oestrogen lack. Many women experience psychological symptoms around menopause, and although these may be associated with oestrogen deficiency, they may also result from the changes in family life that often occur around this time. Disturbance of sleep pattern and sleep deprivation, associated with menopause, are likely to contribute to the psychological symptoms. Many women find treatment with estradiol restores normal sleep and psychological problems are then reduced. Some of the mood changes will respond to counselling and psychotropic drugs. Treatment with oestrogens at high doses (patches of 100 μcg or implants of 50 mg) has also been shown to improve depression scores. If a progestogen is added into the regimen, then the results are less predictable since progestogen use is related to mood changes, particularly in women who have previously suffered from the pre-menstrual syndrome. Age negatively influences almost all sexual function domains in a significant manner.

HRT improves some aspects of sexual function during menopause, but it does not appear to improve the domains of desire and arousal. The lowered libido experienced during menopause is associated with reduced levels of circulating androgen resulting from ovarian failure. It has been demonstrated that subcutaneous implants of testosterone, 100 mg every 6 months, will increase the libido in a high proportion of patients.

Central nervous system

The relationship between oestrogen and neurodegenerative conditions, in particular, Alzheimer's disease (Mulnard et al., 2000), has received attention in the light of an observation that there is an increased incidence of the disease in older women. The development of plaques of amyloid-β, a protein that disrupts nerve cell connections in the brain, occurs more rapidly in the absence of oestrogen. This effect of amyloid-β production results in the symptoms of short-term memory loss and disorientation which occur in Alzheimer's disease (AD). Further studies are essential to clarify the relationship between HRT and Alzheimer's disease. There is some evidence that heavier women, who have higher free estradiol levels, exhibit better cognitive function in several domains. Such women may also have a greater clinical response when using exogenous oestrogen. It should also be noted that conjugated equine oestrogen is composed primarily of oestrone sulphate and this oestrogen has a much lower affinity for oestrogen receptors than oestradiol. Hence, the findings with respect to exogenous oestrogen and neurological function remain equivocal. The length of oestrogen deprivation before supplementation is also important as early administration of oestrogen for a period of several years may yet be found to be beneficial. Evidence is emerging that the progestogenic component in combined HRT is important and medroxyprogesterone acetate usage has been associated with negative cognitive outcomes. The potential of selective oestrogen receptor modulators (SERMs) as neuroprotectants has been evaluated in a breast cancer prevention trial which compared tamoxifen with raloxifene (Yaffe et al., 2001). Both agents were found to have similar effects on cognition. It is possible that HRT may have a neuroprotective effect under certain circumstances in some women and neuroimaging, for example, PIB (Pittsburgh compound B – a fluorescent agent). PET scanning may reveal effects not detectable using cognitive testing.

Case studies

Case 46.1

A 50-year-old patient has been on cyclical combined hormone replacement therapy for 6 months for troublesome hot flushes. Her periods were irregular before starting HRT. The hot flushes have resolved with this treatment and the withdrawal bleeds are acceptable, but she is struggling with the progestogenic side effects. A friend has told her to ask for the 'no-bleed' HRT as she thought this might suit her better.

Questions

1. What is the problem with considering a no-bleed preparation?
2. What other options could you suggest?

Answers

1. No-bleed preparations include continuous combined HRT and tibolone. If these are used in women before they become truly menopausal (rather than just peri-menopausal), they are associated with significant problems of unscheduled bleeding as the dose of hormone in the preparation is insufficient to override any residual ovarian activity. In women who start on HRT while still peri-menopausal, it can be difficult to know when they are truly menopausal. The recommendation therefore is that women should not take continuous combined HRT or tibolone until they are at least 12 months from their last menstrual period or are 54 years of age (when it is estimated that 80% of women will be post-menopausal).
2. Two options could be considered. Tridestra® could be used. This is a preparation where a 14-day course of combined estradiol valerate and medroxyprogesterone acetate is taken following a 70-day course of estradiol valerate. Seven days of inactive tablets follow during which the patient would be expected to have a withdrawal bleed. This means that the patient only experiences a bleed every 3 months rather than monthly. The other option would be to consider using the levonorgesterel IUS as the progestogen component of HRT together with either an oral or transdermal oestrogen preparation. This has the advantage of very few progestogenic side effects and the possibility that the patient will be rendered amenorrhoeic. If the levonorgesterel IUS is used, it should be replaced after 4 years rather than the usual 5 years when used for contraception or as a treatment for menorrhagia.

Case 46.2

An educated 57-year-old lady has been on oestrogen only HRT (Premarin® 1.25 mg) following a hysterectomy and bilateral oophorectomy for menstrual problems 10 years ago. She has mild, well-controlled hypertension. She has no personal or family history of breast disease, but her mother has osteoporosis. Her primary care doctor has suggested she should stop HRT because of concern about the long-term risks. The patient, however, is not keen, as when she tried to stop it in the past, she felt terrible.

Questions

1. What are the risks and also are there any benefits to her continuing with HRT?
2. How could she be managed?

Answers

1. She has a small increased risk of developing breast cancer, but there does not appear to be an increase in the risk of dying from breast cancer. HRT was started at the time her menopause, that is following a surgical menopause. Therefore, her risk of cardiovascular disease or stroke is not increased and may even be reduced. There may be a very small increase in the risk of venous thromboembolism, but this risk is greatest in the first year after starting HRT. There may be a reduction in the risk of developing colo-rectal cancer with HRT use. Treatment with HRT prevents osteoporosis but is not now recommended in the UK as first-line treatment for bone protection because of the balance of risk and benefit and the efficacy of other treatments such as bisphosphonates. For many women, the greatest benefit is the improved quality of life.
2. The lowest dose of HRT which relieves her menopausal symptoms, such as hot flushes, should be used. It would be sensible to halve the dose to start with and then consider a further slow reduction in dose. The patient's osteoporosis risk should be identified by reviewing diet, exercise, body mass index, etc., and bone densitometry. The risks and benefits should be discussed with the patient, taking into consideration both personal and family history. Once all the risk/benefit issues have been discussed and understood, the patient will then be in a position to make the final decision concerning treatment.

Case 46.3

A 43-year-old lady was started on cyclical HRT at the age of 37 when she was diagnosed with an early menopause after a 15-month period of amenorrhoea. She has no significant menopausal symptoms and regular light withdrawal bleeds. However, she has read that HRT should only be continued for 5 years and thinks she might stop HRT now.

....

Questions

1. Why should she be advised to continue HRT until the age of 50?
2. What advice would you give her regarding the dose and type of HRT?

....

Answers

1. Once a woman enters menopause, the fall in oestrogen levels increases the risk of cardiovascular disease and also increases bone loss causing a greater risk of osteoporotic fractures. The earlier the menopause, the greater the risk. Concern about breast cancer rates rising with increased HRT was derived from data in women over the average age of the natural menopause, that is, in their 50s, 60s and 70s. Therefore, it should not be extrapolated to women who have undergone early menopause. Women with an early menopause should be advised that any increase in the breast cancer risk only becomes important once HRT use continues beyond 50. In addition, the benefits of continuing HRT up to the age of 50 in terms of cardiovascular and bone health are significant.

2. Current advice is that the lowest dose of HRT to control menopausal symptoms should be used. This can result in the dose of HRT falling below the bone protective dose, and therefore a risk assessment for osteoporosis should be undertaken. This should include assessing lifestyle (dietary calcium, weight, weight-bearing exercise, etc.) in addition to a bone densitometry scan. This lady may wish to consider treatment with levonorgestrel IUS and oral or transdermal oestrogen as there may be a reduction in breast cancer risk associated with this combination when compared with standard cyclical HRT. This is because of limited systemic progestogen absorption. Cardiovascular well-being should be assessed, for example, family history, body mass index, blood pressure, lipids, aerobic exercise and improved where possible. This is especially important if following discussion of the risks and benefits, the patient still decided to stop HRT.

Drugs in pregnancy and lactation 47

P. Russell, L. Yates, E. Grant and P. Golightly

Key points

Drugs in pregnancy

- Assess risk/benefit ratio for the mother-fetus pair.
- Avoid non-essential drugs.
- Where drug treatment is clinically indicated, select an effective agent with the best safety profile.
- Use the lowest effective dose for the shortest possible time.
- Provide timely and accurate counselling to help avoid unfounded maternal fears about drug safety that may otherwise result in non-adherence with drug therapy or unnecessary pregnancy termination.
- Use the statement 'avoid all drugs in the first trimester where possible' cautiously as drug exposure in the second and third trimesters may still result in fetal harm.
- Remember that the harmful effects of a drug on the fetus may differ depending on the trimester of exposure.

Drugs in lactation

- Avoid unnecessary use of drugs.
- Maternal therapy only rarely constitutes a reason to avoid breastfeeding.
- Assess the risk/benefit ratio for both mother and infant.
- Monitor the infant for unusual signs or symptoms.
- Avoid use of new drugs if there is a therapeutic equivalent for which data on use in lactation are available.

Drugs in pregnancy

The use of both prescription and over-the-counter drugs in pregnancy presents a number of challenges to those asked to provide advice to women either pre-conceptually or during pregnancy. This is in part due to the fact that no two cases are the same, and that each enquiry ideally requires an individual risk assessment that takes into account what is known about the drug and its effects on the developing fetus, as well as the woman's personal medical and family history. It is now well recognised that certain drugs, chemicals and other agents, readily cross the placenta and may act as teratogens, resulting in harm to the unborn child. Robust scientific human data on the effects of many of these drugs, particularly newer preparations, are, however, frequently lacking.

There is now a greater appreciation of the risks of drug use in pregnancy, and it is generally accepted that maternal pharmacotherapy should be avoided or minimised where possible.

Nevertheless, it has been estimated that over 80% of expectant mothers take three or four drugs at some stage of pregnancy (Headley et al., 2004) with a significant number of women taking medication at the time their pregnancy is detected. Indications for drug use range from chronic illnesses such as epilepsy and depression to those commonly associated with pregnancy such as hypertension, urinary tract infections and gastro-intestinal complaints.

Approximately 2–3% of all live births are associated with a congenital anomaly. Although exogenous factors such as drugs may account for only 1–5% of these (affecting <0.2% of all live births), given that drug-associated malformations are largely preventable, they remain an important consideration.

Drugs as teratogens

A teratogen is defined as any agent that results in structural or functional abnormalities in the fetus, or in the child after birth, as a consequence of maternal exposure during pregnancy. Examples of drugs that are known to be human teratogens are shown in Box 47.1. The teratogenic mechanism for most drugs remains unclear, but may be due to the direct effects of the drug on the fetus and/or as a consequence of indirect physiological changes in the mother or fetus. Perhaps the best known, and most widely studied teratogen is thalodimide, a mild sedative

Box 47.1   Examples of drugs considered to be human teratogens
ACE inhibitors
Androgens
Carbamazepine
Carbimazole

Warfarin

739

that was widely marketed as a remedy for pregnancy-related nausea and vomiting. In 1961, thalidomide was withdrawn from the UK market following numerous reports of severe anatomical birth defects in infants of mothers who took the drug in early pregnancy. Whereas external congenital anomalies such as limb abnormalities, spina bifida and hydrocephalus may be obvious at birth, some defects may take many years to manifest clinically or be identified. Examples of delayed effects of teratogens are the behavioural and intellectual disorders associated with *in utero* alcohol exposure and the development of clear-cell vaginal cancer in young women following maternal intake of diethylstilboestrol, used first in the 1930s for the prevention of miscarriage and preterm delivery (Herbst et al., 1971).

Critical periods in human fetal development

The human gestation period is approximately 40 weeks from the first day of the last menstrual period (38 weeks' post-conception) and is conventionally divided into the first, second and third trimesters, each lasting 3 calendar months. Another method for classifying the stage of pregnancy is according to the stage of fetal development. This is a more useful approach when assessing the potential risks associated with drug use in pregnancy.

Pre-embryonic stage (weeks 0–2 post-conception)

The first two weeks post-conception are regarded as the pre-embryonic stage and describe the period up to implantation of the fertilised ovum. Teratogenic exposure during the pre-embryonic stage is thought to elicit an 'all-or-nothing' response, leading either to death of the embryo or complete recovery and normal development of the fetus. Fetal malformations following drug exposure during this period are therefore thought to be unlikely, except where the half-life of the drug is sufficient to extend exposure into the embryonic stage. A good example of the latter is isotretinoin and related vitamin A derivatives which have half-lives up to a week, and which when used systemically, for example, for the treatment of acne and psoriasis, are recognised teratogens (Nulman et al., 1998).

Embryonic stage (weeks 3-8 post-conception)

Organogenesis occurs predominantly during the embryonic stage and, with the exception of the central nervous system, eyes, teeth, external genitalia and ears, is complete by the end of the 10th week of pregnancy. Exposure to drugs during this critical period therefore represents the greatest risk of major birth defects. For this reason, women are often advised to avoid or minimise all drug use in the first trimester whenever possible. It is important to bear in mind however, that very few drugs are in fact proven teratogens and that exposure in the second and third trimesters may still result in fetal harm.

Fetal stage (weeks 9–38 post-conception)

During the fetal stage, the fetus continues to develop, grow and mature and, importantly, remains susceptible to some drug effects. This is especially true for the central nervous system, which can be damaged by exposure to certain drugs, for example, ethanol, at any stage of pregnancy. The external genitalia also continue to form from the seventh week until term, and consequently, danazol, which has weak androgenic properties, can cause virilisation of a female fetus if given in any trimester after the eighth week of pregnancy when the androgen receptors begin to form (Rosa, 1984).

Further examples include the angiotensin-converting enzyme (ACE) inhibitors, which if given in the second and third trimesters can result in fetal renal dysfunction and subsequent oligohydramnios, that is, reduced amniotic fluid volume (Sedman et al., 1995). The non-steroidal anti-inflammatory drugs (NSAIDs) are another important group of drugs that may cause problems specifically in the third trimester. These drugs inhibit prostaglandin synthesis in a dose-related fashion and, when given late in pregnancy, may result in premature closure of the fetal ductus arteriosus and fetal renal impairment (Koren et al., 2006). NSAIDs should therefore be avoided during the third trimester.

Principles of teratogenesis

In 1959, James Wilson, co-founder of The Teratology Society, proposed several principles of teratogenesis that have since been expanded and modified but remain fundamental in assessing whether a drug or chemical exposure during pregnancy is likely to be associated with reproductive or developmental toxicity. A basic understanding of these factors is essential to both the interpretation of preclinical (animal) reproductive toxicity studies and to enable accurate risk assessment in clinical practice. A subset of Wilson's principles are discussed as follows.

Timing of exposure

The stage of pregnancy at which a drug exposure occurs is key to determining the likelihood, severity or nature of any adverse effect on the fetus. Risk both between and within trimesters may be variable. For example, folic acid antagonists, for example, trimethoprim, are associated with an increased risk of neural tube defects if exposure occurs before neural tube closure (third to fourth week post-conception), but not after this period (Hernandez-Diaz et al., 2001). It has also been suggested that trimethoprim should be avoided after 32 weeks' gestation in view of the theoretical risk of severe jaundice in the neonate as a result of bilirubin displacement from protein binding, although clinical evidence to support this is lacking (Dunn, 1964). Unfortunately, the precise period of teratogenic risk is known for very few substances. One drug for which this period has been established is thalidomide, where exposure between days 20 and 36 post-conception is associated with a high risk of congenital malformation (Lenz, 1988; Newman, 1986).

Drug dose

A threshold dose above which drug-induced malformations are more likely to occur has now been demonstrated for certain teratogenic compounds, although for most a 'safe dose'

has not been conclusively determined. The likelihood of a dose relationship underlies the recommendation to use the lowest effective dose in pregnancy. For this reason, more frequent monitoring of drug levels may be recommended for certain drugs during pregnancy.

Species

Teratogenicity of a drug may be species dependent. Interestingly, preclinical thalidomide studies in mice and rats did not result in congenital malformation in the offspring (Breitkreutz and Anderson, 2008; Miller et al., 2009; Vorhees et al., 2001). Birth defects or other adverse reproductive outcomes observed in animal studies cannot therefore be simply extrapolated to the human situation. Further, the drug dose and route of administration used in early animal studies may not be comparable to clinical use in humans.

Genotype and environmental interaction

Not all fetuses exposed to known teratogenic drugs show evidence of having been affected *in utero*. It remains undetermined as to whether this variable susceptibility to teratogenic drugs is a result of genetic differences in the exposed mothers, the fetal genotype, modifying environmental factors or a combination of all three. Malformations are reported to occur in only 20–50% of infants born to mothers exposed to thalidomide during the period of greatest risk for embryopathy, that is, days 20–36 post-fertilisation (Lenz, 1966; Newman, 1985).

Similarly, maternal treatment with systemic isotretinoin during the first trimester results in fetal malformation in only 18–35% of the live born infants, with a further 30% of children exhibiting developmental delay in the absence of physical deformity (Benke, 1984; Braun et al., 1984; Hill, 1984).

Pharmacological effect

Pharmacological effects on the fetus are by far the most common drug effects during pregnancy, and the consequences are often minor and reversible compared to the idiosyncratic effects that can lead to major irreversible anomalies. Pharmacological effects are usually dose related and to some extent predictable. Drugs may adversely affect the fetus via effects on the maternal circulation or they may cross the placenta and exert a direct pharmacological effect on the fetus. Equally, drugs are sometimes administered to pregnant women in order to treat fetal disorders; for example, flecainide has been used to resolve fetal tachycardia.

The neonate can also be adversely affected by maternal drug therapy (see Table 47.1). It is generally only at birth that signs of fetal distress are observed due to *in utero* drug exposure or the effects of abrupt discontinuation of the maternal drug supply. The capacity of the neonate to eliminate drugs is reduced, and this can result in significant accumulation of some drugs, leading to toxicity. Neonatal withdrawal effects may require treatment.

Idiosyncratic drug effects in the fetus and neonate are possible but occur rarely compared with pharmacological effects.

Table 47.1 Examples of drugs with pharmacological effects on the fetus or neonate (adapted from Schaefer et al., 2007)

Drug	Possible adverse pharmacological effect	Notes
ACE inhibitors	Fetal and neonatal hypoxia, hypotension, renal dysfunction, oligohydramnios and intra-uterine growth retardation	Monitor fetus if long-term therapy in the second or third trimester
β-Blockers, for example, atenolol	Neonatal bradycardia, hypotension and hyperglycaemia	Neonatal symptoms are usually mild and improve within 48 h. No long-term effects
Benzodiazepines	'Floppy infant syndrome' Withdrawal reactions	Risk if regular use in third trimester Neonatal observation recommended
Corticosteroid (high dose)	Fetal adrenal suppression	Dependent on dose and treatment interval
NSAID	Premature closure of the ductus arteriosus (affecting fetal circulation) and fetal renal impairment (decreased urine output)	Avoid repeated use after week 28. If unavoidable, fetal circulation monitored regularly
Opioids	Neonatal withdrawal symptoms Respiratory depression	Risk if used long-term Risk if used near term
Phenothiazines	Neonatal withdrawal and transient extrapyramidal symptoms	Observation for at least 48 h. Symptoms may last for several weeks
Tricyclic and SSRI antidepressants	Neonatal withdrawal symptoms	Risk if used long-term and/or near term. Observation for at least 48 h

Maternal pharmacokinetic changes

There are a number of maternal changes which occur during pregnancy and are summarised in Table 47.2.

Absorption

Gastric and intestinal emptying time increases by 30–40% in the second and third trimesters (Pavek et al., 2009) and could be important in delaying absorption and time to onset of action for some drugs (Loebstein et al., 1997). There is also a reduction in gastric acid secretion in the first and second trimesters and an increase in mucus secretion. As a consequence of the increase in gastric pH, the ionisation, and hence absorption, of weak acids and bases can be affected.

Cardiac output and respiratory volume increase during pregnancy leading to hyperventilation and increased pulmonary blood perfusion. These changes cause higher pulmonary absorption of anaesthetics, bronchodilators, pollutants, cigarette smoke and other volatile drugs.

Distribution

The volume of distribution of drugs may be altered because of an increase of up to 50% in blood (plasma) volume and a 30% increase in cardiac output. Renal blood flow increases by up to 50% at the end of the first trimester and uterine blood flow increases and peaks at term (36–42 L/h). There is also a mean increase of 8 L in body water (60% to placenta, fetus and amniotic fluid and 40% to maternal tissues). As a consequence, there may be increased dosage requirements for some drugs to achieve the same therapeutic effect, provided these effects are not offset by other pharmacokinetic changes. Both the total plasma and the free-drug concentrations of phenytoin, carbamazepine and valproic acid decrease during pregnancy, but the free-drug fraction (ratio of free to total plasma concentration) may increase (Pavek et al., 2009).

Table 47.2 Summary of pharmacokinetic changes during pregnancy (adapted from Schaefer et al., 2007)

Absorption	Change during pregnancy
Gastro-intestinal motility	↓
Lung function	↑
Skin blood circulation	↑
Distribution Plasma volume Body water Plasma protein Fat deposition	 ↑ ↑ ↓ ↑
Metabolism Liver activity	 ↑↓
Excretion Glomerular filtration	 ↑

Protein binding

Albumin is the main plasma protein responsible for binding acidic drugs such as phenytoin and salicylates, whilst α_1-acid glycoprotein predominantly binds basic drugs, including β-blockers and opioid analgesics. As pregnancy progresses, the plasma volume increases at a greater rate than the increase in albumin which results in hypoalbuminaemia. In addition, steroid and placental hormones occupy the protein-binding sites. This leads to an increase in the fraction of unbound drug. Clinical effect is related to the concentration of unbound drug, which usually remains unchanged even though the total (bound plus unbound) plasma concentration is decreased. Thus, a fall in the total plasma concentration does not usually require an increase in dose. The α_1-acid glycoprotein concentrations remain the same as those in non-pregnancy.

Phenytoin is bound to albumin and exhibits the effects described earlier, but the situation is further complicated by increased hepatic metabolism that may necessitate a dose increase. Consequently, therapy can only be reliably guided by clinical assessment or measurement of unbound rather than total plasma concentration.

Metabolism

The metabolic activity of cytochrome P450 isoenzymes CYP3A4, CYP2D6, CYP 2A6 and CYP 2C9 and uridine 5′-diphosphate glucuronosyltransferase (UGT) isoenzymes (UGT1a1, UGT1A4 and UGT2B7) is increased during pregnancy. Drugs metabolised by these isoenzymes may therefore require dose adjustment. This may decrease the amount of the drug available for transfer across the placenta and thereby influence fetal exposure. In contrast, the metabolic activity of CYP1A2 and CYP2C19 is decreased during pregnancy and drugs metabolised by these isoenzymes may need dose reduction to minimise toxicity (see Table 47.3).

In general, the effects on individual drugs are inconsistent and difficult to predict, but knowledge of the effect of pregnancy on isoenzymes may inform decisions about possible monitoring and/or dose alterations.

Excretion

Within the first few weeks of pregnancy, the glomerular filtration rate (GFR) increases by approximately 50%. Consequently, those drugs which are excreted primarily unchanged by the kidneys, for example, lithium, digoxin and penicillin, show enhanced elimination and lower steady-state concentrations. The following drugs have shown pregnancy-induced increases of 20–65% on their renal elimination (Anderson, 2005):

- Ampicillin
- Cefuroxime
- Ceftazidime
- Cefazolin
- Pipericillin
- Atenolol

Table 47.3 Summary of pregnancy-induced effects on hepatic metabolism of some drugs (adapted from Anderson, 2005)

Isoenzyme	Drugs/probes	Effect on clearance		
		First trimester	Second trimester	Third trimester
CYP1A2	Caffeine	↓ 33%	↓ 50%	↓ 65%
CYP2A6	Nicotine	ND	↑ 54% (combined data)	
CYP2C9	Phenytoin	No effect	No effect	↑ 20%
CYP2C19	Proguanil	ND	↓ 50%	↓ 50%
CYP2D6	Dextromethorphan[a] Metoprolol	ND	ND	↑ 50%
CYP3A4	Cortisol[a] Nifedipine	ND	ND	↑ Variable[b]
UGT1A4	Lamotrigine monotherapy polytherapy	↑ 200% ↑ 65%	↑ 200% ↑ 65%	↑ 300% ↑ 90%
UGT2B7 (limited data)	Morphine	ND	ND	↑ Variable[b]

ND, not detectable.
[a]Dextromethorphan and cortisol used as probes of CYP2D6 and CYP3A4 activity.
[b]Extent variable depending on the drug studied.

- Sotalol
- Digoxin
- Lithium
- Dalteparin sodium
- Enoxaparin sodium

Fetal-placental transfer

Most drugs diffuse easily across the placenta and thus enter the fetal circulation to some extent. In general, the ratio fetal:maternal drug concentration is less than 1. Drugs differ in the extent to which they bind to fetal and maternal proteins. For example, fetal and newborn plasma proteins appear to bind ampicillin and benzylpenicillin with less affinity and salicylates with greater affinity, than maternal proteins. Maternal albumin gradually decreases during pregnancy and fetal albumin concentrations increase, so different fetal: maternal albumin concentrations occur at different stages of pregnancy. The degree of protein binding of any drug is an important determinant of its movement across the placenta. Drugs which are highly protein bound tend to achieve higher maternal and lower fetal concentrations. Drugs with very large molecular weights such as insulin and heparin have negligible transfer. Lipophilic, un-ionised drugs cross the placenta more easily than polar drugs, and weakly basic drugs may become 'trapped' in the fetal circulation due to the slightly lower pH compared with maternal plasma. Some other factors such as enzymes or drug efflux transporters in the placenta may facilitate or restrict the transfer of a drug to the fetus.

Drug dosing in pregnancy

As a general principle, the dose of a drug given at any stage of pregnancy should be as low as possible to minimise potential toxic effects to the fetus. Drug therapy that is considered essential can be tapered to the lowest effective dose either before conception (ideally) or at the time the pregnancy is diagnosed. Where drug exposure during the third trimester is predicted to have an adverse effect on the neonate postpartum, consideration may be given to slowly reducing the dose towards term to minimise the risks to the baby. Such decisions are, however, not always straightforward. Recommendations to wean an expectant mother off antidepressants and antipsychotics to reduce the likelihood of neonatal withdrawal syndrome (characterised by jitteriness, altered muscle tone, poor feeding and irritability) and, in the case of the SSRIs, avoid the possible increased risk of persistent pulmonary hypertension of the newborn (PPHN) are now being challenged. Not only are there insufficient data to conclusively demonstrate neonatal benefit or an optimal time of weaning, but also the increased risk of psychiatric problems and relapse in the immediate postpartum period needs to be taken into account.

Many physiological changes occur during pregnancy which may affect the way the body handles drugs. Knowledge of these changes can allow some prediction of the impact on pharmacotherapy while remaining aware that there is variability in the extent of these changes during the pregnancy, and high inter-individual variability. The need for changes in dosages is influenced by whether the drug is excreted unchanged by the kidneys or which metabolic isoenzymes are involved in its elimination. Women taking drugs with enhanced clearance

and for which a good correlation between plasma levels and therapeutic effect exist, should have their plasma concentrations closely monitored and dose adjusted to reduce the risk of suboptimal therapy, for example, phenytoin, carbamazepine, lithium and digoxin. Similarly, highly protein-bound drugs may require free-drug concentration monitoring. However, there is no clear guidance for adjusting doses during pregnancy, and for most drugs, the concentration of free drug, and therefore the effect of that drug, is unchanged.

Pregnancy itself can cause a temporary worsening or improvement of some diseases and in that way influence drug dosages.

Drug selection in pregnancy

Although there are few, if any, drugs for which safe use in pregnancy can be absolutely assured, only a handful of drugs in current clinical use have been conclusively shown to be teratogenic. In general, drugs that have been used extensively in pregnant women without apparent problems are recommended in preference to new drugs for which there is less experience of use. For example, methyldopa is used rarely to treat hypertension in the non-pregnant state but has historically been preferred in pregnancy because of a long history of safe use (Schaefer et al., 2007). However, older drugs may be less effective in terms of controlling maternal illness and are often associated with an increased side-effect risk profile.

In most cases, the decision as to whether to commence or continue with a medication in pregnancy will depend on the risk–benefit analysis for that specific mother–infant pair. A frequent error made by health professionals is to apply the U.S. Food and Drug Administration (FDA) pregnancy risk categories (A (*no demonstrable risk*), B, C, D and X (*teratogenic agents that are considered to be completely contraindicated in pregnancy*) when considering whether or not to prescribe a drug in pregnancy. It is now widely accepted that these categories are oversimplified and are of little practical help in a clinical setting. The FDA has proposed that the existing categories be replaced with more detailed information sheets containing a summary of the fetal risk and the additional maternal factors that need to be taken into consideration. Importantly, the need for a detailed section discussing the available data including observed human versus animal data, the study design, dose exposure, and reported congenital malformations and/or adverse events has been emphasised (see http://www.fda.gov for up-to-date information).

It is worth noting that standard literature sources often contain unhelpful information such as 'do not use in pregnancy unless the benefits outweigh the risks'. This is understandable from a medico-legal point of view but offers little in terms of risk assessment. The primary literature is frequently inadequate because ethical and legal restraints mean that randomised controlled trials are rarely undertaken in pregnant women. Often, the only information that is available is confined to retrospective studies, voluntary reporting schemes and/or animal studies. The rate of anomalies in retrospective studies and voluntary reporting databases may be erroneously elevated due to preferential reporting of abnormal outcomes. Individual case reports are also difficult to interpret as the denominator of drug exposure is unknown, and an abnormal outcome may be coincidental to the drug exposure. More recently, prospective controlled trials have been utilised where the pregnancy outcomes of a defined cohort of women exposed to the drug are compared with outcomes of a matched control group. Complete follow-up of each pregnancy and post-natal monitoring is an essential feature of this type of investigation.

Pre-conception advice

Drug use during the first trimester, in particular, the embryonic stage, carries the greatest risk of malformation as this is when the fetal organs are being formed. Ideally, all unnecessary drug therapy should be discontinued prior to conception. However, inadvertent drug exposure frequently occurs, as approximately half of all pregnancies are unplanned. It is thus critical to make careful drug choices when prescribing for women of reproductive potential.

Women with chronic illnesses requiring drug treatment should be offered specialist counselling before conception, and the options explored to reduce or change drug therapy to a safer agent. Epilepsy is an example, in which, if continued drug treatment is necessary, attempts are made to stabilise treatment with a single drug at the lowest effective dose. It is also important to note that many pregnant women become less adherent to their drug therapy out of concern about possible harm to their infant. In many cases, such as asthma, inflammatory bowel disease, epilepsy, inadequate treatment of the underlying disease may be more detrimental to the mother–fetus pair than the drugs used to treat the condition. It is thus essential that women of reproductive potential are given clear and accurate information so that unrealistic fears about the risks to their baby do not result in unnecessary pregnancy termination or disease relapse.

All women planning a pregnancy should be offered general advice to minimise the risk of congenital anomalies. This includes avoidance of recreational drugs, 'natural' or herbal remedies, alcohol, smoking, vitamin A products, minimisation of caffeine consumption and beginning daily supplementation with at least 400 μcg of folic acid to reduce the risk of neural tube defects. It is recommended that the daily dose of folic acid be increased to around 4–5 mg daily in women who have epilepsy or who have had a previous child with a neural tube defect. Some infectious diseases may carry important fetal consequences if contracted during pregnancy. For example, rubella infection in the first 20 weeks of pregnancy is associated with an increased risk of miscarriage and a syndrome comprising problems such as deafness, cardiac defects and mental retardation in more than 20% of pregnancies. Women who lack immunity to rubella should be immunised prior to conception.

Post-conception advice

It is important to draw distinction between advice given to women pre-conceptually and that provided to a pregnant woman who has already been exposed to a drug. In the former setting, it may be recommended that an alternative

preparation be considered or that a drug treatment be stopped where clinically appropriate. This advice often hinges on the lack of definitive safety data and does not automatically translate to exposure to that drug in pregnancy being an indication for discontinuing the drug, additional fetal monitoring or termination of the pregnancy on the basis of the exposure. Any change to the woman's medication should be based on a careful and individual risk assessment and include a discussion with the woman to provide her with accurate up-to-date evidence-based advice. In many such cases, the woman can be reassured that a normal baby is the most likely outcome, or where appropriate be offered additional prenatal investigation to screen for congenital malformation where the risk to fetus is considered to be significant.

Teratology Information Services and Pregnancy Registries

It is difficult to keep up to date with the published literature. There is an increasing need for summary documents that include and critically appraise all available data, and which enable health care providers to have a balanced and informed discussion with patients regarding the risks and benefits of a certain therapy in pregnancy. This is evidenced by the current debate surrounding the teratogenic potential of various antidepressants with conflicting opinion even amongst experts in the field.

Teratology information services (TISs) have been established in several countries across the world and provide evidence-based, up-to-date information and individual case-based risk assessments. In addition to reviewing published literature on drugs, teratology services also have access to specialist online databases and discussion forums. A number routinely collect pregnancy outcome data on the women about whom they receive an enquiry, to enable surveillance for potential teratogens.

For some new drugs, pregnancy registries have been initiated that record all reported drug exposures and follow up the outcome of the pregnancy. These registries are cumulative and work on the basis that specific anomalies would be identified relatively quickly and that there will eventually be sufficient statistical power to detect the magnitude of any increased risk relative to the general population. These registries may be held by a TIS, or by independent groups with an interest in a defined area. The 2009 A/H1N1 influenza pandemic provided an example of teratology services across the globe responding to the urgent need for safety data by establishing registries on antiviral and pandemic vaccine exposure during the pandemic.

Drugs in lactation

Breast milk is the best form of nutrition for young infants. It provides all the energy and nutrients required for the first 6 months of life. The World Health Organization (WHO, 2001) and the United Nations Children's Fund (UNICEF) recommend exclusive breastfeeding for this period. Benefits of breastfeeding include protection of the infant against gastric, respiratory and urinary tract infections (Kramer and Kakuma, 2002), and reduction in rates of obesity

(Horta et al., 2007), juvenile-onset diabetes (Horta et al., 2007) and atopic disease (Fewtrell, 2004). Adults who were breastfed as infants often have lower blood pressure and lower cholesterol levels (Horta et al., 2007). Maternal benefits include reduced risk of developing pre-menopausal breast cancer and delayed resumption of menstrual cycle. Breastfeeding also strengthens the mother–infant bond.

There are few contraindications to breastfeeding, although maternal HIV infection in developed countries is a notable exception. The percentage of women exclusively breastfeeding their infants after 6 months is often less than 20% (Scott et al., 2006). Reasons for early discontinuation of breastfeeding include return to work, concerns about inadequate lactation or safety of drug use.

Breastfeeding mothers frequently require treatment with prescription medicines or may self-medicate with over-the-counter preparations, nutritional supplements or herbal medicines. It is important for health professionals to understand the principles of safe use of medications during lactation in order to provide appropriate advice.

There are two main goals to consider when formulating advice for nursing mothers. These are to protect the infant from maternal drug-related adverse effects and to allow, whenever possible, necessary maternal medication (Berlin et al., 2009).

Transfer of drugs into breast milk

Most drugs pass into breast milk to some degree although transfer is usually low. The drug 'dose' ingested by the infant via breast milk only rarely causes adverse effects. Examples of adverse effects observed in breastfed infants exposed to medication via breast milk are given in Table 47.4, although not all of these are proven to be directly due to the drug ingested via breast milk.

Table 47.4 Adverse reactions reported in breastfed infants	
Atenolol	Bradycardia, cyanosis, hypotension
Ciprofloxacin	Pseudomembranous colitis
Codeine	Death
Dapsone	Haemolytic anaemia
Diazepam	Lethargy, sedation, poor suckling
Doxepin	Sedation and respiratory arrest
Erythromycin	Pyloric stenosis
Fluoxetine	Colic, irritability, sedation
Indometacin	Seizures
Lithium	T-wave abnormalities
Naproxen	Prolonged bleeding, haemorrhage, anaemia
Phenytoin	Methaemoglobinaemia

Almost all drugs enter milk by passive diffusion of un-ionised, unbound drug through the lipid membranes of the alveolar cells of the breast, according to the pH partitioning theory. Several factors influence the rate and extent of passive diffusion. These include maternal plasma level, physiological differences between plasma and milk and the physicochemical properties of the drug. Differences in composition between blood and milk determine which physicochemical characteristics influence diffusion.

Milk differs from blood in that it has a lower pH (7.2 vs. 7.4), less buffering capacity and higher fat content. The following drug parameters affect the extent of transfer into milk:

- pK_a. This is a measure of the fraction of the drug that is ionised at a given pH, for example, physiological pH. Highly ionised drugs tend not to concentrate in milk. For basic drugs, for example, erythromycin, a greater fraction will be ionised at an acidic pH, so the milk compartment will tend to 'trap' weak bases. In contrast, acidic drugs, for example, penicillins, are more ionised at higher pH values and will be 'trapped' in the plasma compartment. Drugs with higher pK_a values generally have higher milk/plasma ratios.
- *Protein binding*. Drugs that are highly bound to plasma proteins, for example, warfarin, are likely to be relatively retained in maternal plasma because there is a lower total protein content in the milk. High protein binding essentially restricts the drug to the plasma compartment as only the free fraction of the drug crosses the biological membrane. Milk concentrations of highly protein-bound drugs are usually low.
- *Lipophilicity*. The alveolar epithelium of the breast is a lipid barrier. Transfer of water-soluble drugs and ions is inhibited by this barrier. CNS active drugs usually have the characteristics required to pass into milk.
- *Molecular weight*. Drugs with low molecular weights (<200) readily pass into milk through small pores in the cell walls of alveolar cells. Drugs with higher molecular weights cross cell membranes by dissolving in the lipid layer which may substantially reduce milk concentrations. Proteins such as heparin or insulin with very large molecular weights of > 6000 are virtually excluded from milk.

The profile of a drug that passes minimally into milk would therefore be an acidic drug that is highly protein bound and has low to moderate lipophilicity, for example, most NSAIDs. In contrast, a weakly basic drug that has low plasma protein binding and is relatively lipophilic will achieve higher concentrations in the milk compartment, for example, sotalol.

In the first few days of life, large gaps exist between the alveolar cells. These permit enhanced passage of drugs into milk. By the end of the first week, these gaps close under the influence of prolactin (Lawrence and Lawrence, 2011). There is greater passage of drugs into colostrum (early milk) than in mature milk as the former contains more protein and less fat. There is also some variation in fat and protein content of milk between the beginning and end of a feed, but these changes have less influence on drug passage than the physicochemical properties of the drug.

Another method by which a drug may enter milk is by a pumping system whereby energy is used to effect transfer into milk. The most important example is iodides which pass into milk in high concentrations (Hale, 2010).

Milk to plasma concentration ratio

Several methods have been proposed to determine the amount of drug transferred to breast milk. The milk to plasma (M/P) ratio is often used as a measure of the extent of drug transfer into breast milk. It is usually obtained from case reports or small clinical studies and may be based on paired concentrations or full area under the concentration–time curve (AUC) analysis. M/P ratios that are based on a pair of milk and plasma samples collected simultaneously may be inaccurate as they assume that the concentrations of drug in milk and plasma are in parallel, which may not be the case. It is better to collect multiple samples of plasma and milk across a dosing interval or until the drug is cleared from both phases after a single dose, for determination of an M/P ratio based on the respective AUCs (M/P_{AUC}). Figure 47.1 demonstrates the markedly different estimates of M/P ratio that can be obtained via both sampling methods. The true M/P ratio may vary significantly during the same episode of breastfeeding.

If human-derived M/P ratios are lacking for a particular drug, it may be possible to predict the extent of transfer using known physicochemical properties, for example, pK_a, and a published predictive model (Atkinson and Begg, 1990; Begg et al., 1992). M/P ratios obtained from animal studies should not be used for clinical decision making, as they may not correlate well with human M/P ratios.

Studies in humans demonstrate that most drugs have an M/P ratio less than 1.0, with the range of reported ratios being from around 0.1 to 5.0. It is often thought that drugs with high M/P ratios (e.g. 5.0) are unsafe because the concentration in milk exceeds that in plasma, while those with low ratios (<1.0) are believed to be safe. This is not always the case as the M/P ratio often fails to correlate with the 'dose' of drug the infant
Fig. 47.1 Diagrammatic representation of a drug concentration–time profile in the maternal plasma and milk phases after a single oral dose. The points a, b and c illustrate simultaneous sampling times from both phases. Sampling at 'a' would yield an estimated M/P value of 0.2, at 'b' a value of 1.0, and at 'c' a value of 9.3. All can be misleading. The true M/P ratio calculated by the AUC method is 1.2 when extrapolated to infinity.

ingests via milk. The amount of drug transferred into milk is principally determined by the maternal plasma level. Thus, even where the *M/P* ratio is high, if the maternal plasma level is low, drug transfer is still low. Therefore, the *M/P* ratio must never be used as the sole measure of drug safety in breastfeeding. However, it can be used to estimate the 'dose' ingested via milk, which is a better predictor of safety.

Calculating the infant 'dose' ingested via milk

Infant plasma drug levels are the most accurate indicator of drug exposure, but these are seldom available.

When using quantitative data from milk analyses, the most accurate estimation of the infant 'dose' is from studies in which the milk is collected over a complete dose interval at steady state and the total dose is calculated (Fig. 47.2). Unfortunately, these studies are seldom performed. Therefore, information must be obtained from less than ideal conditions.

If the *M/P* ratio is known from published studies, the likely infant dose (D_{inf}) can be calculated as follows, with some assumptions:

$$D_{inf} = Cp_{mat} \times M/P \times V_{milk}$$

where Cp_{mat} is the average maternal plasma concentration. M/P_{AUC} is used in preference to a ratio based on paired concentrations when available, but this is seldom the case. The volume of milk ingested (V_{milk}) is not known but is generally assumed to be around 150 mL of milk per kilogram of body weight per day. The above equation simplifies if the actual milk concentration data are available:

$$D_{inf} = C_{milk} \times V_{milk}$$

The likely infant plasma drug concentration (Cp_{inf}) can be calculated by:

$$Cp_{inf} = F \times D_{inf} / Cl_{inf}$$

where F is oral availability and Cl_{inf} is the infant clearance. Unfortunately, neither F nor Cl_{inf} is known accurately for
Fig. 47.2 The cumulative dose received by the infant is plotted against time. The arrows represent the maternal dose times. This type of study is undertaken by the mother expressing all the milk, from both breasts, at usual feeding times. An aliquot of milk is taken and assayed for the drug. The volume of milk is measured and the total amount of drug at each time is calculated as the product of concentration and volume. This type of study must be undertaken at steady state.

infants, so estimation of the likely steady-state average plasma drug concentration will be very approximate. Weight-adjusted Cl_{inf} values, that is, L/h/kg, are often significantly less than adult values in the early stages of life (Table 47.5).

Given the difficulty in estimating infant plasma drug concentrations, the relative infant dose, for example, compared with a therapeutic infant dose, is often used as a surrogate of exposure. To give some basis for comparison, the likely infant dose from milk can be compared with an infant therapeutic dose. This is reasonable for drugs such as paracetamol that are usually administered to infants but is unsuitable for drugs such as antidepressants that are not. In the absence of a clearly defined range of infant doses, the weight-adjusted maternal dose expressed as a percentage (% dose) is widely used to indicate infant drug exposure.

$$\text{Relative infant dose (RID)} = \frac{\text{Dose in infant via milk } [D_{inf}(\text{mg} / \text{kg} / \text{day})]}{\text{Dose in mother } [D_{mat}(\text{mg} / \text{kg} / \text{day})]} \times 100$$

For the great majority of drugs, this calculation yields infant doses in the order of 0.1–5.0% of the weight-adjusted maternal dose expressed as a percentage (% dose). It is generally thought that relative infant dose values of less than 10% of the maternal dose are probably safe. However, the inherent toxicity of the drug should be taken into account when using this figure.

To calculate the daily infant drug intake via milk, the standard milk intake of 150 mL/kg/day is multiplied by the concentration of the medication in milk:

Estimated daily infant intake = Drug concentration in milk (μcg/L) × 0.15/infant weight (kg)

Some authors use the peak concentration in milk to indicate the maximum infant intake.

Variability

To complicate matters further, there will be significant variability between and within individuals in the values used to estimate infant exposure (i.e. D_{inf}, F, Cl_{inf}, where D_{inf} is itself a function of the estimated parameters Cp_{mat}, M/P, volume of milk). Some of this variability will change over time due to developing organ function in the maturing baby and part will

Table 47.5 Approximate drug clearance by age as percentage of maternal value (Begg, 2000)

24–28 weeks' post-conceptual age	5%
28–34 weeks' post-conceptual age	10%
34–40 weeks' post-conceptual age	33%
40–44 weeks' post-conceptual age	50%
44–68 weeks' post-conceptual age	66%
Over 68 weeks' post-conceptual age	100%

be unexplained variability. In addition to this pharmacokinetic variability, there will be variability in response of the infant to any given concentration of the drug. It is fortunate that most drugs seem to fall readily into safe (RID <10%) based on expected exposure. However, care should be taken when using these values to assess drug safety in lactation, when variability in the estimates of the parameters used may impact on the accuracy of prediction of their safety. This is especially true for those circumstances when initial estimates of these parameters are less precise, for example, in neonates.

Recently, attention has been focused on the possible role of pharmacogenetic factors in affecting the safety of breast-fed infants exposed to drugs via milk (Madadi et al., 2009). Sedation (and one death) occurred in infants of mothers with rare genotypes of cytochrome P450 2D6 leading to ultra-rapid metabolism of codeine to morphine. The incidence of these genotypes varies amongst different populations. The overall percentage of Western Europeans with the CYP2D6 ultra-rapid metaboliser phenotype is 5.4% (Ingelman-Sundberg, 2005). Higher percentages have been reported in populations from northeast Africa and the Middle East.

Assessing the risk to the infant

Many factors must be considered when assessing the risk of maternal drug therapy to the breastfeeding infant (Box 47.2).

Inherent toxicity of the drug will be a main factor in determining infant safety. Thus, antineoplastic drugs, radionuclides and iodine containing compounds would be of concern. Multiple maternal therapy with drugs with similar side-effect profiles, for example, psychotropic drugs or anticonvulsants is likely to increase the risk to the infant. Oral bioavailability is an indicator of the drug's ability to reach the systemic circulation after oral administration. Drugs with a low oral bioavailability are either poorly absorbed from the gastro-intestinal tract, broken down in the gut or undergo extensive 'first pass' metabolism in the liver before entering plasma.

The presence of active metabolites, for example, desmethyldiazepam, may prolong infant drug exposure and lead to drug accumulation, especially where drug clearance is low such as in the neonatal period. Similarly, drugs with long half-lives, for example, fluoxetine, may be problematic at this time. Drug clearance by the infant does not reach adult values until 6–7 months (Table 47.5). A premature infant of 30 weeks' gestational age has a drug clearance value of about 10% of the maternal value. It is important to distinguish between gestational age and time after delivery. A 2-week-old infant born at 28 weeks will have a gestational age of 30 weeks.

Box 47.2 Factors affecting infant risk from maternal therapy

Drug adverse reaction profile
Relative infant dose (RID)
Oral bioavailability
Active metabolites
Half-life
Gestational age of the infant
Full maternal drug regimen
Pharmacogenetic factors

The maternal drug regimen can affect infant risk. Single doses or short courses seldom present problems, whereas chronic therapy can be problematic. Topical or inhalation therapy usually results in much lower plasma drug levels and therefore lower passage into milk. Multiple maternal medications increase the risk to the infant.

Reducing risk to the breastfed infant

A number of strategies may be adopted to reduce the risk of drug-related side effects in the breastfed infant. One technique that has been recommended for reducing infant exposure is to give the maternal dose immediately after the infant has been fed with the aim of avoiding feeding at peak milk concentrations. However, this is often impractical, especially where young infants are feeding frequently up to 2 hourly. In addition, accurate data on times of peak levels in milk are often unavailable, and it cannot be assumed that times of peak milk levels mirror those in plasma. This technique should be used selectively, that is, where the drug has a short half-life and where peak and trough levels are predictable, for example, antibiotics, anaesthetics.

Where a single dose of a drug known to be hazardous is given to a breastfeeding mother, for example, a radiopharmaceutical, it will usually be possible to resume breastfeeding after a suitable washout period, calculated as five times the half-life. Where the half-life is very long, the washout period necessary to avoid hazardous exposure to the infant may exceed the period of sustainable lactation.

Breastfeeding mothers should be advised to avoid self-medication. Where drug use is clearly indicated, the lowest effective dose should be used for the shortest possible time. Use of topical therapy such as eye/nasal drops for hay fever would reduce drug exposure in comparison to oral antihistamines.

The maternal regimen should be simplified wherever possible. A review of therapy before delivery will help to reduce risks to the neonate. New drugs are best avoided if a therapeutic equivalent is available for which data on safe use in lactation exists. All infants exposed to drugs via breast milk should be monitored for any untoward effects. Measures to ensure the safety of the breastfed infant are summarised in Box 47.3. Some commonly used drugs thought to be safe to use in mothers of full-term healthy infants are listed in Table 47.6.

Special situations

Neonates and premature infants

Neonates and especially premature infants are at greater risk of developing adverse effects after exposure to drugs via breast milk. Gastric emptying time is significantly prolonged and, in some cases, may alter absorption kinetics. Protein binding is decreased and values for total body water are higher than for adults. Renal function is limited because the kidney is anatomically and functionally immature. The neonate's capacity to conjugate drugs in the liver is often deficient. For example, the half-life of oxazepam (which is subject to glucuronidation) is three to four times longer in neonates than in adults.

Box 47.3 Measures to ensure the safety of the breastfed infant

Avoid unnecessary maternal drug use
Seek professional advice on the suitability of over-the-counter products
Avoid herbal products because of lack of data to support safe use
Assess the risk/benefit ratio for both mother and infant
Use the minimum clinically effective dose for the shortest possible time
Review maternal therapy towards the end of pregnancy
Choose a drug regimen and route of administration which presents the minimum of drug to the infant via breast milk
Avoid drugs known to cause serious toxicity in adults or children
Monitor the infant for unusual signs or symptoms
Avoid new drugs if there is a therapeutic equivalent with data to support safe use in lactation
Recognise risk factors, for example, prematurity, infant morbidity, multiple maternal medications

Table 47.6 Examples of commonly used drugs thought to be safe for use in breastfeeding mothers of full-term healthy infants[a]

Drug groups	Individual drugs
Antacids	Cetirizine
Bulk laxatives	Clotrimazole
Cephalosporins	Cromoglycate
Inhaled medications, for example, salbutamol	Diclofenac
	Heparin
Penicillins	Ibuprofen
Progestogens	Insulin
Vaccines (except smallpox)	Iron supplements
Vitamins (except high-dose A and D)	Lactulose
	Levothyroxine
	Loratadine
	Nystatin
	Paracetamol
	Warfarin

[a]This table is to be used as a guide only. Expert advice is required when the maternal dose is high, if the infant is premature, has renal or hepatic disease or G6PD deficiency.

Glucose-6-phosphate dehydrogenase deficiency

Infants with glucose-6-phosphate dehydrogenase (G6PD) deficiency are susceptible to adverse effects even when only small amounts of certain drugs are present in milk. G6PD is an enzyme present in erythrocytes that is responsible for maintaining the antioxidant compound glutathione in its active form. Deficiency of this enzyme makes the erythrocyte more susceptible to oxidative stress, resulting in haemolysis. Only small amounts of drug are needed to cause such a reaction. Breastfeeding should be avoided or a safer alternative chosen if the infant has a known or suspected G6PD deficiency and the mother is taking drugs that have been reported to cause oxidative stress (e.g. nitrofurantoin, dapsone).

Allergy

The theoretical possibility exists for an allergic reaction in an infant exposed to a drug in breast milk. Even minimal exposure to the drug could cause an allergic response. However, in practice, such reactions are very rare and only if the infant has already experienced an allergic reaction to a particular drug should maternal use be discouraged or breastfeeding avoided.

Recreational drug use

Accurate details relating to maternal use of recreational drugs may be difficult to obtain. Usage may be chronic or sporadic. The role of the health professional in ensuring the safety of the breastfed infant is important, and the advice should be that substances such as cannabis, LSD and cocaine should be avoided whilst breastfeeding.

Significant amounts of alcohol pass into milk although it is not normally harmful to the infant if the quantity and duration of intake are limited. The occasional consumption of a small alcoholic beverage is acceptable if breastfeeding is avoided for about 2 h after the drink. Chronic or heavy consumers of alcohol should not breastfeed. High intakes of alcohol decrease milk let down and disrupt nursing until maternal levels decrease. Heavy maternal use may cause infant sedation, fluid retention and hormone imbalances in breastfed infants.

Nicotine has been suggested to decrease basal prolactin production although effects may be variable. Ideally, mothers should be encouraged not to smoke whilst breastfeeding. Nicotine and its metabolite, cotinine, are both present in milk. Undertaking smoking cessation with a nicotine patch is a safer option than continued smoking. Whilst transdermal nicotine patches produce a sustained lower nicotine plasma level, nicotine gums produce large variations in peak levels. A 2-3 h washout period is recommended before breastfeeding after maternal use of a nicotine gum.

Caffeine appears in breast milk rapidly after maternal intake. Fussiness, jitteriness and poor sleep patterns have been reported in infants of mothers with very high caffeine intakes equivalent to about 10 or more cups of coffee daily. Preterm and newborn infants metabolise caffeine very slowly and are at increased risk of adverse effects.

Drug effects on lactation

Drugs that affect dopamine activity are the main cause of effects on milk production, mainly mediated by effects on prolactin. Early postpartum use of oestrogens may reduce the volume of milk, but the effect is variable and depends on the dose and the individual response. Progestogen contraceptives are preferred.

Drugs may occasionally be used therapeutically for their effect on lactation. Dopamine agonists such as cabergoline decrease milk production, and this effect may be utilised, for example, after an infant death. Dopamine agonists should not

be used routinely for relief of the symptoms of postpartum pain or engorgement which can be managed with simple analgesics or breast support. Dopamine antagonists such as domperidone may be used in cases of inadequate lactation which have not responded to first-line methods such as improved technique or milk expression by hand or pump.

Other drugs may affect lactation as an unwanted side effect, for example, diuretics. When these are used on a long-term basis, infant weight gain should be monitored.

Case studies

Case 47.1

A woman is 6 weeks' pregnant and has been diagnosed with depression that warrants pharmacological intervention. She wishes to recommence venlafaxine, which has been helpful in the past. She is also anxious that the ethanol she consumed around the time of conception may have harmed her baby.

Questions

1. What are the safest antidepressants in the first trimester of pregnancy?
2. Is it reasonable for her to commence venlafaxine?
3. Is there any risk from the ethanol ingestion?

Answers

1. Tricyclic antidepressants (TCAs) have been extensively used in pregnancy and are generally regarded as safe. For this reason, past practice was to recommend that TCAs should be used preferentially for the treatment of depression in pregnancy when considering teratogenic risk to the fetus. TCAs are, however, associated with side effects including risk of maternal cardiotoxicity, particularly in overdose. Further, available data on TCA use in pregnancy do not prove that they are less teratogenic than other antidepressant classes such as SNRIs and SSRIs. An antidepressant other than TCAs may therefore be appropriate for use in pregnancy, and the risks and benefits for each should be considered and ideally discussed with the patient on a case-by-case basis.
2. Experience with the use of venlafaxine and many other antidepressants, for example, moclobemide, in pregnancy is limited. However, in some instances, it may be necessary to use an agent such as venlafaxine. For example, if the mother had a history of severe depression that did not respond to multiple trials of other antidepressants, then venlafaxine may be considered the most appropriate choice of antidepressant for that woman. In this case, any potential risks associated with venlafaxine are likely to be less than those associated with inadequately treated depression.
3. Ethanol is a human teratogen. Fetal alcohol spectrum disorders are characterised by low birth weight, facial dysmorphogenesis and delayed development. A 'safe limit' for alcohol consumption in pregnancy has not been defined, and it is possible that very low amounts of alcohol may produce subtle effects on the fetus. Therefore, the best practice is to avoid all alcohol exposure in pregnancy. In this case, the mother ingested ethanol at the time of conception. She should be reassured that this is regarded as a relatively safe period and is not expected to adversely affect the fetus . However, further ethanol ingestion should be avoided.

Case 47.2

A 30-year-old woman with epilepsy is currently taking valproic acid 1500 mg daily. She wishes to conceive but is concerned about the possibility of birth defects due to valproate exposure in pregnancy. Her seizures have been difficult to control with alternative anticonvulsants.

Questions

1. What are the risks associated with valproate treatment in pregnancy?
2. How can these risks be minimised?

Answers

1. Valproate is a human teratogen, with early first-trimester exposure associated with a 1–2% risk of neural tube defects, as well as other malformations such as orofacial clefts. Valproate has also been associated with neonatal complications such as seizures. It is frequently advised that valproate is avoided in pregnancy and that the valproate dose should be gradually tapered and discontinued prior to conception. However, this is not a realistic option for many women with epilepsy. In fact, seizures may lead to greater problems such as maternal–fetal injury, miscarriage or hypoxia.
2. The patient should be reassured that most pregnancies in women with epilepsy end with a healthy baby without malformations. Concern about the risk of fetal abnormalities may result in reduced adherence, which may have greater maternal–fetal risk than the drug itself. As the patient is not yet pregnant, this is an optimal time for her current drug regime to be reviewed and optimised by a neurologist or health professional with expertise in managing women with epilepsy during pregnancy. There is some evidence to suggest that higher doses/concentrations of valproate are associated with greater risk of malformations. Where valproate remains the drug of choice, the lowest effective dose should be used throughout pregnancy. Monitoring free valproate concentrations may be useful in pregnancy, perhaps with the view to maintaining those concentrations shown to be effective in the non-pregnant stage. However, doses should be adjusted based on clinical need and not concentrations alone. Women with epilepsy should be commenced on high-dose folic acid 4–5 mg daily pre-conceptually. They should also be offered the option of prenatal diagnostic techniques that screen for neural tube defects such as ultrasound and serum α-fetoprotein.

Case 47.3

A 2-day-old full-term infant has excessive shrill crying, is jittery and is feeding poorly. The medical team cannot find any cause for these effects. The mother is worried that they may be due to paroxetine exposure via breast milk and wonders whether St John's wort would be a safer alternative. She has taken paroxetine 20 mg daily throughout pregnancy, and this has been continued after delivery.

You note from a specialist textbook that the likely infant exposure is about 2% of the weight-adjusted maternal dose.

Questions

1. What is the most likely drug-related explanation?
2. Is it safe for the mother to continue to take paroxetine whilst breastfeeding?
3. Is St John's wort a reasonable alternative?

Answers

1. The most likely explanation is a neonatal withdrawal syndrome from SSRI use near term. Symptoms typically occur 12 h–5 days after birth. The adult half-life of paroxetine is about 24 h, but this is much longer in a neonate. There will be a gradual decline in paroxetine plasma levels in the neonate after delivery. Drug exposure in pregnancy is much greater than exposure via milk. There may be some overlap of symptoms resulting from drug transfer into breast milk and from *in utero* exposure – agitation, jitteriness, hypotonia and gastro-intestinal symptoms. However, sedation has only been reported after drug exposure via breast milk. Paroxetine is one of the preferred SSRIs in breastfeeding as the half-life is shorter than most members of the group and the incidence of reported adverse effects is low.
2. The mother should be reassured that the effects are not due to the transfer of excessive amounts of paroxetine into milk. Withdrawal symptoms usually settle after a few days, whereas adverse effects due to the drug via milk will remain with continued exposure. If symptoms persist, further medical advice should be sought.
3. Herbal remedies are often perceived as safe as they are natural. In general, there is a lack of data to support the safe use of herbal remedies in lactation, and their use should be avoided. If a pharmacological treatment is indicated, then a drug for which data in lactation is available, for example, paroxetine should be used.

Case 47.4

A breastfeeding mother returned to see her midwife 4 weeks after delivery of a full-term healthy infant. She is complaining of bilateral nipple pain during and after breastfeeding, a problem that was constant for the past 4 days. She was advised to use miconazole cream 2% to the nipples after each feed. This provided initial relief but symptoms returned after a few days. She was given a course of fluconazole 200 mg daily for 14 days for a presumed candidal infection but expressed concern that the medication might affect the infant.

Questions

1. Is this regimen safe to use in lactation?
2. What other therapeutic measures should be taken?

Answers

1. Topical miconazole is effective in treating superficial candidal infections, but oral therapy with fluconazole is needed when the infection spreads to the milk ducts. Assuming a mean fluconazole milk level of 2.3 mg/L, an infant weight of 4 kg and a milk intake of 150 mL/kg/day:

   The estimated daily infant intake via milk will be 2.3 × 0.15 × 4 = 1.38 mg or 0.345 mg/kg/day.

   This represents 10.35% of the weight-adjusted dose for a 60-kg woman taking 200 mg of fluconazole daily and 5.75% of the paediatric dose of 6 mg/kg/day. The mother may be reassured that the amount of drug reaching the infant via milk is only a small fraction of the dose that would be used to treat an infection in the infant.
2. Candidal infections are easily passed between the mother and the infant, and both should receive treatment. Infants can be treated with nystatin suspension or oral miconazole gel. The latter is not suitable for young infants under 4 months because of the risk of choking on the viscous formulation, and care is still needed with older infants.

Case 47.5

A mother who wishes to give up smoking seeks advice on the safety of nicotine replacement therapy (NRT) whilst breastfeeding. She is currently in the latter stages of pregnancy but does not wish to use these products until after delivery and has not been successful in significantly reducing her smoking without aids.

Questions

1. What effect is smoking likely to have on breastfeeding?
2. Can NRT be used safely whilst breastfeeding?
3. If so, which products are preferred?

Answers

1. Women who smoke during pregnancy are less likely to breastfeed and more likely to wean their infants earlier. Nicotine reduces basal prolactin levels which may lead to a decrease in milk supply. It also causes adrenaline release which may inhibit the release of oxytocin and affect the milk let-down reflex. Tobacco smoke may produce breathing difficulties and other problems in infants. Maternal smoking is a major factor for sudden infant death syndrome (SIDS) and breastfeeding provides significant protection.
2. Ideally, breastfeeding mothers should stop smoking, preferably by using non-pharmacological methods. If this is not possible, most authorities advise that the amount of nicotine passing into milk after use of NRT is very much smaller than that after smoking and less harmful than the second-hand smoke an infant might breathe if the mother continues to smoke. NRT products are devoid of tars, carbon monoxide and respiratory irritants found in cigarettes. Where the infant has breathing difficulties, NRT should be avoided. Other members of the household who smoke should also be encouraged to give up smoking.
3. Breast milk levels of nicotine after use of a 21-mg transdermal patch are roughly equivalent to smoking 17 cigarettes a day. Maternal plasma levels of nicotine after using a nicotine spray are about one-third those of smokers and levels after using a gum are variable but can be similar to those seen after smoking. If possible, nicotine patches should be avoided during breastfeeding because they provide a continuous (but low) passage of nicotine into breast milk. If patches are used, they should be removed at night time to decrease nocturnal exposure. For shorter-acting preparations (e.g. gums, lozenges), it is best to breastfeed immediately before use and allow a 2–3 hour period before resumption of breastfeeding to minimise infant exposure.

Prostate disease 48

M. Martinez and M. Satheesh

Key points

Benign prostatic hyperplasia

- Benign prostatic hyperplasia (BPH) is a common condition which increases in prevalence with age.
- A combination of increased adrenergic tone in the prostatic stroma and bladder neck as well as the anatomical effects of an enlarging prostate lead to lower urinary tract symptoms (LUTSs) and bladder outflow obstruction (BOO).
- Surgical treatments such as transurethral resection of the prostate (TURP) are effective, but less invasive procedures such as laser therapy, and less commonly thermotherapy, are used.
- α-Adrenoceptor blocking drugs are effective in reducing symptoms.
- 5α-Reductase inhibitors reduce prostate size, improve symptoms, increase urinary flow rates and reduce the risk of developing complications such as acute urinary retention (AUR) or the need for prostate surgery.

Prostate cancer

- Prostate cancer (PC) typically progresses slowly but is influenced by factors such as tumour grade, stage of the disease, co-morbidities and life expectancy.
- Aetiology is multi-factorial and includes age, race, family history and dietary habit.
- Early detection is difficult because there are no symptoms specific to PC.
- A combination of digital rectal examination (DRE), serum prostate-specific antigen (PSA) and transrectal ultrasonography (TRUS) is used to confirm diagnosis.
- Curative treatments include radical prostatectomy or radiotherapy.
- Treatment depends on the grade and stage of tumour, life expectancy and patient choice.

Prostatitis

- Prostatitis is classified as acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis/chronic pelvic pain syndrome and asymptomatic inflammatory prostatitis.
- There is no absolute diagnostic tool for prostatitis. Diagnosis is based on physical examination and clinical history.
- The pathophysiology of prostatitis is poorly understood and the aetiology is unclear in the majority of patients.
- Prostatitis cases associated with infection or inflammation are treated with antibiotics.
- α-Adrenoceptor antagonists are used for the treatment of chronic prostatitis/chronic pelvic pain syndrome.

Benign prostatic hyperplasia

Epidemiology

Benign prostatic hyperplasia (BPH) is the most common benign tumour in men and is responsible for urinary symptoms in the majority of males over the age of 50 years. Autopsy studies have revealed the histological presence of BPH in 50% of males aged 51–60 years, increasing to 90% in those over 85. By the age of 80 years, virtually all men exhibit one or more of the symptoms associated with BPH.

BPH is seen in all races although the overall size of the prostate varies from race to race.

Pathophysiology

The prostate is a part glandular, part fibromuscular structure about the size of a walnut that surrounds the first part of the male urethra at the base of the bladder (Fig. 48.1). In simple terms, the prostate can be divided into a lobular inner zone encapsulated by an external layer. The inner zone is where benign hypertrophic changes are generally found, whereas most malignant changes originate in the peripheral zone.

Prostatic hypertrophy is directly related to the ageing process and to hormone activity. Within the prostate, testosterone is converted by 5α-reductase to dihydrotestosterone (DHT). DHT is five times more potent than testosterone and is responsible for stimulating growth factors that influence cell division leading to prostatic hyperplasia and enlargement.

Histologically, depending on the predominance of the type of prostatic tissue present, prostatic hypertrophy can be stromal, fibromuscular, muscular, fibroadenomatous or fibromyoadenomatous.

As the prostate enlarges, it can compress the urethra (Fig. 48.2) and this, together with increased adrenergic tone, can lead to bladder outflow obstruction (BOO) and lower urinary tract symptoms (LUTSs). Therefore, the term BPH includes benign prostatic enlargement (BPE), the clinical features associated with urinary obstruction and LUTSs.
Fig. 48.1 Male urinary system demonstrating the location of the prostate.

Symptoms

Men with BPH can develop bothersome LUTSs that can impact negatively on their quality of life. It is important to emphasise that not all men who experience LUTSs have BPH. LUTSs can have different aetiologies including bladder cancer or stones, urinary tract infection (UTI) or urethral stricture. Furthermore, a histological diagnosis of BPH does not mean the patient will suffer from LUTSs.

LUTSs can be divided into symptoms of failure of urine storage (irritative) and those caused by failure to empty the bladder (obstructive or voiding).

Irritative symptoms

- Frequency
- Nocturia
- Urgency and urge incontinence

Obstructive symptoms

- Poor urinary flow
- Hesitancy in initiation of micturition
- Post-micturition dribble
- Sensation of incomplete emptying
- Occasional acute retention of urine requiring emergency treatment

Examination and investigations

There is a range of investigations and diagnostic tests available for the evaluation of patients with suspected BPH. Some tests are standard during the assessment of all men with LUTSs. Other investigations are optional and are only performed depending on the patient's presentation and the clinician's judgement.
Fig. 48.2 Diagrammatic representation of the impact of prostate hyperplasia on the urethra demonstrating overgrowth of cells in the inner zone of the prostate.

History

A focussed medical history of all men with LUTSs should be taken to elucidate the aetiology of their symptoms. As part of the process, LUTSs should be evaluated using a validated scoring tool such as the international prostate symptom score (IPSS). This can be used to monitor the severity and progression of the disease and assess the impact of therapy on LUTSs.

Physical examination

All patients who present with suspected BPH should undergo a digital rectal examination (DRE) which involves the examiner palpating the prostate with a finger through the rectum wall. A DRE is performed to exclude the presence of prostate cancer (PC) and can also be used to estimate the shape and size of the prostate, although transrectal ultrasonography (TRUS) provides a more accurate measurement of prostate volume.

Urodynamic studies

Simple non-invasive urodynamic studies provide a surrogate measure of BOO. These include maximum flow rate and post-void residual (PVR). Large PVRs of 300 mL, for example, are indicative of bladder dysfunction and predict a poor response to therapy. Definitive proof of BOO requires invasive pressure flow studies.

Imaging

In the past, upper tract imaging involving an ultrasound scan and intravenous urography were used routinely to evaluate LUTSs associated with BPH. These tests are not normally undertaken except in patients with abnormal renal function and LUTSs who should have an ultrasound scan of their kidneys. The following represent the imaging options used for the assessment of men with BPH.

Flexible cystoscopy

Flexible cystoscopy provides an endoscopic image of the bladder for the assessment of prostatic obstruction and informs possible management options. For example, if the prostate has grown and there is intravesical extension, each time the patient tries to void the internal urethral meatus is obstructed. This type of tissue requires surgical removal, whereas simple lateral lobe enlargement may well respond to non-surgical measures.

Prostatic ultrasound scan

Prostatic ultrasound or TRUS uses high-frequency scanners to produce images of the prostate. This imaging is used to obtain an accurate evaluation of the prostate volume and to detect malignant change. TRUS is also used to guide the placement of the needle when obtaining prostatic biopsies.

Other investigations

Other investigations may be carried out to facilitate the diagnostic assessment of patients with LUTSs due to BPH, and these include urinalysis, urine cultures if infection is suspected,

and serum creatinine to assess renal function and establish possible upper urinary tract damage. The measurement of serum prostate-specific antigen (PSA) can be considered after counselling the patient, particularly if DRE reveals a nodular or hard prostate.

Treatment

Most men over the age of 50 years exhibit some of the symptoms of BPH. The range of treatment options for the management of BPH includes watchful waiting, medical therapies and surgical interventions. The key issue, therefore, is deciding who should be treated and when.

The British Association of Urological Surgeons has published guidelines for the management of BPH in primary care (Speakman et al., 2004), focussing on when urological referral is required and when non-invasive treatment can be initiated (Fig. 48.3).

Watchful waiting

Men with mild or moderate and not significantly bothersome LUTSs should be offered a trial of watchful waiting. This management strategy does not include any medical or surgical treatment but involves regular active monitoring. In some cases, symptoms remain unchanged for years and no further interventions are necessary since disease progression is minimal. Patients that adopt this modality should be offered education and lifestyle advice (Box 48.1) to manage their urological symptoms together with a review of their medication, particularly diuretics or other medicines known to affect the urinary system.

Therapeutic management

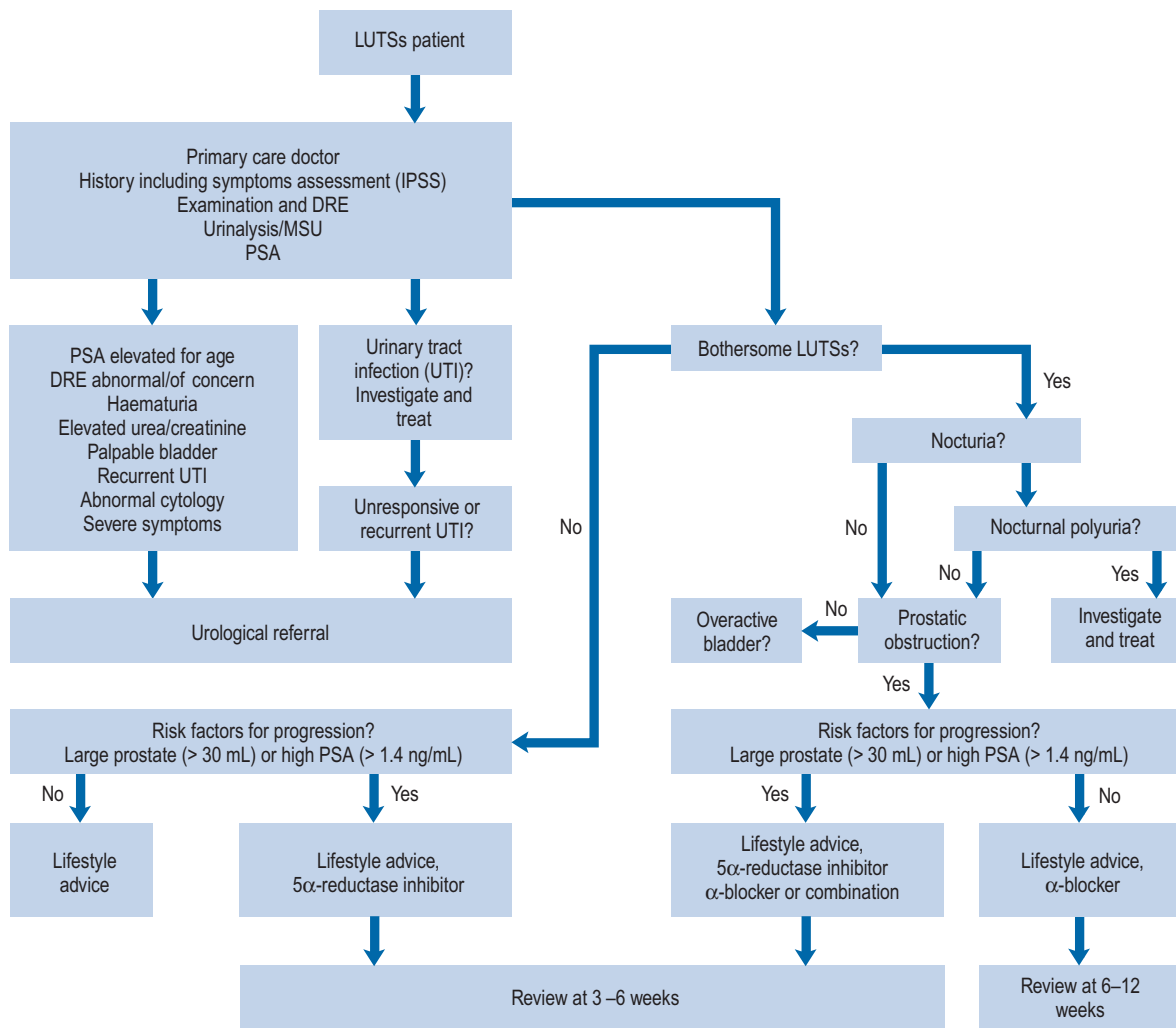
The principal treatment options are α-adrenoceptor blocking drugs, 5α-reductase inhibitors and combination therapy. Phytotherapy is also used in the management of BPH, although the benefits remain unproven.


Fig. 48.3 Algorithm for the treatment of lower urinary tract symptoms (LUTSs) in males in primary care (from Speakman et al., 2004) (DRE, digital rectal examination; MSU, mid-stream urine sample; PSA, prostate-specific antigen).

α-Adrenoceptor blocking drugs

The prostate gland is very responsive to adrenergic stimulation. In fact, prostatic outlet obstruction in BPH is partly due to the hypertrophied bulk of the gland, but it also arises from an increase in adrenergic tone. In the prostate, α_1-receptors predominate and mediate the contraction of the gland's smooth muscle. At least three subtypes of this receptor exist (α_{1A}, α_{1B} and α_{1D}). The α_{1A} is thought to be the dominant receptor in the prostate, although its role clinically has still to be confirmed. This increase in sympathetic tone is potentially reversible by α-adrenoceptor antagonists.

In general, all the agents are considered to produce similar clinical improvements of LUTSs and urinary flow. Benefits can be seen usually within the first few days of therapy and can be maintained in the long-term. α-Adrenoceptor antagonists also have a comparable side-effect profile, which includes postural hypotension, dizziness, fatigue, headache, drowsiness, nasal congestion and ejaculatory dysfunction.

Patients with BPH frequently experience erectile and ejaculatory dysfunction. The treatment of BPH should also aim to improve sexual function. However, the effect of α_1-adrenoceptor antagonists on male sexual function is variable and influenced by the choice of agent and patient characteristics (Van Dijk et al., 2006).

Prazosin. Prazosin was the first α_1-blocker used to relieve the symptoms of BPH but it lacks relative selectivity for α_{1A} receptors and has been associated with many adverse affects such as drowsiness, weakness, headache and postural hypotension (especially after the first dose).

Terazosin. Terazosin was the first in the category to appear in controlled trials aimed at evaluating the efficacy and safety profile of long acting α_1-blockers in the management of BPH. Efficacy is dose dependant and dose titration is necessary, as terazosin can cause postural hypotension. Adverse effects, although generally mild, occur more frequently than with other α_1-adrenoceptor antagonists, resulting in up to a four-fold increase in treatment discontinuation.

Indoramin. Indoramin is readily absorbed from the gastro-intestinal tract and undergoes extensive first-pass hepatic metabolism. Its hypotensive effect may be increased by diuretics and other anti-hypertensive agents. Alcohol has been reported to increase the bioavailability and sedative effects of indoramin.

Doxazosin. Doxazosin has a long half-life of about 22 h, which allows for once-daily dosing. When starting treatment, dose titration is recommended to limit postural hypotension. There would appear to be no significant difference in symptom score regardless of whether the standard or controlled-release preparation is used (Kirby et al., 2001).

Tamsulosin. Tamsulosin is a selective inhibitor of the α_{1A}- and α_{1B}-adrenoceptor. It has an elimination half-life of about 13 h and is available as a prolonged release formulation that allows once-daily dosing. There is no requirement to titrate the dose upward when initiating treatment. Although the side-effect profile of tamsulosin is similar to other α_1-adrenoceptor antagonists, it is normally well tolerated (O'Leary, 2001). Intraoperative floppy iris syndrome (IFIS) has been reported during cataract surgery in men treated with tamsulosin, as it is highly selective to iris dilator muscle (Chaim et al., 2009). IFIS can lead to complications and poor outcomes during cataract surgery. As a result, it is essential that patients inform their cataract surgeon that they are taking tamsulosin during the pre-operative assessment. It has been recommended to avoid starting treatment and to discontinue treatment with tamsulosin 1–2 weeks before cataract surgery.

Alfuzosin. Alfuzosin displays a higher selectivity for the prostate compared with tamsulosin or doxazosin. It has a half-life of 5 h, but it is available as a once-daily formulation. It has a rapid onset of action and good tolerability (MacDonald and Wilt, 2005). It reduces the overall clinical progression of BPH and it appears to have a sustained beneficial effect on quality of life (Roehrborn, 2006). Alfuzosin has the least effect on ejaculatory function. Alfuzosin should not be co-administered with potent inhibitors of cytochrome P450 3A4 such as itraconazole, ketoconazole and ritonavir, since this can lead to a several fold increase to exposure in alfuzosin.

5α-Reductase inhibitors

The primary androgen responsible for the development and progression of BPH is DHT. There are two isoenzymes of 5α-reductase: type 1 is found in most 5α-reductase producing tissues such as the liver, skin and hair; type 2 is predominant in genital tissue, including the prostate. 5α-Reductase inhibitors downregulate prostate growth by blocking the conversion of testosterone to the more potent DHT.

The two agents currently available in this group are finasteride and dutasteride. Both have been shown to reduce prostate volume, to improve symptom scores and flow rates, and reduce the incidence of complications such as acute urinary retention (AUR) and the need for surgical intervention to treat BPH (Roehrborn et al., 2000, 2002). Improvements in LUTSs are normally seen after the first 6 months of treatment and are sustained during continuous treatment (Lam et al., 2003).

Finasteride. Finasteride is a type 2, 5α-reductase inhibitor that can reduce prostate size by about 30%, improve symptom scores and increase urinary flow. Those most likely to benefit are men with a prostate larger than 40 mL. Side effects include decreased libido, impotence, reduced ejaculatory volume and, less commonly, gynaecomastia and breast tenderness. Serum

concentrations of PSA may be reduced by 50% in the first year of treatment with finasteride, a fact which must be taken into account when attempting to interpret the PSA concentration in men with suspected PC.

Dutasteride. Dutasteride inhibits both type 1 and type 2 isoenzymes of 5α-reductase. Although the clinical significance of this is unclear, this double inhibition can reduce serum dihydotestosterone levels by about 90%. Dutasteride decreases prostate volume by up to 26% and reduces the risk of progression to serious complications of BPH. LUTSs also improve after 6 months of treatment. Dutasteride is well tolerated although side effects which include erectile and ejaculatory dysfunction and breast enlargement occur with similar frequency to finasteride.

Combination therapy

It is well established that α-adrenoceptor antagonists are best for managing acute symptoms but have no impact on reducing the risk of complications such as AUR or progression to prostate surgery. In contrast, 5α-reducatase inhibitors have little impact on short-term acute symptoms but reduce prostate size, improve urinary flow and obstructive symptoms in the long-term. Furthermore, α-adrenoceptor antagonists are effective regardless of prostate volume, whereas the 5α-reductase inhibitors are more suited for the management of LUTSs in men with large prostates. In terms of long-term benefits, continued treatment with 5α-reductase inhibitors decreases the risk of AUR and BPH-related surgery. Therefore, it appears logical to use a combination of an α-adrenoceptor antagonist and a 5α-reductase inhibitor to manage acute symptoms and reduce progression of BPH.

The benefits of using a combination of doxazosin and finasteride compared to monotherapy have been demonstrated in over 3000 men (McConnell et al., 2003). Similarly, the combAT trial (Roehrborn et al., 2010) involved nearly 5000 men with moderate to severe symptoms of BPH and prostate enlargement treated with a combination of dutasteride and tamsulosin. This study demonstrated a significant improvement in BPH symptoms over a 4-year period when compared to either agent used alone. The combination was also found to reduce AUR and progression to BPH-related surgery and, although superior to tamsulosin with respect to these complications, combination therapy was not better than dutasteride. Overall, the adverse events associated with combination therapy were few and treatment was well tolerated.

Combination therapy with an α-adrenoceptor antagonist and a 5α-reductase inhibitor has now been adopted widely into routine practice for the early management of LUTSs and to reduce progression of BPH.

Phytotherapy

A number of plant extracts are reputed to be effective in the management of symptoms of BPH. They include saw palmetto berry (*Serenoa repens*), African plum tree (*Pygeum africanum*), stinging nettle (*Urtica dioica*) and rye grass pollen. Their mechanism of action remains unclear but may exert an anti-inflammatory effect by inhibition of prostanoid formation and perhaps produce some degree of inhibition of 5α-reductase. Most of the data available to support the use of plant extracts derive from poorly designed studies. As evidence to assess efficacy and safety is lacking, phytotherapy remedies are not currently recommended by international guidelines for the management of BPH.

Surgical treatments

Surgical interventions are commonly performed in men with LUTSs caused by BPH that have failed to respond to medical treatment. Surgery is also indicated in patients who develop complications such as intractable or recurrent urinary retention, renal impairment, persistent haematuria, recurrent UTIs or bladder stones.

Transurethral resection of the prostate. Transurethral resection of the prostate (TURP) is a common and effective procedure which achieves a high level of improvement in symptoms and flow rate. It is the preferred surgical intervention in men with a prostate volume between 30 and 80 mL. Sections of prostate are removed using electrical wire loops attached to a tube-like telescope (resectoscope) inserted into the urethra. The tissue removed is collected for histological assessment. There is a small incidence of perioperative mortality associated with TURP along with complications such as bleeding, UTIs and epididymitis. Long-term complications include stress incontinence, urethral and bladder neck strictures and erectile dysfunction.

Open prostatectomy. Open prostatectomy involves the surgical removal of an enlarged prostate. Typically, an incision is made through the lower abdomen although sometimes the incision is between the rectum and the base of the penis. This procedure is now performed infrequently and restricted to very enlarged prostate glands (larger than 100 mL) and those with large bladder stones or bladder diverticula (Stoevelaar and McDonnell, 2001). Open prostatectomy requires a longer hospital stay than transurethral resection and is associated with a higher incidence of bleeding and other complications.

Minimally invasive techniques

Various treatment modalities have been tried as alternatives to TURP to reduce the risks associated with resection. Thermotherapy and laser technology are the most commonly used. Thermotherapy uses techniques such as electrovaporisation and transurethral microwave heat treatment (TUMT), which heats the prostate to cause vaporisation of the tissue. Various types of laser energy can also be used to destroy prostatic tissue mainly by coagulation or vaporisation.

Patient care

Patients generally seek medical help for BPH because of the impact of symptoms on their quality of life. Most men tolerate a high degree of symptoms and impact on daily activities before they seek help. Table 48.1 lists some common

Table 48.1 Common therapeutic problems and proposed management strategies in benign prostatic hyperplasia

Problem	Solution
Patient taking α-blocker still symptomatic after 2 weeks	Patients should be advised that it may take 2–6 weeks before symptomatic treatment relief is seen
Patient taking an α-adrenoceptor blocker complains of cardiovascular adverse effects such as dizziness, syncope, palpitations, tachycardia or angina	These side effects are more likely in elderly patients. They are most common after the first dose and reflect the hypotensive effects of the drugs. They can be reduced by titrating the dose or using more uroselective drugs such as tamsulosin
Sexual dysfunction	Decreased libido or impotence can occur in patients taking finasteride and dutasteride. Abnormal ejaculation can be caused by α-blockers. Tamsulosin in particular can cause a dry climax (retrograde ejaculation). Patients should be forewarned when discussing treatment options
Patient taking finasteride notices breast enlargement	Unilateral or bilateral gynaecomastia is a frequently reported side effect with finasteride and patients need to be counselled accordingly when discussing treatment options
Patient taking finasteride or dutasteride has a sexual partner who is pregnant	Exposure to semen should be avoided as both drugs can cause abnormalities to genitalia in a male fetus. The patient should be advised to use a condom

therapeutic problems in the management of BPH. Patients should receive information about the management options available, the investigations that they need to undergo and possible treatment outcomes and adverse effects. Patients receiving drug therapy should receive specific information about their treatment, including potential benefits, timeline of expected outcomes and possible side effects.

There are two websites which produce particularly useful educational material on prostatic disease: the Men's Health Forum (http://www.menshealthforum.org.uk/) and the Prostate Research Campaign (http://www.prostateuk.org/index.htm).

Prostate cancer

Epidemiology

PC is the second most common cancer in the world and the most common form of cancer in men. Incidence varies from country to country with the highest rates in America, Canada and Scandinavia and the lowest rates in China and other Asian countries (Quinn and Babb, 2002; Gronberg, 2003). In the UK, nearly a quarter of all new male cancer diagnoses are of the prostate. The lifetime risk of PC is 1 in 10 in males in the UK.

The aetiology of PC is multi-factorial. Testosterone and DHT have an important role in the disease as males who undergo castration before puberty do not develop PC. Other factors which can influence the risk of developing PC include the following:

Age. PC is rare before 50 years in Caucasians and before 40 years in Africans, but after this age, the incidence and mortality increase exponentially with every passing decade. Most cases are detected around the age of 70.

Race. Incidence and mortality is high among Caucasians and African Americans and lowest in Chinese males. Environmental factors may play a role in this variation as studies have found an increased incidence in East Asian men who relocate to western countries.

Family history. Presence of PC in a first-degree relative or in multiple family members who need not be first-degree relatives increase risk. Inheritance of a susceptible gene or polymorphism of gene may be responsible for this.

Diet. Although there is no compelling evidence to prove the direct influence of diet, high intake of fat, red meat and dairy produce, typically the main sources of dietary fatty acids in a Western diet, have individually been linked with PC. The low incidence of PC in China and Japan may be due to their use of soya bean products which contain isoflavones and inhibit protein tyrosine kinases responsible for cell proliferation.

Other factors. These include exposure to cadmium (found in cigarette smoke), pesticides, alkaline batteries, radionuclides and heavy metals.

Pathophysiology

The growth and differentiation of cells in the prostate is under androgen control. In the prostate, free testosterone diffuses into the epithelial cells where it is converted to DHT. Various growth factors are present in stromal cells, and the interaction of these with epithelial cells can play a role in cell proliferation and growth. The development of PC is generally a slow, gradual process where cellular structure changes from normal through dysplastic to cancer. High-grade prostatic intra-epithelial neoplasia (HGPIN) represents the precancerous stage of cellular proliferation in prostate cells and can be detected by biopsy. It can predate carcinoma by 10 years or more. There is no link between PC and BPH but they can coexist.

Screening

Population-based screening based on PSA levels is prevalent in the USA, and the annual incidence here has doubled due to this. In the UK, screening is not advocated as the prevailing view is that there is a lack of evidence to support it. Due to the aetiology and nature of PC, most patients will not be symptomatic in their lifetime and screening may increase the risk of overtreatment.

Symptoms

Clinical symptoms of PC are similar to those for BPH, and there are no symptoms which correlate specifically to early PC. As more than 50% of men above the age of 50 years have prostate-related symptoms, it is difficult to detect early PC. Advanced PC typically presents with symptoms of urethral and bladder outlet obstruction, anaemia, weight loss, haematuria or bone pain.

Examination and investigation

Physical examination

A DRE is an important diagnostic tool for PC with an estimated sensitivity of more than 60%. A palpable tumour will have a distinctive texture, but the accuracy of detection may depend on the experience of the clinician. False-positive results can occur in the presence of BPH or cysts.

Imaging

TRUS of the prostate is commonly used to aid the diagnosis of PC. Sensitivity ranges from 48% to 100%. Cancer in the anterior and central region of the prostate can, however, be missed. Computerised tomography, MRI scan of the pelvis and isotope bone scan are also useful to stage PC, but they are not effective as screening methods.

Prostate-specific antigen

Measurement of PSA is an accurate and clinically useful biochemical marker because it is specific to prostate tissue and produced by the columnar epithelial cells in the prostate gland. Unfortunately, PSA is not cancer specific as any damage to the internal architecture of the prostate can result in release. As a consequence, it is not a useful tool for diagnosing cancer on its own, but it is useful in monitoring the effect of treatment or tumour progression in untreated patients. Generally, PSA is high in PC, but it can sometimes be low in high-grade malignancy. The standard assay for PSA measures total prostate-specific antigen (tPSA) and includes all molecular forms. Age-specific ranges are available (Table 48.2) and help make it a better predictor, but this is only a rough guide as variations occur due to racial difference. There is no threshold for PSA below which PC cannot be found.

Table 48.2 Age-specific levels of prostate-specific antigen

Age	Prostate-specific antigen (ng/mL)
40–49	≤2.5
50–59	≤3.5
60–69	≤4.5
>70	≤6.5

Prostate biopsy

This is a definitive method to detect PC. TRUS guided biopsy will help obtain samples from the peripheral and transitional zones of the prostate and other suspicious areas. The peripheral zone of the prostate is the location where the majority of the PC occurs and the most common location for HGPIN. It is difficult to identify PC from trans-urethral resection of the prostate specimens as not much of it occurs in the transitional zone. In the UK, USA and Europe, the most widely accepted histological grading system, which corresponds to biological malignancy, is based on the Gleason scale (Gleason and Mellinger, 1974). Histological examination of biopsy tissue is undertaken to identify cancer cells and these are scored from 1 to 5 depending on the different pattern of glandular tissue (Fig. 48.4). A score of 1 corresponds to well-differentiated cells, while a score of 5 corresponds to poorly differentiated cells. The higher the score, the more aggressive the cancer. The number for the two most common types of cell in the sample are added together to get a Gleason score. The score ranges from 2 to 10. This is an important prognostic factor as it can help predict the future behaviour of the tumour and determine the treatment required.
Fig. 48.4 Gleason scale.

Cancer staging

Results from a DRE, biopsy and scan are used to identify the extent of the cancer. The tumour volume, whether there is invasion into or through the capsule, and spread to lymph nodes or bone are all taken into consideration for staging. Staging based on the tumour, node, metastasis (TNM) system is a classification accepted worldwide (Epstein et al., 2005). Based on the TNM classification, PC can be classified into localised disease, locally advanced disease and advanced/metastased disease.

Treatment

The factors that must be considered to aid the treatment decision relate to the tumour and the patient:
Tumour: Staging result, histology, Gleason score and the PSA concentration.
Patient: Age at diagnosis, life expectancy and the presence of co-morbidities such as cardiovascular disease, chronic obstructive pulmonary disease and diabetes (Fig. 48.5).

Localised prostate cancer

Established treatments with curative intent

Active surveillance. It is difficult to distinguish PC which may not cause any problems to that which may grow and spread aggressively. Curative treatment can improve longevity but has side effects which include impotence and incontinence and can affect the quality of life of the individual. Patients on active surveillance are monitored closely by repeated testing of PSA levels, DRE and biopsy with the intention to make a radical intervention to treat if there is disease progression. A 20-year outcome study following conservative management of localised PC found that the annual mortality rates did not support aggressive treatment (Albertsen et al., 2005). Although active surveillance can spare side effects of treatment without compromising survival, regular biopsies used to monitor the disease can also be uncomfortable and carry a risk of infection. The optimal schedule for measuring PSA and repeating biopsies is unclear.

Radical prostatectomy. This is the treatment of choice and the procedure involves the total removal of a prostate, seminal vesicle, distal vasa, ejaculatory ducts and prostatic urethra. In the open procedure, it is performed by the retro pubic or perineal approach based on the surgeon's choice. Laparoscopic prostatectomy, and more recently robotic-assisted laparoscopy, has been developed. The most common complications of prostatectomy are blood loss, post-operative thromboembolism, urinary incontinence, impotence and rectal injury. Systemic review and meta-analysis have shown that the laparoscopic and robotic methods are associated with less blood loss and transfusion, but oncological outcomes, incontinence and erectile dysfunction rates are similar with all three types of prostatectomy.

Radical external-beam radiotherapy. Radiotherapy is used for locally confined disease and more recently for locally advanced disease state as well. In this treatment, high-energy photons produced by a linear accelerator are targeted at the prostate. Sometimes, special particles such as protons and heavy ions are used and have advantages over photons in terms of dose distribution. The side effects of radiotherapy include impotence, genitourinary stricture, rectal bleeding, haematuria and incontinence.

Interstitial brachytherapy. With interstitial brachytherapy radioactive isotope seeds are placed in the prostate under ultrasound or fluoroscopic control. These implants can emit radiation of low energy over several weeks and can be temporary or permanent. This treatment has the potential advantage of less erectile dysfunction than other treatment.

Minimal invasive procedures

The minimal invasive procedures are in the development stage and, although they may be used in some centres, there are no medium- or long-term follow-up data to prove efficacy. The various procedures include:

Cryosurgical ablation of prostate (CSAP). Cryosurgical ablation involves freezing the prostate which results in cell death by protein denaturation, direct rupture of cellular membranes and apoptosis. Freezing is achieved by placing 12–15 cryoneedles into the prostate guided by a transrectal ultrasonograph and using the cryoneedles to create freeze thaw cycles using temperatures of $-40\,°C$.

High-intensity focussed ultrasound (HIFU). In this technique, ultrasound waves from a transducer are focussed on the prostate tissue to cause damage to the cells by mechanical and thermal effects. The malignant tissue is subjected to temperatures above $65\,°C$ and hence is destroyed by coagulative necrosis.

Radio-frequency interstitial tumour ablation (RITA). A needle electrode is placed inside the prostate and radio-frequency waves are delivered through it to heat the tissue up to $100\,°C$ thereby causing necrosis.

Watchful waiting

This approach implies that the patient is observed for symptomatic progression and will only receive palliative treatment when clinical symptoms develop. Since the disease often progresses slowly, watchful waiting is an option for patients with early disease as it maintains their quality of life and avoids complications related to surgery or radiation therapy. On the downside, it is not a curative option, the cancer can metastasise and be a source of pain and reduce life expectancy.

Locally advanced prostate cancer

Hormonal therapy/androgen deprivation therapy

In locally advanced disease involving areas outside the capsule, there is an increased risk of relapse and lymph node metastasis after prostatectomy.

Androgens are produced both in the testes (95%) under the stimulation of luteinising hormone (LH) and luteinising hormone-releasing hormone (LHRH) from the pituitary

gland, and in the adrenal glands (5%) under the stimulation of adrenocorticotropic hormone (ACTH). The androgens produced by the adrenal gland are hormone precursors that are enzymatically converted to testosterone and DHT in prostatic and peripheral tissue. Since testosterone is a well-known etiologic factor associated with PC, it follows that testosterone deprivation can be utilised as part of treatment. In practice, this can be achieved by either surgical or medical castration with the response time varying from a few months to years.

Surgical castration. This is further discussed under metastatic disease.

Medical castration. A number of drugs can be used to reduce the levels of testosterone to those achieved by castration.
Fig. 48.5 Diagrammatic representation of the site of action of some treatments used in prostate cancer.

LHRH agonists. LHRH is released in the hypothalamus and stimulates the secretion of LH by binding to the LHRH receptors in the pituitary. This LHRH receptor complex is normally broken down by enzymes which lead to the release of lutenising hormone and frees the receptors for further binding with LHRH. LHRH agonists are synthetic analogues that bind to the LHRH receptor and the complex formed is resistant to enzymatic action. Thus, they maintain a continuous presence on the receptor and render the pituitary gland refractory to hypothalamic regulation compared to the pulsatile release in normal individuals. Continuous administration of LHRH agonists exhibits a biphasic response. There is an initial increase in LH, and testosterone release referred to as 'tumour flare up' followed by a fall over the following 1–2 weeks due to the down regulation and decrease in LHRH

release as the receptors are continuously occupied. 'Tumour flare up' is prevented by first initiating treatment with an anti-androgen before the use of LHRH agonist. The anti-androgen is then continued for a further 3–4 weeks. Currently available LHRH analogues include buserelin (nasal spray), goserelin, triptorelin and leuprorelin. Goserelin is administered subcutaneously at monthly or 3 monthly intervals, whereas triptorelin and leuprorelin are administered intramuscularly at monthly or 3 monthly intervals.

In advanced PC, therapy with an LHRH agonist is comparable in efficacy to surgical orchiectomy or diethylstilboestrol but with reduced physical and psychological discomfort of the former or the cardiovascular risks of the latter. There would appear to be little difference between the various formulations of LHRH agonists. UK, U.S. and European guidelines support the use of LHRH agonists as first-line agents in the treatment of advanced PC.

More recently, a novel agonist called histrelin was introduced. This is a 1-year subcutaneous preparation which is surgically implanted.

Anti-androgens. Anti-androgens competitively inhibit the effect of androgens peripherally by competing with testosterone and DHT for binding sites in the prostate. This results in inhibition of cell growth and apoptosis. Based on their chemical structure, the anti-androgens can be further divided into steroidal agents, which include cyproterone acetate, megesterol acetate and medroxyprogesterone, and non-steroidal agents such as nilutamide, flutamide and bicalutamide.

The steroidal agents also possess progestational activity and inhibit leutinising hormone secretion by acting centrally on the pituitary thereby reducing serum testosterone levels. The non-steroidal agents do not possess this additional property. Cyproterone is the most widely used steroidal agent normally administered in two or three daily doses of 100 mg despite having a half-life of 30–40 h. It can be used to treat the hot flushes associated with LHRH agonists or orchiectomy. Side effects include hepatoxicity, loss of libido and potency, fatigue and depression. Use of medroxy progesterone and megestrol is limited because of less favourable outcomes in clinical trials compared to cyproterone.

Non-steroidal anti-androgens are used in patients who wish to preserve their quality of life as they do not suppress testosterone and hence preserve libido, physical performance and bone mineral density. The disadvantage of nilutamide, flutamide and bicalutamide is a reduced survival when used as monotherapy because of a gradual rise in testosterone. All three agents have side effects of gynaecomastia, gastrointestinal upsets, idiopathic hepato-cellular toxicity and haematuria. Bicalutamide has a better safety and tolerability profile compared to nilutamide and flutamide (Inverson, 2002). Some trials show that non-steroidal anti-androgens used in combination with surgical castration or LHRH agonists bring about complete or total androgen blockade by also reducing the production of androgens from the adrenal glands, which normally accounts for 5% of the body's production, thereby conferring a small survival advantage.

LHRH agonists and the non-steroidal anti-androgen flutamide have been used as neoadjuvant (treatment to reduce tumour size before further surgery or other treatment) or

adjuvant (treatment given in addition to primary/initial treatment to reach a treatment goal) with radiotherapy to improve disease-free and overall survival in patients with locally advanced disease.

Metastatic prostate cancer

LHRH agonists

Patients with metastatic cancer of the prostate usually respond to treatment with LHRH agonists and use is as described above for locally advanced disease.

Surgical castration

Surgical castration by bilateral orchiectomy is the treatment of choice for metastatic disease. Advantages include its low cost and morbidity with testosterone levels falling to castration levels within 5–12 h of surgery. The disadvantages include psychological trauma, its irreversible nature and the fact that nearly half experience side effects including loss of libido and potency, hot flushes and bone and muscle loss.

Other palliative treatments

LHRH antagonists. LHRH antagonists, which include abarelix and degarelix, work by competitively binding to LHRH receptors in the pituitary thereby suppressing LH release and creating a rapid and sustained decrease in testosterone levels. They do not cause an initial surge in testosterone levels and hence there is no 'tumour flare up' or need for short-term treatment with anti-androgens unlike the LHRH agonists. Abarelix requires an induction regimen followed by monthly injections and use is associated with anaphylactic reactions. Degarelix is given as a monthly depot injection; the most common side effect is a local reaction at the injection site such as swelling and erythema. Degarelix has a place in high-risk PC where the patient is acutely symptomatic with impending spinal cord compression, ureteric obstruction and urinary retention. Degarelix reduces testosterone, LH and PSA levels faster than LHRH agonists and reduces microsurges of testosterone.

The European Association of Urology (EAU) guidelines on PC recommend the use of LHRH antagonists in patients with metastasis and impending spinal cord compression (Heidenreich et al., 2009).

Bisphosphonates. Skeletal involvement in PC can be disease related or due to androgen depletion therapy. Bisphosphonates are pyrophosphates that inhibit osteoclast activity in bones and hence prevent and treat bone lesions. Pamidronate prevents bone loss but zolendronate not only increases bone mass while on androgen depletion therapy but also reduces skeletal complications in patients with bone metastasis secondary to PC (Saad and Schulman, 2004). Bisphosphonates are also recommended for pain relief when analgesics and palliative radiotherapy to bone have failed. Dental examination needs to be carried out before commencing treatment with a bisphosphonate due to the risk of osteonecrosis of the jaw in those with a history of dental trauma, infection or surgery.

Ketoconazole. This broad-spectrum, imidazole, anti-fungal can be used at a higher dose than is normal for its anti-fungal effect to inhibit the testicular and adrenal cytochrome P-450 enzyme synthesis of sex sterols. It has a rapid onset of action and is usually prescribed at a dose of 400 mg three times daily. As it causes adrenal suppression, hydrocortisone supplementation is necessary. Side effects of ketoconazole include drug-induced toxicity, adrenal suppression and hepatotoxicity.

Dexamethasone. Dexamethasone is used if spinal cord compression is suspected.

Castrate resistant prostate cancer

Androgen deprivation therapy can fail to control disease progression. The reasons for this are unclear but include the clonal selection hypothesis or adaption hypothesis. In the clonal selection hypothesis, the premise is that the basal cells are the stem cells of the prostate and generate secretory epithelial cells. Whilst the secretory epithelial cells undergo apoptosis upon androgen withdrawal, this is not the case with basal or stromal cells. As a consequence, there is selective survival of these androgen independent cells within the tumour. With the adaption hypothesis, there is the assumption that androgen independence may be an intrinsic, but dormant property of some prostate cells that is activated by androgen deprivation. Whatever the explanation, when there is failure of first-line therapy, quality of life can be improved by using single or combination therapy that includes a second-line hormone treatment (oestrogens), corticosteroids, ketoconazole, chemotherapy and bisphosphonates for short-term palliative response.

Oestrogen

Diethylstilboestrol (DES) is a synthetic oestrogen which acts by producing negative feedback on the hypothalamus and anterior pituitary, thereby down regulating the secretion of LHRH and hence the production of testosterone. Diethylstilboestrol is the least expensive of the synthetic oestrogens and causes fewer hot flushes and psychological trauma compared to the surgical option. Side effects include gynecomastia, loss of libido and potency, oedema, nausea and vomiting, and increased risk of thromboembolism. It is usually used in a dose of 1 mg once daily to reduce the risk of cardiovascular side effects as it is associated with increased cardiovascular mortality.

Corticosteroids

Both prednisolone and hydrocortisone are anti-inflammatory and can alter the body's immune response to various stimuli and are used in combination with other treatments.

Chemotherapy

Chemotherapy inhibits cell growth and proliferation; it has a variable response rate and is used as a last resort. In the USA, a regimen using mitoxantrone and prednisolone is approved

for use in palliation of advanced PC. In the UK, it is recommended that docetaxel is used within its licensed indication to treat men with hormone refractory metastatic disease. Repeat courses of treatment are not recommended if the disease reoccurs when the planned course is complete.

Chemoprevention

Chemoprevention is defined as the administration of micro-nutrients, dietary products or drugs to prevent or delay the progression of PC.

Diet

There has been interest in a variety of products and numerous studies have been conducted. Currently in favour are soya-containing foods, green tea, pomegranates and omega-3 fatty acids. Selenium and vitamin E are no longer considered favourable. Similarly, vitamin D and lycopene found in tomatoes are also out of favour due to the lack of positive outcomes.

Drugs

5α-Reductase inhibitors which are currently used in BPH to reduce prostate size due to their inhibitory effect on the production of DHT are thought to have potential for chemoprevention.

Studies with dutasteride have shown it can reduce the risk of PC and improve outcomes in BPH by reducing AUR. On the down side, it appears to increase the risk of cardiac failure and consequently is not routinely used in chemoprevention.

Patient care

Treatment is decided after discussing the various options and side effects with the individual. Urinary and sexual function related problems are common side effects of most treatments in PC and need to be discussed in detail with the patient. Emotional factors like depression may also need to be addressed as they can adversely affect the quality of life of the individual. Some of the common problems associated with PC are listed in Table 48.3. Patients can also be referred to http://www.nhs.uk/prostatecancer for facts, information and details of choices available in the diagnosis and treatment of PC. Information on how to cope with the disease and live with PC together with details of various support organisations are available from http://www.cancerhelp.org.uk, whilst http://www.prostate-link.org.uk describes various patient experiences.

Prostatitis

Epidemiology

The term prostatitis comprises a range of disorders that have been defined and classified (Table 48.4) by the International Prostatitis Collaborative Network (IPCN) into four categories (Krieger et al., 1999).

Prostatitis has been estimated to affect up to 16% of adult men. Unlike BPH and PC, which are more prevalent in older men, prostatitis affects men of all ages.

In most instances (between 90% and 95%), the aetiology of prostatitis is unknown with bacteria isolated in only 5–10% of men presenting with prostatitis.

Table 48.3 Common problems associated with prostate cancer

Problem	Solution
Loss of erectile function after prostatectomy	Phosphodiesterase 5 inhibitors such as sildenafil have shown efficacy in prevention and help improve chance of spontaneous erection. If medication fails or is contraindicated a vacuum device, intraurethral inserts or penile prosthesis may be used
Advanced disease with impending spinal cord compression	Treat with oral dexamethasone and either cyproterone or ketoconazole with external-beam radiotherapy. LHRH agonist treatment is not advisable as the tumour flare up in the initial stage can stimulate tumour growth and exacerbate the condition
Bleeding and coagulation disorder	Prostate cancer can cause disseminated intravascular coagulation as a pathological response to the disease. This is a rare condition where small blood clots are formed in the body, disrupt the normal coagulation process and cause bleeding. This can be further complicated if the patient has co-morbidities which require treatment with anti-coagulants. Prompt treatment of the cancer with hormones and in some cases replacement of blood, platelets and clotting factors may be required
Hot flushes during androgen deprivation therapy	The hypothalamus is the centre for thermoregulation. Orchiectomy and LHRH agonists inhibit some of the peptides involved in thermoregulation. This increases central adrenergic activity and inappropriate stimulation of thermoregulatory centres, causing peripheral body vasodilatation and hot flushes. Low dose cyproterone acetate (100 mg a day) has been used to suppress hot flushes

Table 48.4 International Prostatitis Collaborative Network (IPCN) classification of prostatitis

IPCN classification	Comment
I. Acute bacterial prostatitis	Acute infection of the prostate
II. Chronic bacterial prostatitis	Chronic infection of the prostate
III. Chronic prostatitis/chronic pelvic pain syndrome	No evidence of infection
A. Inflammatory	Leucocytes in prostatic secretions, post prostate massage urine, or semen
B. Non-inflammatory	No evidence of inflammation
IV. Asymptomatic inflammatory prostatitis	Lack of genitourinary symptoms

Pathophysiology

Acute bacterial prostatitis (ABP) is caused by bacterial infection. The most common isolated uropathogen is *Escherichia coli*. Other causative agents include *Proteus* spp., *Klebsiella* spp., *Pseudomonas* spp. and, less commonly, enterococci, *Bacteroides and Staphylococcus* spp. Chronic bacterial prostatitis (CBP) usually involves recurrent bacterial urinary infections caused by the same organism involved in acute bacterial prostatitis. Both syndromes are of infective origin and represent the minority of cases of prostatitis.

In contrast, the aetiology of chronic prostatitis/chronic pelvic pain syndrome is poorly understood. Several possible mechanisms have been proposed including autoimmune disorders, infection, neurogenic inflammation and voiding dysfunction.

Symptoms

In prostatitis, the clinical presentation and symptoms are a strong diagnostic determinant. A validated, nine-point questionnaire, the Chronic Prostatitis Symptom Index (CPSI) quantifies the severity, frequency and location of pain and discomfort. It is also used to assess urinary symptoms and to establish the impact of symptoms on the patient's quality of life.

Patients with acute bacterial prostatitis usually present with symptoms of a UTI which may include dysuria, urinary frequency or urgency, whilst some may present with pain of penile, lower back or perineal origin. Signs and symptoms of systemic infection can be present in some cases and include pyrexia, rigors, malaise and myalgia. Acute bacterial prostatitis can sometimes precipitate AUR due to prostatic inflammation.

In chronic bacterial prostatitis, symptoms of UTI and pain can also be present. Typically, men with chronic bacterial prostatitis remain asymptomatic between infective episodes.

The main feature in chronic prostatitis/chronic pelvic pain syndrome is urological pain (perineum, lower abdomen and back, rectum, penis and testicles). These symptoms are usually present for at least 3 months before a diagnosis can be made. LUTSs and ejaculatory dysfunction can also affect men with chronic prostatitis/chronic pelvic pain syndrome.

Patients with asymptomatic inflammatory prostatitis have no symptoms. The condition is usually diagnosed when patients undergo investigation to assess other genitourinary complaints. For example, prostatitis may be found in biopsies taken from patients investigated for elevated PSA or when leucocytes are found in semen samples from men being investigated for infertility.

Examination and investigations

If acute bacterial prostatitis is suspected, a urine dipstick and culture are performed to reveal the presence of pathogens and leucocytes. Depending on the clinical picture, a blood culture may be indicated to diagnose concomitant bacteraemia. An ultrasound scan of the bladder can be conducted to evaluate the residual volume of urine and problems with voiding and urinary retention.

Chronic bacterial prostatitis is diagnosed in men with a history of recurrent or relapsing UTIs. A positive urine dipstick and culture is a common finding during acute episodes. Microscopy and culture of lower tract urinary secretions (urine and prostatic) between symptomatic periods can be performed and will help identify the prostate as the main focus of infection. Imaging of the urinary tract can be conducted to rule out any structural abnormalities.

Chronic prostatitis/chronic pelvic pain syndrome is a diagnosis of exclusion. Typical disorders which must be excluded include the presence of active urethritis, urogenital cancer, urinary tract disease, functionally significant urethral stricture or neurological disease affecting the bladder (Krieger et al., 1999). The main component of this syndrome is the presence of genitourinary pain. After taking a detailed medical history, the evaluation of symptoms can be done using the Chronic Prostatitis Symptom Index. Other investigations include a DRE, urinalysis, urine culture and cytology, screening for sexually transmitted diseases, urodynamic studies, prostatic TRUS and serum PSA.

Treatment

Acute bacterial prostatitis can present as a serious infection and therapy normally includes empirical treatment with parenteral antibiotics. Commonly used agents include broad-spectrum penicillins, fluoroquinolones or third-generation cephalosporins usually in combination with aminoglycosides. Urine culture and sensitivities will inform the choice of future antibiotic treatment, which is recommended to be continued for 2–4 weeks. General supportive measures such as maintenance of appropriate hydration and pain relief are important. Suprapubic catheterisation may be required if AUR is present.

The treatment of chronic bacterial prostatitis involves long courses (at least 4 weeks) of antibiotics. Fluoroquinolones are used as first-choice agents because of good prostatic penetration, their spectrum of anti-bacterial activity and favourable safety profile. If infective episodes are frequent, patients can be offered prophylactic antibiotics for several months with periodic follow-up to monitor progress (McNaughton-Collins et al., 2007).

Since the aetiology of most cases of chronic prostatitis/chronic pelvic pain syndrome is unknown, management often involves empirical treatment. Despite not being considered to have an infective nature, up to 50% of patients with chronic prostatitis/chronic pelvic pain syndrome respond to long courses of fluoroquinolones (Nickel et al., 2001), especially men with symptoms of relatively recent onset (a few weeks). Patients with longstanding symptoms refractory to treatment are less likely to benefit from fluoroquinolones. α-Adrenoceptor antagonists are also used alone or in combination with antibiotics in the management of chronic prostatitis/chronic pelvic pain syndrome. The evidence for efficacy is conflicting but remains an option for patients with persistent symptoms. There are also limited data describing the use of other therapies in chronic prostatitis/chronic pelvic pain syndrome such as fluoxetine, pollen extract, quercertin, finasteride, mepartricin and pelvic electromagnetic therapy.

No treatment is necessary for patients with asymptomatic inflammatory prostatitis since the condition is characterised by the lack of symptoms.

Patient care

Patients need to be made aware that prostatitis is common and affects between 1 and 2 out of every 10 men. The cause is generally poorly understood and it is difficult to diagnose. In chronic cases of prostatitis, symptoms may persist for long periods, although the severity can vary over time. Treatment may involve several therapies. Patients treated with antibiotics must be informed of the importance of completing the prolonged courses necessary to eradicate infection.

The British Prostatitis Support Association has a website (http://www.bps-assoc.org.uk) that offers patients information and support.

Case studies

Case 48.1

A 64-year-old man presents with complaints of poor urinary flow and having to visit the toilet at least twice during the night to pass urine. There is no family history of prostate disease and he is taking no medication.

Question

What investigations are appropriate and how should this patient be managed?

Answer

This patient should be asked to present a frequency volume chart of voided urine and undergo a full clinical examination, including measurement of PSA. The PVR volume of urine within the bladder should be measured after micturition.

If the PSA is within the normal range and the residual volume is less than 100 mL, the patient can be reassured about his condition and a 'watch and wait' policy adopted. If the patient finds this unacceptable, then he should be offered treatment with an α-adrenoceptor antagonist. If he is not hypertensive, a uroselective drug such as tamsulosin can be considered. This should have few systemic side effects and requires no initial titration of dose. If he is hypertensive, a less specific α-blocker may be more appropriate which will serve the dual purpose of an anti-hypertensive agent as well as treating his urinary symptoms. Careful dose titration may be necessary initially to counter any potential postural hypotension. The combination of an α-adrenoceptor antagonist and 5α-reductase inhibitor may be considered the treatment of choice for this patient.

Case 48.2

A 50-year-old man requests treatment from his primary care doctor for a 'bladder infection'. On questioning, he describes symptoms of urinary frequency, urgency and urge incontinence, but fever is absent.

Question

How should this patient be treated?

Answer

The lay person may interpret the symptoms of frequency and urgency as representing a UTI, but in the absence of dysuria this is unlikely. The patient should be referred for a full clinical assessment which should include urodynamic studies, filling and voiding cystometry, an ultrasound scan of the upper urinary tract, measurement of PSA and assessment of renal function. It is likely the patient has an outflow obstruction which has given rise to secondary instability of the detrusor muscle in the bladder, causing involuntary contractions of the bladder and resulting in incontinence. The obstruction may be due either to prostate enlargement or a dysfunctional bladder neck. In either case, treatment with an α-adrenoceptor antagonist is appropriate to reduce the outflow resistance. Should the flow be adequate but symptoms of incontinence persist, then concurrent treatment with an anti-muscarinic drug such as oxybutynin or tolterodine may be necessary to inhibit the cholinergic-mediated contractions of the detrusor.

There is emerging evidence that phosphodiesterase-5 inhibitors may also be useful in the management of LUTSs. It is known there is an abundance of the phosphodiesterase-5 isoenzyme in the prostate, and it is thought this is involved in the regulation of smooth muscle tone. A number of small-scale studies have shown the benefit of agents such as sildenafil and tadalafil, although both are currently licensed only for the treatment of erectile dysfunction. It may be appropriate to prescribe one of these agents for the patient in question.

Case 48.3

A 75-year-old male presents with AUR and a history of nocturia for the past 2–3 months. His medical history includes a heart valve replacement. He denies any haematuria or dysuria and

has good flow while passing urine. On DRE, the prostate is found to be hard and nodular on one side and the PSA was 662 ng/mL

Questions

1. What investigations are recommended and how should this patient be managed?
2. What treatment choice is available for this patient?
3. What are the most likely future complications expected in this patient?

Answers

1. Since AUR is painful and can cause renal damage, he needs to be catheterised to relieve his bladder. A hard and nodular prostate on DRE together with elevated PSA suggests PC. The patient needs to have a range of baseline investigations including a TRUS biopsy, MRI of the pelvis and isotope bone scan. Although the DRE is suggestive of PC, the TRUS biopsy helps to grade the cancer using the Gleason scale and helps in making the decision about treatment. The bone scan helps identify bone metastasis which along with the results from MRI is used to stage the cancer based on the TNM score.

   The MRI pelvis revealed an enlarged and irregular prostate with intra-vesicle extension of the medial lobe into the bladder neck. The patient was confirmed to have adenocarcinoma of the prostate with a Gleason score of 8 and with bone metastasis.
2. Surgical castration can bring down the testosterone levels immediately and is relatively inexpensive but may have a psychological impact on the patient in addition to impotence and hot flushes. Medical castration with LHRH analogues would be effective treatment as well. LHRH agonists can be used to treat systemically as it produces response in more than 70% men, but the concern with this group of drugs is the flare up of the disease due to the initial surge in testosterone levels in addition to the other side effects of decreased libido, hot flush and impotence. Flare can precipitate life-threatening symptoms of the disease if the cancer is close to the spinal cord where it may cause spinal cord compression and paralysis. If lymph nodes near the ureter are involved the flare can increase the node size and compress the ureter causing renal impairment. It can also increase bone disease causing severe bone pain. Although initiation of anti-androgens can reduce symptoms of hot flushes associated with flare up to some extent, the preferred option for patients with increased risk of spinal cord compression would be LHRH antagonist as it can reduce testosterone levels much more quickly with no flare up.

   Hormonal treatment was commenced with an LHRH agonist injection together with a 1-month course of cyproterone acetate to protect against tumour flare. His PSA fell from 662 to 130 ng/mL in 5 months and continued to fall to 3.2 ng/mL after 9 months indicating a good response to hormonal treatment. Although the patient wanted to be catheter free, he failed several trials without a catheter and was offered radical radiotherapy and TURP to control local obstructive symptoms.
3. As the disease progresses, the patient can develop hormone resistance and non-hormonal treatment such as chemotherapy with docetaxel and ketoconazole may need to be considered. Osteoporosis is an important potential complication of long-term androgen deprivation therapy and metastatic bone disease and consequently the patient may experience severe bone pain. Palliative radiotherapy to metastatic bone areas and NSAIDs are recommended to control the symptoms initially, but if pain persists use of bisphosphonates may be necessary as they are known to inhibit osteoclast activity and relieve bone pain.

Case 48.4

A 35-year-old man presents with a 3-month history of dysuria, frequency and hesitancy. He also complains of pain in the perineum and discomfort while ejaculating. A DRE reveals the size and shape of his prostate seems to be normal although it is tender on examination.

Question

What are the various conditions that need to be considered and what medication will help confirm the diagnosis?

Answer

A urine dipstick and culture is recommended to rule out UTI. PSA can be measured but is raised in BPH, PC and prostatitis and hence is not a definitive test. The symptoms and physical examination are suggestive of chronic prostatitis. A swab should be taken to rule out chlamydia and other sexually transmitted diseases. Prostatitis needs to be confirmed after ruling out other possibilities like epididymitis, epididymo-orchitis, urethral stricture, renal calculus, PC, bladder and colorectal cancer.

The available evidence suggests a cure or an improvement in symptoms will occur if a quinolone antibiotic is prescribed for 4 weeks. NSAIDs and paracetamol can be used to relieve any associated pain whilst faecal softeners may be required to reduce discomfort and pain when opening bowels.

Case 48.5

A 43-year-old male seeks advice from a community pharmacist regarding his difficulty, over the past 3–4 months, when attempting to start urinating and then urinating for a long time. On questioning, he does not have any other significant medical history and he has no symptoms of a UTI, pain or haematuria.

Questions

1. Is it appropriate to sell over-the-counter tamsulosin to this patient?
2. Does the pharmacist need to maintain a record of the sale?

Answers

1. LUTSs, like hesitancy and weak stream, indicate BPH which is prevalent in one in four men above the age of 40 years. Since it is a very sensitive topic for most males, the patient needs to be consulted in a private area to assess the severity of his symptoms by using the IPSS. This is a sum of seven urinary symptoms which include incomplete emptying, frequency, intermittency, urgency, weak stream, straining and nocturia. If these symptoms severely affect the quality of life and there are no contraindications, a supply of tamsulosin 400 μcg to be taken once daily for 2 weeks initially and then for a further 4 weeks can be made while simultaneously referring the patient to his primary care doctor to confirm diagnosis and to assess his suitability for long-term treatment. If the symptoms do not improve within 14 days or the symptoms worsen, the patient should be asked to discontinue treatment and seek medical advice.
2. Record keeping is necessary to confirm that the doctor has assessed the patient within 6 weeks of initiating treatment and thereby permit further supply. It is important that the patient's consent is obtained to keep this record.

Anaemia 49

C. Acomb and R. Sanderson

Key points

- Anaemia is a common condition which is caused by a number of pathologies and can be subdivided into microcytic, megaloblastic and haemolytic types.
- Iron deficiency is the commonest form of microcytic anaemia worldwide. Once the primary cause has been corrected, ferrous salts are the standard treatment.
- Folate deficiency results in a macrocytic anaemia and is treated with replacement therapy.
- Lack of intrinsic factor prevents absorption of vitamin B_{12} leading to a macrocytic anaemia. Treatment with parenteral B_{12} reverses the blood picture but does not always alleviate the accompanying neuropathy.
- Haemolytic anaemias include the generic disorders of sickle cell anaemia, thalassaemia and glucose-6-phosphate dehydrogenase deficiency. In these diseases, abnormal forms of haemoglobin lead to haemolysis.
- Sideroblastic anaemia is a rare anaemia caused by impaired haem synthesis where the body has adequate iron stores but is unable to incorporate them into haemoglobin.

Anaemia is not one disease, but a condition that results from a number of different pathologies. It can be defined as a reduction from normal of the quantity of haemoglobin in the blood. The World Health Organisation defines anaemia in adults as haemoglobin levels less than 13 g/dL for males and less than 12 g/dL for females. However, there are apparently normal individuals with levels less than this. The low haemoglobin level results in a corresponding decrease in the oxygen-carrying capacity of the blood.

Epidemiology

Anaemia is possibly one of the most common conditions in the world and results in significant morbidity and mortality, particularly in the developing world. Worldwide, over 50% of pregnant women and over 40% of infants are anaemic. In the UK, 14% of women aged 55–64 and 3% of men aged 35–64 have been found to be anaemic.

Aetiology

The low haemoglobin level that defines anaemia results from two different mechanisms:

- Increased haemoglobin loss due to either:
  - haemorrhage (red cell loss) or
  - haemolysis (red cell destruction).
- Reduced haemoglobin synthesis due to either:
  - lack of nutrient or
  - bone marrow failure.

Reduced haemoglobin synthesis leads to either reduced proliferation of precursors or defective maturation of precursors or both (see Table 49.1). It is not unusual to find more than one cause in a single patient.

This chapter will cover some of the more common anaemias that involve drug therapy:

Microcytic anaemias	iron deficiency anaemia
	anaemia of chronic disease
	sideroblastic anaemia
Megaloblastic anaemias	folate deficiency
	vitamin B_{12} deficiency
Haemolytic anaemias	autoimmune haemolytic anaemia
	sickle cell disease
	thalassaemia
	glucose-6-phosphate dehydrogenase deficiency

Table 49.1 Examples of conditions that cause reduced haemoglobin synthesis

Reduced proliferation of precursors	Defective maturation of precursors
Iron deficiency	Vitamin B_{12} deficiency
Anaemia of chronic disease	Folate deficiency
Anaemia of renal failure	Iron deficiency
Aplastic anaemia (primary)	Disorders of
Aplastic anaemia (secondary to drugs, etc.)	– globin synthesis (thalassaemias)
Infiltration of the bone marrow:	– iron metabolism (e.g. sideroblastic)
– leukaemia or lymphoma	Myelodysplastic syndrome
– myelofibrosis	
– metastases	

Normal erythropoiesis

It is thought that white cells, red cells and platelets are all derived from a common cell known as the pluripotent stem cell found in the bone marrow. As these cells mature, they become committed to a specific cell line (Fig. 49.1). The red cells mature through the various stages, during which time they synthesise haemoglobin, DNA and RNA. Reticulocytes are found in the peripheral circulation for 24h before maturing into erythrocytes. Reticulocytes are released into the peripheral circulation prematurely during times of increased erythropoiesis.

Erythropoietin is a hormone produced by the cells of the renal cortex. The kidney responds to hypoxia and anaemia by increasing the production of erythropoietin. The red cell progenitors BFU-E and CFU-E have receptors on their surface. When erythropoietin binds to these receptors, it promotes differentiation and division, and consequently increased erythropoiesis. Patients with end-stage renal disease fail to produce appropriate amounts of erthropoietin and so develop anaemia. Erythropoietin production is also impaired in other conditions such as rheumatoid arthritis, cancer and sickle cell disease, though the impairment is not as great as in renal disease. Also of interest is the fact that theophylline decreases erythropoietin production, though the clinical relevance of this is uncertain.

Each day approximately 2×10^{11} erythrocytes enter the circulation. Normal erythrocytes survive in the peripheral circulation for about 120 days. Abnormal erythrocytes have a shortened lifespan. At the end of their life, the red cells are destroyed by the cells of the reticuloendothelial system found in the spleen and bone marrow. Iron is removed from the haem component of haemoglobin and transported back to the bone marrow for reuse. The pyrole ring from globin is excreted as conjugated bilirubin by the liver, and the polypeptide portion enters the body's protein pool.

Clinical manifestations

In its mildest form anaemia results in tiredness and lethargy; at its most severe it results in death unless treated. There is some suggestion that even mild anaemia may inhibit physical exercise and result in reduced mental performance. The reduced oxygen-carrying capacity of the blood leads to reduced tissue oxygenation and widespread organ dysfunction (Box 49.1).

A rapid blood loss, for example, haemorrhage, produces shock, with collapse, dyspnoea and tachycardia. Anaemia that develops over a period of time allows the body to partially compensate. As the anaemia becomes worse, more and more signs and symptoms may develop.

Even though in anaemia the amount of haemoglobin is reduced, all the blood that passes through the lungs is fully oxygenated. Increasing the respiratory rate or increasing the FiO_2 (fraction of inspired oxygen) will not improve tissue oxygenation. When the haemoglobin falls below 7 or 8 g/dL, there is almost always a compensatory increase in cardiac output.

Investigations

It is essential to find the cause of the anaemia; there is no place for 'blind' treatment. In most patients, the anaemia is a consequence of a reduced concentration of haemoglobin in each red cell and/or a reduced number of red cells in the peripheral circulation. Blood volumes may be increased in pregnancy and heart failure and haemoglobin concentration appear falsely low. Splenomegaly and signs of heart failure are sure signs of an increased blood volume. A blood transfusion in such a patient would precipitate left ventricular failure.

The most important parameter to assess anaemia is the haemoglobin concentration of the blood. It is also usual to count the number of red cells. In addition the size, shape and colour all contribute to the investigation (Box 49.2). The mean corpuscular volume (MCV) is a useful parameter that helps determine the type of the anaemia. However, care must be

taken since the MCV indicates the average size of the cells. If there are two pathologies, where one causes large cells and other causes small cells, the MCV may appear normal or be misleading. Following on from this baseline other investigations may be required. Bone marrow examination by either aspiration or trephine may be needed to make a diagnosis.

Iron deficiency anaemia

Epidemiology

Iron deficiency anaemia is the commonest form of anaemia worldwide and may be present in up to 20% of the world's population. A diet deficient in iron, parasitic infestations, for example, hookworm (causing blood loss), and multiple pregnancies contribute to its high prevalence in underdeveloped countries. Even in Western societies, it has been reported that as many as 20% of menstruating females show a rise in haemoglobin levels on iron therapy.

Aetiology

In Western societies, the commonest cause of iron deficiency is due to blood loss. In women of childbearing age, this is most commonly due to menstrual loss. Amongst adult males, the most likely cause is gastro-intestinal bleeding. Other causes of blood loss associated with iron deficiency anaemia include haemorrhoids, nosebleeds or postpartum haemorrhage. A loss of 100 mL of blood represents the amount of iron normally absorbed from a Western diet over 40 days. The major causes of iron deficiency are listed in Box 49.3.

Pathophysiology

The elimination of iron is not controlled physiologically, so the homeostasis is maintained by controlling iron absorption. Iron is absorbed mainly from the duodenum and jejunum. Absorption itself is inefficient; iron bound to haem (found in red meat) is better absorbed than iron found in green vegetables. The presence of phosphates and phytates in some vegetables leads to the formation of unabsorbable iron complexes, whilst ascorbic acid increases the absorption of iron. In a healthy adult, approximately 10% of the dietary iron intake will be absorbed. Iron is transported around the body bound to a serum protein called transferrin. Normally, this protein is only one-third saturated with iron.

Anaemia may result from a mismatch between the body's iron requirements and iron absorption. The demand for iron varies with age (Table 49.2). Diets deficient in animal protein or ascorbic acid may not provide sufficient available iron to meet

Box 49.3 Major causes of iron deficiency anaemia

Inadequate iron absorption
  Dietary deficiency
  Malabsorption
Increased physiological demand
Loss through bleeding

Table 49.2 Typical daily requirements of iron

Infant (0–4 months)	0.5 mg
Adolescent male	1.8 mg
Adolescent female	2.4 mg
Adult male	0.9 mg
Menstruating female	2.0 mg
In pregnancy	3–5 mg
Postmenopausal female	0.9 mg

the demand. Poor nutrition in children in inner cities in the UK frequently leads to anaemia. Milk fortified with iron given to inner city infants up to the age of 18 months has been shown to increase haemoglobin levels and improve developmental performance compared to unmodified cow's milk (Williams et al., 1999). A systematic review showed that iron supplementation in children over seven improved intelligence tests scores in those who were initially anaemic (Sachdev et al., 2005). However, universal iron supplementation may not be appropriate because there is a theoretic increased risk of susceptibility to infectious diseases, although this has only been demonstrated for diarrhoea (Gera and Sachdev, 2002) and malaria in endemic areas (Prentice et al., 2007). Targeting supplementation only to children with anaemia and withholding iron supplementation during malaria treatment is sensible as iron may inhibit treatment, and absorption of oral iron is blocked by the inflammatory response.

Malabsorption of iron has been reported in patients with coeliac disease and in 50% of patients following partial gastrectomy. Tetracyclines, penicillamine and fluoroquinolines bind iron in the gastro-intestinal tract and reduce the absorption of iron from supplements. They probably do not affect the absorption of dietary iron.

During pregnancy, there is an increase in red cell mass but there is also a proportionally bigger increase in plasma volume, which results in a physiological dilutional anaemia. It is thought that the gut increases its ability to absorb iron during pregnancy to meet the additional demands of fetal red cell production. Some of the increased demand is met by the stopping of menstruation. If, however, there is inadequate iron absorption, then anaemia may result.

Clinical manifestations

In addition to the general symptoms of anaemia, various other features may be present (Box 49.4). The colour of the skin is very subjective and often unreliable. Patients at risk of heart failure may present with breathlessness when anaemic. Koilonychia, dysphagia and pica are found only after chronic iron deficiency and are relatively rare.

A full blood count is an essential screening test. The cells of the peripheral blood are microcytic and hypochromic with poikilocytes (often pencil shaped) and occasional target cells

---

Box 49.4 Features of iron deficiency anaemia

Pale skin and mucous membranes
Painless glossitis
Angular stomatitis
Koilonychia (spoon shaped nails)
Dysphagia (due to pharyngeal web)
Pica (unusual cravings)
Atrophic gastritis

(abnormal thin erythrocytes which when stained show a dark centre and peripheral ring).

The main parameter used to help establish the iron status of the patient is the serum ferritin. The serum ferritin level is low in iron deficiency anaemia and markedly raised in iron overload. It is a good measure of the iron stores in the body. Care needs to be used in interpreting raised ferritin levels as these are sometimes found in cancer, inflammatory conditions and liver disease. Serum iron is a less useful parameter and exhibits diurnal variation, being higher in the morning.

Investigations

The aim of treatment is to correct the anaemia and replenish iron stores. Although the treatment of iron deficiency anaemia is relatively simple, it should not be embarked upon lightly. It is important to resolve the underlying cause as far as possible. Since gastro-intestinal blood loss is the most common cause in men and postmenopausal women, examination of the upper and lower tract is an important investigation. If necessary, this may need to include upper gastro-intestinal tract endoscopy, colonoscopy, barium enema and small bowel biopsy.

Over-the-counter sales of iron should be discouraged except in those patients who have been fully investigated. It is not unknown for patients to be given iron unnecessarily, resulting in iron overload. Also, giving iron therapy to a patient who is continuing to bleed from their gastro-intestinal tract will not help resolve the underlying problem.

Treatment

Prophylaxis of iron deficiency anaemia was widely used in pregnancy (together with folic acid); however, it is now only used for women who have additional risk factors for iron deficiency, for example poor diet. Prophylaxis may also be used in menorrhagia, after partial gastrectomy and in some low birth weight infants, for example, premature twins.

If gastro-intestinal investigation has been performed and any underlying cause treated, all patients should receive iron supplementation to correct their anaemia and replenish stores. Oral iron in the ferrous form is cheap, safe and effective in most patients. Depending on the state of the body's iron stores, it may be necessary to continue treatment for up to 6 months to both correct the anaemia and replenish body stores. The standard treatment is ferrous sulphate 200 mg two to three times a day. It typically takes between 1 and 2 weeks for the haemoglobin level to rise 1 g/dL. An earlier indication

of the patient's response can be seen by looking at the reticulocyte count, which should start to rise 2–3 days after starting effective treatment. Nausea or abdominal pains trouble some patients and this tends to be related to the dose of elemental iron. Giving the iron with food makes it better tolerated but tends to reduce the amount absorbed. Alternative salts of iron are sometimes tried; these tend to have fewer side effects simply because they contain less elemental iron (Table 49.3). Taking fewer ferrous sulphate tablets each day would have the same effect. A change in bowel habit (either constipation or diarrhoea) is sometimes reported, and this is probably not dose related. During the early stages of treatment, the body absorbs oral doses of iron better. Absorption is commonly around 15% of intake for the first 2–3 weeks but falls off to an average of 5% thereafter. It has been shown that for some patients eradication of *Helicobacter pylori* aids recovery from iron deficiency anaemia (Annibale et al., 1999).

There are a number of modified-release oral preparations available. They have no clear therapeutic advantage over ferrous sulphate and are not recommended. Indeed, the modified-release characteristic may cause the oral iron to be carried into the lower gut, which is much poorer at absorbing iron than the duodenum. Modified-release preparations may be more likely to exacerbate diarrhoea in patients with inflammatory bowel disease or diverticulae.

There is a limited place for parenteral iron in iron deficiency anaemia; it should be reserved for patients who fail on oral therapy, usually because of poor adherence or intolerable gastro-intestinal side effects. For most patients when equivalent doses of oral and parenteral iron are used, there is no difference in the rate of at which the haemoglobin level rises. Patients who have lost blood acutely may require blood transfusions. The need for a rapid rise in haemoglobin is not an indication for parenteral iron. Intravenous iron has been shown to have some benefit during the perioperative management of anaemia in selected patients undergoing orthopaedic surgery, but not been observed in other types of surgery (Beris et al., 2008).

There is a risk of anaphylactoid reactions with intravenous iron but the incidence appears to be lower with the newer products than with the older preparations which have now been discontinued. Patients given the newer licensed

Table 49.3 Elemental iron content of common oral preparations

Preparation	Approximate iron content (mg)
Tablets	
Ferrous sulphate 210 mg	68
Ferrous gluconate 300 mg	35
Ferrous fumarate 322 mg	100
Ferrous fumarate 210 mg	68
Oral liquids	
Ferrous fumarate 140 mg in 5 mL	45
Ferrous sulphate 125 mg in 1 mL	25
Sodium feredetate 190 mg in 5 mL	27.5

products, iron dextran (CosmoFer®), iron sucrose (Venofer®), iron III isomaltoside (Monofer®) and ferric carboxymaltose (Ferinject®) should have a test dose, and there should be facilities for cardiopulmonary resuscitation available. The dose for all products is calculated from the body weight and iron deficit. The manufacturer's product information provides details on administration. Some products can be given as a bolus injection (small doses) or by a short intravenous infusion or by a total dose infusion method. There seems to be a higher incidence of adverse reactions with the total dose infusions. Iron dextran may also be given by deep intramuscular injection. Intravenous iron should not be given during acute bacterial infections, since it may stimulate bacterial growth. As intravenous iron significantly reduces the oral absorption of iron, there is no rationale for giving oral iron for several days after administering intravenous iron.

Patient care

It is usual practice to advise patients to take iron products with or after meals as this probably reduces the incidence of nausea. Patients should be told that their faeces may become darker and that this is nothing to worry about. This is important in patients who have had malaena since they may associate their dark stools with the bleed and worry that they are still bleeding from the gastro-intestinal tract. The length of treatment, and adherence should be discussed and an explanation given that iron stores need to be replenished and that this takes time.

Anaemia of chronic disease

Epidemiology

This is the second most common form of anaemia (after iron deficiency). It is associated with a wide variety of inflammatory diseases including arthritis, malignancies, inflammatory bowel disease, HIV and other infections. It is increasingly being referred to as 'anaemia of inflammation'. Related to anaemia of inflammation are the anaemias associated with chronic kidney disease and chronic heart failure.

Aetiology

In anaemia of inflammation, there appears to be impaired response to erythropoietin and the inflammatory cytokines lead to a reduction in the availability of circulating iron. This cytokine-mediated shift of iron from the circulation into reticuloendothelial system leads to iron restricted erythropoiesis, despite normal iron stores. In malignancies, in addition to the anaemia of inflammation, the cytotoxic treatments themselves decrease erythrocyte production through their anti-proliferative effects on the bone marrow. Certain cytotoxic agents, such as platinum-based therapies, are more likely to cause anaemia.

In chronic kidney disease and chronic heart failure, the reduced renal blood flow leads to a decreased production of erythropoietin.

Pathophysiology

During infections, inflammation and cancer, the inflammatory cytokines, in particular interleukin-6 released from macrophages, lead to an increased production of hepcidin. Hepcidin, a peptide produced by hepatocytes, plays a key role in iron availability. The hepcidin causes

- increased uptake of iron by hepatocytes;
- reduced iron absorption;
- reduced release of iron from macrophages.

The reduction of circulating iron is thought to limit this essential nutrient's availability to invading microbes and tumour cells, blocking their proliferation.

In addition, the inflammatory cytokines increase the production of white blood cells which potentially lead to fewer stem cells being available for red cell production.

Clinical manifestations

Patients have the general symptoms of anaemia in addition to their symptoms of the chronic inflammatory condition. The anaemia frequently leads to a reduced quality of life for these patients.

Investigation

Patients have a hypochromic microcytic anaemia similar to iron deficiency anaemia, but the two conditions can be differentiated by reviewing other serum factors (see Table 49.4).

Treatment

Treating the underlying chronic condition is important. Blood transfusions are rarely needed in anaemia of inflammation. Oral iron therapy is not usually indicated despite the apparent reduced iron availability since these patients have a functional iron deficiency rather than an actual iron deficiency; also, the raised hepcidin levels reduce the oral absorption of iron.

A number of patients with chronic renal failure appear to have a functional iron deficiency that responds to intravenous iron. These patients, despite receiving oral iron and erythropoietin analogues, do respond with a rise in haemoglobin when given regular intravenous iron together with an erythropoietin

Table 49.4 Differentiation between iron deficiency anaemia and anaemia of chronic disease

Test	Iron deficiency anaemia	Anaemia of chronic disease
Serum iron	Low	Low
Serum ferritin	Low	Normal or high
Serum transferrin	High	Normal or low
Total iron binding capacity	High	Low

analogue (Silverberg et al., 1996). Intravenous iron in combination with erythropoietin analogues is widely used in chronic kidney disease. The patient's serum ferritin is monitored to check for iron overload. Concerns have been expressed about the possible long-term complications of intravenous iron, for example, atherosclerosis or increased risk of infection (Cavill, 2003). There appears to be a slightly increased risk of infections, but the improvement in anaemia leads to an improved quality of life.

Patients with anaemia-associated inflammatory bowel disease or with rheumatoid arthritis respond to intravenous iron; however, the use of intravenous iron in chronic inflammatory conditions is not generally recommended because of an increased risk of infections and also possible increased risk of acute cardiovascular events. Some small studies have shown intravenous iron to be beneficial in patients with heart failure, but currently this should be reserved for patients with proven iron deficiency and failure on oral iron (Dec, 2009).

Some patients with chronic disorders respond to erythropoietin analogues, none are licensed for use in chronic disease states other than anaemia associated with chronic renal failure or cancer. Elevated endogenous erythropoietin levels in patients with heart failure are associated with adverse outcomes (Felker, 2010). Some clinical trial data show a higher mortality and increased risk of tumour progression in patients with anaemia associated with cancer who have been treated with erythropoietins. It is not recommended that erythropoietin analogues are routinely used in the management of cancer treatment-induced anaemia (NICE, 2008). However, they may be considered, in combination with intravenous iron, for:

- women receiving platinum-based chemotherapy for ovarian cancer who have symptomatic anaemia with a haemoglobin concentration of 8 g/100 mL or lower. The use of erythropoietin analogues does not preclude the use of existing approaches to the management of anaemia, including blood transfusion when necessary;
- patients who cannot be given blood transfusions and who have profound cancer treatment-related anaemia that is likely to have an impact on survival.

Tocilizumab, the interleukin-6 antagonist monoclonal antibody licensed for use in rheumatoid arthritis, has been shown to improve haemoglobin levels (Raj, 2009). It has also been suggested that drugs which downregulate interleukin-6 may have some effect (Altschuler and Kast, 2005). Olanzepine and quetiapine (potent H_1 antagonists) are known to be regulators of interleukin-6 but are not used clinically for this purpose. Furthermore, it is not known what the other effects of modifying interleukin-6 or hepcidin would have on the chronic inflammatory condition.

Patient care

Some patients hearing they have anaemia may be tempted to go and purchase iron or other supplements. Careful explanation will help them make an informed decision.

Sideroblastic anaemias

Epidemiology

Sideroblastic anaemias are a group of conditions that are diagnosed by finding ring sideroblasts in the bone marrow. There are both hereditary and acquired forms. The hereditary forms are rare, whilst some of the acquired forms are relatively common with as many as 30% of alcoholics admitted to hospital having sideroblastic anaemia.

Aetiology

In the majority of hereditary forms, there is an X chromosome-linked pattern of inheritance. Both autosomal dominant and autosomal recessive families have been described. The main defect is a reduced activity of the enzyme 5-aminolevulinate synthase (ALAS) which is involved in haem synthesis.

The acquired forms include idiopathic forms, forms associated with myeloproliferative disorders and forms secondary to the ingestion of drugs (Box 49.5). Regardless of the cause, there is impaired haem synthesis, where the body has adequate iron stores but is unable to incorporate it into haemoglobin.

Pathophysiology

An examination of the bone marrow typically shows a number of erythroblasts that have iron granules surrounding the cell nucleus. These cells are known as ring sideroblasts. In the hereditary forms, there are low levels of ALAS. This mitochondrial enzyme is involved in the first step in the synthesis of haem and requires pyridoxal phosphate as a co-factor. Pyridoxine is a precursor for pyridoxal.

Drugs and toxins

Alcohol can lead to the formation of ring sideroblasts. Ethanol is metabolised to acetaldehyde. It is the acetaldehyde that lowers the levels of ALAS and pyridoxal. Isoniazid is a known cause of sideroblasts. In slow acetylators of

isoniazid, the drug reacts with pyridoxal and the resulting product is then rapidly excreted. Pyridoxine prophylaxis is usually given to all patients on isoniazid. Doses of chloramphenicol over 2 g a day invariably lead to sideroblasts. This is thought to be due to the inhibition of mitochondrial protein synthesis. Sideroblastic anaemia is also associated with copper deficiency which can be caused by an overdose of the chelators: penicillamine, trientine and the experimental tetrathiomolybdate. These are all used in the treatment of Wilson's disease.

Clinical manifestations

The hereditary forms typically develop in infancy or childhood. The anaemia can be severe or mild (haemoglobin typically 4–10 g/dL). There may be splenomegaly, which can lead to mild thrombocytopenia. The idiopathic acquired forms tend to develop insidiously usually in middle age or later. Many patients may be asymptomatic for long periods. In the forms associated with other disorders, the clinical picture tends to be dominated by the underlying diseases.

Investigations

The common finding in all forms is the presence of sideroblasts in the bone marrow. In the hereditary form, the red cells in the peripheral blood are hypochromic and microcytic. Despite this, there are frequently increased iron stores in the bone marrow. The serum iron and ferritin may also be high. In the acquired forms, the peripheral blood has hypochromic cells, which may be either normocytic or macrocytic.

Treatment

In patients with the hereditary forms, large doses of pyridoxine (typically 100–200 mg daily or even up to 400 mg) may reduce the severity of the anaemia. Long-term high-dose pyridoxine has been associated with peripheral neuropathy and so lower maintenance doses are sometimes tried. There have been case reports of patients responding to parenteral pyridoxal-5-phosphate after failing to respond to pyridoxine. Patients with an acquired form occasionally respond to high-dose pyridoxine, and a 2- to 3- month trial may be helpful in symptomatic patients. The response tends to be slow and only partial. Haem arginate (licensed for use in porphyria) has been shown to increase the red cell count and decrease the number of ring sideroblasts in some patients with acquired sideroblastic anaemia, in common with other conditions where an increased turnover of cells in the bone marrow and folate supplements are often necessary.

Although the peripheral blood cells are frequently hypochromic and microcytic, the condition is associated with increased iron stores; therefore, iron supplements should be avoided. The drugs and toxins (Box 49.5) tend to cause a reversible anaemia. Removing the offending agent usually resolves the anaemia.

Iron overload

Inevitably, some patients fail to respond to these treatments and frequent blood transfusions are required. This leads to the complications of iron overload and sensitisation and the risk of blood-borne virus transmission. The chelating agent desferrioxamine is given either by intravenous or by subcutaneous infusion. It binds free iron and iron bound to ferritin. Therapy should be considered when the serum ferritin level reaches 1000 μcg/L. Patients with very high ferritin levels may need daily infusions. Daily subcutaneous infusions using a disposable infusor or small infusion pump are suitable for home use. In the UK, a number of commercial healthcare companies provide a desferioxamine home care service. Published evidence suggests that for an equivalent dose, a longer infusion time results in increased iron excretion. Intravenous infusions can be given whenever the patient comes into hospital for a blood transfusion. Small doses (<200 mg) of vitamin C increase the effectiveness of desferrioxamine probably by facilitating iron release from the reticuloendothelial system. Higher doses of vitamin C are reported to increase the cardiotoxicity of iron overload. Patients with cardiac failure should not be given vitamin C with desferrioxamine. Desferrioxamine should not be given concurrently with prochlorperazine as prolonged unconsciousness may result.

There are two oral agents (desferiprone and deferasirox) licensed for iron overload. Deferiprone unfortunately causes reversible neutropenia in some patients and weekly neutrophil counts are required. It is licensed for patients intolerant of desferrioxamine. Deferasirox has been more recently introduced and comes as a dispersible tablet that needs to be taken at least 30 min before food. It is associated with a high incidence of gastro-intestinal ulcers and renal impairment. Decreased hearing and lens opacities have been reported. Auditory and ophthalmic testing is recommended before the start of treatment and at regular intervals thereafter (every 12 months).

Patient care

Few patients with hereditary or the idiopathic acquired forms have completely reversible anaemia. Patients need to be aware that treatment with pyridoxine may take several months before any signs of improvement are seen. They should be advised not to purchase over-the-counter iron or vitamin supplements, particularly ascorbic acid or pyridoxine, without discussing it with their consultant.

Megaloblastic anaemias

The megaloblastic anaemias are macrocytic anaemias (raised MCV). There is an abnormality in the maturation of haematopoietic cells in the bone marrow. In addition to abnormal red cells, the white cells and platelets may be affected. The two major causes are folate deficiency and vitamin B_{12} deficiency. Pernicious anaemia is a specific autoimmune disease that causes malabsorption of vitamin B_{12} due to a lack of intrinsic factor.

Epidemiology

Folate deficiency anaemia

Much of the world's population has a marginal dietary intake of folate. Body stores are low, and as soon as there is a decrease in dietary intake or there is increased folate demand, deficiency readily occurs.

Vitamin B_{12} deficiency anaemia

Strict vegans (e.g. Hindus) commonly have low vitamin B_{12} levels due to their dietary deficiency though actual anaemia is rarer. All patients who have had a total gastrectomy and up to 15% of those with a partial gastrectomy will develop vitamin B_{12} deficiency anaemia.

Pernicious anaemia

Pernicious anaemia is found most commonly in people of northern European descent. In Britain, the incidence is about 120 per 100,000 being higher in Scotland than in the south of England. Pernicious anaemia is usually a disease of the elderly, the average patient presenting at 60 years of age.

Non-megaloblastic macrocytic anaemia caused by alcohol abuse, hypothyroidism or paroxysmal nocturnal haemoglobinuria will not be discussed in this chapter.

Aetiology

Folate deficiency anaemia

Folate is readily available in a normal diet. Fruit, green vegetables and yeast all contain relatively large amounts of folate. Despite this relative abundance of folate in many foods, dietary deficiency is common, either as the sole cause of the folic acid deficiency anaemia or in conjunction with increased folate utilisation.

Vitamin B_{12} deficiency anaemia

Deficiency occurs from inadequate intake or malabsorption. The only dietary source of vitamin B_{12} (cyanocobalamin) is from food of animal origin. It is present in meat, fish, eggs, cheese and milk. Cooking does not usually destroy vitamin B_{12}. Daily requirements are between 1 and 3μcg. Deficiency arises either from inadequate intake over a prolonged period or more commonly, in the West, from impaired absorption due to lack of intrinsic factor.

Malabsorption occurs if the distal ileum is removed; it may also occur with certain intestinal pathologies, particularly stagnant loop syndrome, tropical sprue and fish tapeworm infestation. Passive absorption does take place in the jejunum, but this is very inefficient and usually accounts for less than 1% of an oral dose.

Pathophysiology

The common biochemical defect in all megaloblastic anaemias is the inhibition of DNA synthesis in maturing cells.

Folate deficiency anaemia

The folate found in food is mainly conjugated to polyglutamic acid. Enzymes found in the gut convert the polyglutamate form to monoglutamate, which is readily absorbed. During absorption, the folate is methylated and reduced to methyltetrahydrofolate monoglutamate. This travels through the plasma and is transported into cells via a carrier specific for the tetrahydrofolate form. Within the cell, the methyl group is removed (in a reaction requiring vitamin B_{12}) and the folate is reconverted back to a polyglutamate form (Fig. 49.2). It has been suggested that the polyglutamate form prevents the folate leaking out of cells. The folate eventually acts as a coenzyme involved in a number of reactions including DNA and RNA synthesis. Defective DNA synthesis mainly affects cells with a rapid turnover, for example, gastro-intestinal cells and red blood cells, hence the sore tongue and anaemia seen in folate deficiency. During DNA synthesis, the folate coenzyme is oxidised to the dihydrofolate form, which is inactive and has to be reactivated by the enzyme dihydrofolate reductase. This is the enzyme inhibited by methotrexate and to a lesser extent by trimethoprim and pyrimethamine. Co-trimoxazole has been shown to increase the severity of megaloblastic anaemia.

Vitamin B_{12} deficiency

Absorption of vitamin B_{12} is mainly by an active process. Enzymes in the stomach release vitamin B_{12} from protein complexes. One molecule of vitamin B_{12} then combines with one molecule of a glycoprotein called intrinsic factor. The intrinsic factor protects the vitamin B_{12} from breakdown by microorganisms. There are specific receptors in the distal ileum for the intrinsic factor-vitamin B_{12} complex. The vitamin B_{12} enters the ileal cell and is then transported through the blood attached to transport proteins. Intrinsic factor does not appear in the blood.
Fig. 49.2 Simplified pathway of folate metabolism: (a) vitamin B_{12} is required as a coenzyme for this reaction: (b) the enzyme dihydrofolate reductase converts inactive dihydrofolate back to the active tetrahydrofolate.

Since intrinsic factor is only produced by the gastric parietal cells, a total gastrectomy always leads to vitamin B_{12} deficiency. Approximately 10–15% of patients who have had a partial gastrectomy also develop deficiency. The onset of anaemia is usually delayed because the body typically has stores of 2–3 mg, which is sufficient for 2–3 years. Vitamin B_{12} is a coenzyme for the removal of a methyl group from methyltetrahydrofolate. Lack of vitamin B_{12} traps the folate as methyltetrahydrofolate and prevents DNA synthesis (Fig. 49.2). The exact mechanism by which vitamin B_{12} deficiency causes neuropathy is not clear but may be due to a defect in the methylation reactions needed for myelin formation.

Pernicious anaemia

Pernicious anaemia is probably autoimmune in origin. Patients typically have a gastric atrophy and no (or virtually no) intrinsic factor secretion. Although not present in all patients, two different antibodies have been found in the serum of some patients with pernicious anaemia.

Clinical manifestations

In addition to the general features of anaemia, megaloblastic anaemia, of which folic acid deficiency and B_{12} deficiency anaemia are the two most common examples, has certain characteristics described in Box 49.6.

Folate deficiency anaemia

Alcoholics and the elderly are particularly prone to nutritional deficiency. Elderly people living alone on tea and toast are typical examples of patients at risk. Many alcoholics develop deficiency due to their poor diet; although some beers contain small amounts of folate, spirits contain none. A number of drugs have been implicated in causing folate deficiency (Box 49.7). Actual megaloblastic anaemia from drug therapy is uncommon, and the exact mechanism(s) has not always been established. Serious malabsorption can occur in tropical sprue and coeliac disease. Reduced absorption is seen in Crohn's disease and following partial gastrectomy or jejunal resection.

There is a physiological increase in folate utilisation during pregnancy. There may be an increased utilisation in various

pathological conditions, in association with inflammation or in a number of chronic haemolytic anaemias, particularly thalassaemia major, sickle cell disease and autoimmune haemolytic anaemia. Chronic folate deficiency probably predisposes patient to thrombosis, depression and neoplasia (Green and Miller, 1999).

Vitamin B_{12} deficiency anaemia

The megaloblastic anaemia caused by vitamin B_{12} deficiency has similar features to folate deficiency (Box 49.6). In addition to the macrocytosis, anisocytosis and poikilocytosis, there is often mild thrombocytopenia. The spleen may be slightly enlarged and there may be a slight fever. Mild jaundice may be present due to the increased breakdown of haemoglobin found in the abnormal red cells. The onset is slow and insidious, so patients often present late or are diagnosed during other investigations. The feature that separates vitamin B_{12} deficiency from the other megaloblastic anaemias is progressive neuropathy. It is symmetrical and affects the legs rather than the arms. Patients notice a tingling in their feet and a loss of vibration sense. Occasionally, patients have muscle weakness, difficulty in walking or experience frequent falls.

Investigations

Folic acid deficiency anaemia

Many patients are symptomless initially, and the diagnosis is made following a full blood count carried out for another reason. The peripheral blood reveals large oval red cells. Anisocytosis and poikilocytosis are common. Some of the neutrophils are hypersegmented, and thrombocytopenia may be present. The red cell folate concentration accurately reflects folate stores and is a more preferable parameter than the serum folate concentration, which is subject to changes in diet and does not correlate as closely with anaemia.

Vitamin B_{12} deficiency anaemia

Following the detection of macrocytes in the full blood count, one of the first investigations will be the determination of the serum vitamin B_{12} level. The serum vitamin B_{12} level is

low in mild anaemia and may be very low if there is marked megaloblastic anaemia or neuropathy. If there is no concurrent folate deficiency, the serum folate level tends to be raised whilst the red cell folate level falls, possibly due to a failure of folate polyglutamate synthesis in cells. False positives (low vitamin B_{12} level without true deficiency) may be seen in multiple myeloma, excessive ascorbic acid intake and pregnancy. In contrast, liver disease, lymphoma, autoimmune disease and myeloproliferative disorders may lead to a false-negative result (normal levels in the presence of true deficiency).

The detection of autoantibodies is helpful to distinguish pernicious anaemia from other forms. The presence of intrinsic factor antibodies is virtually diagnostic of pernicious anaemia being rarely found in any other condition. However, it is not a very sensitive test since only half the patients with pernicious anaemia have these antibodies. Gastric parietal cell antibodies are found in 85% of patients with pernicious anaemia (a more sensitive test) but unfortunately also found in up to 10% of people without pernicious anaemia (less specific) (see Table 49.5).

Oral vitamin B_{12} absorption can be measured using the Schilling test though this is now rarely used in practice as most vitamin B_{12} deficiencies are treated in the same way. The test measures the absorption of radiolabelled oral dose of vitamin B_{12}.

Treatment

It is necessary to establish whether the patient with megaloblastic anaemia has vitamin B_{12} deficiency or folic acid deficiency or both. Treatment of vitamin B_{12} deficiency with folic acid may lead to the resolution of the haematological abnormalities but does not correct the neuropathy, which continues to deteriorate. If it is not possible to delay until a definitive diagnosis is made, both folic acid and vitamin B_{12} may be given.

Folate deficiency anaemia

Folate deficiency is usually managed by replacement therapy. The duration of the treatment depends on the cause of the deficiency. Changes in dietary habits or removal of any precipitating factor should also be considered.

The normal daily requirement of folic acid is approximately 100 µcg a day; despite this, the usual treatment doses given are 5–15 mg a day. Even in malabsorption states, because of these large doses, sufficient folate is usually absorbed. Therefore,

parenteral folic acid treatment is not normally required. Treatment for 4 months will normally be sufficient to ensure that folate deficient red cells are replaced.

Large doses of folic acid can produce a partial haematological response in patients with vitamin B_{12} deficiency. The blood picture appears nearly normal but the neurological damage due to the vitamin B_{12} deficiency continues. Folic acid therapy should not be started until vitamin B_{12} deficiency has been excluded. It has also been suggested that patients on long-term folic acid therapy should have their vitamin B_{12} levels checked at regular intervals (e.g. yearly).

Pregnancy. The folate requirement increases in pregnancy and is higher in twin pregnancies. Folate deficiency regularly occurs in patients with a poor diet who do not take supplements. Prophylaxis with folate (350–500 µcg daily) is now frequently given in pregnancy, often in combination with iron, starting before conception and during the first 12 weeks of pregnancy. It is important that these products with low doses of folate are not used to treat megaloblastic anaemia. Although this low-dose folate should be started before conception to prevent a first occurrence of neural tube defect, higher doses (5 mg daily) are required in women with a history of neural tube defects and again continued until week 12 (DH, 1992).

Vitamin B_{12} deficiency anaemia

The majority of patients with vitamin B_{12} deficiency require lifelong replacement therapy. Occasionally, specific therapy related to the underlying disorder may be all that is necessary, for example, treatment of fish tapeworm.

Since the anaemia has developed slowly, the cardiovascular system does not tolerate blood transfusions very well and is easily overloaded. Transfusions should not normally be given. In severe cases where emergency transfusion is deemed necessary, packed cells may be given slowly whilst blood (mainly plasma) is removed from the other arm. Diuretics may also need to be given, especially if the patient has congestive heart failure and poorly tolerates fluid overload.

For most patients, a definite diagnosis is made before treatment is started. The standard treatment is hydroxocobalamin 1 mg intramuscularly three times a week for 2 weeks then 1 mg every 3 months. Where there is neurological involvement, a slightly higher dose regimen is recommended, 1 mg on alternate days, until no further improvement then 1 mg every 2 months. There is no evidence that larger doses than those recommended provide any additional benefit in neuropathy. In the UK, hydroxocobalamin is the treatment of choice. It is retained in the body longer than cyanocobalamin, and reactions to it are very rare. US texts recommend cyanocobalamin rather than hydroxocobalamin because of the fear that some patients appear to develop antibodies to the vitamin B_{12} transport protein complex in the serum. The haematological response to both is probably identical. A small amount of passive absorption of vitamin B_{12} does take place from the gastro-intestinal tract. High (1 mg) daily oral and sublingual doses of cyanocobalamin are absorbed in sufficient quantities to manage pernicious anaemia. There have been calls for this oral regimen

Table 49.5	Autoantibodies in pernicious anaemia	
	Intrinsic factor antibodies	Parietal cell antibodies

People who do not have pernicious anaemia	Rarely detected	Detected in up to 10%

to replace regular injections as used in other countries. This is potentially cheaper than injections, but this indication is currently unlicensed. It may be worth considering in patients who are unable to have injections. In the UK, cyanocobalamin tablets are not available on the NHS except to treat or prevent vitamin B_{12} deficiency in a patient who is a vegan or who has proven vitamin B_{12} deficiency of dietary origin.

Hypokalaemia develops in some patients during the initial haematological response because potassium is an intracellular ion used in the production of new cells. Potassium supplements may be needed in the elderly and patients receiving diuretics or digoxin. The serum iron level also falls as it is incorporated into haemoglobin. The more severe the anaemia, the more likely it is to see a fall in the serum potassium or iron level.

Not only is it very gratifying to follow the response to treatment, but it is also important to monitor the response to ensure that the patient returns to normal without any attendant problems. There is often a subjective improvement before an objective one. Typically, the patient feels better within 24–48 h, and yet there may be no discernible haematological response. The first haematological change in the peripheral blood is a rise in the reticulocyte count starting around day 3 or 4 and peaking after 7–8 days. The more severe the anaemia, the higher the peak reticulocyte count. The reticulocyte count should remain raised whilst the haematocrit is less than 35%. Failure to remain raised during this time indicates the need for further evaluation. The arrest or slowing down of erythropoiesis may be due to inadequate stores of other essential factors, for example, iron, or may be due to coexisting disease such as hypothyroidism or infection.

The red cells return to normal and the platelet count rises to normal (or even higher) after 7–10 days. The haemoglobin takes much longer to return to normal. It should rise by approximately 2–3 g/dL each fortnight. Neurological damage may be irreversible. Peripheral neuropathy of recent onset often partially improves, but any spinal cord damage is irreversible even with optimum therapy.

Patient care

Folic acid deficiency anaemia

In patients who have a dietary component to their deficiency, appropriate nutritional advice should go alongside their folic acid therapy. If the cause of the deficiency has been eliminated, patients can expect to receive folic acid for approximately 4–6 months. In patients with a continuing requirement, for example, haemolytic anaemia patients can expect lifelong treatment. Those commencing folic acid therapy can anticipate feeling better after a few days but should be informed that their blood count will take much longer to return to normal.

Vitamin B_{12} deficiency anaemia. Patients feel subjectively better very shortly after their first hydroxocobalamin injection. They can be told that their sore tongue will start to improve within 2 days and return to normal after 2–4 weeks. Patients need to be informed that they need regular injections, usually every 3 months. Surprisingly, some patients say that

they feel they are ready for this injection as they approach their appointment time and feel better after their injection.

Haemolytic anaemias

In the haemolytic anaemias, there is a reduced life span of the erythrocytes. Anaemia occurs when the rate of destruction of the erythrocytes exceeds their rate of production. There are a wide range of haemolytic anaemias with both genetic and acquired disorders (Table 49.6). Only autoimmune haemolytic anaemia, sickle cell anaemia, thalassaemia and glucose-6-phosphate dehydrogenase deficiency will be briefly discussed. Haemolytic anaemias account for approximately 5% of all anaemias.

General clinical manifestations

Patients with acute haemolytic anaemia commonly complain of malaise, fever, abdominal pain, dark urine and jaundice. They have haemoglobulinaemia, hyperbilirubinaemia, reticulocytosis and increased urobilinogen levels in the urine. Patients with chronic haemolytic anaemia also usually have splenomegaly. Their anaemia is usually normochromic and normocytic.

General treatment

Many patients with chronic haemolytic anaemia will have an over active bone marrow to compensate for the chronic haemolysis. This increases demand for folate and therefore folic acid supplements are often required, particularly for patients with a poor diet. Patients who require frequent transfusions are at risk of iron overload and require chelation therapy with desferioxamine, desferiprone or deferasirox (as previously discussed under sideroblastic anaemia).

Autoimmune haemolytic anaemia

Epidemiology

This is a range of conditions consisting of warm autoimmune haemolytic anaemia (WAIHA) and cold autoimmune haemolytic anaemia also known as cold agglutinin disease (CAD).

Table 49.6 Some examples of haemolytic anaemias

Genetic disorders of	Examples
Haemoglobin	Sickle cell anaemias
	Thalassaemias
Energy pathways	Glucose-6-phosphate deficiency
Membrane	Hereditary spherocytosis
	Hereditary ovalcytosis
Acquired disorders	
Immune	Autoimmune
	Rh or ABO incompatibility
Non-immune	Infections (parasitic, bacterial)
	Drugs and chemicals
	Hypersplenism

Both forms can be subdivided into idiopathic and acquired forms, and the condition is found in all races. The most common form being idiopathic WAIHA occurring in approximately 40% of all cases with an incidence of between 1 in 4000 and 1 in 80,000. Idiopathic CAD tends to present in middle age.

Aetiology

WAIHA is frequently associated with other diseases with an immunological component, for example, chronic lymphocytic leukaemia, systemic lupus erythematosus and hepatitis B. Acquired CAD is sometimes associated with viral or bacterial infections: cold agglutinins develop in more than 60% of patients following infectious mononucleosis but haemolytic anaemia is rare. A number of drugs have been implicated as leading to immune haemolysis (Box 49.8).

Pathophysiology

The anaemia results from the presence of autoantibodies which agglutinate or lyse the patient's own erythrocytes. In WAIHA, the haemolysis is usually extravascular and mediated by IgG. These antibodies react best at body temperature. CAD is usually mediated by IgM and is capable of fixing complement. The IgM antibody attaches to the erythrocytes and causes them to agglutinate at temperatures below 37 °C resulting in impaired blood flow to fingers, toes, nose and ears when exposed to cold.

Clinical manifestations

The symptoms in WAIHA depend on the severity of the haemolysis. In CAD, there is a range in severity of the clinical manifestations from an inconsequential laboratory finding of a benign variety to serious manifestations, such as acute haemolytic crises and Raynaud-type phenomena. A common complaint is painful fingers and toes with purplish discolouration associated with cold exposure. In chronic CAD, the patient is more symptomatic during the colder months.

Investigations

A positive direct Coomb's test indicates the presence of antibodies to red blood cells**.** Further laboratory serological testing helps determine the exact nature of the reaction.

Box 49.8 Drugs associated with autoimmune haemolytic anaemia

Ciclosporin
Fludarabin
Interferon A
Levodopa
Mefenamic acid
Methyldopa
Penicillin
Quinine
Quinidine

Drug-induced haemolytic anaemia may be difficult to distinguish from other forms of autoimmune haemolytic anaemia, and a clear medication history will help. The antibodies produced may react with the red cells only in the presence of the drug (or one of its metabolites) or may also react without the drug being present.

Treatment

Treatment is dependent on the specific cause (Pruss et al., 2003). In WAIHA, the standard treatment is high-dose corticosteroids. Patients who do not respond can be managed with azathioprine or cyclophosphamide. Blood transfusions are necessary in severe cases, although providing blood free from underlying alloantibodies is difficult. Rituximab, the anti CD-20 monoclonal antibody, has been shown to be beneficial in some patients who fail to respond to the forementioned conventional anti-inflammatory therapy. However, this is an unlicensed indication. (D'Arena et al., 2007) Patients with CAD need to be kept warm with supportive measures as well as treated for any underlying disorder.

Patient care

Patients requiring rituximab will require careful explanation of its unlicensed use and the necessary pretreatment with paracetamol and chlorphenamine.

Sickle cell anaemia

Epidemiology

Sickle cell disease is a hereditary condition. Several different variants of sickle cell disease exist. It is found in a number of ethnic groups, mainly in populations that originate from tropical regions. In the UK, approximately 5000 people, largely from the Afro-Caribbean population, have sickle cell disease.

Aetiology

Patients with sickle cell disease have a different form of haemoglobin. Patients with the most common variant of sickle cell disease have haemoglobin S (Hb S). Normal haemoglobin is usually designated Hb A. Haemoglobin S has valine substituted for glutamic acid as the sixth amino acid in the β-polypeptide compared with normal haemoglobin. Patients with homozygous haemoglobin S develop many problems including anaemia.

Sickle cell trait is where a person is a carrier of the gene (heterozygous for the sickle cell gene). These people are usually asymptomatic. Sickle cell trait provides some protection from malaria and is more common in those ethnic groups originating from geographical areas that are endemic for malaria. The offspring from a father with the trait and a mother with the trait has a one in four chance of having sickle cell disease (Fig. 49.3).

AA   Normal

AS   Sickle cell trait (heterozygous)

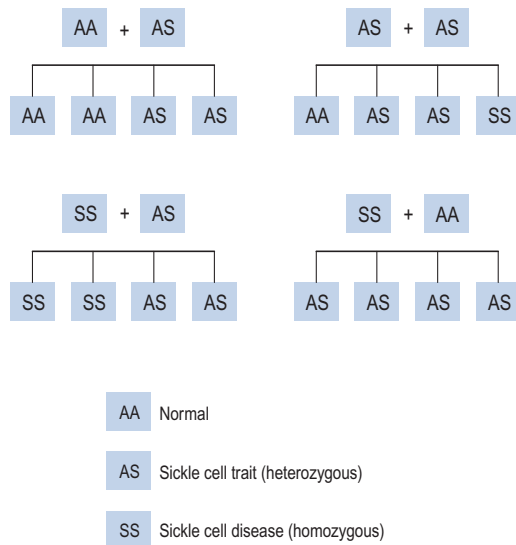
SS   Sickle cell disease (homozygous)


Fig. 49.3   Inheritance patterns in sickle cell trait and sickle cell disease.

Pathophysiology

The membrane of red cells containing haemoglobin S is damaged, which leads to intracellular dehydration. In addition, when the patient's blood is deoxygenated, polymerisation of haemoglobin S occurs, forming a semisolid gel. These two processes lead to the formation of crescent-shaped cells known as sickle cells. Sickle cells are less flexible than normal cells (flexibility allows normal cells to pass through the microcirculation). The inflexibility leads to impaired blood flow through the microcirculation, resulting in local tissue hypoxia. Anaemia results from an increased destruction (haemolysis) of red cells in the spleen. Some red cells in patients with sickle cell disease contain fetal haemoglobin (Hb F). These cells do not become sickle cells.

Clinical manifestations

Patients with severe variants of the disease have chronic anaemia, arthralgia, anorexia, fatigue and splenomegaly. They have crises more frequently than patients with other variants of the disease. A crisis can be precipitated by infection and fever, dehydration, hypoxia or acidosis. A combination of these factors is sometimes present. The clinical manifestation of a crisis can vary with the most common being an infarct crisis. Infarction of the long bones and larger joints or an infarction of a large organ, for example, the liver, lungs or brain, may all occur. Severe pain is a common feature, depending on the site of the infarction. Destructive bone and joint problems are frequently seen.

Investigations

The common form usually presents in the first year of life. From then on, the patients have a chronic haemolytic anaemia interspersed with crises. Abnormal haemoglobin can be detected using electrophoresis. The proportion of haemoglobin S is a useful monitoring parameter. Regular serum ferritin determinations identify the need for desferrioxamine therapy and are used to monitor progress.

Treatment

Patients with sickle cell disease have a high incidence of pneumococcal infections. A number of studies have shown the benefit of prophylactic antibiotics. Penicillin V 250 mg twice a day is usual for adults with erythromycin prescribed for patients allergic to penicillin. Administration of pneumococcal vaccine and *Haemophilus influenzae* vaccine is now common. Folic acid is commonly used because of the high turn over of red cells.

Attempts have been made to increase the proportion of haemoglobin F and reduce the proportion of haemoglobin S in the circulation. Several drugs (Box 49.9) have been shown (some only in animal models) to stimulate fetal haemoglobin production (Charache et al., 1995).

Hydroxycarbamide is effective and may reduce the frequency of crises but is limited by its cytotoxicity. Erythropoietin has been shown to increase haemoglobin F in some animal models, but this has yet to be fully demonstrated in humans. Transfusions and exchange transfusions have also been used to decrease the proportion of haemoglobin S. This is limited by the usual complications of chronic infusions: iron overload, the risk of blood-borne virus transmission and sensitisation.

Sickle cell crises require prompt and effective treatment. Removal of the trigger factor, hydration and effective pain relief are the mainstays of treatment. Appropriate antibiotic therapy should be started at the first signs of infection. Strong opioids are required for pain relief. Traditionally, many patients have been given frequent intramuscular injections of pethidine. Pethidine is not ideal since it is short acting, not very potent and repeated injections lead to the accumulation of metabolites that have been associated with seizures. Morphine is a more logical choice of opioid and has been successfully used in patient-controlled analgesia systems.

Patient care

Patients need to be encouraged to take their prophylactic penicillin and folic acid therapy regularly between crises. During a crisis, some health professionals worry about the patient developing opioid addiction. While this may happen, it is also important to recognise that crises are extremely painful and the patient requires effective analgesia.

Box 49.9   Drugs that may increase fetal haemoglobin production

5-Azacytidine
Cytarabine
Vinblastine
Hydroxycarbamide
Erythropoietin
Short chain fatty acids (butyrates, valproate)

Thalassaemias

Epidemiology

The thalassaemias are a group of inherited autosomal recessive diseases. The β thalassaemias occur mainly in populations from around the Mediterranean, North and West Africa, Middle East and Indian subcontinent. More than 100 β thalassaemia mutations have been identified, and they tend to produce severe anaemia. The α thalassaemias are more common, of which the milder variants do not cause severe anaemia, whilst the severe homozygotes lead to death *in utero* or infancy.

Aetiology

In α thalassaemia, there is either no α chain production (α^0 thalassaemia) or reduced production of a chain (α^+ thalassaemia). Similarly for β thalassaemia. Heterozygotes are usually symptomless, whilst homozygotes are more severely affected, as are compound heterozygotes in which there is a thalassaemia gene and a gene from another haemoglobin variant, for example, haemoglobin S.

Pathophysiology

In β thalassaemias, there is a reduced or absent production of the globin β chain. This leads to a relative excess of α chain which when unpaired become unstable and precipitates in the red cell precursors. There is ineffective erythropoiesis and those mature cells that reach the circulation have a shortened life span.

In α thalassaemias, the pathology is slightly different. The deficiency of α chains leads to an excess of γ or β chains. This time erythropoiesis is less affected, but the haemoglobin produced (haemoglobin Bart's or Haemoglobin H) is unstable when the cells are in the circulation and precipitates as the cells grow older. This leads to a shortened life span with the spleen trapping many of the cells. Haemoglobin Bart's or haemoglobin H is also physiologically useless.

Clinical manifestations

The anaemia causes erythropoietin production to increase and results in expansion of the bone marrow. In severe disease, this causes bone deformity and growth retardation. The spleen is actively involved in removing the abnormal mature cells from the circulation and becomes enlarged.

Investigations

For β thalassaemia, the diagnosis is relatively straightforward: haemolytic anaemia from infancy and racial background. Haemoglobin electrophoresis is used to determine the amounts of abnormal haemoglobin.

Treatment

There is currently no effective treatment. Patients with thalassaemia minor (those who carry the thalassaemia gene, but still make enough normal haemoglobin) usually do not require treatment. Many patients with severe forms are dependent on blood transfusions from an early age. This inevitably leads to iron overload. Desferrioxamine, deferiprone and deferasirox are routinely needed for such patients (see sideroblastic anaemia for additional information). Splenectomy helps some patients, and allogeneic stem cell transplant is used in severe cases. Prevention is actively explored with genetic counselling programmes in Italy and Greece, and antenatal screening in a number of countries.

As in sickle cell disease, much attention is being placed on the idea of switching the bone marrow to the production of fetal haemoglobin rather than the defective adult haemoglobin of β thalassaemia. It is likely that a combination of drugs (hydroxycarbamide and erythropoietin) will provide some clinical improvement.

Patient care

Drug therapy does not currently play a large part in treatment. If hydroxycarbamide becomes standard treatment, pharmacists will become involved in educating the patient particularly with regard to its cytotoxic nature.

Glucose-6-phosphate dehydrogenase deficiency

Epidemiology

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is a recessive hereditary disease and affects approximately 400 million people worldwide. There are more than 300 different forms of G6PD deficiency, only some of which cause anaemia. The most common form of G6PD deficiency is found in 15% of black Americans. It causes anaemia when the individual is exposed to a trigger factor. A more severe form is the Mediterranean variant of G6PD deficiency. Some of these individuals may have chronic haemolytic anaemia even in the apparent absence of exposure to a precipitating factor.

Aetiology

There are a large number of variants of G6PD activity found in different populations and ethnic groups. G6PD is an erythrocyte enzyme that is indirectly involved in the production of reduced glutathione. Glutathione is produced in response to, and protects red cells from, oxidising reagents.

Pathophysiology

G6PD is essential for the production of (NADPH) in erythrocytes. If there is a deficiency in G6PD, this decreases the production of NADPH which is needed to keep glutathione in a reduced form. Reduced glutathione helps erythrocytes deal with oxidative stress. Hence, in G6PD deficiency, if the erythrocytes are exposed to an oxidising agent, the cell membrane becomes damaged, the haemoglobin becomes oxidised and forms what are known as Heinz bodies. Some of the red cells haemolyse and others have their Heinz bodies removed by the spleen to form 'bite cells'.

Clinical manifestation

Clinically, the two most important types of G6PD deficiency occur in the black population and in people originating from the Mediterranean. The black population has a milder form that results in an acute self-limiting haemolytic anaemia following exposure to an oxidising agent, for example, infection, acute illness, broad beans (fava) beans or drugs (Box 49.10). The haemolytic anaemia is self-limiting because the young cells produced by the bone marrow have higher levels of G6PD activity than old cells. Following exposure to the oxidising agent, the old cells are haemolysed but the new cells produced in response are more capable of tolerating the insult until they grow old. In the Mediterranean form of the disorder, the enzyme activity is very low, haemolysis is not usually self-limiting and, indeed, some patients have a chronic haemolytic anaemia despite the absence of an obvious causative factor.

Investigations

The history and the clinical findings steer the diagnosis, which is then confirmed by measuring G6PD activity. Care must be taken during the acute phase since there are increased numbers of young cells with higher levels of activity that may be misleading. The increased numbers of young cells result from the selective destruction of older cells and the increased production of reticulocytes.

Treatment

Prevention of haemolysis by avoiding trigger factors (drugs or food) is important. Vaccination against hepatitis A and hepatitis B may reduce attacks. In cases of acute haemolytic anaemia, the causative oxidising agent should be stopped and general supportive measures adopted. In chronic haemolytic anaemia, most patients become reasonably well adjusted to their anaemia. They need to avoid known precipitating factors to prevent acute episodes occurring on top of their chronic haemolytic anaemia.

Box 49.10   Common drugs implicated in causing haemolysis in G6PD deficiency

Drugs to be avoided in all variants
Ciprofloxacin (and probably other quinolones)
Dapsone
Methylene blue
Primaquine (reduced dose may be used in milder variants)
Nalidixic acid
Sulphonamides (including co-trimoxazole)

Drugs to be avoided in more severe variants
Aspirin (low dose used under supervision)
Chloramphenicol
Chloroquine (may be acceptable in acute malaria)
Menadione
Probenecid
Quinidine
Quinine (acceptable in acute malaria)

There is no specific drug treatment. During acute episodes, the patient should be kept well hydrated to ensure good urine output to prevent haemoglobin damaging the kidney. Blood transfusions may be necessary. Vitamin E (an antioxidant) appears to have little clinical benefit in preventing haemolysis.

Patient care

Since drug therapy does not play a large part in the management of these patients, pharmacists do not often become involved in patient education. Patients can be given a list of drugs to avoid, but since most of these drugs are prescription only medicines, it is important that patients remind health care professionals of their condition.

Case studies

Case 49.1

Mr HA, a 60-year-old single unemployed man, was admitted to hospital for investigation of anaemia. He presented with a 6-month history of lethargy, chest pain, dizziness and falls and a past history of having a gastrectomy 26 years ago. The drug history on admission showed that Mr HA was taking diazepam and GTN spray.

Review of systems revealed no vomiting and no melaena. He complained of some indigestion after meals and reported his appetite was fine if someone else cooked. On examination he was pale, with a blood pressure of 140/80, pulse 90 and haematoglobin level of 2.5 g/dL (normal range: 13.5–18.0 g/dL). A gastroscopy was normal and a biopsy showed no evidence of coeliac disease. A barium enema was normal and faecal occult bloods (FOBs) negative.

Over the first 2 days, he was transfused with 8 units of blood and given furosemide 40 mg with alternate bags. On day 7 he was started on ferrous sulphate 300 mg three times a day, folic acid 5 mg twice daily and ascorbic acid 200 mg three times a day.

....

Questions

1. What additional questions should Mr HA have been asked at admission?
2. Comment on the use of vitamin C in Mr HA.
3. How long should Mr HA remain on ferrous sulphate?

....

Answers

1. Although Mr HA's prescribed drugs were documented, it is possible that he was taking purchased medication. On admission, he complained of indigestion over the last 3 months, and on questioning revealed that he was self-medicating with aluminium hydroxide mixture. From a theoretical point of view, antacids may reduce the amount of iron absorbed by increasing the pH of the stomach and by reducing the solubility of ferrous salts. It is unlikely that this contributed significantly to the development of his anaemia, but if he intends to continue using an antacid after discharge, which he should be discouraged from doing, it would be better not to take a dose of the antacid within 1–2 h of his ferrous sulphate. It would also be worth checking to see if he has been self-medicating with a purchased

aspirin or ibuprofen-based product, both drugs have been implicated in causing gastro-intestinal blood loss, though in this case his gastroscopy was normal and FOBs negative.

2. Ascorbic acid increases the absorption of iron in some patients, it probably keeps iron in solution either in the ferrous form or by being a soluble chelat with the ferric form. In most patients, this has little clinical benefit. It may be an advantage in Mr HA since he may also benefit from a short course of multivitamins.

3. Mr HA needs to continue iron therapy until he has at least replenished his iron stores. This may take up to 6 months after which time he should be reassessed, taking into account whether he is now having a suitable diet. In practice, since his iron was dangerously low on admission, it may be quite reasonable to leave him on iron for the rest of his life.

Case 49.2

Mr WK, a 46-year-old mechanic, is referred to hospital by his primary care doctor. He gave a history of diarrhoea and vomiting a week ago and now was complaining of headaches and feeling 'lousy'. His doctor had given him metoclopramide and ferrous sulphate. Mr WK did not appear jaundiced although he said he had noticed his urine was unusually dark a few weeks ago. On examination, he was obese with a blood pressure of 120/80 mmHg and had a pulse of 80. Rectal examination revealed black stools. He had a normal gastroscopy with three negative FOBs. His serum biochemistry showed a normal level of alanine transaminase and a slightly raised total bilirubin level. Mr WK's reticulocyte count was 13.5% (normal range: 0.5–1.5%). He was diagnosed with having G6PD deficiency, probably triggered by an infection.

Questions

1. How do you explain Mr WK's dark urine and dark stools?
2. Would Mr WK benefit from any medication following admission?
3. Why is it necessary to repeat his red cell G6PD levels after 2 months?

Answers

1. Mr WK's dark urine was a consequence of his haemolytic anaemia. Bilirubin is a breakdown product of haemoglobin that is transported to the liver and conjugated before being excreted in the bile. Bacteria in the intestine converts this to urobilinogen, most of which is excreted in the stools. Small amounts of urobilinogen are reabsorbed and some of this appears in the urine. Urobilinogen is oxidised to urobilin, which is coloured. During episodes of haemolysis, erythrocytes are destroyed faster than normal, and hence there is an increase in the formation of bilirubin and increased excretion of urobilinogen in the urine. Also during haemolysis, free haemoglobin may be released into the blood. If the haemolysis is severe enough, the normal mechanism for removing haemoglobin from the circulation is overcome and haemoglobin may appear in the urine. Dark stools may indicate melaenia and upper gastro-intestinal bleeding. In Mr WK's case, his gastroscopy was normal and he had three negative FOBs. His dark stools were due to the ferrous sulphate prescribed by the primary care doctor prior to admission.

2. His raised reticulocyte count indicates he is rapidly replacing his lost red cells. Erythropoiesis consumes folate and iron and since his folate is towards the lower end of the reference range, it may be worth giving him a short course of folate supplements.

3. Young red cells tend to have higher levels of enzyme activity than more mature cells. Determining G6PD levels during the acute phase may be misleading since there is a relatively high proportion of young cells. Mr WK's result 2 months later would more accurately represent his normal state.

Case 49.3

Ms PR, a 58-year-old lady, was admitted to the emergency department. She had fallen over and bruised herself but had not broken any bones. On examination, it was noted that she appeared pale with possibly a lemon-yellow tinge to her skin, she was slightly confused and had paraesthesiae of the feet and fingers. She has a past history of heart failure and was taking furosemide and enalapril. She was admitted for investigation and discovered to have a macrocytic anaemia. Pernicious anaemia was suspected. Folate level, vitamin B_{12} levels and Schilling test were carried out before commencing treatment.

Questions

1. What are the features that may lead you to consider a diagnosis of pernicious anaemia?
2. Can Miss PR have a blood transfusion after samples have been taken for folate and vitamin B_{12}?
3. The red cell folate is reported as 150 mg/L (reference range: 160–640 mg/L). Would Ms PR benefit from folate therapy?

Answers

1. Macrocytic anaemia and paraesthesia are typical features, though not diagnostic of pernicious anaemia. Patients may be mildly jaundiced which is often described as lemon-yellow in colour. Interestingly, pernicious anaemia is more common in women than men and is associated with blue eyes and early greying of the hair. Miss PR may have other features of pernicious anaemia which include glossitis, angular stomatitis and altered bowel habit.

2. Patients with pernicious anaemia develop their anaemia over a long period of time and tend not to tolerate increases in blood volume very well. A transfusion may result in fluid overload and precipitate heart failure. Miss PR already has heart failure, so unless she becomes severely compromised by anaemia, a transfusion should not be given. In patients who have such pronounced anaemia that an urgent transfusion is required, an exchange transfusion of a small volume of packed cells may be appropriate.

3. In vitamin B_{12} deficiency folate tends to leak from cells and the red cell folate is often low (serum folate is sometimes raised). Many patients initially require both folate and vitamin B_{12} although folate can usually be stopped after a short course. Folate therapy must never be given to patients who have not been fully investigated for vitamin B_{12} deficiency. If vitamin B_{12}-deficient patients are given large doses of folate without hydroxocobalami, the full blood count may appear to improve but the peripheral neuropathy from the vitamin B_{12} deficiency progresses.

Case 49.4

Mrs GN, a 76-year-old retired factory worker, was seen by her primary care doctor, complaining of tiredness. She had been seen 2 months earlier and started on ferrous sulphate for microcytic anaemia. Initially, she had felt better but the tiredness soon returned. A bone marrow aspiration revealed increased erythropoiesis, iron stores and red cell precursors.

A diagnosis of sideroblastic anaemia was made and it was decided to give her monthly transfusions. She was started on pyridoxine 50 mg three times a day in addition to ferrous sulphate.

Questions

1. What are the potential problems with Mrs GN's treatment?
2. After 3 months there appeared to be little benefit to show from pyridoxine. How might management be improved?

Answers

1. Mrs GN's bone marrow aspiration and serum ferritin level showed that she has high levels of stored iron. Repeated monthly transfusions will also have contributed to further iron accumulation. In sideroblastic anaemia, the bone marrow appears to be inefficient at incorporating the iron into haem. The administration of iron leads to iron overload which may result in damage to the heart, liver and endocrine organs. The ferrous sulphate must be stopped. If iron accumulation remains a problem, desferrioxamine therapy must be tried.
2. Pyridoxine does not always improve the blood picture in patients with sideroblastic anaemia. In sideroblastic anaemia, the dose of pyridoxine required is usually 400 mg daily. So, in the case of Mrs GN, an increase in dose should be tried. In addition, patients with sideroblastic anaemia often do not realise that pyridoxine is not just a simple vitamin but a specific treatment for anaemia. Therefore, counselling the patient may improve adherence.

Case 49.5

Mrs RO, a 70-year-old retired teacher, presented with a history of increased tiredness over the last 6 weeks. She has a past history of a partial gastrectomy 4 years ago. On questioning, her relevant symptoms included 'pins and needles' in her toes and loose bowels. She said that she had never been a good eater but ate red meat twice a week.

Questions

1. Why was it 4 years after her gastrectomy before Mrs RO developed vitamin B_{12} deficiency?
2. How long will it take for Mrs RO to respond to treatment?
3. What therapy will Mrs RO require?

Answers

1. Vitamin B_{12} requires intrinsic factor produced by the stomach for absorption. Patients with a total gastrectomy and some with a partial gastrectomy malabsorb vitamin B_{12}. Most patients have good body stores and even if no new vitamin B_{12} enters the body (e.g. following a total gastrectomy) it will take at least 2 years to deplete the stores.
2. Many patients will feel better within days of starting treatment with hydroxocobalamin and before a change in their haemoglobin concentration can be detected. Mrs RO's blood picture may take a number of weeks to return to normal. However, her 'pins and needles' may be a sign of peripheral neuropathy which can be irreversible and may not respond to the hydroxocobalamin treatment.
3. Mrs RO will require lifelong replacement therapy. The standard treatment for vitamin B_{12} deficiency is hydroxocobalamin 1 mg intramuscularly three times a week for 2 weeks, then 1 mg every 3 months. If neurological involvement is identified, as in the case of Mrs RO, then a slightly higher dose regimen is recommended of 1 mg on alternate days until no further improvement, followed by 1 mg every 2 months thereafter.

50 Leukaemia

G. Jackson and G. Jones

Key points

- Leukaemias are uncommon malignancies.
- Acute lymphoblastic leukaemia (ALL) is the most common malignancy in childhood.
- With the exception of ALL, leukaemias are more common in the elderly.
- Age is one of the most important prognostic factors in the treatment of leukaemia. With the exception of neonates, older patients are less likely to be cured than younger patients.
- The treatment of leukaemia is continually improving with the introduction of more focused therapy and improvements in supportive care.
- The use of bone marrow transplantation in the treatment of all forms of leukaemia is increasing. Some of the results are exciting, but the short- and long-term problems of this type of intensive treatment need to be considered.

Leukaemias and lymphomas are the commonest forms of haematological malignancy. Although rare, they are of particular interest in that dramatic improvements in the prognosis of patients with these cancers have been achieved through the use of chemotherapy, and cure is now a possibility for many patients.

Many forms of leukaemia exist, but they are all characterised by the production of excessive numbers of abnormal white blood cells. The leukaemias can be broadly divided into four groups:

- acute myeloblastic leukaemia (AML)
- acute lymphoblastic leukaemia (ALL)
- chronic myelocytic leukaemia (CML)
- chronic lymphocytic leukaemia (CLL)

The adjectives 'myeloid' and 'lymphoid' refer to the predominant cell involved, and the suffix-cytic and -blastic to mature and immature cells, respectively. These characteristics can be determined by a combination of cellular appearances, surface antigen expression and cytogenetic features. The international standard for leukaemia classification is the WHO system (Swerdlow et al., 2008).

Epidemiology

Haematological malignancies account for only 5% of all cancers; of these, CLL is the most common form of leukaemia. UK incidence data are presented in Table 50.1. CLL mainly

Table 50.1 Incidence of leukaemia in the UK (Leukaemia and Lymphoma Research, 2010)

	New cases/year	Incidence per 100,000 of the population
CLL	2750	4.58
CML	750	1.5
ALL	650	1.00
AML	1950	3.25

affects an older age group: 90% of patients are over the age of 50 and nearly two-thirds are over 60 years old at diagnosis. It rarely occurs in young people and is twice as common in men as in women. CML is primarily a disease of middle age with the median onset in the 40–50 year old age group, but it can occur in younger people.

Acute leukaemia is rare, with a total annual incidence of approximately 4 per 100,000 population. The more common form of the disease is AML, which accounts for 75% of cases. The incidence of AML rises steadily with age, occurring only rarely in young children. In contrast, ALL is predominantly a childhood disease, with the peak incidence in the 3–5 year age group, and is the most common childhood cancer.

Aetiology

In common with other cancers, the aetiology of leukaemia is not fully understood. Leukaemia is thought to result from a combination of factors that induce genetic mutations which allow mutated cells to proliferate faster than normal cells and/or to fail to die in response to normal apoptotic signals. Epidemiological studies have, however, identified a number of specific risk factors for the development of leukaemia, which are described as follows.

Radiation

The association between the ionising radiation and the development of leukaemia is evident from nuclear disasters such as Hiroshima and more recently Chernobyl. Long-term

follow-up of survivors of Nagasaki and Hiroshima has shown an increase in all forms of leukaemia other than CLL. The link is also apparent for patients who received radiotherapy for the treatment of malignant and non-malignant conditions such as Hodgkin's disease or ankylosing spondylitis. The effect of chronic low-level exposure to radiation is less certain.

Exposure to chemicals and cytotoxic drugs

There is a small but definite risk of acute leukaemia occurring in patients successfully treated for other malignancies with cytotoxic and immunosuppressive agents. The combination of chemotherapy, especially alkylating agents such as cyclophosphamide and radiotherapy, presents the highest risk. This has practical implications as an increasing number of patients achieve a 'cure' as a result of combination therapy, while occupational exposure of health professionals to these agents is also an area of concern. Occupational exposures to paint, insecticides and solvents, in particular, the aromatic solvent benzene, have all been associated with the development of leukaemia, but it is difficult to be certain whether such exposures genuinely cause the disease.

Viruses

Human T-cell lymphotrophic virus, an RNA retrovirus endemic in Japan and the West Indies, has been linked to a rare T-cell leukaemia/lymphoma.

Genetic factors

Down's syndrome, constitutional trisomy of chromosome 21, is associated with an increased risk of leukaemia. Disorders that predispose to chromosomal breaks such as Fanconi's anaemia and ataxia telangectasia are also associated with an increased risk of developing acute leukaemia. These alterations may permit the expression of oncogenes, which promote malignant transformation.

Haematological disorders

Many patients with other haematological disorders have a greatly increased risk of developing leukaemia, particularly AML. These disorders include the myelodysplastic syndromes, the non-leukaemic myeloproliferative disorders, aplastic anaemia and paroxysmal nocturnal haemoglobinuria.

Pathophysiology

In leukaemia, the normal process of haemopoiesis is altered (Fig. 50.1). Transformation to malignancy appears to occur in a single cell, usually at the pluripotential stem cell level, but it may occur in a committed stem cell with capacity for more limited differentiation. Accumulation of malignant cells leads to progressive impairment of the normal bone marrow function.

Acute leukaemias

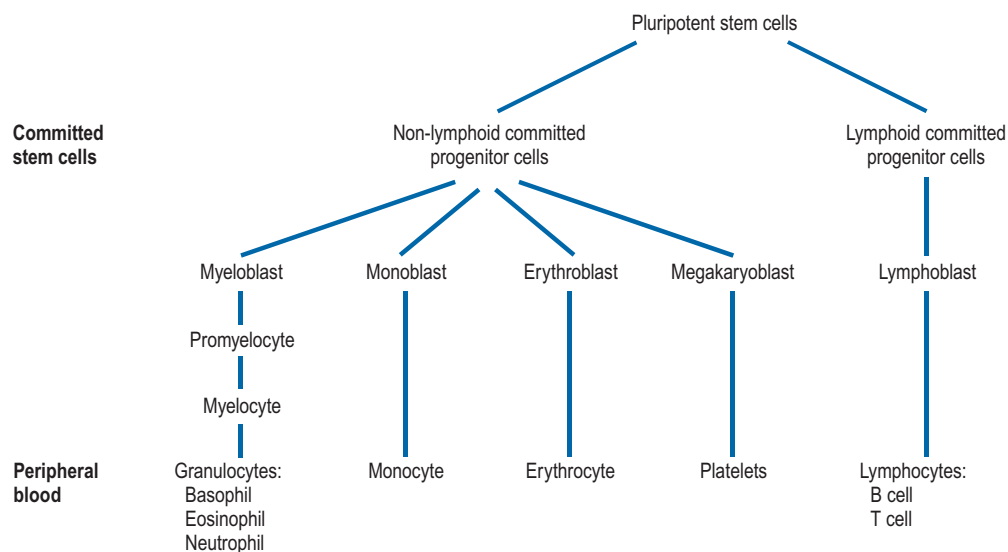
In acute leukaemia, the normal bone marrow is replaced by a malignant clone of immature blast cells derived from the myeloid (in AML) or lymphoid (in ALL) series. More than 20% of the cellular elements of the bone marrow are replaced with blasts. This is usually associated with the appearance of blasts in the peripheral circulation accompanied by worsening pancytopenia as a result of the marrow's reduced ability to produce normal blood cells as the proportion of malignant cells increases. In ALL, the blasts may infiltrate lymph nodes and other tissues such as liver, spleen, testis and the meninges, in particular. In AML, blasts tend to infiltrate skin, gums, liver and spleen.


Fig. 50.1 Haemopoiesis.

Classification of acute myeloblastic leukaemia

AML has traditionally been classified on the basis of morphological features of the disease. Subtypes displaying granulocytic, monocytic, erythroid and megakaryocytic differentiation can be demonstrated. Recently, the World Health Organization (WHO) has updated this system (Table 50.2). AML is now classified using a combination of morphological, genetic and immunological cell marker features (surface antigen expression) in an attempt to define disease groups of greater prognostic significance (Swerdlow et al., 2008).

Classification of acute lymphoblastic leukaemia

As with AML, the WHO classification system takes account of morphological, genetic and immunological features. The disease is, however, mainly classified immunologically, based on the presence or absence of B- or T-cell markers (Table 50.3). Each subtype displays different clinical presentations, response to treatment and, ultimately, prognosis, with pre-B having the best prognosis and B-ALL the worst. It is worth noting that B-ALL (Burkitt's type), which is associated with translocations of the myc gene normally located on chromosome 8, seems to be a morphologically and biologically distinct form of leukaemia.

Table 50.2	WHO classification of AML
Subgroup	Examples
AML with recurrent genetic abnormalities	Inversion chromosome 16 (inv 16) t(15;17) t(8;21)
AML with multilineage dysplasia Therapy-related AML	
AML not otherwise classified	AML without maturation AML with granulocytic maturation AML with granulocytic and monocytic differentiation AML with monocytic differentiation AML with erythroid differentiation AML with megakaryocytic differentiation

Table 50.3	Classification of ALL
Pre-B ALL	Possessing the common ALL antigen CD 10
B cell type	B-ALL of Burkitt's type
T cell type	T-ALL
Null	Non-B, non-T and lacking the common ALL antigen CD 10

Chronic leukaemias

In chronic leukaemia, the normal bone marrow is replaced by a malignant clone of maturing haemopoietic cells.

Chronic lymphocytic leukaemia

CLL is characterised by a clonal expansion of morphologically mature lymphocytes of B-cell origin. These cells accumulate in the peripheral blood and give rise to a lymphocytosis that may be very marked. Lymphocytes accumulate in lymph nodes and spread to the liver and spleen, which become enlarged. The bone marrow is progressively infiltrated. Although the malignant lymphocytes appear morphologically normal, they are functionally deficient.

Chronic myelocytic leukaemia

The characteristic feature of CML is the predominance of maturing myeloid cells in blood, bone marrow, liver, spleen and other organs. CML was the first cancer to be associated with a specific chromosomal abnormality: the Philadelphia chromosome translocation (Ph) seen in over 90% of cases. This is a translocation of genetic material between the long arms of chromosome 22 and chromosome 9. This results in the apposition of the BCR gene (chromosome 22) and the ABL gene (chromosome 9). This novel BCR-ABL gene encodes a fusion protein which has tyrosine kinase activity. This genetic event is believed to be crucial in the pathogenesis, or perhaps even to initiate the development, of CML since overactivity of the tyrosine kinase results in the uncontrolled growth characteristic of leukaemic cells (Cilloni and Saglio, 2009).

Clinical manifestations

Acute leukaemia

Most of the clinical manifestations of acute leukaemia are related to bone marrow failure. The disease commonly presents with a short history, and left untreated, it is rapidly fatal. Symptoms of infection, anaemia and bleeding are common and life-threatening presenting problems. Bleeding may be particularly severe in one subtype of AML, acute promyelocytic leukaemia (APL). This condition is associated with a translocation of genetic material between chromosomes 15 and 17, t(15;17). Disseminated intravascular coagulation (DIC) is commonly the presenting feature of this disease. Some patients with AML develop symptoms and signs due to infiltration of major organs by leukaemic cells.

The involvement of other tissues such as spleen, liver, lymph nodes and meninges is more common in ALL than AML. Involvement of the central nervous system (CNS) may give rise to headaches, vomiting and irritable behaviour. CNS disease is rare at presentation, but develops in up to 75% of children with ALL unless specific prophylactic treatment is given. Less commonly, patients present with features of hypermetabolism, hyperuricaemia or generalised aches and pains.

Chronic leukaemia

Chronic myelocytic leukaemia

Patients with CML commonly present with non-specific symptoms, such as malaise, weight loss and night sweats. The main physical sign is an enlarged spleen that may give rise to abdominal discomfort. Hepatomegaly is also detected in approximately 40% of newly diagnosed patients. Neutropenia and thrombocytopenia are uncommon at presentation. Thus, unlike the acute leukaemias, patients with CML rarely present with symptoms of infection or haemorrhage. In up to 30% of cases, patients are asymptomatic and the disease is detected as a result of a routine blood test performed for other reasons.

CML is a triphasic disease. The initial chronic phase may last from several months to 20 years; the median is around 5 years. During this time, treatment can alleviate symptoms and reduce the white blood count (WBC) and spleen size, allowing patients to lead near normal lives. An accelerated phase eventually occurs where the disease becomes more aggressive with progressively worsening symptoms: unexplained fevers, bone pain, anaemia, thrombocytopenia or thrombocytosis. Finally, after a period of weeks or months, a blast crisis occurs, resembling fulminating acute leukaemia. In a small percentage of patients, this occurs abruptly with no prior accelerated phase.

Chronic lymphocytic leukaemia

An increasing number of patients are diagnosed as having CLL by chance, when a full blood count is performed for an unrelated reason. Symptomatic patients often suffer B symptoms: night sweats, unexplained fever and weight loss. At diagnosis, findings may include generalised lymphadenopathy and some enlargement of the liver and spleen. The course of CLL is variable; in some patients, the disease may remain indolent for many years, while others experience a steady deterioration in their health. Survival typically varies from 2 to 20 years depending on the extent of disease. Patients are immunocompromised with a reduction in serum gammaglobulin and are at increased risk of bacterial and viral infections. There is an increased susceptibility to autoimmune disease, particularly immune haemolytic anaemias and thrombocytopenia. With progressive disease, bone marrow failure becomes apparent, resulting in fatigue, infection and bleeding, and the disease becomes less responsive to treatment. Patients with CLL also have an increased risk of developing a more aggressive malignancy such as high-grade non-Hodgkin's lymphoma (known as Richter's transformation) or prolymphocytic leukaemia (PLL).

Investigations

Examinations of peripheral blood and bone marrow are the key laboratory investigations carried out in cases of suspected leukaemia. However, some additional investigations can help in the diagnosis and classification of this group of diseases. Some of the main findings at diagnosis are presented in Table 50.4.

Table 50.4 Findings at diagnosis in leukaemia

	AML	ALL	CML	CLL
WBC	↑ in 60%, may be N or ↓	↑ in 50%, may be N or ↓↓	↑↑ commonly 100×10^9–250×10^9 L^{-1}	Commonly ↑
Differential WBC	Mainly myeloblasts	Mainly lymphoblasts	Granulocytes ↑↑, especially neutrophils, myelocytes, basophils and eosinophils <10% blasts present	>5×10^9 L^{-1} monoclonal lymphocytes
RBC	Severe anaemia	Severe anaemia	Anaemia common	Anaemia in 50% of patients, generally mild
Platelets	↓↓	↓↓	Usually ↑, may be N or ↓	↓ in 20–30%
Bone marrow aspiration and trephine	Predominantly blasts	Predominantly blasts	Hypercellular blasts < 10%	Lymphocytic infiltration
Cytogenetic analysis	Important abnormalities detected	Important abnormalities detected	Presence of Ph chromosome	
Lymphadenopathy	Rare	Common	Rare	Common
Splenomegaly	50%	60%	Usual and severe	Usual and moderate
Other features	DIC, high urate	High urate, CNS involvement	↑ Serum uric acid	Immune paresis

N, normal; ↓, reduced; ↑, increased; WBC, white blood cells; DIC, disseminated intravascular coagulation; Ph, Philadelphia; RBC, red blood cells.

In acute leukaemia, leukaemic blast cells are usually seen on the peripheral blood film. The blasts of ALL and AML are distinguished using morphology, cytochemical stains, cytogenetics and cell surface antigen analysis. In CML, the principal feature is a leucocytosis with WBC usually ranging from 10×10^9 L^{-1} to 250×10^9 L^{-1} and comprising the complete spectrum of myeloid cells. In CLL, it is lymphocytes, in particular, which are increased, with clonal lymphocyte counts exceeding 5×10^9 L^{-1}. Non-random chromosome abnormalities are increasingly being identified in patients with leukaemia. The information obtained from cytogenetic analysis of bone marrow or peripheral blood cells can be used to confirm the diagnosis and classification of leukaemia and may provide a guide to the likely response to treatment and prognosis.

Treatment

Although significant progress has been made in the treatment of leukaemia, work continues to further improve prognosis. As leukaemias are rare malignancies, the most important studies are undertaken on a national or international basis. In addition to the specific anti-leukaemia treatment, general supportive therapy is vital to manage both the disease and the complications of therapy.

Acute leukaemia

At the outset, intensive combination chemotherapy is given in the hope of achieving a complete remission (CR). This initial phase of treatment is termed induction or remission induction chemotherapy. A CR can only be achieved by virtual ablation of the bone marrow, followed by recovery of normal haemopoiesis. If two cycles of therapy fail to induce CR, an alternative drug regimen can be used. If this is unsuccessful, it is unlikely that CR will be achieved. The subsequent duration of the first remission is closely linked to survival.

Remission is defined as the absence of all clinical and microscopic signs of leukaemia, less than 5% blast forms in the bone marrow and return of normal cellularity and haemopoietic elements. Despite achieving CR, occult residual disease (also termed minimal residual disease or MRD) will persist, and further intensive therapy is given in an attempt to sustain the remission. This post-remission consolidation therapy may comprise chemotherapy or a combination of chemotherapy and bone marrow transplantation.

Acute lymphoblastic leukaemia

Treatment of ALL in childhood has been one of the success stories of the past 3 decades. Over 80% of children will achieve a remission lasting more than 5 years, and current studies are often focused on trying to identify the 20% of children with poor risk disease and treating them more aggressively (Vrooman and Silverman, 2009). Unfortunately, the results in adults are not so impressive. The combination of vincristine, prednisolone, anthracyclines and asparaginase induces CR in about 90% of children with ALL and 80% of adults, although sadly relapse is far more common in adults (Table 50.5). Other active drugs in the treatment of ALL include methotrexate, 6-mercaptopurine, cyclophosphamide and mitoxantrone.

Table 50.5 Treatment of ALL (adapted from MRC protocol UKALL 12-2005)

	Dose	Route	Regimen
Induction (4 weeks)			
Vincristine	1.5 mg/m²	i.v.	Weekly for 4 weeks
Prednisolone	40 mg/m²	oral	Daily for 4 weeks
L-Asparaginase	6000 u/m²	i.m.	3 × weekly for 3 weeks
Daunorubicin	45 mg/m²	i.v.	Daily for 2 days
Intensification (1 week)			
Vincristine	1.5 mg/m²	i.v.	1 dose
Daunorubicin	45 mg/m²	i.v.	Daily for 2 days
Prednisolone	40 mg/m²	oral	Daily for 5 days
Etoposide	100 mg/m²	i.v.	Daily for 5 days
Cytarabine	100 mg/m²	i.v.	2 × daily for 5 days
Thioguanine	80 mg/m²	oral	Daily for 5 days
CNS prophylaxis (3 weeks)			
Cranial irradiation	24 Gy		
Methotrexate	i.t. weekly for 3 weeks also given during induction and intensification		
Maintenance therapy (2 years)			
Methotrexate	20 mg/m²	oral	Weekly
6-Mercaptopurine	75 mg/m²	oral	Daily
Prednisolone	40 mg/m²	oral	5 days/month
Vincristine	1.5 mg/m²	i.v.	Monthly

i.m., intramuscular; i.v., intravenous; i.t., intrathecal; MRC, Medical Research Council; ALL, acute lymphoblastic leukaemia.

Patients with ALL are at a high risk of developing CNS infiltration. Cytotoxic drugs penetrate poorly into the CNS which thus acts as a sanctuary site for leukaemic cells. For this reason, all patients with ALL receive CNS prophylaxis. Cranial irradiation plus intrathecal methotrexate or high-dose systemic methotrexate can be used.

Maintenance treatment is important to sustain a CR. It is usually milder than induction or consolidation chemotherapy, but is carried on for at least 18 months. Treatment usually consists of weekly methotrexate and daily 6-mercaptopurine with intermittent vincristine and prednisolone.

The treatment of relapsed disease varies with the site of relapse. Isolated CNS or testicular relapse may be successfully treated with radiation and reinduction therapy. Cure can still be achieved for some patients. Bone marrow relapse is much more difficult to cure, especially if it occurs early.

A small proportion of paediatric patients and a larger proportion of adult patients have the Philadelphia chromosome translocation within their ALL blasts. Such patients have a relatively poor prognosis and therefore require more intensive therapy. There is some evidence that drug combinations including imatinib may enhance the response of these leukaemias to therapy.

Acute myeloblastic leukaemia (non-acute promyelocytic leukaemia)

As for ALL, the treatment of AML involves induction and consolidation chemotherapy. In AML therapy, however, the chemotherapy regimens used to achieve remission are much more myelotoxic, and patients require intensive supportive care to survive periods of bone marrow aplasia (Fig. 50.2). The pyrimidine analogue cytarabine has formed

Fig. 50.2 One example of a possible treatment regimen for AML. The figure demonstrates that patients are treated with initial induction therapy, then remission is consolidated with at least two courses of chemotherapy. This figure provides a summary only and should not be used as a guide to prescribing or dispensing therapy.

the basis of treatment for AML for 20 years. The addition of daunorubicin and oral thioguanine has achieved a CR rate of 75% in patients under the age of 60 years and about 50% in those over 60 years (Dohner et al., 2010). The precise dose and scheduling of these agents is continually being refined in order to improve the response rates. Despite the numbers of patients who achieve CR following induction therapy, the majority relapse, with only about 25% becoming long-term disease-free survivors (Stone et al., 2004). Thus, in common with ALL, additional post-remission therapy is required. Intensive consolidation chemotherapy with high-dose cytarabine and daunorubicin or amsacrine appears to improve survival rates to approximately 50% after 3 years, with even more encouraging results being obtained in patients under 25 years of age (Dohner et al., 2010; Robak and Wierzbowska, 2009). There is generally no role for maintenance therapy in AML. Similarly, CNS prophylaxis is not routinely indicated though patients thought to be at particularly high risk of CNS disease, such as those with testicular or sinus involvement, should receive prophylactic therapy.

An alternative approach to post-remission therapy is stem cell transplantation. In patients under 40 years of age, allogeneic bone marrow transplantation has resulted in disease-free survival of 45–65% at 5 years post-transplant. These patients are considered cured of their disease. Only about 10% of patients are suitable for allogeneic bone marrow transplants, and there is little evidence to suggest that autologous stem cell transplantation improves the outcome for patients with AML in first CR. It is always worth remembering that AML is most common in the elderly, and intensive intravenous chemotherapy regimens are not always appropriate for this population of patients.

Treatment of AML in relapse is difficult and the prognosis is generally poor. Encouraging results have been seen using a combination of fludarabine, cytosine arabinoside and granulocyte colony-stimulating factor (G-CSF). Novel approaches in AML therapy are often piloted in this group of poor-risk patients. A combination of anti-CD33 antibody, which targets myeloid blasts, with calicheamicin, an anthracycline antibiotic, is a promising and effective approach (Stone et al., 2004), but appears most effective when given in combination with conventional chemotherapy. A newly developed purine analogue, clofarabine, has also been shown to have activity against AML. This drug is a promising agent, particularly in the treatment of older patients, as pilot studies suggest that its toxic effects may be less severe than those associated with other chemotherapy regimens (Robak and Wierzbowska, 2009). 5-Azacytidine is also of interest, especially in older patients and those whose disease has evolved from myelodysplastic syndrome MDS. This agent inhibits DNA methyltransferase resulting in DNA hypomethylation. This process is thought to increase activity of some tumour suppressor genes resulting in anti-tumour effects. The agent has been shown to slow the rate of progression to AML in patients with high-risk myelodysplastic syndrome and is currently the subject of clinical trials in AML.

Acute Promyelocytic Leukaemia

This subtype of AML deserves special consideration as the treatment is quite different from that of other AML variants. APL is associated with the t(15;17) translocation which involves a genetic translocation of material between chromosomes 15 and 17. The disease is clinically characterised by the presence of disseminated intravascular coagulopathy (DIC) at presentation. Since these patients are so prone to life-threatening haemorrhage at diagnosis, the management of a new case of APL is considered a medical emergency. The leukaemic cells are exquisitely sensitive to all-trans retinoic acid (ATRA), which induces blast maturation and can induce remission when used as a single agent (Sanz et al., 2009; Soignet and Maslak, 2004). Using a combination of ATRA and anthracycline chemotherapy, it is now possible to achieve long-term cure in >80% patients. There are some data to suggest that the ongoing use of ATRA in consolidation and maintenance treatment improves outcome further. A number of studies have been published demonstrating the efficacy of arsenic trioxide (ATO) in treating relapsed or refractory APL. Comparison of ATRA and anthracyclines against ATO and ATRA is now the subject of a large UK study of newly diagnosed patients (AML 17). The latter regimen has the potential advantage of avoiding significant myelosuppression.

Chronic leukaemia

Chronic myelocytic leukaemia

Until recently, the treatment of CML has been essentially palliative, producing modest increases in survival, but with the main aim of keeping patients asymptomatic by normalising the WBC. Hydroxycarbamide was the most widely used drug in the management of CML in chronic phase. Treatment with hydroxycarbamide is initiated at a dose of 1.5–2 g/day and usually brings the WBC under control within 1–2 weeks. The dose can then be reduced to a maintenance dose of 0.5–2 g/day. Withdrawing or reducing the dose abruptly can cause a rebound increase in WBC. The side effects of hydroxycarbamide are generally mild but include rashes and gut disturbances.

Interferon can control symptoms of CML but was also the first agent shown to modify the disease process. It promotes the expression of suppressed normal haemopoiesis at the expense of the malignant clone. Studies have shown that interferon-α therapy prolongs the chronic phase and improves the median survival of patients with CML, and its effects seem to be enhanced by the addition of low-dose cytarabine (Sawyers, 1999).

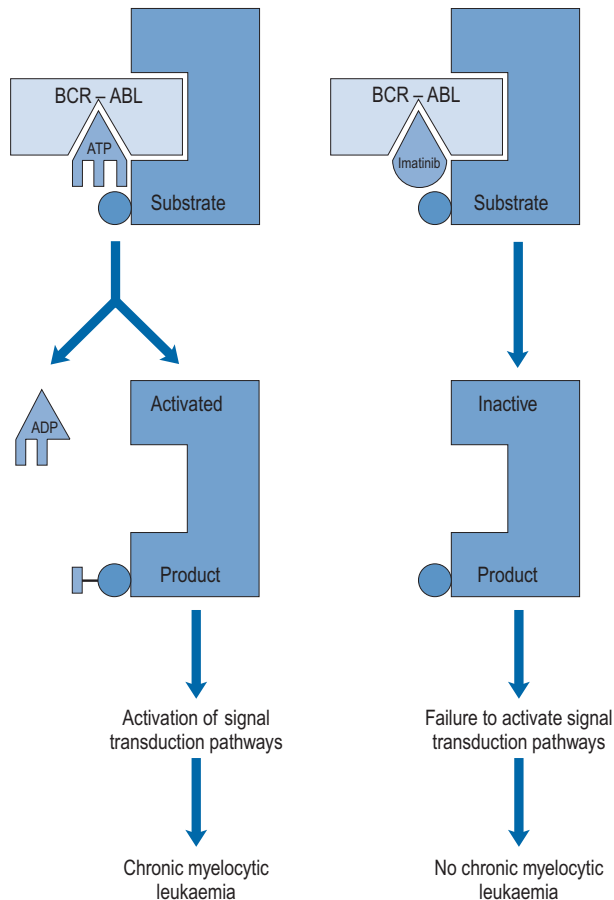
Therapeutic options for patients with CML have changed dramatically in the past 10 years due to the development of imatinib mesylate. This drug was specifically designed to target the abnormal tyrosine kinase product of the BCR-ABL fusion gene (Fig. 50.3). In a large randomised controlled trial, patients were randomised to receive imatinib or a combination of interferon-α and cytarabine. Many patients were intolerant of the interferon and cytarabine combination and crossed over to receive imatinib after trial commencement.


Fig. 50.3 Inhibition of BCR-ABL protein by imatinib. The protein product of the BCR-ABL fusion gene (BCR-ABL protein) acts as a constitutively active tyrosine kinase and uses ATP, bound within a kinase pocket in the molecule, to phosphorylate tyrosine (o) in a variety of substrates. In doing so, ATP (adenosine triphosphate) is reduced to ADP (adenosine diphosphate) which falls out of the kinase pocket to be replaced by further ATP. Imatinib prevents the action of the BCR-ABL protein by blocking ATP entry into the kinase pocket.

Despite this problem, progression-free survival at 1 year was 97% in the imatinib arm and 80% in the interferon and cytarabine arm in an intention-to-treat analysis (O'Brien et al., 2003). The Philadelphia chromosome became undetectable in 68% of imatinib recipients compared to 7% of those in the alternative arm (Hughes et al., 2003). However, more sensitive testing methods, such as real-time polymerase chain reaction (PCR), have now shown that many patients who are Philadelphia chromosome negative still possess very low levels of the abnormal BCR-ABL gene produced by the Philadelphia translocation.

Dasatinib and nilotinib are second-generation tyrosine kinase inhibitors (TKIs) designed to overcome resistance to imatinib caused by mutations in the kinase domain of BCR-ABL. Both agents work well as second-line therapies, producing complete cytogenetic responses in about 50% of patients. The use of dasatinib and nilotinib in newly diagnosed patients is currently being evaluated in ongoing clinical trials. Due to the effectiveness of imatinib therapy and the development of

second-generation agents, allogeneic stem cell transplantation is now rarely used to treat CML, but it does represent a potentially curative option for patients with resistant disease.

Transformation of CML into acute leukaemia can be treated in the same manner as *de novo* acute leukaemia, in an effort to achieve a second chronic phase. Treatment is slightly more successful if transformation is lymphoid rather than myeloid. Imatinib, typically at higher doses than are used in chronic phase disease, can also be used to attempt to return patients to chronic phase disease. In general, remissions are rare and the median survival is less than 6 months.

Chronic lymphocytic leukaemia

Currently, there is no cure for CLL. All treatment is, therefore, considered palliative. There is no evidence that early treatment of asymptomatic patients improves outcome. Indications for treatment are:

- rapidly increasing WBC
- increasing or troublesome lymphadenopathy
- systemic symptoms
- marrow failure
- autoimmune complications.

Formerly, the alkylating agent chlorambucil was the most common agent used in the treatment of CLL. Corticosteroids can reduce the lymphocyte count without contributing to myelosuppression and are used to treat autoimmune phenomena such as haemolytic anaemia and immune thrombocytopenia. The use of purine analogues, particularly fludarabine, marked the beginning of an exciting phase in the treatment of CLL. Although CRs were unusual, good responses were seen even in patients whose leukaemia was resistant to alkylating agents. With regard to initial therapy of CLL, fludarabine-treated patients show a higher response rate than patients treated with chlorambucil. However, no survival advantage for the use of fludarabine has been demonstrated (Rai et al., 2000). More recently, a large randomised study comparing fludarabine and cyclophosphamide with and without the anti-CD20 antibody, rituximab, has been published (Hallek et al., 2009). This study demonstrated an overall response rate of 86% and 73%, respectively. The median progression-free survival with rituximab is the best published in a large randomised controlled trial to date, at 40 months. This combination of fludarabine, cyclophosphamide and rituximab has been adopted, in the UK, as the regimen of choice for first-line treatment of CLL as long as patients are considered fit enough. Chlorambucil remains an excellent choice for patients with significant co-morbidities as the treatment is less immunosuppressive.

Splenic complications may necessitate splenectomy or splenic irradiation. Radiotherapy can also be used to control localised painful lymphadenopathy. Combination chemotherapy, such as CHOP (see Chapter 51) used in lymphoma, may be beneficial in advanced disease. Campath-1H is a humanised monoclonal anti-CD52 antibody. CD52 is present on most lymphocytes including malignant lymphocytes in CLL. Binding of this antibody induces both antibody-mediated

and complement-mediated T-cell cytotoxicity against malignant B cells. In relapsed patients, the duration of response to Campath-1H is relatively short. However, the agent is currently being studied, both in combination with other drugs and as a possible means of purging the bone marrow of residual cells prior to autologous stem cell harvest and transplantation.

Patients with CLL are very susceptible to infection. Herpes viruses, in particular herpes zoster, can cause significant problems. This susceptibility is increased because many treatments, such as campath-1H and fludarabine, have generalised anti-lymphocyte action and are not absolutely specific for malignant lymphocytes.

Stem cell transplantation

The potential role of stem cell transplantation is increasingly being explored in the management of all types of leukaemia.

The basic principle

This technique provides a means of rescuing the patient from the potentially lethal effects on the bone marrow of ablative therapy given in an attempt to eradicate all traces of disease (Fig. 50.4). The conditioning regimen most commonly used is a combination of high-dose cyclophosphamide and total body irradiation. Other conditioning regimens include high-dose melphalan, etoposide, busulphan or cytarabine.

Following administration of conditioning therapy, 2–3 days elapse to allow its elimination from the body, and then previously harvested stem cells are reinfused peripherally. The stem cells will return to and repopulate the marrow, restoring normal haemopoiesis. Peripheral blood counts recover in 2–4 weeks. Throughout this time, patients require intensive supportive care and the procedure, particularly allogeneic stem cell transplantation, causes significant morbidity and has a mortality rate of 5–30%.

The source of stem cells

During allogeneic stem cell transplantation (allograft), stem cells are obtained from a human leucocyte antigen (HLA)-matched donor. These stem cells can be removed directly from the bone marrow, under general anaesthetic, or harvested from the peripheral blood. Under certain circumstances, in the absence of a matched donor, an autologous bone marrow or peripheral blood stem cell transplant (autograft) can be performed. Following conditioning, the patients receive their own cryopreserved marrow or peripheral blood stem cells, previously harvested from them while in CR. There is a potential risk, however, that stem cells obtained in this way may contain undetected, residual disease. Attempts have been made to purge the bone marrow of disease *in vitro*, but these have generally been unsuccessful.

Peripheral blood stem cell transplantation

This technique for rescuing bone marrow following ablative conditioning therapy is used to restore haemopoiesis (Russell, 1998). Patients receive the haematopoetic growth factor G-CSF, either alone or following an infusion of high-dose chemotherapy such as high-dose cyclophosphamide. Patients receive G-CSF for a period of about 7 days. This stimulates the release of stem cells into the peripheral circulation. Stem cells are then harvested from the peripheral circulation by a process of cell pheresis. The harvested cells can then be reinfused, fresh, into the patient following conditioning therapy or frozen and stored for later use.

Peripheral stem cell transplantation offers some advantages over conventional bone marrow transplant techniques; collection of peripheral stem cells negates the need for general anaesthesia and it has been found that the haemopoietic recovery period following transplantation is shortened by 5–10 days. This technique can also be used to harvest stem cells from allogeneic donors. In this case, G-CSF is used alone to stimulate stem cell release into the peripheral circulation. It is sometimes impossible to harvest enough stem

cells from patients to allow an autologous transplant to be performed. The commonest reason for this is that the patient has been heavily pretreated with chemotherapy or radiotherapy. A new CXCR4 chemokine antagonist, plerixafor, is now available. This agent is thought to reduce adhesion of stem cells within the bone marrow milieu. It can be given along with G-CSF and allows a proportion of patients who have failed to mobilise stem cells using G-CSF alone to mobilise cells for an autograft.

Complications

Infection is almost inevitable in patients undergoing bone marrow transplantation. Other significant complications of allografts include interstitial pneumonitis and hepatic veno-occlusive disease, but the major life-threatening complication is acute graft-versus-host disease (GVHD). The likelihood of graft-versus-host disease occurring increases with age, and for this reason, myeloblative allografts are largely restricted to patients under 45 years of age. Graft-versus-host disease is caused by T-lymphocytes in the donated marrow reacting to host tissues. The severity of the reaction ranges from a mild maculopapular rash to multisystem organ failure with a high mortality rate. Acute graft-versus-host disease typically occurs within 100 days of the bone marrow transplantation and typically presents with fever, rash, diarrhoea and liver dysfunction. Prophylactic therapy is routinely given with methotrexate or ciclosporin, alone or in combination, for 6–12 months post-transplant. Should acute graft-versus-host disease develop, high-dose methylprednisolone, ciclosporin, antithymocyte globulin and, more recently, anticytokine monoclonal antibodies, for example, anti-TNF (tumour necrosis factor) antibodies, have been used to treat the condition.

Chronic graft-versus-host disease can occur after 3 months following bone marrow transplantation. It is a multisystem disorder associated with chronic hepatitis, severe skin inflammation and profound immunosuppression. Treatment is successful in approximately 50% of patients and consists of immunosuppression with azathioprine and prednisolone together with prophylactic antibiotics. Ciclosporin and thalidomide have also been used successfully in the treatment of chronic steroid-refractory graft-versus-host disease. The main cause of death amongst patients with chronic graft-versus-host disease is infection.

Reduced intensity allografting

Myeloblative allogeneic transplantation, as described earlier, is a very intensive procedure associated with significant morbidity and mortality, hence its restriction to younger patients. Attempts have been made to reduce the intensity of transplant conditioning regimens whilst using increased immunosuppression to facilitate marrow engraftment. Although such an approach reduces the intensity of therapy delivered to any residual tumour, the possible downside of this reduction is offset by an immunological graft-versus-tumour effect and by reduced early post-transplant mortality. This form of

Table 50.6 Indications for allogeneic stem cell transplantation in leukaemia

AML	First remission with the exception of patients with good risk genetic abnormalities: t(15;17), t(8;21) and inversion of chromosome 16
CML	Chronic phase but only if patient fails to respond to first- and second-line tyrosine kinase inhibitors
ALL	First remission in adults Second remission in children
CLL	Not generally appropriate as part of standard therapy but under investigation within several clinical studies

transplant is often offered to older patients who are considered unfit to receive a standard allograft. However, the long-term outcomes of this approach are under continual review. Several trials now suggest that the overall survival after myeloablative and reduced intensity transplants may be similar though the causes of death in the two groups are different. More patients die of disease relapse after reduced intensity transplants, and more die of transplant-related complications in the myeloablative group (Pollack et al., 2009).

The place of stem cell transplantation

The place of stem cell transplantation in the management of a particular form of leukaemia depends very much on the prognosis of patients treated with conventional chemotherapy (Table 50.6). For example, the results of intensive chemotherapy in children with ALL are good, and bone marrow transplantation is generally only considered for children who have relapsed and in whom a second remission can be achieved. However, conventional treatment of adults is less successful, and allogeneic bone marrow transplantation may be offered to adults in first remission.

Patient care

Supportive care

The treatment of CLL and CML is largely carried out on a hospital outpatient basis, with patients taking oral medication at home or attending outpatient clinics on a weekly or monthly basis for injections of chemotherapy. Patients are routinely monitored to follow the progress of disease and to observe treatment-related side effects. Supportive therapy such as blood transfusions can also be given on an outpatient basis. In contrast, the intensity of induction and consolidation regimens used in the management of patients with acute leukaemia renders them severely pancytopenic. Therapy is usually given as a hospital inpatient with patients often remaining in hospital following treatment for 3–4 weeks until

their bone marrow recovers sufficiently. This is in contrast to therapy for most solid tumours where, following administration of treatment, patients are often well enough to remain at home until their next cycle of chemotherapy is due.

Advanced leukaemia, bone marrow transplantation and aggressive chemotherapy for acute leukaemia all result in pancytopenia. Red cell transfusions are given to patients to maintain their haemoglobin above 9–10 g/dL. Evidence of bleeding includes petechial haemorrhages in skin and mucous membranes, and patients receiving aggressive treatment must be examined daily for any of the above signs. Platelet concentrates are given to thrombocytopenic patients who have signs of bleeding and are given prophylactically should platelets fall below 10×10^9 L^{-1}. The probability of infection developing rises as the WBC, specifically the neutrophil count, falls. With an absolute neutrophil count of below 0.5×10^9 L^{-1}, patients are at high risk of infection, with the risks being even greater if the period of neutropenia is prolonged.

Chapters 51 and 52 examine many of the non-haematological toxicities which result from the use of cytotoxic drugs, and these are clearly pertinent to haematology patients. The major contributors to morbidity and mortality in patients with leukaemia are relapsed disease and infection.

Infection in the immunocompromised patient

A number of intrinsic and extrinsic factors all contribute to the risk of infection in this vulnerable group of patients (Fig. 50.5).

While cross-infection can occur via staff, other patients or contaminated objects, the main sources of infection in this group of patients are endogenous, arising from commensal gut and skin organisms. The normal host defences to infection are broken down; damage to mucous membranes, particularly in the gastro-intestinal tract, occurs with chemotherapy and radiotherapy, allowing infecting organisms to enter the bloodstream. Most infections in neutropenic patients arise from three main sites: the gastro-intestinal and respiratory tracts, and the skin. Table 50.7 lists the main pathogens responsible for infection in this group of patients.
Fig. 50.5 Infection risk in immunocompromised patients.

Table 50.7 Pathogens commonly causing infection in neutropenic patients

Gram-negative bacteria	*Pseudomonas* spp. *Escherichia coli* *Klebsiella* spp. *Enterobacter* spp. *Proteus* spp. *Serratia* spp. *Legionella pneumophilia*
Gram-positive bacteria	*Streptococcus* spp. *Staphylococcus epidermidis* *Staphylococcus aureus*
Anaerobes	*Clostridium difficile* *Clostridium perfringens* *Bacteroides* spp.
Fungi	*Candida* spp. *Aspergillus* spp.
Viruses	Herpes simplex Herpes zoster Cytomegalovirus Hepatitis
Protozoa	*Pneumocystis carinii*

Preventive measures

Oral hygiene. Mouth care is important in all patients receiving chemotherapy but particularly neutropenic patients. Patients are generally asked to use mouthwashes regularly, and prophylactic antifungal therapy may also be given. Although it is important to avoid any sort of trauma to the oral mucosa, teeth should be cleaned regularly using a soft toothbrush. Attention must also be paid to the care of dentures. Patients require careful counselling on mouth care, stressing the importance of oral hygiene.

Prophylactic anti-infectives. In general, prophylactic antibiotics are avoided because of the possible development of resistant organisms, but they may have a place in the management of periods of prolonged myelosuppression following chemotherapy and bone marrow transplantation. Prophylactic antifungal agents are often given and patients undergoing bone marrow transplantation and therapy for ALL require prophylaxis against herpes virus and *Pneumocystis carinii* (Table 50.8).

Gut decontamination. Gut decontamination using a combination of non-absorbable oral antibiotics and antifungal agents reduces the burden of potentially pathogenic organisms in the intestine. One such combination includes neomycin sulphate, colistin sulphate, nystatin and amphotericin. However, opinions are divided over this practice, as gut decontamination can lead to the overgrowth of resistant organisms.

Growth factors. An exciting development in the care of patients with leukaemia has been the production of haemopoietic growth factors using recombinant DNA technology. The first of these, G-CSF, given daily by subcutaneous

Table 50.8 Prophylactic anti-infectives

Gram-negative bacteria	Ciprofloxacin
Candidiasis	Nystatin Fluconazole Itraconazole
Herpes simplex	Aciclovir
Pneumocystis carinii	Co-trimoxazole

injection or intravenous infusion after completion of chemotherapy, stimulates neutrophil production and may reduce the duration of neutropenia by up to 7 days. The cost of these compounds is a major issue and results of studies investigating the effects of G-CSF on morbidity and mortality, following chemotherapy, have been disappointing (Smith et al., 2006). Newer pegylated growth factors have been introduced. These have a longer half-life than standard agents, and thus fewer injections are required. The impact of these agents on morbidity and mortality post-chemotherapy, however, remains controversial.

Aseptic technique. Careful attention should be paid to the care of intravenous cannulae, particularly central venous catheters. The increased incidence of staphylococcal infection in immunocompromised patients can largely be attributed to their use. Invasive procedures, such as venepuncture, must be carried out using strict aseptic technique. Similarly, urinary catheters are a major source of infection and their use should be avoided if at all possible.

Protective isolation. Reverse barrier isolation during periods of neutropenia, nursing in strict sterile environments and high-efficiency particulate air (HEPA) filtration have been used in an attempt to reduce infection rates. This is extremely demanding for staff and patients alike and is generally only appropriate following bone marrow transplantation.

Treatment of infection

Commonly, neutropenic patients show no signs of focal infection; they are unable to form pus. The only clinical manifestations of septicaemia might be general malaise, fever or hypotension. A patient's condition can deteriorate very rapidly, with collapse occurring within hours of the first signs of infection. Treatment should be instigated as soon as infection is suspected. Following a clinically serious febrile episode (temperature: 37.5 °C for more than 1 h or 38 °C or more on a single reading), samples are taken for culture; these may include blood, urine, sputum and stool cultures along with line and throat swabs. Intravenous antibiotics must be started empirically without delay (Sipsas et al., 2005). Standard empirical therapy varies from unit to unit but may involve the combination of an aminoglycoside with an antipseudomonal penicillin such as piperacillin to provide broad-spectrum bactericidal cover. In penicillin-allergic patients, ceftazidime or cefotaxime may be substituted, but local resistance patterns

are of paramount importance. Antibiotics with a broad spectrum of activity, such as ciprofloxacin, have been used as single agents.

Vancomycin or teicoplanin are often prescribed if an infected central venous catheter is suspected, to provide additional cover against Gram-positive organisms. Microbiological advice should be sought in cases of methicillin-resistant *Staphylococcus aureus* (MRSA) infection. Metronidazole may be added to the antibiotic regimen to cover anaerobes if the clinical presentation suggests that the source of the infection may be oral, perineal or gut. Anti-infective therapy should subsequently be modified on the basis of cultures, but in the majority of neutropenic patients, a causative organism is never identified.

If the pyrexia persists for more than 4 days in spite of broad-spectrum antibiotics, or if the patient's condition is deteriorating, systemic fungal infection should be suspected. Empirical antifungal therapy for neutropenic patients with antibiotic-resistant fever reduces mortality and is considered a standard of care. A number of broad-spectrum agents are now available for use in this setting, including standard amphotericin, lipid formulation of amphotericin, caspofungin and voriconazole. Intravenous amphotericin is often the first choice to ensure that *Aspergillus* and *Candida* are covered. The main limitation of amphotericin is its toxicity, in particular, nephrotoxicity. Lipid formulation of amphotericin may be appropriate in patients with pre-existing renal impairment or in cases where conventional amphotericin has induced nephrotoxicity. Voriconazole is a useful agent with a similarly broad spectrum of activity. Hepatotoxicity, visual disturbances and prolonged QT interval are the most common side effects of voriconazole. This agent has the advantage of being available as both intravenous and oral preparations, so the conversion from parenteral to oral therapy is straightforward.

Although the antifungal activity of the echinocandin, caspofungin, is more limited than that of amphoteracin or voriconazole, it has been shown to be effective for empirical therapy as it has good efficacy against *Candida* and *Aspergillus* spp. It has the advantage of reduced toxicity in comparison with other available agents. The most common side effect is hepatotoxicity. Since this agent has a relatively limited spectrum of activity, it is probably best avoided in the setting of presumed fungal sinus or CNS infection, which are often caused by fungi other than *Aspergillu*s or *Candida* spp. Table 50.9 lists some of the common problems encountered in the treatment of the leukaemias.

The following practice points should be used to control infection in immunocompromised patients.

- Measures to prevent infection are important.
- Particular attention should be paid to scrupulous hand washing, mouth care and the use of antifungal, antiviral and antipneumocystis prophylaxis for patients at high risk.
- Preventive measures do not eliminate the risk of infection.
- Treatment of fever in a neutropenic patient is a medical emergency.
- Empirical antifungal therapy should be used to treat neutropenic patients with antibiotic resistant fever, at high risk of fungal infection.

Table 50.9 Common therapeutic problems in the leukaemias

Problem	Cause	Solutions
Mucositis and oral ulceration	Chemotherapeutic agents directly toxic to mucosal epithelium Radiotherapy is directly toxic to the mucosa and also reduces saliva production by salivary glands Vulnerable mucosa is likely to be attacked by infective agents, for example, herpes simplex, *candida*	Regular mouth toilet including the use of antibacterial mouthwash Prophylactic use of antiviral and antifungal agents for patients in whom myelosuppression is likely to be prolonged
Fever in neutropenic patients	Infection predominantly caused by bacteria and/or fungi	Broad-spectrum antibiotics must be commenced as soon as blood cultures have been taken A strategy of planned progressive therapy including use of an antifungal agent in non-responsive fever is appropriate
Graft-versus-host disease (GVHD)	T lymphocytes from the donor react against host tissues	Use a sibling donor if possible Use the donor most closely HLA matched to the patient Consider T-cell depletion of graft (though this may increase the risk of disease relapse) Prophylactic therapy with methotrexate and ciclosporin Treat GVHD with corticosteroids, ciclosporin, anti-thymocyte, globulin, FK 506, anticytokine monoclonal antibodies Irradiate all blood products
Late complications of treatment	Risks of haemopoietic malignancy and non-haemopoietic malignancy are increased post-chemotherapy Late cardiotoxicity secondary to anthracyclines	Aim to tailor therapy to the underlying disease, that is, do not overtreat and do not undertreat Do not exceed maximum cumulative doses of anthracyclines Liposomal anthracyclines may be useful in the future

Case studies

Case 50.1

A 30-year-old woman recently diagnosed with CML attends the haematology clinic to discuss the options for treatment.

Questions

1. Which treatment options are available?
2. Which treatment is likely to be the best choice for this patient?

Answers

1. There are clearly a number of potential treatment options which need to be explored with the patient.
   The various treatment options are:

   - palliative therapy with hydroxycarbamide to control cell counts
   - interferon-α
   - interferon-α and cytosine
   - imatinib
   - allogeneic matched sibling transplant

   - matched unrelated donor (MUD) transplantation if a matched sibling is not available
   - treatment as part of a clinical trial which is likely to involve imatinib in varying doses or in combination with other effective agent.

2. A purely palliative approach is unlikely to be acceptable to a young patient, but hydroxycarbamide can still be used acutely to control high cell counts. There is no doubt that use of interferon-α alone results in cytogenetic remission in a small percentage of patients, and this effect is enhanced by the addition of cytosine. The side effects of interferon-α include flu-like and affective symptoms. The addition of cytosine increases myelosuppression and risk of mucositis. Although these treatments can induce cytogenetic remission, the duration of such responses is unclear and only a minority of patients respond completely. The high risk of side effects and the low chance of complete cytogenetic response to interferon-α, with or without cytosine, are likely to make these therapeutic modalities unattractive to this patient.

   It remains true that allogeneic stem cell transplantation is the only proven curative therapy for patients with CML. The difficulty with this approach is that the mortality rate for transplant recipients remains high. The 1-year mortality rate for a 30-year-old patient transplanted using a sibling donor is approximately 15–20%, and this may rise to 25–30% if a MUD

has to be used. The major causes of death in this group are GVHD and infection. In addition to this high risk of mortality in the short-term, there is also a risk of long-term morbidity post-allograft. Chronic graft-versus-host disease can have a significant impact on quality of life for many patients and requires long-term medical follow-up. Ironically, patients with a degree of chronic graft-versus-host disease are at reduced risk of disease relapse since a graft-versus-host response is also associated with a graft-versus-leukaemia effect; some disparity between the immune systems of the transplant donor and recipient is helpful. In addition to these problems, all transplanted patients are at increased risk of a second malignancy developing later in life as a consequence of the conditioning therapy received as part of the transplant and probably also as a consequence of deficiencies within the transplanted immune system.

Given the problems associated with the various therapeutic strategies discussed earlier, it is not surprising that there was great excitement surrounding the development of a targeted tyrosine kinase inhibitor, imatinib. Results with this agent, particularly for patients with newly diagnosed chronic phase disease, are excellent. Complete cytogenetic responses have been seen, although very sensitive quantitative PCR techniques can still detect the abnormal BCR-ABL gene in the vast majority of CML patients in whom the Philadelphia chromosome itself is undetectable. In addition, the drug has been shown to delay progression to accelerated phase disease or blast crisis. It is still not possible, however, to say that imatinib cures patients with CML.

Although no randomised study has been undertaken, it is clear from historical data that, in the short-term, the mortality associated with allogeneic stem cell transplantation far exceeds that associated with imatinib. In addition to these very encouraging data which pertain to the effect of the drug on the disease, the side effects of imatinib are generally mild and patients report this agent far easier to tolerate than interferon-α. The main side effects are rash, cytopenias, fluid retention and abnormalities of liver function tests.

Given the efficacy of imatinib and the fact that the drug is generally very well tolerated, imatinib is regarded as the initial treatment of choice for the vast majority of patients with CML. Ongoing management involves haematological and molecular monitoring of the patient to determine whether they have a good response to imatinib. In the event of a good response, the patient continues to take the drug. If at a later stage the molecular response to the agent begins to diminish, then transplantation is reconsidered. Amongst patients who fail to respond or respond poorly to imatinib, transplantation options are likely to be considered at an earlier stage.

Case 50.2

A patient with AML is currently in first CR and has a fully HLA-matched brother who is medically fit. You have been asked to counsel the potential transplant donor about stem cell collection.

Questions

1. What methods are available for the collection of stem cells for haemopoietic stem cell transplantation?
2. What are the advantages and disadvantages of each of these stem cell collection methods for the transplant donor?
3. What are the advantages and disadvantages of each of these stem cell collection methods for the transplant recipient?

Answers

1. There are two main methods of collection of haemopoietic stem cells from a sibling donor. These are:

   • direct harvesting of cells from the bone marrow in the pelvis;
   • collection of circulating peripheral blood stem cells using an apheresis technique after stimulation of the stem cell compartment using (G-CSF).

2. Direct harvesting of marrow stem cell from the bone marrow is an operative procedure and is performed under general anaesthetic. Clearly, there are risks associated with the use of general anaesthesia, but the risk of death associated with this approach is less than 1 in 10,000 procedures. Marrow harvesting involves a hospital stay, usually for one night post-operatively, but some units also require donors to be admitted the night before surgery. Donors are likely to experience pain around the pelvis, and there is a risk of mechanical back pain in the short to medium term due to pressure applied to the pelvis during repeated needle insertions. This risk is increased in those with a history of back problems prior to the procedure. Indeed, such potential donors may prefer a peripheral blood stem cell harvesting approach. Donors must be warned about bruising and potential infection at the site of their wounds.

   One of the other potential problems associated with marrow harvesting is that it is impossible to select the type of blood cell harvested and a large component of the volume of fluid collected comprises red blood cells. This can lead to a degree of anaemia in the donor who may take several weeks to normalise their haemoglobin. It is usually possible to avoid blood transfusion in this situation as it is unusual for donors to be significantly symptomatic. Nonetheless, donors must be warned that the need for allogeneic blood transfusion is a possibility with this procedure.

   Peripheral blood stem cell harvesting has several advantages over direct marrow harvesting from the iliac crests. The procedure can be undertaken during hospital outpatient visits and does not require the use of a general anaesthetic. As the stem cell-harvesting procedure allows selective collection of mononuclear cells, significant anaemia is very unlikely after this procedure. Clearly, red cells do circulate within the apheresis circuit, and if the circuit clots off and has to be disconnected from the donor, then red cells will be lost. This is unlikely to be of clinical significance unless the donor is a child and hence has a relatively low blood volume.

   Disadvantages of this approach include the need for stimulation of donor haemopoiesis by the G-CSF.

   Marrow stimulation can result in significant pain especially around the shoulders, back and pelvic girdle. Most donors can manage this pain at home with simple analgesia, but very occasionally hospital admission is required for pain control. Very occasionally patients develop splenic pain, and there have been a couple of reports of splenic rupture in normal donors after G-CSF stimulation, but this is very rare. One difficulty with the use of G-CSF is that it has only been in routine use for the past 15 years. This makes it impossible to categorically reassure potential stem cell donors that use of G-CSF in this way is absolutely safe in the long-term. There is, however, currently no evidence that acting as a peripheral blood stem cell donor increases one's risk of leukaemia development later in life. Some potential donors find this element of uncertainty difficult and prefer to undertake a marrow harvest in which the risks, although present, are better quantified.

   The apheresis procedure itself involves the donor lying relatively still with a needle in one or both arms (depending upon the type of apheresis kit used) for approximately 4–5 h. Some collections can be done in one procedure, but some donors will need to be harvested in two procedures, over 2 days.

One prerequisite for peripheral blood stem cell donation is that the potential donor has good enough peripheral veins to allow reliable venous access. If this is not the case and the donor prefers to donate using this method, a temporary central venous line has to be inserted.

Most donors tolerate the apheresis procedure with few problems. One of the most common complications of the procedure is hypocalcaemia which results from calcium binding by the citrate anticoagulant used to prevent clotting within the apheresis circuit. Donors may notice perioral tingling or paraesthesia in other areas and are asked to report this immediately. The problem is easily treated by reducing the concentration of anticoagulant in the circuit and by asking the donor to drink a small amount of milk. If this problem is not picked up early, the consequences can be more severe, with the development of tetany which would require intravenous calcium replacement.

In summary, peripheral blood stem cell donation is generally a less invasive and better-tolerated procedure than direct stem cell harvest from the marrow space. However, the associated procedural risks are more easily quantifiable for the latter procedure.

3. There are some potential advantages, to the transplant recipient, in the use of peripheral blood stem cells as opposed to bone marrow stem cells. Engraftment is quicker, so the recipient spends less time in the neutropenic phase, and hence the risk of infection is reduced. Similarly, there is evidence that duration of hospital stay is reduced when peripheral blood stem cells are used. One potential disadvantage of this approach is that the graft includes a larger dose of T-lymphocytes than a graft of stem cells derived directly from the marrow (approximately a 10-fold increase). There is some evidence that rates of chronic graft-versus-host disease are increased amongst recipients of peripheral blood stem cells, but this observation has not been borne out in all studies. This potential disadvantage of peripheral blood stem cells is negated if a T-cell-depleted approach is used, as is the case for most matched unrelated procedures.

Case 50.3

A 25-year-old woman is admitted with newly diagnosed AML. Once her condition is stabilised, the consultant seeks her consent to start intensive chemotherapy.

Questions

1. How should the consultant ensure the consent process is performed as well as possible?
2. What side effects should the consultant discuss?

Answers

1. It is vital that consent is taken only after very careful discussions. Consent for such intensive chemotherapy usually requires several conversations. The final consent conversation should be done in a quiet private room if possible, and interruptions should be kept to a minimum. The patient should be allowed to have a friend, partner or relative present if they wish, and ideally a clinical nurse specialist should be present too. If possible, the patient should be given some written material on chemotherapy before consent even if it is important the treatment is started promptly. The patient should be given a clear explanation of their potential treatment options and should be informed of any clinical trials that may be available to them. It is vitally important to fully inform patients regarding their condition and its prognosis, and about treatment options and their potential advantages

and disadvantages. Only if the patient has all the necessary information can they decide on the treatment option that is most appropriate/acceptable to their individual circumstances.

2. The consent discussion should include a discussion of all common side effects and less common but severe side effects of treatment. Common side effects of AML chemotherapy would include nausea, vomiting, mucositis, tiredness, malaise, infections, hair loss, bleeding and anaemia. Patients should be warned that they will require transfusions of blood and platelets. They will always need good venous access and usually a Hickman or other long-term in-dwelling central line. They will need to be warned they will have to spend at least 3–4 weeks in hospital. Severe side effects may include infertility and a premature menopause in young women. Options for the prevention and treatment of infertility must be discussed before treatments commences. Anthracyclines can be associated with cardiac problems, infections and bleeding can be life threatening and patients must be warned that they may not respond to therapy or may relapse after treatment. They should also be warned that a cure cannot be guaranteed. There is a risk of treatment-related mortality of around 1–2%. Longer-term risks include a greater lifetime risk of cancers including skin cancer and lung cancer, particularly in smokers.

Case 50.4

A 24-year-old patient with ALL is undergoing chemotherapy and needs intrathecal chemotherapy to prevent relapse in the meninges. Giving drugs by this route is EXTREMELY DANGEROUS. Several patients have died as a result of the inadvertent administration of vinca alkaloids into the CSF.

Question

What steps have been taken nationally to try to prevent the inadvertent intrathecal injection of vincristine and other agents not suitable for intrathecal use?

Answer

In the UK, there are now strict guidelines for administration of intrathecal chemotherapy. It can only be performed in hospital units which have passed a rigorous peer review process. The procedure must be undertaken in a specially designated area. Intravenous drugs must not be given in this area. The intrathecal drugs must only be prescribed by a consultant or specialist registrar who has been trained to prescribe or give intrathecal chemotherapy and whose name appears on a locally held register. Drugs for intrathecal administration must only be prescribed on a specially designated prescription sheet. Once the prescription has arrived in pharmacy, the drugs must be manufactured and checked by pharmacists trained in the manufacture and checking of intrathecal prescriptions. The drugs must be positively labelled 'for intrathecal use only' and must be dispensed by a trained pharmacist. They can only be dispensed once the patient has been given any intravenous drugs that are due that day. The doctor collecting the drugs must sign to confirm that the i.v. drugs, if due, have been given before the drugs are dispensed. The drugs must only be dispensed to a doctor trained and on the register for giving intrathecal drugs. The intrathecal drugs must be transported in a specially designated container, and if they need to be stored, then it must be in a separate, specially designated fridge, that is separate from any intravenous chemotherapy. Once the procedure is under way, the intrathecal drugs must be checked by the registered doctor and by a nurse who has been trained and appears on a register of nurses trained to check intrathecal drugs. The drugs should

also be checked by the patient or a patient's representative. Intrathecal drugs must not be given in hospitals not approved for the procedure, in non-designated areas, outside office hours or at the weekend unless there are exceptional circumstances. All staff working on oncology or haematology units should be taught about the rules for giving intrathecal therapy.

In addition, in order to prevent inadvertent vincristine administration into the intrathecal space, hospitals giving intrathecal chemotherapy should follow special rules for labelling vinca alkaloid prescriptions and vinca alkaloids should be made up in a minimum volume of 20 mL in order to prevent intrathecal administration.

Case 50.5

A 37-year-old dental technician presented with acute promyelocytic leukaemia (APL). He had a number of bleeding problems at presentation. He was randomised on an APL trial to be commenced on oral all-trans retinoic acid (ATRA) and arsenic trioxide (ATO).

Questions

1. Why is ATRA used in this circumstance and what are its side effects?
2. Why is ATO used in this circumstance and what are its side effects?

Answers

1. APL is a variant of AML which presents with coagulation defects, low platelet counts and severe bleeding. Patients are at risk of severe haemorrhage at presentation but have a relatively good prognosis with chemotherapy. ATRA can rapidly correct the coagulopathy found at presentation. This agent also increases the likelihood of the patient entering remission, when combined with standard high-dose chemotherapy. It is also used as a maintenance agent and when used with 6-mercaptopurine and methotrexate, it increases the number of patients who remain in long-term remission. The side effects of ATRA include dry eyes and a dry mouth. In addition, ATRA can cause a severe and life-threatening sterile pneumonitis. It is important to recognise this syndrome quickly as it often responds to high-dose dexamethasone and if left untreated leads to respiratory failure and death.
2. ATO has been shown to bring about remission in patients who have APL in association with the 15;17 chromosomal translocation and the PML:RARA genetic abnormality. It is not considered a conventional chemotherapeutic agent and seems to work in a synergistic fashion with ATRA. There is a lot of interest in combining these agents in an attempt to reduce the exposure of these patients to chemotherapy. Side effects include the APL differentiation syndrome, similar to the ATRA differentiation syndrome.

ATO can cause QT interval prolongation and complete atrioventricular block. QT prolongation can lead to a torsade de pointes-type ventricular arrhythmia, which can be fatal. The risk of torsade de pointes is related to the extent of QT prolongation, concomitant administration of QT prolonging drugs, a history of torsade de pointes, pre-existing QT interval prolongation, congestive heart failure, administration of potassium-wasting diuretics or other conditions that result in hypokalemia or hypomagnesemia. Prior to initiating therapy with ATO, a 12-lead ECG should be performed and serum electrolytes (potassium, calcium and magnesium) and creatinine should be assessed; pre-existing electrolyte abnormalities should be corrected and, if possible, drugs that are known to prolong the QT interval should be discontinued. For QTc greater than 500 ms, corrective measures should be completed and the QTc reassessed with serial ECGs prior to considering using ATO.

Case 50.6

A 57-year-old man with a 6-year history of CLL presented with a rising white cell count, worsening lymphadenopathy and hepatosplenomegaly. Treatment was commenced with oral fludarabine 40 mg/m² and oral cyclophosphamide 250 mg/m² daily for 3 days with rituximab given on day 1 (FC-R).

Question

What additional precautions would you advise the physician to take and why?

Answer

Fludarabine, cyclophosphamide and rituximab are a very powerful combination available for the initial treatment of CLL. It has been used as a second-line therapy, although recent data support its use as a first-line therapy. It has been associated with more frequent and deeper remissions which are longer than single-agent therapy. It is a very immunosuppressive combination with activity against both T- and B-cells, and patients treated with this regime are at high risk of developing *Pneumocystis* pneumonia. It is important that patients are given prophylaxis against this severe infection. Herpes virus infections including herpes simplex and herpes zoster are also common, and most patients are given acyclovir prophylaxis.

As patients are immunosuppressed, they are also at risk of developing transfusion related graft-versus-host disease. This is a complication of blood product transfusion, caused by engraftment of lymphocytes from the transfused product, which is frequently fatal. This complication can be prevented by irradiation of blood products prior to transfusion. Rituximab is an antibody-based therapy and can be associated with significant reactions which can occasionally be severe and life threatening (see Chapter 51).

Lymphomas 51

L. Cameron and C. Loughran

Key points

- Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL) are aggressive diseases that are fatal if untreated.
- Early-stage HL patients are treated with combined modality treatment usually consisting of two to four cycles of ABVD (Adriamycin (doxorubicin), bleomycin, vinblastine, dacarbazine) and involved field radiotherapy (IFRT) (20–30 Gy); a relapse-free survival rate of 85–90% at 5–10 years is achieved.
- ABVD chemotherapy is the current gold standard regimen for advanced HL, and overall survival at 5 years is 75–80%.
- Low-grade NHL may be treated using R-CVP (rituximab, cyclophosphamide, vincristine, prednisolone) or chlorambucil chemotherapy or by adopting a 'watch and wait' policy.
- R-CHOP (cyclophosphamide, hydroxydaunorubicin (doxorubicin), Oncovin (vincristine), prednisolone, rituximab) chemotherapy is the standard for the treatment of aggressive (intermediate and high grade) NHL, curing 60% of patients.
- Relapsed HL and NHL may be treated with further chemotherapy followed by high-dose chemotherapy with bone marrow or peripheral stem cell transplantation.
- Patients receiving chemotherapy for HL and NHL should have full blood count (FBC) and blood biochemistry monitored at frequent intervals.
- Complications such as nausea and vomiting, tumour lysis syndrome (TLS), mucositis and bone marrow suppression may occur as a result of chemotherapy and are significant factors in morbidity.
- Supportive care of the patient undergoing chemotherapy includes appropriate drug therapy to minimise the adverse effects of the treatment.

Lymphoma is cancer of the lymphatic system and accounts for approximately 3% of new cases of cancer reported in the UK each year. The primary cancerous cell of origin is the lymphocyte; as a result, there is often considerable overlap between lymphomas and lymphoid leukaemias. Lymphomas are subdivided into two main categories: Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL). Both HL and NHL can be further classified based on histology.

The site of malignancy is usually a lymph node. Extranodal disease, most frequently of the stomach, skin, oral cavity and pharynx, small intestine and CNS, can occur and is more common in NHL than HL.

Hodgkin's lymphoma

Hodgkin's disease, now known as HL, was first described by Thomas Hodgkin in 1832. HL accounts for 30% of all lymphomas and has an incidence in the UK of 2.2 per 100,000 for women and 3.3 per 100,000 for men. It is predominantly a disease of young adults, having a peak incidence between the ages of 15 and 35 years.

Aetiology

The cause of HL is unknown, but a number of risk factors have been identified. Epstein–Barr (glandular fever) virus has been identified in 50% of HL cases and is likely to be associated with an increase in risk of developing HL. Certain associations have been identified which suggest a genetic link with HL; for example, same-sex siblings of patients with HL have a 10 times higher risk of developing the disease. Patients with reduced immunity, for example, AIDS or those taking immunosuppressants, may have an increased risk of developing HL.

Pathology

The diagnosis is made by histological examination of an excised lymph node biopsy. The characteristic pathological finding in HL is the identification of a large, abnormal binucleate lymphocyte called a Reed-Sternberg cell. HL as classified by the World Health Organization (WHO) has two distinct entities: classic HL and nodular lymphocyte-predominant Hodgkin's lymphoma (NLPHL). Classic Hodgkin's is further subdivided into four histological types:

- *nodular sclerosis*: this is the most common type in the UK, predominant in young adults and females, and has an excellent prognosis
- *mixed cellularity*: this is second most common type of classic HL and more common in males (70% male)
- *lymphocyte depleted*: this carries a poor prognosis and is more common in HIV-positive individuals
- *lymphocyte rich*: this is a rare type of classic HL

NLPHL accounts for 5% of HL cases and is more common in men.

Signs and symptoms

HL usually presents with painless enlargement of lymph nodes, often in the neck. About 40% of patients will present with fever, night sweats and/or weight loss. These have prognostic significance and are designated B symptoms; others include malaise, itching (25%) or pain at the site of enlarged nodes after drinking alcohol. Bone pain may result from skeletal involvement. Primary involvement of the gut, central nervous system or bone marrow is rare.

If lymph nodes in the chest are involved, patients may present with breathlessness. There is often a disturbance of immune function due to a progressive loss of immunologically competent T-lymphocytes, with patients becoming particularly prone to viral and fungal infections.

Laboratory findings

Laboratory findings include normochromic, normocytic anaemia, a raised erythrocyte sedimentation rate and eosinophilia. One-third of patients have a leucocytosis due to an increase in neutrophils. Advanced disease is associated with lymphopenia (lymphocytes $<0.6 \times 10^9$ L^{-1}). Plasma lactate dehydrogenase (LDH) is raised in 30–40% of patients at diagnosis and has been associated with a poor prognosis.

Investigations and staging

Once the diagnosis has been made on biopsy, further investigations are needed to assess disease activity and the extent of its spread through the lymphoid system or other body sites. This is called staging and is essential for assessing prognosis, with cure rates for localised tumours (stage I or II) being much higher than those for widespread disease (stage IV). The staging of HL is assessed by the Cotswolds modification of the Ann Arbor classification system (Box 51.1). Information about prognostic factors such as mediastinal mass and bulky disease is included in the classification system. The tests required to establish the stage include a complete history, physical examination, FBC, urea and electrolytes (U and Es), chest X-ray and computed tomography (CT). Other useful tests include erythrocyte sedimentation rate (ESR), serum LDH and liver function tests (LFTs). Positron emission tomography (PET) can be used to detect active residual disease.

Management

HL is potentially curable and, in general, sensitive to both chemotherapy and radiotherapy; therefore, the two main goals of treatment are to maximise the likelihood of cure whilst minimising the risk of late toxicity such as infertility. Stage of disease is the biggest factor in treatment choice and outcome. The management of classic HL is determined by the stage of the disease, and this is summarised in Fig. 51.1. Localised NLPHL frequently involves one isolated lymph node and tends to be indolent (slow growing). If there are no risk factors, it can be

Box 51.1 Cotswolds modification of the Ann Arbor classification system for Hodgkin's lymphoma

Clinical stage	Defining features
I	Involvement of a single lymph node region or lymphoid structure
II	Involvement of two or more lymph node regions on the same side of the diaphragm
III	Involvement of lymph node regions or structures on both sides of the diaphragm: III_1 – with or without involvement of splenic, hilar, coeliac or portal nodes III_2 – with involvement of para-aortic, iliac or mesenteric nodes
IV	Involvement of extranodal site(s) beyond that designated E

Modifying characteristics
A: no symptoms
B: fever, drenching sweats, weight loss
X: bulky disease
  >one-third width of the mediastinum
  >10 cm maximal dimension of nodal mass
E: involvement of a single extranodal site, contiguous or proximal to known nodal site
CS: clinical stage
PS: pathological stage

treated with IFRT alone (30 Gy); all other types are treated as advanced (stage III or IV) classic HL.

In Europe, the treatment of classic HL is determined by whether the disease is staged as early favourable disease, early unfavourable disease, advanced disease or relapsed (see Box 51.2).

Early-stage (favourable) disease

The cure rate for patients with stages I and IIA disease is greater than 90%. Patients with stages I and IIA disease may be cured with radiotherapy alone (wide or extended field irradiation). However, due to radiation-related late effects, cardiac toxicity and secondary malignancy and the incidence of relapse (25–30%), most receive combined modality treatment (chemotherapy and radiotherapy). This usually consists of two to four cycles of ABVD (Adriamycin (doxorubicin), bleomycin, vinblastine, dacarbazine) chemotherapy followed by IFRT of 20–30 Gy (Diehl et al., 2004). The aim of chemotherapy is to destroy subclinical disease outside the field of radiotherapy.

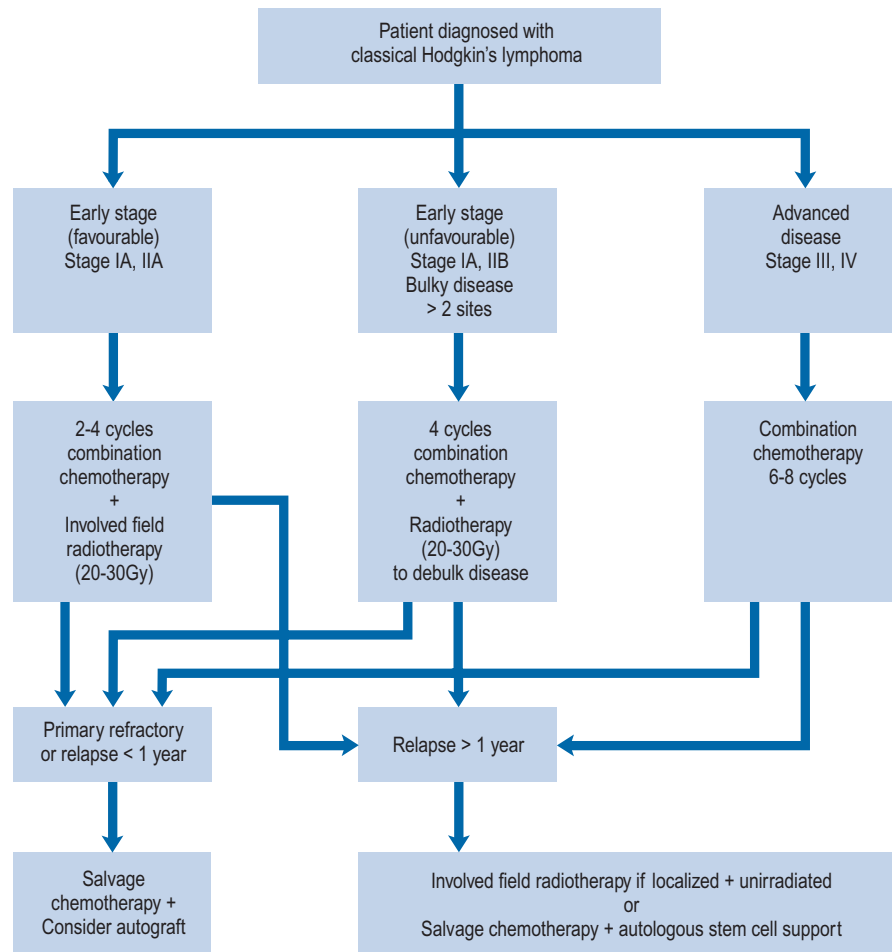
Where disease is confined to above the diaphragm, the mantle field is used (Fig. 51.2). The inverted Y is employed when the disease is confined below the diaphragm. This group of patients have a relapse-free survival rate of 80% at 5–10 years. Patients should be considered for entry into the National Cancer Research Institute (NCRI) 18–30 study or NCRI Lymphoma Groups PET in Hodgkin's Disease Study.


Fig. 51.1 Treatment algorithm for classic Hodgkin's lymphoma.

Early-stage (unfavourable) disease

Patients with stage I or II presenting with bulky disease, B symptoms or with more than two sites of disease are considered to be poor risk if treated with radiotherapy alone. B symptoms are any of the following symptoms: unexplained loss of weight, unexplained fever, drenching night sweats. These patients are treated with four to six cycles of combination chemotherapy, for example, ABVD, and radiotherapy (20–30 Gy) to sites of bulky disease. Patients should be considered for entry into the NCRI 18–30 study.

Advanced disease

Patients with advanced disease (stages III and IV) are treated with combination chemotherapy. The first widely used combination chemotherapy regimen was MOPP (mechlorethamine, vincristine (Oncovin), procarbazine and prednisolone) which produced a response rate of 80% and long-term disease-free survival of approximately 50%. ABVD has replaced MOPP chemotherapy as the regimen of choice as it is as effective but less toxic in terms of fertility, haematological toxicity, and the development of acute leukaemia and myelodysplasia. Six

to eight cycles of ABVD is considered the current standard treatment for advanced disease.

Despite advances in HL, 30–40% of patients progress or relapse and respond poorly to salvage chemotherapy. A number of regimens have been investigated to both increase dose intensity and density of treatment, for example, BEACOPP (bleomycin, etoposide, Adriamycin (doxorubicin), cyclophosphamide, vincristine, procarbazine, prednisolone) and escalated BEACOPP (Table 51.1). In a trial comparing escalated BEACOPP, standard BEACOPP and COPP-ABVD, escalated BEACOPP demonstrated increased overall survival compared with the other two treatment arms but at the cost of significant toxicity (Engert et al., 2009). First-line escalated BEACOPP can only be recommended currently as part of a clinical trial. A study to investigate the role of BEACOPP and PET imaging in patients with advanced HL is under way and will close in 2012 (UK Clinical Research Network Study Portfolio, 2010).

Other options for patients unlikely to tolerate ABVD include ChlVPP (chlorambucil, vinblastine, procarbazine, prednisolone) and CHOP (cyclophosphamide, doxorubicin (hydroxydaonorubicin), vincristine (Oncovin), prednisolone, rituximab.

Fig. 51.2 The mantle and inverted Y fields commonly employed in the treatment of Hodgkin's lymphoma with radiotherapy (from Souhami and Tobias, 1998, p. 437, with permission from Blackwell Science).

Salvage therapy for relapsed disease

Relapsed disease refers to disease progression after completion of primary treatment which resulted in a complete remission. Depending on previous treatment, options include salvage radiotherapy, salvage chemotherapy or high-dose chemotherapy with autologous stem cell support. In this procedure, stem cells are collected from the patient and returned following high-dose chemotherapy. Patients who relapse after initial radiotherapy alone have a good chance of cure with combination chemotherapy, at least equal to that of patients initially treated with chemotherapy for advanced disease. Occasionally, radiotherapy is used if the disease is localised and previously non-irradiated. Those who relapse after combination chemotherapy have a worse prognosis, although durable remissions can be obtained with further conventional therapy.

Length of remission following first-line chemotherapy influences the success of subsequent salvage therapy and so failure of chemotherapy can be used to classify disease and determine appropriate therapy. If the duration of remission was greater than 12 months (late relapse), then the patient can be re-treated with their initial chemotherapy, salvage regimen or considered for high-dose chemotherapy with autologous transplantation.

Commonly used chemotherapy salvage regimens are listed in Table 51.2. If relapse occurs less than a year after treatment (early relapse), then high-dose chemotherapy with autologous stem cell support should be considered. A patient who has never achieved complete remission (primary refractory disease) should receive high-dose chemotherapy with autologous stem cell support.

High-dose chemotherapy plus autologous stem cell support is associated with a 40–50% 5-year survival rate. However, the significant toxicity of autologous stem cell transplantation means that it should be reserved for patients in whom there is a clear increase in chance of cure. Allogeneic transplant is an option in patients relapsing after autologous transplant (Brusamolino et al., 2009).

New agents

The anti-CD20 antibody rituximab has shown remission in 80% of cases of NLPHL, but due to short follow-up, its use is still considered experimental. Other monoclonal antibodies targeting CD30, which is expressed in the majority of classic HL cases, are being investigated. The most promising of these is a novel immunotoxin conjugate SGN-35 (Younes, 2009).

Panobinostat, a histone deacetylases (HDAC) inhibitor, has been granted orphan drug designation for the treatment of HL.

Gemcitabine has shown activity in relapsed classic HL with response rates up to 79% in a small series of heavily pre-treated patients (Ng et al., 2005). Bortezomib and lenalidomide licensed for myeloma are also being investigated in those who have relapsed HL.

Non-Hodgkin's lymphoma

The NHLs are a heterogeneous group of lymphoid malignancies ranging from indolent, slow-growing tumours to aggressive, rapidly fatal disease. Paradoxically, the

Table 51.1 Combination chemotherapy regimens effective in the treatment of Hodgkin's lymphoma

Regimen	Dose and route	Frequency
ABVD (28-day cycle)		
Doxorubicin	25 mg/m² i.v.	Days 1 and 15
Bleomycin	10,000 iu/m² i.v.	Days 1 and 15
Vinblastine	6 mg/m² i.v.	Days 1 and 15
Dacarbazine	375 mg/m² i.v.	Days 1 and 15
BEACOPP escalated (21-day cycle)[a]		
Bleomycin	10,000 iu/m² i.v.	Day 8
Etoposide	200 mg/m² i.v.	Days 1–3
Adriamycin (doxorubicin)	35 mg/m² i.v.	Day 1
Cyclophosphamide	1250 mg/m² i.v.	Day 1
Vincristine	1.4 mg/m² i.v. (max. 2 mg)	Day 8
Procarbazine	100 mg/m² orally	Days 1–7
Prednisolone	40 mg/m² orally	Days 1–14
BEACOPP standard dose (21-day cycle)[a]		
Bleomycin	10,000 iu/m² i.v.	Day 8
Etoposide	100 mg/m² i.v.	Days 1–3
Adriamycin (doxorubicin)	25 mg/m² i.v.	Day 1
Cyclophosphamide	650 mg/m² i.v.	Day 1
Vincristine	1.4 mg/m² i.v. (max. 2 mg)	Day 8
Procarbazine	100 mg/m² orally	Days 1–7
Prednisolone	40 mg/m² orally	Days 1–14
ChlVPP		
Chlorambucil	6 mg/m² orally	Days 1–14
Vinblastine	6 mg/m² i.v.	Days 1 and 8
Procarbazine	100 mg/m² orally	Days 1–14
Prednisolone	40 mg/m² orally (max 60 mg)	Days 1–14

[a]Escalated BEACOPP and standard BEACOPP have shown activity in Hodgkin's lymphoma, but their usage is not standard in the UK.

Table 51.2 Salvage chemotherapy regimens effective in the treatment of lymphoma

Regimen	Dose and route	Frequency
DHAP		
Cisplatin	100 mg/m² i.v.	Days 1
Cytarabine	2000 mg/m² i.v. 12 hourly	Day 2

Etoposide	100 mg/m² i.v.	Days 1–3
IVE		
Epirubicin	50 mg/m² i.v.	Days 1
Etoposide	200 mg/m² i.v.	Days 1–3
Ifosfamide	3000 mg/m² i.v.	Days 1–3

AUC, area under the curve; GFR, glomerular filtration rate.
[a]Carboplatin dose (mg) = target AUC (mg/mL × min) × (GFR (mL/min) + 25).

more aggressive NHLs are more susceptible to anticancer therapy. The overall incidence of NHL in the UK is 11 per 100,000 per year and accounts for approximately 3% of all cancers in the UK. The disease is rare in subjects under 30 years of age and the incidence steadily increases with increasing age; the median age at presentation is about 60. NHL is slightly more common in men than in women (1.5:1).

Aetiology

The aetiology is unclear although immunosuppression, for example, following organ transplantation, may predispose to the development of lymphoma. Viruses have been implicated in the pathogenesis of NHL; for example, Burkitt's lymphoma is one of the most common neoplasms to develop in HIV-related immunosuppressed patients, human T-lymphotrophic virus type 1 (HTLV-1) is associated with a rare type of T-cell lymphoma, the adult T-cell leukaemia/lymphoma (ATLL) and Epstein–Barr Virus (EBV) is associated with post-transplant lymphoproliferative disorder (PTLD). Exposure to certain chemicals such as pesticides and solvents can increase the risk of developing NHL. There is an increased incidence of gastro-intestinal lymphomas in patients with Crohn's disease.

Signs and symptoms

The most common presentation of NHL is painless lymph-adenopathy, frequently in the neck area in the supraclavicular and cervical regions. Spread of disease is haematogenously (via the blood), and so extranodal sites may be involved. Signs and symptoms of infection, anaemia or thrombocytopenia may be present in patients with bone marrow involvement. Hepatosplenomegaly may also be present. Patients may also present with any of the following symptoms: unexplained loss of weight, unexplained fever, drenching night sweats. These symptoms are described as B symptoms and patients without these symptoms are classified as category A. B symptoms are more commonly seen in advanced or aggressive NHL but may be present in all stages and histological subtypes.

Laboratory findings

Laboratory examinations may reveal anaemia, a raised eryth-rocyte sedimentation rate and a raised serum LDH level. There may be a reduction in circulating immunoglobulins, and a monoclonal paraprotein may be seen in a small number of cases. The immune disruption caused by the disease may also result in an increased susceptibility to viral infection or autoimmune haemolytic anaemia or thrombocytopenia.

Histopathology and classification

There have been many attempts to classify the NHLs into his-tological categories that have clinical significance. Despite this, many problems and areas of confusion remain. Approximately 85% of NHLs are of B-cell origin, while 15% are of T-cell ori-gin or are unclassifiable.

There are two classification systems in common use. The Working formulation, developed in 1982, divides the lympho-mas into low, intermediate and high grade. More recently, the revised European–American lymphoma (REAL) classifica-tion system has been developed (Table 51.3) and adopted by the World Health Organization (Box 51.3) to classify the grade of lymphoma. The REAL/WHO classification incorporates some diagnoses not included in the Working formulation and is a list of lymphomas using morphology, immunophenotype, genotype and clinical behaviour. It recognises the three major categories of lymphoid malignancies: B-cell neoplasms, T-cell/natural killer cell neoplasms and HL. However, in practice, the clinical behaviour of lymphomas informs the treatment strat-egies employed as these are based on the initial classification into indolent (low grade) or aggressive (intermediate and high grade) NHL. A more biologically relevant classification of lymphoma using the REAL/WHO classification and immu-nological and molecular characteristics increases the diagnos-tic specificity and improves selection and targeting of therapy.

Diagnosis

Diagnosis is based on a thorough history, physical examina-tion and investigation of a lymph node. A definitive diagnosis of NHL can only be made by biopsy of pathological lymph

Table 51.3 Clinical grade and frequency of lymphomas in the REAL classification

Diagnosis	% of all cases
Indolent lymphomas	
Follicular lymphoma	22
Marginal zone B-cell, mucosa-associated lymphoid tissue	8
Chronic lymphocytic leukaemia/small lymphocytic lymphoma	7
Marginal zone B-cell nodal	2
Lymphoplasmacytic lymphoma	1
Aggressive lymphoma	
Diffuse large B-cell lymphoma	31
Mature (peripheral) T-cell lymphomas	8
Mantle cell lymphoma	7
Mediastinal large B-cell lymphoma	2
Anaplastic large cell lymphoma	2
Very aggressive lymphomas	
Burkitt's lymphoma	2
Precursor T-lymphoblastic	2
Other lymphomas	7

nodes or tumour tissue. An expert histopathologist may need to utilise sophisticated techniques such as immunocy-tochemistry (e.g. CD20) or genotyping to obtain an accurate subclassification.

Chromosomal abnormalities are of diagnostic importance. Most translocations involve genes associated with either proliferation (e.g. c-MYC) or apoptosis (e.g. BCL-2).

Additional investigations should also be performed to accurately stage the disease and exclude other disease. FBC from peripheral blood and routine biochemistry and uric acid should be performed. Peripheral blood lymphocytosis (increased lymphocytes) with circulating malignant cells is common in low grade and mantle cell lymphomas. A bone marrow aspirate and trephine are required to exclude leukae-mia and will detect bone marrow involvement, which is more common than in HL. CT scans of the chest, abdomen and pel-vis are required to assess the extent of the disease. The use of PET scans, capable of locating sites not thought to be affected from CT scan images, is increasing. Lumbar punctures should be performed for patients at high risk of CNS involvement, for example, Burkitt's lymphoma. Erythrocyte sedimentation rate, LDH and serum β_2-microglobulin levels may indicate disease activity and can be of prognostic importance.

Staging

Determining the extent of disease in patients with NHL provides prognostic information and is useful in treatment planning. Patients with extensive disease usually require dif-ferent therapy from those with limited disease. The NHLs can be staged according to the Ann Arbor classification (see Box 51.1). In this system, NHL is defined as stage I, II, III or IV, stage I being disease limited to a single lymph node

Box 51.3 Revised European–American lymphoma classification as adopted by the WHO (REAL/WHO classification)

Precursor B-cell neoplasm
Precursor B-cell acute lymphoblastic leukaemia or lymphoma

Mature (peripheral) B-cell neoplasm
  B-cell chronic lymphocytic leukaemia or small lymphocytic lymphoma
  B-cell prolymphocytic leukaemia
  Lymphoplasmacytoid lymphoma
  Splenic marginal zone B-cell lymphoma (with or without villous lymphocytes)
  Hairy cell leukaemia
  Plasma cell myeloma or plasmacytoma
  Extranodal marginal zone B-cell lymphoma (with or without monocytoid B-cells)
  Follicular lymphoma
  Mantle cell lymphoma
  Diffuse large B-cell lymphoma
  Mediastinal large B-cell lymphoma
  Primary effusion lymphoma
  Burkitt's lymphoma or Burkitt's cell leukaemia

Precursor T-cell neoplasm
Prescursor T-cell acute lymphoblastic leukaemia or lymphoma

Mature (peripheral) T-cell and natural killer neoplasms
  T-cell prolymphocytic leukaemia
  T-cell granular lymphocytic leukaemia
  Aggressive natural killer cell leukaemia
  Adult T-cell lymphoma or leukaemia
  Extranodal natural killer/T-cell lymphoma

Plasma lactate dehydrogenase level	Above normal
Number of extranodal sites of involvement	≥2
Performance status	≥ECOG 2 or equivalent

ECOG, Eastern Co-operative Oncology Group.

it is not curable, patients survive for prolonged periods with minimal symptoms. Aggressive (high-grade) lymphomas result in death within weeks or months if untreated. These lymphomas, however, are very responsive to chemotherapy and up to 50–60% may be cured with combination chemotherapy (Fig. 51.3).

CD20 is essential for cell cycle regulation and cell differentiation. It is expressed on normal B-cells and the majority of malignant B-cell lymphomas. The introduction of rituximab, a monoclonal antibody with specificity for CD20, has changed the way patients with NHL are treated and is now incorporated into most chemotherapy regimens. The mechanism of action of rituximab is not fully understood but is thought to involve complement-mediated lysis of B-cells and antibody-dependent cellular cytotoxicity. Other potential mechanisms include induction of apoptosis and inhibition of cell cycle progression.

Indolent non-Hodgkin's lymphoma

The median age at which patients present with indolent NHLs is 50–60 years, and generally patients have a good performance status. If left untreated, indolent NHL has a comparatively long survival (median: 9 years). Follicular lymphoma is the most common of the indolent lymphomas. For the minority of patients presenting with limited-stage disease (stage I), radiotherapy to the involved field is generally used. However, the majority (80%) of patients present with advanced disease (stages II–IV) where the aim of treatment is to reduce disease bulk and offer symptom relief. Rituximab, cyclophosphamide, vincristine, prednisolone (R-CVP) is used as the first-line treatment for advanced (stage III or IV) follicular lymphoma following the results of a study comparing R-CVP with CVP (cyclophosphamide, vincristine, prednisolone) (Marcus et al., 2005). This approach has been incorporated into national guidance (NICE, 2006). R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, prednisolone) can also be used as first-line treatment for young patients with aggressive disease and is an option in relapsed disease (Table 51.5).

and stage IV being advanced disease, with involvement of extralymphatic sites. The International Prognostic Index (Table 51.4) uses the following factors as predictors of poor prognosis: elevated LDH, stage III or IV disease, greater than 60 years of age, the higher the number of extranodal sites involved and the Eastern Co-operative Oncology Group (ECOG) performance status of two or higher. Other prognostic factors include bulky disease, presence of B symptoms and transformation from low- to high-grade disease. Prognostic indicators are important because they inform the treatment plan to avoid overtreating those with good prognosis and undertreating those with poor prognosis.

Treatment

When designing a treatment plan for an individual patient, various factors must be taken into account. These include the patient's age and general health, the extent or stage of the lymphoma and the particular histological subtype. Indolent (low-grade) lymphoma tends to run a slow course and although

Fig. 51.3 Typical treatment algorithm for non-Hodgkin's lymphoma.

Table 51.5 Chemotherapy regimens effective in the treatment of non-Hodgkin's lymphoma

Drug	Dose and route	Day of administration
R-CHOP (21-day cycle)		
Cyclophosphamide	750 mg/m² i.v.	Day 1
Doxorubicin (hydroxydaunorubicin)	50 mg/m² i.v.	Day 1
Vincristine (Oncovin)	1.4 mg/m² (max 2 mg) i.v.	Day 1
Prednisolone	100 mg orally	Days 1–5
Rituximab	375 mg/m² i.v.	Day 1
R-CVP (21-day cycle)		
Cyclophosphamide	750 mg/m² i.v.	Day 1
Vincristine (Oncovin)	1.4 mg/m² (max 2 mg) i.v.	Day 1
Prednisolone	100 mg orally	Days 1–5
Rituximab	375 mg/m² i.v.	Day 1
FC (28-day cycle)		
Fludarabine	40 mg/m² orally	Days 1–3
Cyclophosphamide	250 mg/m² daily orally	Days 1–3
CHOP (21-day cycle)		
Cyclophosphamide	750 mg/m² i.v.	Day 1
Doxorubicin (hydroxydaunorubicin)	50 mg/m² i.v.	Day 1
Vincristine (Oncovin)	1.4 mg/m² (max 2 mg) i.v.	Day 1
Prednisolone	100 mg orally	Days 1–5

For patients who are asymptomatic at diagnosis, adopting a 'watch and wait' policy with active monitoring and initiating treatment when symptomatic is an option. Patients could be considered for recruitment to clinical trials; there are ongoing studies comparing R-CVP with R-FC (rituximab, fludarabine, cyclosphosphamide) followed by rituximab maintenance and investigating the benefit of bendamustine compared to R-CVP. If patients fail to tolerate the standard treatment options, an oral alkylating agent, for example, chlorambucil, with or without a steroid can be used. Repeated courses may be given.

Relapsed indolent non-Hodgkin's lymphoma

Relapsed patients may be re-treated with rituximab if the time to relapse post-rituximab is greater than 6 months (NICE, 2008). If the time to relapse is less than 6 months, Yttrium-90 labelled ibritumomab tiuxetan (Zevalin®) may be considered. Zevalin® is a new therapeutic development that utilises monoclonal antibodies as tumour-specific vehicles to deliver systemic radiation therapy concurrent with immunotherapy to the targeted tumour. However, for some resistant or relapsing patients, particularly if their condition is too poor to merit further radical chemotherapy, palliation will be appropriate. Radiotherapy may be an option in this situation and this is being evaluated through an ongoing clinical trial.

Aggressive non-Hodgkin's lymphoma

The median age of presentation of aggressive NHL is 60–70 years when 50–60% of patients will present with an advanced stage of the disease. The most common presentation is diffuse large B-cell lymphoma (DLBCL), and therefore the treatment strategies described later refer to this alone. Other aggressive lymphomas, for example, mantle cell, are managed differently. The most important strategy when treating this group of patients is to maintain the dose intensity of chemotherapy and minimise any delay in chemotherapy administration. Treatment is given with curative intent.

The treatment for advanced-stage aggressive NHL is six cycles of the combination of R-CHOP chemotherapy (NICE, 2003). Doxorubicin can cause cardiotoxicity and patients with a reduced cardiac ejection fraction or co-morbidities may not tolerate R-CHOP. The use of gemcitabine (R-GCVP) is currently being investigated for this patient group as part of a clinical trial. The addition of bortezomib to R-CHOP in DLBCL is also being investigated as a clinical trial for patients with high-risk disease.

Relapsed aggressive non-Hodgkin's lymphoma

Combination chemotherapy with R-CHOP probably cures 40–60%. This, therefore, implies that over half of all patients have refractory disease or relapse after first treatment.

In younger patients with aggressive NHL, the aim will be to introduce remission with further chemotherapy, using an alternative, salvage regimen, and then to consolidate remission with high-dose therapy (HDT). HDT is usually supported by mobilised peripheral blood stem cells (PBSCs) and an autologous PBSC transplantation (auto-PBSCT). Lymphoma is the most frequent indication for auto PBSCT in Europe. The European Group for Blood and Marrow Transplantation (EBMT) suggests that the upper age limit for autologous transplantation is 65 years. HDT, with autologous stem cell support, is also used as part of primary treatment for younger patients with indolent lymphoma. Patients who receive HDT after their initial treatment can have progression-free survival rates of around 50% at 5 years.

To induce a remission in patients with aggressive lymphoma and relapsed disease, it may be reasonable to use the same or similar regimen used for front-line chemotherapy. However, in most cases, the regimen chosen introduces new agents that are potentially not cross-resistant with those used in the initial treatment regimen. There are several salvage regimens in use and they generally have response rates of between 40% and 70%. Examples of salvage regimens are ICE (ifosfamide, carboplatin, etoposide), ESHAP (etoposide, methylprednisolone, cytarabine, cisplatin) and DHAP (cisplatin, cytarabine, dexamethasone) (see Table 51.2). Gemcitabine, a pyrimidine analogue, may be of benefit for patients with relapsed or refractory disease after two lines of treatment. Gemcitabine is used in combination with other agents, such as cisplatin and methylprednisolone. Rituximab can also be added to these salvage regimens. PBSCs are usually

harvested after the second course of the salvage regimen. Patients then receive a high-dose regimen such as BEAM (carmustine, etoposide, cytarabine, melphalan) (Table 51.6) conditioning prior to stem cell infusion (autograft). Patients should only undergo an autograft if they have demonstrated a response to salvage chemotherapy.

CNS prophylaxis for diffuse large B-cell lymphoma. Approximately 5% of patients with DLBCL develop CNS disease. The optimum approach to CNS prophylaxis is uncertain, and it usually involves a course of intrathecal chemotherapy.

The updated national guidance for the safe administration of intrathecal chemotherapy (DH, 2008) sets out the minimum requirements of a hospital providing an intrathecal chemotherapy service.

Very aggressive lymphoma

Burkitt's lymphoma is a rare form of B-cell NHL which occurs most commonly in children and young adults. The median age of adult patients is 30 years. Untreated, survival is measurable in days or weeks, and it is widely accepted that combination chemotherapy should be urgently commenced. Intensive chemotherapy is necessary, together with CNS prophylaxis, and cure is possible in a high proportion of cases.

Multi-agent chemotherapy regimens including high-dose methotrexate, high-dose cytarabine, etoposide and ifosfamide are used and a schedule such as CODOX-M (cyclophosphamide, vincristine, doxorubicin, high-dose methotrexate)/IVAC (ifosfamide, etoposide, high-dose cytarabine) is common.

There is an on-going debate about the value of adding rituximab to the CODOX-M/IVAC regimen.

Lymphoblastic lymphomas/leukaemia

Lymphoblastic lymphomas comprise about 2% of adult NHLs. Patients are often treated with the same regimens used in acute lymphoblastic leukaemia (ALL). Despite a very high

rate of complete responders, long-term survival remains poor. Patients who fail after first-line chemotherapy have a long-term disease-free survival of less than 10%. These cases are subsequently treated as leukaemias (see Chapter 50).

Patient care

The chemotherapy regimens used to treat HL and NHL (see Tables 51.1 and 51.5) are usually administered on a hospital outpatient basis with the patient visiting the clinic regularly for assessment and treatment. The patient is monitored by FBCs carried out before each cycle of chemotherapy and at the 'nadir' between cycles. The nadir is when the blood count is at its lowest point, usually 10–14 days after the first day of chemotherapy. The interval between each cycle of chemotherapy enables normal body cells to recover before the patient receives further treatment. Disease response to treatment is monitored by repeating some of the diagnostic investigations, such as CT, at suitable intervals and the use of PET. If there is little or no response to treatment, a different chemotherapy regimen will be used or a decision made to withdraw from active therapy and provide optimum supportive care.

Counselling and support

Counselling is an essential part of the care of the cancer patient and involves not only the explanation of drug therapy and investigations but also the provision of psychological support for the patient and family. Prior to treatment with chemotherapy, the patient will be counselled by the doctor, chemotherapy nurse and, increasingly, by oncology pharmacists. It is necessary to explain how the chemotherapy is to be given and discuss both potential and inevitable side effects. The probability of successful treatment must be weighed against the prospect of serious and life-threatening adverse effects. Patients must be made aware of the long-term complications of chemotherapy and radiotherapy, such as secondary malignancy.

The support available to the cancer patient, to help cope with both the illness and its treatment, has improved dramatically in recent years. Multidisciplinary teams working within specialised units have become skilled in anticipating the problems of lymphomas and their treatment. In addition, many charities provide care, support and advice such as Macmillan Cancer Support (www.macmillan.org.uk) and the Lymphoma Association (www.lymphoma.org.uk).

Patient-specific treatment modifications

The selection of appropriate therapy must also take into consideration the individual patient. Factors include the patient's age, renal and hepatic function and underlying medical conditions, such as heart disease, diabetes or chronic pulmonary disease. The patient's tolerance of side effects and complications of therapy may then be predicted. The decision is based on an understanding of the pharmacodynamics and pharmacokinetics of the drugs being used as well as the clinical condition of the patient.

Table 51.6 Conditioning chemotherapy for autologous transplantation

Drug	Dose and route	Day of administration
BEAM		
Carmustine	300 mg/m^2 i.v.	6 days before reinfusion
Etoposide	200 mg/m^2 i.v.	5–2 days before reinfusion
Cytarabine	200 mg/m^2 12 h i.v.	5–2 days before reinfusion
Melphalan	140 mg/m^2 i.v.	1 day before reinfusion
Reinfusion of stem cells		Day 0
LACE		
Lomustine	200 mg/m^2 orally	7 days before reinfusion
Etoposide	1000 mg/m^2 i.v.	7 days before reinfusion
Cytarabine	2000 mg/m^2	6–5 days before reinfusion
Cyclophosphamide	1800 mg/m^2 i.v.	4–2 days before reinfusion
Reinfusion of stem cells		Day 0

Supportive care

During a course of chemotherapy, the patient requires supportive care to minimise the adverse effects of treatment. The common adverse effects of the chemotherapy regimens discussed in this chapter are outlined in Table 51.7. These will occur to varying degrees depending on the combination of drugs and the doses used as well as individual patient factors.

Nausea and vomiting

Nausea and vomiting is the most distressing and most feared adverse effect of chemotherapy. Its effect on the patient should not be underestimated, and its treatment is an important part of supportive care. The severity will depend on the combination of drugs used. For example, oral chlorambucil is generally well tolerated by almost all patients and requires no antiemetic cover. Regimens such as ABVD, which is highly emetic, will make most patients vomit if no antiemetics are given. Aprepitant, an NK1 receptor antagonist, is licensed for cisplatin chemotherapy regimens and may be useful for managing emesis with DHAP, ESHAP, etc. The patient should be counselled on the appropriate use of prescribed antiemetics (see Table 51.7).

Tumour lysis syndrome

The lymphomas are, in general, highly sensitive to chemotherapy. The resulting lysis of cells which occurs following initiation of chemotherapy may lead to hyperuricaemia,

Table 51.7 Adverse effects associated with chemotherapy regimens used in the lymphomas with supportive measures and counselling points

Adverse effect	Cytotoxics implicated	Supportive measures	Counselling points
Bone marrow suppression	Chlorambucil Cyclophosphamide Dacarbazine Etoposide	Blood transfusion Platelet transfusions Mouth care Antibiotic therapy for febrile episodes	Expect tiredness Report bleeding or unusual bruises Importance of good personal hygiene Adhere to mouth care regimen
	Vinblastine	Granulocyte-colony stimulating factor (GCSF)	Avoid people with infections
	Prednisolone		Monitor temperature Report febrile episodes or signs of infection immediately
Nausea and vomiting Mucositis	Cyclophosphamide Doxorubicin	Antiemetic therapy	Emphasise regular use. A short course is more effective than 'as required' treatment
	Procarbazine Dacarbazine		Take tablets before meals Report episodes of vomiting (especially if taking oral cytotoxics). For dexamethasone, emphasise short course not to be continued to ensure the patient does not receive repeat prescriptions from primary care doctor
	Doxorubicin	Mouth care regimen	Importance of good oral hygiene, instruct how mouth-washes are used, stress importance of regular use
Tumour lysis syndrome	High tumour load sensitive to chemotherapy	Hydration, allopurinol	Stress importance of regular allopurinol until appropriate to stop
		Rasburicase	Drink plenty of fluids
Alopecia	Cyclophosphamide Doxorubicin, etoposide	Provision of wig if wanted	Hair usually regrows on completion of therapy
Impaired gonadal function	Alkylating agents Procarbazine, doxorubicin (to a lesser degree)	Sperm storage	Refer to doctor, depends on regimen, reversible in some cases
Neuropathy	Vincristine	Discontinue use or substitute vinblastine	Report tingling sensations or difficulty with buttons, jaw pain or stiffness
Constipation			Do not self-treat but refer to doctor
Cardiomyopathy	Doxorubicin		Report breathlessness, tiredness
Lung fibrosis	Bleomycin		Report breathlessness

hyperkalaemia and hypocalcaemia in patients with bulky disease, and result in urate nephropathy. There is a high incidence of tumour lysis syndrome (TLS) in tumours with high proliferation rates and tumour burden such as Burkitt's lymphoma and T-lymphoblastic lymphoma. The mainstay of TLS prevention is hydration with the patient encouraged to maintain a high fluid intake. Hyperuricaemia is controlled with allopurinol and close monitoring of renal function, serum urate levels and electrolytes. Allopurinol must be commenced before chemotherapy and continued until the tumour load has reduced and serum urate levels are normal. In aggressive forms of NHL, rasburicase, a recombinant urate oxidase, may be indicated as prophylaxis. Allopurinol should not be prescribed concurrently with rasburicase because it will inhibit the production of uric acid, the substrate for rasburicase.

Rasburicase can also be used to treat TLS but will only correct hyperuricaemia. Treatment of TLS should include vigorous hydration and diuresis. Historically alkaline diuresis has been recommended, but overzealous alkalinisation can lead to problems such as metabolic acidosis (Cairo and Bishop, 2004). Hypocalcaemia should be corrected if the patient is symptomatic, but this may increase calcium phosphate deposition. Hyperkalaemia and hyperphosphataemia should be corrected; patients may require haemofiltration or dialysis.

Mucositis

Chemotherapy may cause mucositis, which is inflammation of or damage to the surface of the gastro-intestinal tract. In the mouth, this may lead to painful ulceration, local infection and difficulty in swallowing. Dependent on the severity of mucositis, patients may require analgesia from benzydamine mouthwash to systemic opiates. Disruption of the mucosal barrier will give bacteria and fungi easier systemic access. A mouth care regimen should therefore be instituted with myelosuppressive therapy. This involves good oral hygiene, for example, gentle brushing with a toothbrush to remove plaque or rinsing with saline to remove debris. An antiseptic mouthwash such as chlorhexidine 0.2% should also be used regularly to prevent infection. Palifermin, keratinocyte growth factor (KGF), may have a role in autologous haemopoietic stem cell support.

Bone marrow suppression

Myelosuppression is usually the dose-limiting factor with these regimens, and it is necessary to carry out FBCs before treatment to confirm that recovery has occurred. Each chemotherapy protocol should be referred to so as to ensure appropriate management. Generally, if the platelet count is below 100×10^9 L^{-1} and/or the absolute neutrophil count (ANC) is less than 1×10^9 L^{-1}, the subsequent dose may be reduced or treatment delayed by a week.

Anaemia is treated with blood transfusions and thrombocytopenia with platelet transfusions as necessary. Erythropoietin administration reduces blood transfusion requirements and can improve quality of life. However, the evidence suggesting improvement in patient survival is inconclusive.

Neutropenia is the most life-threatening acute toxicity; the neutropenic patient is at constant risk from infections. Seemingly minor infections such as cold sores can spread rapidly, and infections not seen in the normal population, such as systemic fungal infections, can occur. Supportive measures involve reducing the risks and the aggressive treatment of any infectious episodes. The patient is counselled to avoid contact with people with infection or those who may be carriers. Most infections, however, are from an endogenous source such as the gut or skin. The patient is educated on the importance of good personal hygiene, mouth care, how to monitor body temperature and to report any febrile episodes immediately. Co-trimoxazole 960 mg may be prescribed as prophylaxis against *Pneumocystis* pneumonia in patients receiving chemotherapy for lymphomas, particularly in those receiving a regimen containing fludarabine. Thorough and frequent hand washing helps to prevent the transmission of opportunistic infection to the neutropenic patient.

Febrile neutropenia

A febrile episode in the neutropenic patient is an indication for immediate treatment with broad-spectrum intravenous antibiotics. Susceptibility to infection is likely when the neutrophil count is less than 1×10^9 L^{-1} with increasing risk at levels less than 0.5×10^9 L^{-1} and 0.01×10^9 L^{-1}. Fever, usually defined as a temperature above 38 °C maintained for 1 h or 38.3 °C on one occasion, may be the only sign of infection. The patient should be assessed to determine the site of infection, if possible. Blood cultures from all venous access ports and any other appropriate cultures, for example, midstream urine sample and stool sample, are taken and then antibiotic therapy commenced. Blood cultures are taken prior to starting antibiotics to increase the likelihood of obtaining a positive culture. Infection with Gram-negative bacilli, for example, *Escherichia coli*, *Klebsiella pneumoniae* and *Pseudomonas aeruginosa,* and Gram-positive cocci, for example, coagulase-negative staphylococci, β-haemolytic streptococci, enterococci, and *Staphylococcus aureus* is probable in this situation. First-line therapy should cover these common pathogens. Options include carbapenems, a third-generation cephalosporin or antipseudomonal penicillin with or without an aminoglycoside. If the patient does not respond to this combination within 24–48 h, then second-line therapy, which may include a glycopeptide for Gram-positive cover, is commenced.

Gram-positive infections are becoming more common with the use of indwelling intravenous catheters. If positive microbiological cultures are found, the appropriate antibiotic can be prescribed on the basis of sensitivities; however, if the patient is responding to empiric therapy, the antibiotics should not be changed. Only one-third of suspected infections are ever confirmed, and the pathogen may not be isolated. The febrile episode may not be due to infection; non-infectious causes include blood transfusion and underlying disease.

Growth factor support

Patients with persistent neutropenia or those who have repeated admissions for neutropenic sepsis may be supported with granulocyte-colony-stimulating factor (GCSF). There is evidence that patients with lymphomas receiving a reduced dose of chemotherapy as a consequence of myelosuppression have a worse prognosis when compared with patients who receive full doses. GCSF is indicated as primary prophylaxis, before any episode of febrile neutropenia, for regimens where there is a high (>40%) incidence of febrile neutropenia. GCSF has been investigated as a prophylactic measure to increase the dose intensity of chemotherapy in regimens such as CHOP-14 (cyclophosphamide, hydroxydaunorubicin (doxorubicin), Oncovin (vincristine), prednisolone at 14-day intervals) and BEACOPP-14 (bleomycin, etoposide, Adriamycin (doxorubicin) cyclophosphamide, vincristine, procarbazine, prednisolone at 14-day intervals).

Case studies

Case 51.1

Mr RB is a 50-year-old man receiving a course of fludarabine and cyclophosphamide (see Table 51.5) for mantle cell lymphoma. He has no other medical problems and has normal renal and hepatic function.

Questions

1. What are the key counselling points for the oral chemotherapy drug fludarabine?
2. What antibacterial agent would you expect to see prescribed with fludarabine?
3. What antiemetic regimen would you recommend with the fludarabine and cyclophosphamide?

Answers

1. Immunocompromised patients, for example, those receiving purine analogues, fludarabine, cladribine and pentostatin, are at risk of developing transfusion-associated graft versus host disease (TAGVHD), a rare but usually fatal complication of transfusion.

   Viable T-lymphocytes in donated blood can recognise the recipient as 'foreign', leading to fever, skin rash, hepatitis and bone marrow involvement. Death occurs in 90% of cases, predominantly due to infection.

   γ-Irradiation of cellular blood components is the mainstay of TAGVHD prevention. Patients should be given an appropriate patient information leaflet and an alert card. The risk of TAGVHD is minimised by informing transfusion staff and the patient of their need for irradiated blood products.
2. Mr RB should be prescribed co-trimoxazole prophylactically to prevent *Pneumocystis jiroveci* infection.
3. Chemotherapy drugs are grouped by how likely they are to cause emesis if antiemetics are not given, called emetogenic potential. Antiemetic regimens are then prescribed to prevent the degree of vomiting expected for each group.

   Fludarabine is rarely emetogenic and oral cyclophosphamide is moderately emetogenic. Therefore, the regimen should be classified and treated as moderately emetogenic.

Dexamethasone, granisetron and metoclopramide are frequently employed for moderately emetogenic regimens. Guidelines for antiemetic use in oncology are available (American Society of Clinical Oncology, 2006). As corticosteroids are associated with immunosuppression, some clinicians prefer not to use them for emesis prevention with FC chemotherapy.

Case 51.2

Mrs BC is a 72-year-old widow who has been newly diagnosed with low-grade NHL. She has been seen in the hospital outpatient haematology clinic and has brought a prescription to the pharmacy for chlorambucil 10 mg daily for 14 days. When she hands in her prescription, she expresses concern about the side effects of the tablets. The doctor who saw her had spent a lot of time talking to her about her treatment, but she feels confused with all the information given.

Questions

1. What are the side effects of chlorambucil?
2. How would you counsel this patient?

Answers

1. Chlorambucil, an alkylating agent, is generally well tolerated. The major side effect is bone marrow suppression. Other side effects are uncommon and include nausea and vomiting, rash, mucositis and diarrhoea. Hepatotoxicity and jaundice have been reported. Mrs BC is an elderly patient and is thus more likely to experience toxicity because of deteriorating renal and hepatic function and underlying medical conditions.
2. Mrs BC may be distressed by her diagnosis and may not have been able to absorb all the information she was given in the clinic. She may also be seeking confirmation of information.

   Mrs BC should be counselled to complete the course of tablets as prescribed. She should be told that she will probably feel tired and be more prone to infection because the tablets lower the blood count and resistance to infection. She should be advised to inform the haematologist if she feels unwell. Chlorambucil is unlikely to make her feel nauseous, but if this occurs she should inform the doctor, who will be able to prescribe an antiemetic.

Case 51.3

Mr F is 56 years old and was diagnosed with stage III high-grade NHL (DLBCL) over 10 weeks ago. Since then, he has received three cycles of R-CHOP and has come to the hospital for his nadir blood count. He complains of painful mouth ulcers and a sore throat. On examination, he has mucositis and oropharyngeal candidiasis. He has a white blood cell count (WCC) of 3.2 (normal range: 3.5–11 × 10^9 L^{-1}) with ANC of 0.8 × 10^9 L^{-1}.

Questions

1. How would you treat Mr F's *Candida* infection?
2. How would you counsel this patient?

Answers

1. Mr F has an ANC of 0.8 × 10^9 L^{-1} and is therefore neutropenic (ANC <1.0 × 10^9 L^{-1}). Localised candidal infections can spread rapidly in the immunosuppressed patient, so local therapy with

an antifungal mouthwash will be inadequate therapy. A course of fluconazole, 100 mg daily for at least 7 days, should be prescribed. Therapy should continue for a further 7 days if Mr F is still neutropenic or if the thrush has not completely resolved.

An antibacterial mouthwash, such as chlorhexidine 0.2% 10 mL four times daily, should be used. As Mr F is complaining of pain, an analgesic should be added. Benzydamine mouthwash, a locally acting analgesic, could be prescribed initially. If this does not give adequate pain relief, then systemic analgesics such as dihydrocodeine should be given.

2. Regular mouth care reduces the risk of infection but does not entirely remove it. It is not necessarily a reflection of how well the patient has adhered to his mouth care regimen. Chlorhexidine mouthwash should be used first, held in the mouth as long as possible, ensuring the entire mucosa is covered before spitting out. The mouthwash should be used after meals and at bedtime. He should not eat or drink for at least half an hour after using the mouthwash.

The benzydamine mouthwash should be used before meals as Mr F will probably find eating painful. He should be advised to use a soft toothbrush, to eat soft foods and to avoid hot and spicy dishes. He may be reassured that once his blood count recovers, his mouth ulcers should resolve and that the fluconazole should relieve his sore throat.

Case 51.4

Mr D, 38 years old with advanced HL, is admitted to the haematology ward at the local hospital as an emergency. He had a temperature of 39 °C on the morning of admission, feels generally unwell but has no specific symptoms. It is 12 days since he started his third cycle of ABVD. On admission, he is taking the following medication:

- **co-trimoxazole 960 mg twice daily on 3 days a week**
- **chlorhexidine 0.2% mouthwash 10 mL four times daily**

Blood cultures are taken and piperacillin + tazobactam 4.5 g i.v. three times daily and gentamicin 480 mg i.v. once daily are prescribed, to be commenced immediately. Blood biochemistry results are normal; his FBC was Hb 10.8 (normal range: 13.5–18.0 g/dL for men), WCC 2.5 (normal range: 3.5–11 × 10^9 L^{-1}), neutrophil count 0.6 (normal range: 1.5–7.5 × 10^9 L^{-1}) and platelets 150 (normal range 150–400 × 10^9 L^{-1}). Mr D weighs 86 kg and is 186 cm tall.

....

Questions

1. Comment on the rationale for the antibiotic therapy prescribed.
2. How would you monitor this patient?
3. What would be an appropriate second-line regimen if he remains pyrexial?
4. What modifications would need to be made to subsequent cycles of chemotherapy?

....

Answers

1. Mr D's FBC is probably at its nadir following his last course of chemotherapy. He is neutropenic and febrile; fever is often the only sign of infection in neutropenic patients. Immunosuppression is also a feature of HL and contributes to susceptibility to infection. Treatment should commence immediately after cultures have been taken, as infection can be rapidly fatal in these patients. The antibiotics selected should provide broad-spectrum cover and follow local policy as there are institutional variations in predominant pathogens and antimicrobial sensitivities. The organisms responsible for infectious episodes are constantly changing: in the 1970s, Gram-negative infections predominated but now Gram-positive organisms account for 65% of positive cultures. As Gram-negative infections are more rapidly fatal, first-line therapy should be biased towards these infections. Piperacillin, an antipseudomonal penicillin, and gentamicin therefore form an appropriate combination to use in this patient. Piperacillin + tazobactam monotherapy may be sufficient in cases of uncomplicated neutropenic sepsis.

The dose of piperacillin + tazobactam is appropriate. Infection is considered to be severe in these patients as signs and symptoms are often muted. Single daily dose gentamicin is at least as effective as multiple dosing and less nephrotoxic; it is more convenient and cost effective and overcomes deficiencies of the traditional method such as subtherapeutic dosing and inadequate monitoring. The dose is 5–7 mg/kg and has been calculated correctly for Mr D. He has normal renal function, so no dose modifications are necessary.

2. Monitor temperature, pulse and blood pressure and any patient symptoms for signs of improvement or deterioration. Blood biochemistry should be checked daily to detect any deterioration in renal function. Microbiology reports should be checked and antibiotics reviewed if any micro-organisms have been cultured. However, no change should be made to antibiotics if the patient is showing signs of improvement. The administration of gentamicin should be monitored, checking both administration and sampling time for drug levels. The results should be checked and recommendations for dose modification made where appropriate, using a method such as the Hartford monogram.

3. If the patient remains pyrexial 24–48 h after the first-line antibiotics have been commenced, consideration should be given to broadening cover, for example, adding vancomycin if the patient has mucositis or line infection. If blood cultures show growth, found in only 30–40% of neutropenic patients, the choice of antibiotics should be on the basis of sensitivities. It is important to note that febrile episodes lasting several days may involve more than one infecting organism.

The patient's FBC should start to recover from day 14 but may be delayed by this infection. It is unusual for patients on conventional chemotherapy for HL to require more than one change to antibiotic therapy, and clinical improvement is often seen with recovery of neutrophil count. If Mr D is still pyrexial at 96 h, then the likelihood of fungal infection must be considered and an intravenous amphotericin-based product or caspofungin commenced if appropriate. The incidence of fungal infection is increasing in patients with prolonged neutropenia. As Mr D's neutropenia is short lived, he is more likely to have a bacterial infection.

4. A dose reduction for subsequent cycles of chemotherapy may be considered. However, as this patient is being treated with curative intent, it may be more appropriate to give GCSF and maintain the dose intensity.

52 Solid tumours

N. Wood and A. Lamont

Key points

- Cancer involves a group of relatively normal cells dividing without the controls that usually prevent the cells from growing beyond their usual size, site and nutritional base.
- Cancer is now considered a long-term illness with many subgroups.
- Cancer is a collective term for several diseases each with its own characteristics and natural history according to where it has started. Even for a single site of origin, such as breast cancer, major biological and histological differences can be shown.
- Before treatment, patients must be carefully 'staged' to establish the type and extent of disease.
- Depending on the stage of disease, the aim of treatment may be cure, prolongation of survival or symptom control.
- Cytotoxic chemotherapy is the main treatment for disseminated disease.
- Treatment options depend not only on the 'gold standard' of treatment but also patient factors and preferences.
- Targeted medical therapies are becoming more common, generally have fewer side effects and are given over a longer term than conventional chemotherapy.

The term 'cancer' is used to describe more than 200 different diseases, including those affecting discrete organs (solid tumours) and haematological malignancies (which are not localised in the same way). Whereas some tumours are benign and may be harmless, this chapter will focus on the management of patients with solid malignancies which require some form of treatment. Treatment is generally carried out in specialised cancer centres, cancer units or for some agents, in the patient's home. Therapy may include surgery, radiotherapy, chemotherapy and biological or targeted therapy as single modalities or in combination. Care of the cancer patient demands a broad range of services involving a multidisciplinary team working across the hospital, community and hospice network.

Epidemiology

Cancer is a common disease, and more than one in three people will develop some form of cancer in their lifetime. Although more than a quarter of a million people develop cancer each year in the UK, it is predominantly a disease of the elderly, with 74% of new cases diagnosed in people aged over 60 years. Of all deaths in the UK, one in four is due to cancer. The most common single cause of death (22%) is lung cancer, which is potentially preventable by a reduction in tobacco smoking.

Prostate cancer is now the most common cancer in men (24%) followed by lung (15%) and bowel (14%) cancer. In women, breast cancer is the most common (31%) followed by bowel (12%) then lung (12%). However, there are regional variations. From 1979 to 2008, mortality rates from cancer fell by 20% (Cancer Research UK, 2010).

Aetiology

The causes of cancer may be categorised as either environmental or genetic, although these may be interrelated and the causes of some cancers may be multifactorial.

Environmental factors

Increasingly, lifestyle factors play a large part in the development of many cancers. Cigarette smoking has been identified as the single most important cause of preventable disease and premature death in the UK. The beneficial effect of stopping smoking on the cumulative risk of death from lung cancer reduces with increasing age (Doll et al., 2004). Smoking causes about 90% of lung cancer deaths, and the link between tobacco and cancer was established more than 50 years ago.

The most important lifestyle factor for bowel cancer is diet, while cervical cancer is primarily linked to sexual behaviour through the transmissible agent human papilloma virus (HPV) and secondarily to smoking.

Table 52.1 lists a number of other factors which have been associated with cancer development.

Genetic factors

A number of rare tumours are known to be associated with an inherited predisposition, where an individual is born with a marked susceptibility to cancer. This is due to the inheritance of a single genetic mutation which may be sufficient to greatly increase the risk of one or more types of cancer. Examples include the paediatric malignancies, Wilms' tumour of the kidney and bilateral retinoblastoma, a rare cancer of the eye. Some common cancers such as breast, ovarian and colorectal

Table 52.1 A–K of factors associated with specific cancer sites: An empirical basis for recommending lifestyle changes (Jankowski and Boulton, 2005)

Factor	Associated cancer
Alcohol consumption >3 units a day	Most squamous cancers, especially bladder and oesophagus
Body mass index >25 and certainly >30	All solid cancers
Cigarette smoking at any level (even passive smoking)	Bladder, lung, head and neck, oesophagus and oropharyngeal cancers
Diet, especially one that is high in fat	All solid cancers
Exercising <30 min a day	All solid cancers
Family history of cancer (in at least one first-degree relative and at least three people in two or more generations)	Inherited cancer syndromes, including breast, colorectal, diffuse gastric, ovarian, prostate and uterine cancers
Genital and sexual health (sexually transmitted infections)	Cervical cancer
Health-promoting drugs that may decrease global cancer risks (but need a careful risk/benefit analysis)	Colonic adenomas can be treated with low-dose aspirin but can have serious side effects Hormone replacement therapy linked with breast cancer
Intense sunburn	Melanoma
Job-related factors	Lung cancer (exposure to asbestos and particulates), skin cancer (contact with arsenic)
Known disease associations	Colorectal cancer has predisposing mucosal pathology – adenomas, coeliac disease, ulcerative colitis

cancer may also show a tendency to occur in families, but these represent a small proportion of the overall presentation of common cancers where identifiable risk factors are relevant in only 5–10% of cases, although when the genetic factor is present the cancers tend to have their onset at a younger age (Garber and Offit, 2005).

Screening and prevention

Screening

Screening programmes aim to detect pre-malignant changes or early-stage cancer in asymptomatic individuals in the general population to provide earlier and thus more effective treatment. Any screening test must be simple, reliable, highly specific (to exclude healthy individuals) and highly sensitive (detection: 90–95%). For a screening programme to be effective in reducing morbidity and mortality, there must also be an available, effective, safe and economically viable treatment that can be applied to the abnormalities detected by the screening test. Screening is well established for cancers of the breast, cervix and, more recently, bowel. Population screening for prostate cancer using the prostate-specific antigen (PSA) blood test remains more controversial due to the lack of specificity and sensitivity of the test, and to the limited evidence on the viability and effectiveness of the treatment options in early-stage disease. It is currently not recommended for use in screening programmes in the UK

but is used in the USA. The evidence base for ovarian cancer screening using the blood test CA125 and pelvic ultrasound is evolving through clinical trials.

Prevention

The strong association between cancer risk and lifestyle factors means there is great potential for the primary prevention of cancer through:

- Avoiding tobacco use, especially exposure to cigarette smoke
- Moderate alcohol consumption
- Healthier eating
- Limiting exposure to sunlight and artificial tanning UV exposure
- Encouraging physical exercise
- Maintaining a healthy body weight
- Maintaining adequate protection from asbestos fibres, radon and other occupational and environmental risk factors.

Chemoprevention

Chemoprevention is the prevention of cancer by using medication. The most common example is tamoxifen (pre-menopausal women) or an aromatase inhibitor (post-menopausal women) prescribed daily for 5 years to reduce the risk of developing breast cancer in high-risk women. However, these treatments are not without their side effects, such as menopausal symptoms and increased risk of thromboembolic events. Therefore, the risk-benefit ratio to each patient needs to be carefully assessed.

Another potential future development is the effect of aspirin as a chemopreventive agent for colorectal cancer. Maximal effect requires long-term use of high-dose aspirin that may increase the risk of gastro-intestinal bleeding. Non-steroidal anti-inflammatory drugs (NSAIDs) and selective cyclooxygenase-2 (COX-2) inhibitors may also be candidates for chemoprevention. However, the regular use of these drugs may also cause gastro-intestinal bleeding and increase the risk of cardiovascular events (Herszényi et al., 2008)

Cancer at the cellular level

Cancer arises from the changes in genes that regulate cell growth. For a normal cell to transform into a cancer cell, genetic changes must occur to the genes that regulate cell growth and differentiation. The nature of the genetic change may be a single point change to a DNA nucleotide, or the complete loss/gain of an entire chromosome. However, the most important factor is that a gene which regulates cell growth and/or differentiation must be altered to allow the cell to grow in an uncontrolled manner. Most cancers require a series of genetic mutations in a cell before an invasive tumour results.

Oncogenes

Oncogenes are where the normal gene, called a proto-oncogene, mutates and is then expressed at inappropriately high levels, therefore increasing the function of that gene. Examples of proto-oncogenes are genes that encode growth factors, signal transducers and transcription factors.

Tumour suppressor genes

Tumour suppressor genes are normal genes which have a protective effect against oncogenes, and are also known as 'anti-oncogenes'. The tumour suppressor gene's normal function is usually to control the cell cycle or act as a check point in division. When this function becomes lost due to mutations affecting both copies of the gene in a potentially malignant cell, other genetic mutations have a greater likelihood of progressing to cancer. An example is the *TP53* gene which codes for the suppressor protein product p53.

The p53 protein acts as a regulator of cell growth and proliferation and controls passage from G1 to S phase in cell division (see Fig. 52.1). Agents which damage DNA cause p53 to accumulate. This accumulation of p53 switches off replication in the cell, arresting the cell cycle and allowing time to repair. If repair fails, p53 may trigger cell suicide by apoptosis. Thus, p53 controls and halts the proliferation of abnormal cell growth.

The cancer cell

Cancer cells differ from normal cells in that they function differently. Inherently unstable, they may display different protein or enzyme content and chromosomal abnormalities (such as translocations or deletions) which may be associated with
Fig. 52.1 Normal cell cycle.

differences in their susceptibility to chemotherapy or radiotherapy. The changes in internal structure and function lead to changes in their appearance which are visible under light microscopy, for example, larger and more varied appearance of the cell nuclei, and loss of the appearances of specialised cell function such as gland formation. This allows them to be easily detected, particularly when these lead to changes in the way clusters of cells form structures as a group and relate to normal cells in a tissue or organ.

Tumour growth

A solid tumour represents a population of dividing and non-dividing cells. The time it takes for a tumour mass to double is known as the doubling time. The latter will vary depending on the type of tumour but for most solid tumours it is about 2–3 months. In most solid tumours, the growth rate is very rapid initially (exponential growth) and then slows as the tumour increases in size and age, a pattern described as Gompertzian growth (see Fig. 52.2). The growth fraction is the percentage of actively dividing cells in the tumour, and this decreases with increasing tumour size.

This pattern of tumour growth kinetics has implications for chemotherapy treatment. Generally, chemotherapy is most successful when the number of tumour cells is low and the growth fraction high, which is the situation in the very early stages of cancer.

Tumour spread

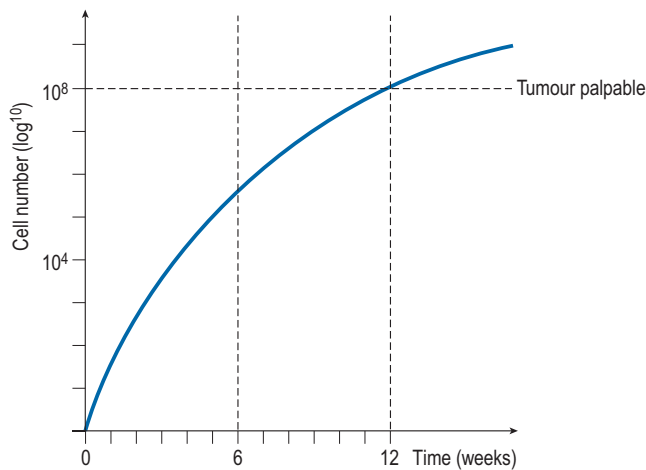
As a primary tumour grows, it both pushes the normal surrounding cells aside and invades between them into normal tissue. It is this property of invasion that characterises a


Fig. 52.2 Example of Gompertzian growth of cancer cells.

malignant tumour and leads to distant spread of the disease, since the abnormal cells often infiltrate through the walls of blood vessels and the lymphatic system. Malignant cells are then released from the infiltrating cluster of tumour cells and are transported by the blood or lymphatic fluid to other organs of the body where they can subsequently form secondary cancers or metastases. The pattern of spread tends to be predictable for different tumour types, influenced by the anatomy of the primary site and by differences in the local factors affecting the viability of malignant calls when they become deposited elsewhere. For example, breast cancer usually metastasises to the lymph nodes under the arm, lungs and central nervous system, while prostate cancer tends to metastasise to bone. Generally, when the primary is first detected, the larger the tumour mass the more likely that it has metastasised to other sites.

Patient management

Clinical assessment

Presentation

The clinical features of cancer vary with tumour type. Generally, patients most commonly present with non-specific complaints which include weight loss, unexplained anaemia, malaise, lethargy or pain, or they may have a specific localising symptom such as bleeding from an identifiable site, a non-healing ulcer, a minor symptom such as a cough or hoarseness not resolving in the usual way or the presence of a painful or painless lump. In general, solid tumours are first clinically detectable when there are approximately 10^8–10^9 tumour cells present in a tumour mass in the range of 1–10 g. The patient is usually in the terminal stages of the disease when there are 10^{12} cells present and a tumour burden of around 1 kg. A tumour may be detected by chance during a routine physical examination or by screening or through identification of early symptoms. However, if this does not occur or these symptoms are not present or not recognised, then the disease at presentation is commonly at a stage where there is a high risk that

metastatic spread has already occurred at a microscopic level even if that is not clinically detectable.

Before treatment, each patient must undergo a thorough assessment to establish diagnosis, stage of disease and general fitness level. These factors will influence the choice of treatment and give a guide to prognosis.

Diagnosis

An accurate diagnosis is usually made from a tissue sample taken from a suspected primary or secondary tumour, according to the initial clinical investigations. This sampling procedure, biopsy, may be obtained by an open operation, or less invasively by endoscopy. Such samples may be obtained, for example, during bronchoscopy when lung cancer is suspected or, as in the case of a patient presenting with a breast lump, aspiration through a fine needle.

Malignant tumours vary in their sensitivity to chemotherapy. For example, there are two major groups of lung cancer: small-cell and non-small-cell lung cancer. Each of these groups is treated with different combinations of surgery, radiotherapy and chemotherapy drugs. Therefore, precise histopathology is important.

Tumour markers

Tumour markers are usually proteins associated with a malignancy and are clinically useful to:

- Diagnose a specific tumour
- Monitor response to treatment
- Estimate prognosis
- Detect recurrent disease
- Screen a healthy population or a high risk population for the presence of cancer.

They may be detected in a solid tumour, in circulating tumour cells in peripheral blood, in lymph nodes, in bone marrow or in other body fluids. A number of the tumour markers are presented in Table 52.2.

Staging investigations

Since the cancer is often disseminated at the time of presentation, it is vital that patients undergo thorough staging investigations to establish the extent and nature of disease. This will determine the most appropriate treatment offered to the patient. Baseline investigations range from clinical examination, blood tests, liver function tests, diagnostic imaging such as chest and skeletal X-rays, ultrasound, computed tomography (CT), magnetic resonance imaging (MRI) and positron emission tomography (PET), depending on the disease type and likely pattern of spread. Clinical guidelines for staging and management of malignancies of the various body systems have been produced at local and national level in most developed countries, with relatively minor variations according to local custom and practice (e.g. NICE in UK, see http://www.nice.org.uk/ for guidance and NCI in USA, see http://www.cancer.gov/ for guidance).

Table 52.2 Examples of tumour markers used in detection, diagnosis and monitoring

Tumour marker	Indicative cancer
CA125	Ovarian cancer, although non-specific
α-Fetoprotein (AFP) β-Human chorionic gonadotrophin (β-HCG)	Testicular tumour
5-Hydroxyindole acetic acid (5HIAA)	Carcinoid tumours
Thyroglobulin	Thyroid cancer
α-Fetoprotein	Hepatocellular carcinoma
Prostate-specific antigen	Prostate cancer
Human chorionic gonadotropin	Gestational trophoblastic tumours

Box 52.1 Performance status scales

Karnofsky performance index
100 Normal, no complaints, no evidence of disease
90 Able to carry on normal activity, minor signs or symptoms of disease
80 Normal activity with effort, some signs or symptoms of disease
70 Cares for self, unable to carry on normal activity or do active work
60 Requires occasional assistance but is able to care for most of own needs
50 Requires considerable assistance and frequent medical care
40 Disabled, requires special care and assistance
30 Severely disabled, hospitalisation is indicated, although death is not imminent
20 Very sick, hospitalisation necessary, active supportive treatment is necessary
10 Moribund, fatal processes progressing rapidly
WHO performance scale
0. Able to carry out all normal activity without restriction
1. Restricted in physically strenuous activity but ambulatory and able to carry out light work
2. Ambulatory and capable of all self-care but unable to carry out any work; up and about more than 50% of waking hours
3. Capable of only limited self-care; confined to bed more than 50% of waking hours
4. Completely disabled; cannot carry on any self-care; totally confined to bed or chair

Staging classification

Staging is essentially a measure of how far a tumour has progressed in its development at the time of diagnosis, while grading is a measure of how aggressive its behaviour is likely to be in future based on the microscopic appearance of the cells of the tumour. Both measures are relevant to the patient and clinical team in planning the management.

Most tumours are classified according to the TNM (tumour–nodes–metastases) system where T (0–4) indicates the size of the primary tumour, N (0–3) the extent of lymph node involvement and M (0–1) the presence or absence of distant metastases. Each solid tumour site has a specific grading and staging classification such as Dukes staging in colorectal cancer (Cancer Research UK, 2009) and Gleason scoring for grading prostate cancer (Berney, 2007).

Performance status

The patient's general level of fitness (performance status) at the time of diagnosis is often a surprisingly reliable indicator of prognosis independent of disease-related factors, and will help determine if they are likely to withstand intensive chemotherapy; this therefore influences the choice of treatment. A number of physical rating scales have been devised to assess performance status, including the Karnofsky performance index (Karnofsky and Burchenal, 1949) and the World Health Organization (WHO) performance scale (Box 52.1).

Prognostic factors

These are factors that can predict how the disease is likely to behave and determine an outcome in individual patients. For example, Table 52.3 lists prognostic factors in patients with colorectal cancer.

Table 52.3 Prognostic factors in patients with colorectal cancer

Favourable	Unfavourable
Good performance status	Presence of nodal involvement
No penetration of the tumour through the bowel wall	Presence of distant metastases
Absence of nodal involvement	Bowel obstruction and bowel perforation
Absence of distant metastases	

Treatment

Treatment goals

After the diagnosis of cancer has been confirmed and the extent of disease fully investigated, the goals of treatment have to be considered. Depending on stage of disease, the goal can be the following (and may change throughout treatment):

- Cure – Patients are said to be 'cured' of cancer when they are completely disease free and have a normal life expectancy. The smaller the tumour bulk when treatment is given, the greater the potential of achieving cure. A common measure of 'cure' is the 5-year disease-free survival rate
- Prolong survival while maintaining patient quality of life
- Provide palliative care with relief of symptoms such as pain.

Childhood malignancies, choriocarcinoma and testicular tumours in adults are most responsive to chemotherapy and these patients are frequently cured, even with advanced disease. However, for most patients treated with chemotherapy, cure is less likely and treatment will be given to maximise the probability of cure, prolong survival or be purely palliative. The decision is influenced by factors such as the extent of the disease as well as co-existing symptoms and concurrent medical conditions, performance status and, importantly, the patient's wishes. The possibility of medium-to long-term survival justifies aggressive treatment but with palliative therapy it is particularly important that the toxicity of treatment is carefully weighed against the potential benefits.

Treatment guidelines

Consensus on the best approach to managing each particular type of cancer is continually evolving, based on the evidence from clinical research most reliably in the form of randomised controlled trials. National guidelines aim to promote equity for patients and ensure a consistent treatment approach taking account of the boundaries of affordability for the healthcare system. In the absence of clinical consensus, patients should be encouraged to participate in clinical trials.

Treatment methods

Three main options are available for the treatment of patients with solid tumours: surgery, radiotherapy and chemotherapy. Targeted and biological therapies are at present minor modalities, and it is hoped that these will be employed more as their effectiveness improves. Each treatment may play a number of roles, either alone or in combination, depending on the disease, stage and grade.

Role of surgery

Surgery can be curative when solid tumours are confined to one primary anatomical site or region as in localised disease. It can also be used to remove isolated metastatic masses with curative intent in rare circumstances or to deal with anatomical consequences of a tumour as a palliative procedure, such as relief of bowel obstruction by defunctioning colostomy. Surgical techniques may be used to support chemotherapy administration when given by continuous infusion or by the intraperitoneal route. Surgery may also play a role in diagnosis through tissue biopsy or in staging to ascertain the extent of tumour involvement such as in ovarian cancer. In the latter, it may also be used to debulk or reduce the size of the tumour to effect pain relief or to improve the effectiveness of subsequent radiation or chemotherapy. However, with more widespread disease, systemic treatment becomes necessary, with chemotherapy playing a major role

Role of radiotherapy

Radiotherapy can be used to cure cancer, reduce the symptoms of the tumour, reduce the size of the tumour ready for surgery or to prevent re-occurrence of the tumour after surgical removal. It can be used alone or in combination with surgery and/or chemotherapy. A full exposition of the role of radiotherapy is beyond the scope of this chapter, which concentrates on the role of systemic agents. However, the combination of radiotherapy and systemic treatment is becoming increasingly employed as research shows the benefit to disease control and long-term survival, for example, in carcinoma of the uterine cervix (Green et al., 2009).

Systemic therapy

This encompasses cytotoxic chemotherapy, hormonal, biological and targeted therapies, but the term does not usually encompass the modalities of nutritional, complementary, alternative, or other 'holistic' interventions, even if employed within a conventional medical environment.

Cytotoxic chemotherapy

Chemotherapy regimen

Although chemotherapy is sometimes administered as a single agent, it is more usual to combine two or more drugs to achieve additive or synergistic effects. Generally, drugs used in combination should have established efficacy as single agents, different mechanisms of action and differing toxicity profiles to allow their use at optimal doses.

Chemotherapy scheduling

As chemotherapy does not specifically target malignant cells, any actively proliferating normal cell will be at potential risk of damage, in particular the cells of the bone marrow. This causes a fall in the white blood cell count and with many cytotoxic drugs, the white blood count is at its lowest level (nadir) around 10 days after treatment. Recovery generally occurs by day 20 post-treatment, and therefore chemotherapy treatment is usually repeated every 3–4 weeks. With agents such as mitomycin and lomustine, haematological recovery may be delayed for 42–50 days following treatment, in which case the interval between treatment cycles needs to be increased. In most cases, a course of treatment will comprise a maximum of six cycles of chemotherapy, although in some less common cancers such as sarcomas and in paediatrics, the regime may continue with a much longer period of adjuvant or consolidation therapy.

Figure 52.3 demonstrates the tumour cell kill for each cycle of chemotherapy together with the healthy normal cell kill. Chemotherapy works in situations where the healthy normal cells recover faster or more completely from the effects of chemotherapy compared to the tumour cells. This allows the tumour cells to be progressively killed off, whilst not having a detrimental effect on the patient.

Chemotherapy dose

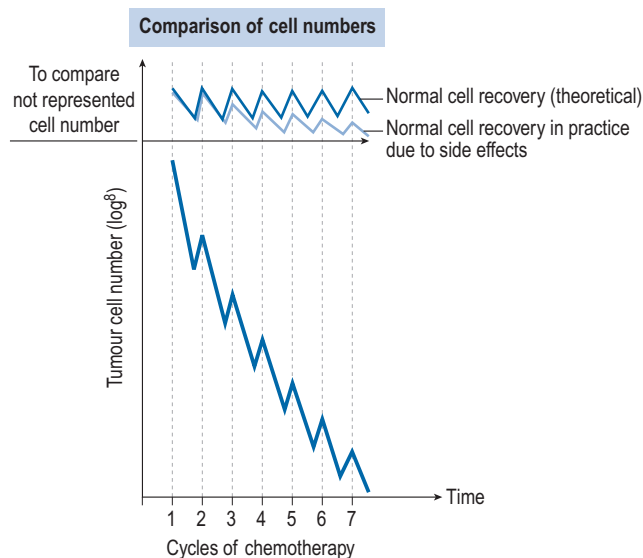
The dose of most chemotherapy agents is calculated using the patient's body surface area (BSA) and is usually given in the form of milligrams per square meter. Body surface area may


Fig. 52.3 The effect of chemotherapy on tumour mass and healthy cells.

be calculated from the height and weight of the patient using a nomogram and may need to be recalculated for subsequent cycles of chemotherapy if the patient experiences significant weight changes. Table 52.4 gives an example of a chemotherapy regimen used in breast cancer. The reliability of body surface area as a predictor of the effective safe dose is diminished for patients who are either very thin (cachectic) or grossly overweight (morbidly obese) since it does not then reflect a reasonable estimate of lean body mass.

Adjuvant chemotherapy

Adjuvant chemotherapy means literally 'additional treatment' and is usually given after surgery or radiotherapy when all detectable disease has been removed, but where there remains

Table 52.4 Example of a chemotherapy regimen FEC–T (Fluorouracil, epirubicin, cyclophosphamide, docetaxel (Taxotere®)) for breast cancer

Indication	Adjuvant Breast Cancer
Length of cycle	21 days
No. of cycles	3 cycles of FEC followed by 3 cycles of Taxotere® (Docetaxel)

FEC		
Fluorouracil	IVB	500 mg/m² day 1
Epirubicin	IVB	100 mg/m² day 1
Cyclophosphamide	IVB	500 mg/m² day 1

T		
Docetaxel	IVI over 1 h	100 mg/m² day 1

IVB, i.v. bolus; IVI, i.v. infusion.

a statistical risk of relapse due to undetectable disease. Adjuvant therapy is, therefore, used to increase the likelihood of cure. Only patients whose cancers have a high or intermediate risk of recurrence tend to be selected for adjuvant chemotherapy since it is not desirable to expose patients whose disease may already have been cured by surgery or radiotherapy to the toxicity of chemotherapy treatment.

In colorectal cancer, for example, adjuvant chemotherapy provides significant disease-free survival benefit by reducing the recurrence rate and also increases overall survival. This indicates the curative role of chemotherapy in the adjuvant setting (Sargent et al., 2009). Similarly, in breast cancer, adjuvant treatment has been shown to increase recurrence-free survival (Levine and Whelan, 2006), and trials are underway to determine which agents and in what combination further improvements in overall survival will be obtained. A recent trial has shown that three-weekly AC/T (doxorubicin, cyclophosphamide, docetaxel [Taxotere®]) is significantly inferior to CEF (cyclophosphamide, epirubicin, 5-flourouricil) or EC/T (epirubicin, cyclophosphamide, docetaxel [Taxotere®]) in terms of recurrence-free survival (Burnell et al., 2010). This is important, as standard treatment choices should move to the superior regimen.

Neo-adjuvant chemotherapy

In neo-adjuvant chemotherapy, chemotherapy is given before local therapy, often preoperatively, to reduce tumour size and facilitate surgical removal. Neo-adjuvant chemotherapy has been of particular value in cases of breast cancer, non-small-cell lung cancer, advanced head and neck cancer, and bone tumours. In Ewings sarcoma, it allows limb-sparing surgery as an alternative to amputation. It also improves survival with reduced morbidity in osteosarcoma.

Synchronous chemoradiation

In several cancers, chemotherapy alongside radical radiotherapy is now established. Agents such as cisplatin are commonly used as a 'radiosensitiser' in head and neck, oesophageal and cervical cancers. The use of cetuximab in combination with radiotherapy for a certain type of head and neck cancer is also recommended (National Institute for Health and Clinical Excellence, 2008). Although common, the use of the term 'radiosensitiser' in this context is somewhat inaccurate and is distinct from the 'true' radiosensitising drugs such as nimorazole, which interact at a chemical level with very short-lived radiation-induced free radicals, and the effect is better termed 'combined modality therapy'.

Adverse effects of cytotoxic drugs

Most cytotoxic drugs have been developed because of their effect on dividing cells. Consequently and as previously mentioned under chemotherapy scheduling, proliferating normal tissue such as bone marrow is at risk. Myelosuppression is frequently the dose-limiting toxicity with these compounds. Neutropenia and thrombocytopenia place patients at risk of life-threatening infection and bleeding, respectively.

The other acute adverse effects occurring most frequently include nausea and vomiting, mucositis, anorexia and alopecia. Individual drugs will also give rise to specific adverse effects, some of which may not be reversible on stopping treatment. Cardiotoxicity, nephrotoxicity and pulmonary toxicity, which are specific to the chemotherapeutic agent or class, may depend on cumulative drug exposure, the schedule of administration and previous therapy. Long-term side effects include infertility due to suppression of ovarian and testicular function and occasionally the induction of a second malignancy.

Chemotherapy-related toxicity is an important issue. Not only can it result in prolonged hospitalisation and a reduction in patients' quality of life, but also successful treatment can be compromised. A reduction in dose intensity, that is the dose of cytotoxic delivered for unit time, because of dose reductions or treatment delays can result in reduced response rates and survival. Recently, the use of granulocyte-colony-stimulating factors (G-CSF) to prevent dose-limiting toxicity of myelosuppression has started to become standard practice. This is often used in adjuvant treatments where the dose intensity given is paramount, and the goal of treatment is cure.

Chemotherapy-specific adjunctive treatments

Both ifosfamide and cyclophosphamide are metabolised to the inactive acrolein which is responsible for bladder toxicity. The co-administration of mesna, a sulphydryl-containing compound which binds to acrolein, has reduced the incidence of haemorrhagic cystitis associated with intravenous regimens of ifosfamide and high-dose cyclophosphamide.

Calcium leucovorin or folinic acid is a reduced form of folic acid and is in effect an 'antidote' to the cytotoxic methotrexate. Folinic acid is effectively used as a form of 'rescue' when high doses of intravenous methotrexate are used to limit the exposure to methotrexate to a defined period of time.

Targeted therapies

In recent years, there has been an increased understanding of biochemical signalling pathways involved in the growth and progression of tumours. This has allowed the development of therapies targeted specifically at the cell receptors involved. A number of these are described. As they are targeted at tumour cells, they suppress disease without inflicting the non-selective toxic effects of cytotoxic chemotherapy on the patient.

Epidermal growth factor receptor

The epidermal growth factor receptor (EGFR) is a transmembrane protein with an intracellular tyrosine kinase domain. Extracellular binding of the epidermal growth factor receptor induces tyrosine phosphorylation which activates signal cascade pathways. These ultimately lead to cellular proliferation and metastasis. Epidermal growth factor receptor expression is low in normal tissues, and overexpression is associated with a variety of tumours including non-small-cell lung cancer, colon, and head and neck.

Inhibitors of epidermal growth factor receptor (also known as human epidermal growth factor receptor type 1 [HER1]) include:

- Small molecules such as the orally administered erlotinib used in the treatment of non-small-cell lung cancer and imatinib used in the treatment of gastro-intestinal stromal tumours (GIST) which specifically inhibit tyrosine kinase.
- Monoclonal antibodies such as cetuximab which binds to the epidermal growth factor receptor. Cetuximab has demonstrated synergy when given in combination with irinotecan chemotherapy, offering prolonged survival in selected patients with metastatic colorectal cancer.

Vascular endothelial growth factor receptor

Angiogenesis is the formation of new blood vessels on which tumour growth depends. Vascular endothelial growth factor (VEGF) is key in angiogenesis and its overexpression has been associated with increased vasculature, aggressive disease and poor prognosis. The monoclonal antibody bevacizumab inhibits VEGF, thereby reducing new blood vessel growth and interstitial pressure within the tumour, allowing improved chemotherapy access. Studies have demonstrated meaningful survival benefits when bevacizumab is administered in conjunction with chemotherapy in patients with advanced or metastatic colorectal cancer (Hurwitz et al., 2004).

Human epidermal growth factor receptor type 2

Overexpression of human epidermal growth factor receptor 2 (HER2) is associated with a particularly aggressive form of breast cancer (about 20% cases are HER2 positive) linked with a poor prognosis. Trastuzumab, a humanised monoclonal antibody, specifically targets human epidermal growth factor receptor 2 and is only effective in patients with elevated levels. It is used widely in metastatic and early breast cancer (National Institute for Health and Clinical Excellence, 2002, 2006a). The use of trastuzumab in other cancers that express human epidermal growth factor receptor 2 is also under investigation. Trastuzumab has also been licensed for use in human epidermal growth factor receptor 2 positive gastric cancer.

Capecitabine

Although capecitabine does not target a particular receptor, it is mentioned in this section, as it preferentially targets tumour cells.

Capecitabine is a fluoropyrimidine carbamate precursor of 5-fluorouracil (5FU). Given orally, it is converted via enzyme pathways to 5-fluorouracil. As these enzymes are found in higher concentrations in tumour cells, treatment is effectively targeted. Capecitabine has been shown to be at least as effective as intravenous 5-fluorouracil (Twelves et al., 2008), and it is widely used in practice. This is of a particular benefit where the total regimen can then be given orally rather than intravenously.

Management of patients receiving cytotoxic chemotherapy

Prescription verification

Over recent years, there has been considerable effort to improve the quality and safety of chemotherapy services for adult patients (National Chemotherapy Advisory Group, 2009). In particular, the importance of all chemotherapy prescriptions being checked by appropriately trained and competent pharmacists is now recognised. A checklist of key points an authorised pharmacist must undertake to verify any prescription for systemic anti-cancer therapy prior to preparation and release has been determined (British Oncology Pharmacy Association, 2010) and is presented in Box 52.2.

Box 52.2 Standards for chemotherapy prescription verification (British Oncology Pharmacy Association, 2010)

1. Check prescriber's details and signature are present and confirm they are authorised to prescribe SACT
2. Ensure regimen has been through local approval processes, for example, clinical governance and financial approval and/or is included on a list of locally approved regimens
3. On the first cycle, check the regimen is the intended treatment as documented in a treatment plan, in the clinical notes or in the electronic record
4. Check regimen is appropriate for patient's diagnosis, medical history, performance status and chemotherapy history (using the treatment plan, clinical notes or electronic record)
5. Check there are no known drug interactions (including with food) or conflicts with patient allergies and other medication(s)
6. Check that the timing of administration is appropriate, that is the interval since last treatment
7. Check patient demographics (age, height and weight) have been correctly recorded on prescription
8. Check body surface area (BSA) is correctly calculated, taking into account recent weight. Note there should be local agreement for frequency of monitoring and checking patient's weight
9. Check all dose calculations and dose units are correct and have been calculated correctly according to the protocol and any other relevant local guidance, for example, dose rounding/banding
10. Check cumulative dose and maximum individual dose as appropriate
11. Check reason for and consistency of any dose adjustments, for example, reduction(s) or escalations and ensure reason is documented
12. Check method of administration is appropriate
13. Check laboratory values, FBC, U&Es and LFTs are within accepted limits if appropriate
14. Check doses are appropriate with respect to renal and hepatic function and any experienced toxicities
15. Check other essential tests have been undertaken if appropriate
16. Check supportive care is prescribed and it is appropriate for the patient and regimen
17. Sign and date prescription as a record of verification

SAT, Systemic anticancer therapy

Cumulative dosing

The use of doxorubicin is limited by a dose-dependent cardiomyopathy. A number of other factors have been implicated, including treatment schedule, patient age and pre-existing cardiac disease, but dose is the most important. The maximum recommended cumulative dose is 550 or $400\,\text{mg/m}^2$ for patients who have received radiotherapy to the mediastinum. Therefore treatment should be monitored closely to make sure the cumulative dose is not exceeded throughout the patient's lifetime. All other anthracycline antibiotics also have a lifetime cumulative dose limit.

Dose modification or delay

Appropriate investigations must be carried out before each treatment to ensure that patients are fit for chemotherapy. In particular, the patient's haematological, renal and hepatic function should be investigated. For some cytotoxic drugs, it may be necessary to adjust the dose, or even stop treatment, in the presence of renal or hepatic impairment to ensure that delayed excretion or reduced metabolism does not result in excess toxicity. Therefore, the individual summary of product characteristics (SPC) for the chemotherapy agent should be consulted and can be found at http://www.medicines.org.uk.

If the bone marrow does not recover sufficiently between cycles of treatment, then a dose reduction or a delay in treatment may be necessary. In general, patients with a neurophil below 1×10^9/L or a platelet count below 100×10^9/L should not be given myelosuppressive cytotoxics at full doses.

Drug interactions

Prescriptions for cancer chemotherapy are often complex, sometimes involving combinations of both parenteral and oral cytotoxic drugs, intravenous fluids and other supportive therapies. The potential for drug interactions to arise is considerable. However, care is required when assessing the clinical significance of potential drug interactions. A documented interaction does not necessarily imply that drugs should not be used together but can necessitate close monitoring of the patient.

Patient information and counselling

All patients must be provided with information about their treatment, including any anticipated side effects. Patients should be encouraged by health professionals to ask questions about their treatment.

Patients must understand the different medication, the specific role of each medicine and duration of treatment. Duration of treatment is particularly important to prevent highly potent medicines from being inadvertently continued beyond their intended course.

Symptom control

Nausea and vomiting

Chemotherapy-induced nausea and vomiting (CINV) is one of the most frequently experienced side effects encountered by chemotherapy patients and is considered to be the most

distressing. In extreme cases, poor symptom control can result in patients refusing further treatment.

In selecting an appropriate anti-emetic regimen, relevant factors include the emetogenic potential of the chemotherapy drugs prescribed, the putative mechanism(s) of inducing emesis, and the likely onset and duration of symptoms. Individual patient characteristics also have to be taken into consideration. For example, predisposing factors which increase a patient's susceptibility to emesis following chemotherapy treatment are:

- Poor control with prior chemotherapy.
- Female sex.
- Younger age <50 years.
- A current or prior history of low chronic alcohol intake.
- History of sickness: pregnancy/travelling/surgery.
- Anxiety.
- Smoking.
- Radiation to gastro-intestinal tract, liver or brain.
- Other medications: various medications can cause nausea and vomiting such as anaesthetic agents, anti-depressants, anti-microbials, anti-fungals, iron, levodopa, carbidopa, NSAIDs.

Differences in the severity of emesis can also occur between patients receiving the same type of chemotherapy and even between treatment cycles in the same patient; however, modern drug treatment can successfully control CINV for the majority of patients.

The 5-hydroxytryptamine type 3 ($5HT_3$) receptor antagonists, which include dolasetron, granisetron, ondansetron, palonosetron and tropisetron, have become the standard management of acute CINV when treating patients with moderately emetogenic chemotherapy regimens. For highly emetogenic chemotherapy regimens such as those including cisplatinum, the use of the NK_1 inhibitor, aprepitant, together with a $5HT_3$ antagonist is becoming the gold standard. These agents are most effective in dealing with acute emesis (less than 24 h duration) when combined with a potent steroid such as dexamethasone.

It is important to achieve optimal control of nausea and vomiting at the outset to avoid subsequent anticipatory symptoms which can prove very difficult to treat.

The route of administration for anti-emetics is an important consideration. With intravenous chemotherapy, it may be simpler to administer all treatments by the intravenous route. Alternatives to the oral route may be useful when vomiting occurs and include the rectal and buccal route.

Pain control

Drug therapy remains the cornerstone of effective pain management but it is often undertreated, thus highlighting the importance of regular patient assessment and appropriate dose or drug treatment changes. For example, patients experiencing intolerable side effects to morphine may be transferred to oxycodone or transdermal fentanyl skin patches. Analgesia should be prescribed both regularly and for breakthrough pain, and stimulant laxatives should be prescribed to prevent constipation. Combinations of analgesics which have synergistic activity, for example, opiates plus NSAIDs, can be highly effective whilst minimising dose-related side effects of each agent.

The route of administration is also important. When patients are unable to manage oral medication, it is important to assess the use of alternative routes such as the rectal, subcutaneous, epidural and transdermal routes.

Bone marrow suppression

Myelosuppression following chemotherapy is common, and for some patients profound. The risk of systemic infection can be reduced by good oral hygiene and mouth care using antiseptic mouthwashes and anti-fungal prophylaxis. Patients must be advised to immediately report symptoms of infection and bruising. Platelet transfusions may be required, but fever or other evidence of infection occurring in a neutropenic patient when the neutrophil count is less than 1.0×10^9/L must be aggressively treated with broad-spectrum intravenous antibiotics to prevent overwhelming infection.

The duration and depth of neutropenia can be dramatically reduced by the administration of G-CSF which stimulate neutrophil production and, in cases of severe neutropenia, effectively rescue the patient. Once the patient's neutrophil count has recovered sufficiently, their use may be safely discontinued. These agents may also be used prophylactically in patients with a high risk of febrile neutropenia before receiving chemotherapy.

Blood transfusions are commonly required by patients at some stage of their treatment due to anaemia. Alternatively, erythropoietin may be useful in some patients receiving chemotherapy to shorten the period of anaemia and improve the patient's quality of life where blood transfusions are not possible.

Extravasation

Extreme care must be taken when administering cytotoxic drugs parenterally because of the dangers of extravasation. Extravasation, which is the accidental leakage of an intravenous drug into the surrounding tissue, can cause pain, erythema and severe local necrosis, resulting in permanent tissue damage. The patient must be asked to immediately report any pain or a stinging sensation at the injection site since the degree of damage is determined by the amount of drug extravasated and the speed at which it is detected. If extravasation is suspected, the administration of further chemotherapy must stop and remedial treatment must commence as soon as possible. The effectiveness of such therapy varies according to the agent extravasated.

Inpatient or outpatient treatment

The majority of patients receive chemotherapy in the outpatient clinic or day-care setting, where cytotoxics are administered mainly by short intravenous infusion at 3- or 4-week intervals. Other treatments include monoclonal antibodies,

Table 52.5 National Cancer Institute common toxicity criteria for anaemia (haemoglobin) (Cancer Therapy Evaluation Program, 1998)

Adverse event, Grade	0	1	2	3	4
Haemoglobin (Hgb)	WNL	<LLN–10.0 g/dL <LLN–100 g/L <LLN–6.2 mmol/L	8.0–<10.0 g/dL 80–<100 g/L 4.9–<6.2 mmol/L	6.5–<8.0 g/dL 65–<80 g/L 4.0–<4.9 mmol/L	<6.5 g/dL <65 g/L <4.0 mmol/L

WNL, within normal limits; LLN, lower limit of normal.

which usually require close monitoring of the patient for several hours in case of anaphylactic reactions. More complex treatments, such as cisplatinum-containing regimens which require prehydration with intravenous fluids, need the patient to attend all day.

Currently, inpatient treatment of chemotherapy only occurs for the small minority of treatments, and this number is declining further as novel ways of administering long infusions are being developed.

Domiciliary treatment

Oral cytotoxic drugs can safely be taken at home so long as the patient is informed and able to monitor side effects. Availability of a 24-h helpline is essential for these patients should they encounter problems whilst on treatment (National Chemotherapy Advisory Group, 2009). In the future, administration of intravenous treatments, such as the monoclonal antibody trastuzumab, may be carried out more frequently in the home setting, particularly when safety permits and where patient preference becomes an influential factor.

Monitoring anti-cancer therapy

As well as desirable outcomes, treatment with chemotherapy may result in a variety of undesirable outcomes; both require careful monitoring.

Toxicity

The toxicity resulting from treatment is routinely assessed following each cycle of chemotherapy, and may result in therapy being modified on subsequent cycles, for example, a dose reduction, a delay in treatment or, in some cases, an alternative treatment. A number of international rating scales are available for rating predictable acute reactions arising from chemotherapy, including that of the National Cancer Institute Common Toxicity Criteria (for an example, see Table 52.5). Standardising the assessment of treatment-related toxicity in this way allows comparison to be made between published reports of clinical trials.

Response to treatment

Throughout treatment, the response to therapy is closely monitored, noting changes in performance status, symptoms and objective measurements of the tumour. This may necessitate repeating some or all of the initial staging investigations. Should the initial treatment prove ineffective, an alternative can then be considered without delay. Assessment of response should be formally documented before proceeding to further therapy.

Definitions of response. These have been standardised by the WHO:

- *Complete response or remission* (CR). Disappearance of all recognisable tumour masses and/or biochemical changes directly related to the tumour and resolution of symptoms determined by two observations at least a month apart.
- *Partial response* (PR). Decrease by 50% or more in all tumour masses, measured by the product of the longest × the widest perpendicular diameters for at least a month.
- *Stable disease* (SD) *or no change* (NC). Changes smaller than those described above for PR or less than for progressive disease for at least a month.
- *Progressive disease* (PD). Occurrence of any new lesion or increase in the longest × widest perpendicular diameters of measurable disease by at least 25%.

Again, this allows comparison of results between different reported studies. An update of the WHO guidelines has been published (Therasse et al., 2000) called RECIST or Response Evaluation Criteria in Solid Tumours. To avoid confusion, it is important to stipulate in trial protocols which system will be used. Although clinical response indicates tumour sensitivity, it may not necessarily predict long-term survival nor does it measure other benefits such as quality of life.

Case studies

Case 52.1

Mrs BH, a 53-year-old post-menopausal mother of two teenage children, has recently completed six cycles of FEC(100)-T (5-fluorouracil, epirubicin, cyclophosphamide, docetaxel) as adjuvant chemotherapy for her node-positive early breast cancer. She tolerated her chemotherapy well and did not require any dose reductions or delays.

Her receptor status at diagnosis was oestrogen receptor positive and progestogen receptor negative (ER+/PR–); she was also HER2 positive.

Her oncologist has recommended that she commences adjuvant treatment with trastuzumab.

Questions

1. What treatment regimen for trastuzumab should be followed?
2. What side effects of trastuzumab should Mrs BH be informed about when giving consent for treatment?
3. What other treatments should be considered for this patient?

Answers

1. Trastuzumab targets the epidermal growth factor receptor (EGFR) and is indicated for the treatment of early breast cancer overexpressing HER2 following surgery, chemotherapy (neo-adjuvant or adjuvant) and radiotherapy if applicable as recommended by National Institute for Health and Clinical Excellence (2006a). The product license for trastuzumab recommends the dosing schedule used in the HERA study (Piccart-Gebhart et al., 2005), that is loading dose of 8 mg/kg body weight, followed by 6 mg/kg body weight 3 weeks later and then 6 mg/kg repeated at three-weekly intervals administered as infusions over approximately 90 min. This is continued for 12 months, stopping sooner if disease reoccurs.

2. The most common side effects experienced by patients are infusion related, such as fever and chills, usually following the first or second treatment. Patients should be closely monitored for at least 6 h after the start of the first infusion and if the treatment has been well tolerated, for 2 h after the start of subsequent infusions. If a reaction occurs, the infusion should be stopped, appropriate symptomatic treatment administered and treatment recommenced at a slower rate only when the symptoms have subsided. Trastuzumab has been associated with cardiotoxicity and patients who have previously received anthracyclines are at increased risk. All patients should have their cardiac function closely monitored at baseline and every 3 months during the period that they are being treated with trastuzumab (National Institute for Health and Clinical Excellence, 2006a). There was an approximate 5% increase in the number of patients with a significant change in cardiac function in the HERA study (Piccart-Gebhart et al., 2005).

3. In view of her receptor status, this patient should be offered hormonal treatment. Depending on the perceived level of risk of recurrence as estimated using a model such as the Nottingham Prognostic Index (Galea et al., 1992), she should be offered either 5 years' treatment with an aromatase inhibitor or planned sequential treatment with tamoxifen switching to an aromatase inhibitor after 2–3 years' therapy. The long-term effect on cardiovascular health (tamoxifen) or bone health (aromatase inhibitors) together with the expected level of benefits should be used to guide choice of treatment. Further information can be found in national guidance for the early management of breast cancer with hormonal treatments (National Institute for Health and Clinical Excellence, 2006a).

Case 52.2

Mr BS, a 67-year-old man with a history of localised prostate cancer, is reviewed by his oncologist. Mr BS was previously treated with radical radiotherapy and more recently several lines of hormonal therapy.

His PSA has risen over the last 6 months and is now 80 ng/mL. It was 0.1 ng/mL on completion of radical radiation therapy. He also complains that his longstanding back pain controlled by low-dose NSAIDs has now become much worse and is out of control.

Questions

1. What is the most likely cause of Mr BS's back pain and raised PSA?
2. What treatment options should be discussed with the patient?

3. Why should he be referred for a dental examination before commencing any further treatment?

Answers

1. The fact that the PSA is markedly raised suggests a recurrence of prostate cancer. Moderate rises in the PSA would have warranted a change in hormonal therapy. The elevated PSA together with the increased back pain suggest metastatic bone disease as a result of distant recurrence of his prostate cancer. This could be confirmed with plain film X-rays or by bone scan. The risk of both local and distant recurrence depends on the stage at presentation.

2. Treatment options for recurrent prostate cancer include second-line hormonal therapy, chemotherapy with or without corticosteroids, and best supportive care. Localised radiotherapy to specific bone lesions could improve his back pain; this would depend on the distribution of treatable lesions identified. The choice of therapy depends on the symptoms, the site of relapse, performance status of the patient and the presence of other co-morbidities. Best supportive care can be provided with radiotherapy, bisphosphonates, steroids and analgesics, and is the only option for patients who are too ill to tolerate further systemic intervention. Tolerability of chemotherapy is of concern, particularly because most patients with prostate cancer are elderly and many have other medical problems. Mr BS has already received more than one line of hormonal therapy; his tumour is unlikely to respond to further hormonal manipulation. An alternative strategy that is available is the use of radioactive isotopes such as Strontium 89 for systemic treatment of multiple bone metastases. The use of chemotherapy in the treatment of hormone-refractory prostate cancer should be considered in patients with a Karnofsky performance status of 60% or greater. Further information on the use of docetaxel for the treatment of hormone-refractory metastatic prostate cancer is available (National Institute for Health and Clinical Excellence, 2006b).

3. Future treatment options for this patient may include use of bisphosphonates to stabilise his bone lesions and reduce his pain. Long-term use of bisphosphonates has been associated with osteonecrosis of the jaw; the risk is exacerbated by poor dental hygiene, concurrent dental procedures, chemotherapy, corticosteroids and malignant disease. Examination and preventive dental treatment should be considered for patients prior to commencing therapy with bisphosphonates in order to avoid any invasive procedures, for instance dental extraction, during bisphosphonate therapy.

Case 52.3

Mr SG, a 46-year-old patient, was diagnosed with Dukes' C colon cancer several months ago. Since then, he has undergone a left hemicolectomy. He is currently receiving capecitabine monotherapy as adjuvant treatment. He telephones the pharmacy department for advice on how to cope with the side effects he is currently experiencing.

Questions

1. What side effects are commonly associated with capecitabine?
2. How do these differ from those associated with intravenous 5-fluorouracil?
3. What advice should he be given?

Answers

1. Side effects most commonly associated with capecitabine treatment are mainly related to the skin and the gastro-intestinal tract.

- Palmar–plantar erythema (hand–foot syndrome) 57%
- Diarrhoea 47%
- Nausea 35%
- Stomatitis 23%
- Vomiting 18%
- Fatigue 16%

2. Although capecitabine is converted enzymatically to 5-fluorouracil, there is a difference in the frequency with which specific side effects are experienced, making it more akin to continuous infusions of 5-flourouracil. Patients receiving intermittent bolus therapy with 5-fluorouracil are more likely to experience the gastro-intestinal side effects, particularly diarrhoea or stomatitis, rather than the cutaneous reactions. Myelosuppression may also infrequently be a problem encountered by these patients.

3. Mr SG should be instructed to contact the emergency telephone number he would have been given with his treatment from the hospital looking after him.

   If detected early, side effects usually improve within 2–3 days. Treatment may be reinstated at the same dose if side effects are moderate, or at a reduced dose if more severe. Symptomatic relief for palmar–plantar erythema may be provided by the use of emollients. There is little evidence to support the use of specific antidotes.

Case 52.4

Mrs PQ, a 59-year-old women, has non-small-cell lung cancer. She has had a course of gemcitabine combined with carboplatin and now requires second-line chemotherapy. The doctor has suggested erlotinib.

Questions

1. What type of treatment is erlotinib and how is it given?
2. What common side effects should Mrs PQ be informed about when she is giving consent for treatment?
3. What other treatments should be considered for this patient?

Answers

1. Erlotinib is an epidermal growth factor receptor/human epidermal growth factor receptor type 1 (EGFR also known as HER1) tyrosine kinase inhibitor. Erlotinib potently inhibits the intracellular phosphorylation of EGFR. Epidermal growth factor receptor is expressed on the cell surface of normal cells and cancer cells. In non-clinical models, inhibition of epidermal growth factor receptor phosphotyrosine results in cell stasis and/or death. It is an oral tablet given once a day until disease progression or unacceptable toxicity.

2. Rash (75%) and diarrhoea (54%) were the most commonly reported adverse drug reactions (ADRs). In general, rash manifests as a mild or moderate erythematous and papulopustular rash, which may occur or worsen in skin areas exposed to the sun. For patients who are exposed to the sun, protective clothing, and/or use of sun screen (with minimum SPF 15, e.g. mineral-containing) may be advisable. The rash generally starts about 8–10 days after starting treatment but usually improves after a few weeks. Diarrhoea is usually mild and

can be controlled with anti-diarrhoeal drugs. Fatigue, nausea and vomiting and sore mouth are also quite common. Some people also develop sore, red eyes (conjunctivitis) or dry eyes.

3. Docetaxel is the other second-line treatment currently available for the treatment of non-small-cell lung cancer.

Case 52.5

Mrs GH is a 64-year-old post-menopausal women with metastatic breast cancer. She has had several cycles of chemotherapy including previous anthracyclines and she had her third cycle of capecitabine 8 days ago. Mrs GH is feeling 'a bit unwell' and her husband thinks she is not at all her usual self, and is, therefore, worried about her.

Questions

1. What side effect may Mrs GH be suffering from?
2. How would you explain to Mrs GH how to take a cycle of capecitabine?
3. What are the possible patient safety concerns regarding oral chemotherapy?

Answers

1. Mrs GH may be suffering from neutropenic sepsis. The signs can be difficult to identify with a small elevation in temperature and a general feeling of not being well. It is important that Mrs GH is prescribed IV antibiotics as soon as possible before she succumbs to the infection. Chemotherapy patients are all at varying degrees of risk for neutropenic sepsis due to the marked decrease in neutrophils in the body due to the chemotherapy. She should also have a blood test to check her neutrophil level, but administration of antibiotics should not wait for these results. Each hospital will have guidelines or a protocol in place to treat neutropenic sepsis in patients receiving chemotherapy.

2. Take the capecitabine dose morning and evening, 12h apart with a glass of water. Mrs GH should take the capecitabine for 14 days and then stop for 7 days. In addition, it is important to make sure that Mrs GH understands her correct dose.

3. Healthcare workers and their staff must be made aware that the prescribing, dispensing and administering of oral anti-cancer medicines should be carried out and monitored to the same standard as injected therapy. This requires:

- Healthcare organisations to prepare local policies and procedures that describe the safe use of these oral medicines
- Treatment to be initiated by a cancer specialist
- All oral anti-cancer medicines to be prescribed only in the context of a written protocol and treatment plan
- Non-specialists who prescribe or administer on-going oral anti-cancer medication to have ready access to appropriate written protocols and treatment plans
- Staff dispensing oral anti-cancer medicines to be able to confirm that the prescribed dose is appropriate for the patient
- Patients to be fully informed and receive verbal and up-to-date written information about their oral anticancer therapy from the initiating hospital.

53 Rheumatoid arthritis and osteoarthritis

D. J. Pang and G. M. Brough

Key points

Rheumatoid arthritis

- Rheumatoid arthritis is the most common inflammatory arthritis affecting 1% of the population.
- It affects 5% of women and 3% of men over 65 years of age.
- The aetiology is unclear.
- Non-pharmacological treatment includes physiotherapy, occupational therapy, education and psychological support.
- On diagnosis of rheumatoid arthritis, early treatment with aggressive disease-modifying anti-rheumatic drugs (DMARDs) should commence to prevent joint destruction.
- Cytokine inhibitors are used in patients who do not respond to DMARD treatment. There are several agents available which target different cytokines in the inflammatory pathway.
- Non-steroidal anti-inflammatory drugs (NSAIDs) may be considered for symptomatic relief and should be co-prescribed with a proton pump inhibitor.
- Steroids are useful for rapid relief of symptoms and in the early stages of DMARD introduction.

Osteoarthritis

- Osteoarthritis is uncommon under the age of 35 years.
- A wide variety of factors are thought to predispose a patient to osteoarthritis including genetic factors, age and mechanical overloading of the joint.
- Lifestyle changes such as maintaining optimal weight and undertaking regular exercise are an essential part of treatment.
- Paracetamol and topical NSAIDs are considered first-line treatments.
- Intra-articular steroids and opioids may be used for severe pain.
- Oral NSAIDs may be useful and should be co-prescribed with a proton pump inhibitor.

Rheumatoid arthritis

Rheumatoid arthritis is one of the most common inflammatory disorders affecting the population worldwide. It is a systemic inflammatory disease which affects not only the joints but a wide range of extra-articular organs. The disease, if not treated early, will lead to progressive joint deformity and increased morbidity and mortality.

Rheumatoid arthritis is a potentially fatal illness, with mortality increased twofold and an average decrease in life expectancy of 7–10 years. Patients with rheumatoid arthritis have an increased prevalence of other serious illnesses. The predominant conditions leading to this increased co-morbidity and mortality include infections, renal impairment, cardiovascular disease and lymphomas. The incidence of lymphoma is twofold higher than expected before taking into account the disease-modifying immunosuppressant drugs used in treating rheumatoid arthritis.

Epidemiology

Approximately 1% of the population worldwide is affected by rheumatoid arthritis, with females being two to three times more commonly affected. The prevalence of rheumatoid arthritis increases with age in both sexes; nearly 5% of women and 3% of men over the age of 65 years are affected by the disease. The peak age of incidence is about 30–50 years in women and slightly older in men. Rheumatoid arthritis also affects young children and its classification and treatment differs slightly from adults.

Aetiology and pathophysiology

The cause of rheumatoid arthritis remains unclear with hormonal, genetic and environmental factors playing a key role. Genetic factors contribute 53–65% of the risk of developing this disease. The HLA-DR4 allele is associated with both the development and severity of rheumatoid arthritis. Cigarette smoking is a strong risk factor for developing rheumatoid arthritis. A study of over 3000 women clearly linked the length of time that people had smoked with rheumatoid arthritis (Karlson et al., 1999). Patients with a smoking history of 25 years or more were increasingly likely to develop seropositive disease with nodules and erosions on radiology.

Pathologically, rheumatoid arthritis is characterised by the infiltration of a variety of inflammatory cells into the joint. The synovial membrane, which is normally acellular, becomes highly vascularised and hypertrophied, creating a so-called pannus formation. There is proliferation of synovial fibroblasts and an increase in the number of inflammatory

832

cells present within the joint. The inflammatory cells involved in rheumatoid arthritis include T-cells (predominantly CD4 helper cells), B-cells, macrophages and plasma cells. Cytokines are released by these cells which cause the synovium to release proteolytic enzymes, resulting in the destruction of bone and cartilage. Key cytokines involved in rheumatoid arthritis include tumour necrosis factor (TNF)-α, interleukin-1, interleukin-6 and granulocyte macrophage colony-stimulating factor (GM-CSF). These play a crucial role in the pro-inflammatory reaction.

Clinical manifestations

There are different patterns of clinical presentation of rheumatoid arthritis. The disease may present as a polyarticular arthritis with a gradual onset, intermittent or migratory joint involvement, or a monoarticular onset. In addition, extra-articular manifestations may be present (Box 53.1). Extra-articular features occur in approximately 75% of seropositive patients and are often associated with a poor prognosis.

Disease onset is usually insidious with the predominant symptoms being pain, stiffness and swelling. Typically, the metacarpophalangeal and proximal interphalangeal joints of the fingers, interphalangeal joints of the thumbs, the wrists, and metatarsophalangeal joints of the toes are affected during the early stages of the disease. Rheumatoid arthritis–associated deformities affecting multiple joints of the hands are shown in Fig. 53.1. Other joints of the upper and lower limbs, such as the elbows, shoulders and knees, are also affected. Morning stiffness may last for 30 min to several hours, and usually reflects the severity of joint inflammation. Up to one-third of patients also suffer from prominent myalgia, fatigue, low-grade fever, weight loss and depression at disease onset.

Rheumatoid arthritis shows a marked variation of clinical expression in individual patients both in the number and pattern of joints affected, disease progression and the rapidity of joint damage. Disease activity may not abate in 10–20% of cases. Remission has been reported in a small proportion of patients but usually is very rare without disease-modifying anti-rheumatic drugs (DMARDs).

Fig. 53.1 Typical ulnar deviation, swan neck and boutonnière deformities.

Diagnosis

A clinical diagnosis of rheumatoid arthritis is made based on the patient's history, presenting symptoms and clinical findings. Family history is useful, as well as investigations including blood tests, ultrasound for the presence of synovitis and X-rays. The latter is used to demonstrate joint destruction which indicates a late manifestation of the disease.

Emphasis on early diagnosis and treatment is extremely important to prevent disease activity, duration and ultimately joint destruction. The American Rheumatism Association (ARA) criteria (Box 53.2) were principally designed for disease classification in patients with established disease and are not sensitive for patients in the early stages of rheumatoid arthritis (Arnett et al., 1988). The Disease Activity Score

Box 53.1 Examples of the extra-articular features of rheumatoid arthritis

Amyloidosis
Carpal tunnel syndrome
Episcleritis
Felty's Syndrome
Fever
Lymphadenopathy
Nodules; may be subcutaneous or within the lungs, eyes or heart
Osteoporosis
Pericarditis
Pleural and pericardial effusions
Scleritis
Vasculitis

Box 53.2 American Rheumatism Association criteria for the diagnosis of rheumatoid arthritis

- Morning stiffness in and around the joints for at least 6 weeks, lasting at least 1 h before maximal improvement
- Swelling of three or more joints for at least 6 weeks
- Swelling of the wrist, metacarpophalangeal or proximal interphalangeal joints for at least 6 weeks
- Symmetric joint swelling for at least 6 weeks
- Hand X-ray changes typical of rheumatoid arthritis that must include erosions or unequivocal bony decalcification around the joints
- Rheumatoid subcutaneous nodules
- Positive rheumatoid factor

The presence of at least 4 of these indicates a diagnosis of rheumatoid arthritis.

using 28 joint counts (DAS28) and American College of Rheumatology (ACR) response are some of the tools used by rheumatologists to assess disease activity and to monitor the patient's response to treatment (see Boxes 53.3 and 53.4).

Investigations

Inflammatory markers, including C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR), are usually but not always elevated in active disease and are useful for monitoring response to treatment. Rheumatoid factor (RF) is an autoantibody directed against the host immunoglobulin and is most commonly found in rheumatoid arthritis. Routinely performed tests only detect immunoglobulin M rheumatoid factor (IgM RF) which is present in 75–80% of patients with rheumatoid arthritis (termed seropositive disease) and 5% of normal subjects. Those patients who do not have a detectable RF are said to be 'seronegative'. RF is not specific to rheumatoid arthritis and is also present in patients with chronic lung and liver disease, other connective tissue diseases, neoplasia, infections (particularly bacterial endocarditis) and cryoglobulinaemia.

Anti-cyclic citrullinated peptide antibodies (anti-CCP antibody) are a more specific test for rheumatoid arthritis with a specificity of 90–96% compared with the specificity of IgM RF of 85%. They are more useful for the early detection of rheumatoid arthritis in a patient with inflammatory arthritis. The sensitivity of both anti-CCP antibody and IgM RF is approximately 70%.

Antinuclear antibodies (ANA) and extractable nuclear antigens (ENA) are useful for establishing the differential diagnosis, such as other connective tissue diseases presenting or associated with an arthritis. ANA is almost universally positive in systemic lupus erythematosus and only positive in 20% of patients with rheumatoid arthritis.

Other abnormal laboratory tests include an elevated alkaline phosphatase, an elevated platelet count, a decreased serum albumin and a normochromic, normocytic anaemia. White cell count, particularly neutrophils, is elevated in patients with infected joints and is also elevated whilst the patient is on steroids.

Treatment

There are four primary goals in the treatment of rheumatoid arthritis:

- Symptom relief including pain control
- Slowing or prevention of joint damage
- Preserving and improving functional ability
- Achieving and maintaining disease remission

Once the diagnosis has been established, an individualised care plan with treatment goals should be agreed, including monitoring of disease severity using objective measures such as the ACR or DAS28 scores. The ultimate aim is to achieve disease remission, which can be defined by a number of methods including a target DAS28 of less than 2.6, CRP, or a reduction in signs and symptoms of disease activity. If remission cannot be achieved, the aim of therapy is to minimise joint destruction and to preserve function. The longer the period of remission or the best possible reduction in disease activity that can be achieved, the better the long-term outcome.

Patients should have access to a multidisciplinary team to address the pharmacological and non-pharmacological aspects of disease management. Education is extremely important as patients cope better if they understand their condition and have realistic expectations of the benefits and disadvantages of their treatment strategies. Patients may need psychological support and employment counselling to help them adjust to living with their condition. Occupational therapy aims to provide support and aid to allow patients to improve function and limit disability in their activities of daily living. This includes devices to alleviate tasks which may be troublesome for those with restricted manual dexterity, such as twisting lids to open bottles. Physiotherapy involves assessment of function and designing a programme to aid pain relief and rehabilitation. The programme should aim to improve general fitness through regular exercise, and tailor exercises to the individual patient to enhance joint flexibility and muscle strength. Alternative short-term pain relief options may also be explored such as transcutaneous electrical nerve stimulators

(TENS) and hydrotherapy. Surgical interventions, such as synovectomy and arthroplasty, may be useful to relieve pain and restore function.

Drug treatment

The pharmacological management of rheumatoid arthritis is evolving rapidly as more advanced therapies become available. The advent of biological therapies has brought new technologies which target different cytokine pathways involved in the pathogenesis of rheumatoid arthritis and have revolutionised disease management.

There are four main categories of drugs employed in the management of rheumatoid arthritis: non-steroidal anti-inflammatory drugs (NSAIDs) including cyclo-oxygenase (COX)-2 inhibitors, glucocorticoids, DMARDs and biological therapies. Simple analgesia also has a small role to play in basic symptom relief and includes paracetamol, codeine, and paracetamol and opiate combination products. These analgesics do not have any anti-inflammatory effect and will not aid disease modification. The aim of analgesia is to achieve symptom relief and reduce the need for long-term use of NSAIDs, COX-2 inhibitors and glucocorticoids.

Guidance for the treatment of rheumatoid arthritis has been issued and this is summarised in Fig. 53.2.

Non-steroidal anti-inflammatory drugs

The analgesic and anti-inflammatory properties of NSAIDs are used to reduce joint pain and swelling. However, as with simple analgesics, these drugs provide only symptomatic relief to improve joint function, and so should always be used in combination with other agents which modify the disease process.

The COX enzyme converts arachidonic acid into prostaglandins and thromboxanes. These prostanoids have a variety of physiological functions, and are also believed to be responsible for causing pain and swelling in inflammatory conditions. There are two main isoforms of the COX enzyme:

Table 53.1 NSAIDs currently licensed in the UK

Non-selective NSAIDs	COX-2 inhibitors
Aceclofenac	Celecoxib
Acemetacin	Etoricoxib
Azapropazone	
Dexibuprofen	
Dexketoprofen	
Diclofenac	
Etodolac	
Fenbufen	
Fluribprofen	
Ibuprofen	
Indometacin	
Ketoprofen	
Meloxicam	
Nabumetone	
Naproxen	
Piroxicam	
Tenoxicam	
Tiaprofenic acid	

COX-1 produces prostaglandins required for homeostatic functions, such as maintaining the gastric mucosa, support of renal function and platelet function. COX-2 is responsible for the production of inflammatory prostanoids.

NSAIDs vary in their selectivity for the COX-1 and COX-2 isoforms, and are categorised as either non-selective NSAIDs or selective COX-2 inhibitors, otherwise known as the coxibs (Table 53.1). Non-selective NSAIDs generally block both COX-1 and COX-2, whereas the coxibs have higher selectivity for the COX-2 isoform. However, COX-2 selectivity in NSAIDs varies according to the dose of drug given, which is demonstrated by the dose-related toxicity exhibited by some agents such as ibuprofen. The three most commonly used non-selective NSAIDs have differing levels of COX-1 or COX-2 selectivity: diclofenac is COX-2 'preferential', whereas ibuprofen and particularly naproxen preferentially inhibit COX-1. Originally, inhibition of COX-2 was thought to be involved solely with the anti-inflammatory, anti-pyretic and analgesic properties of NSAIDs. However, it is possible that COX-2 inhibition may also impair endothelial health, cause a prothrombotic state and promote cardiovascular disease.

Safety

In 2004, rofecoxib, a selective COX-2 inhibitors, was withdrawn from the worldwide market due to evidence of an increased risk of confirmed serious thrombotic events that included myocardial infarction and stroke, following long-term use. In the following years, similar evidence against the other COX-2 inhibitors and also against some of the non-selective NSAIDs accumulated.

At present, the exact cardiovascular risk for individual selective COX-2 inhibitors and NSAIDs is not known. Evidence from clinical trials of COX-2 inhibitors suggests that about 3 additional thrombotic events per 1000 patients/year may occur in the general population (MHRA, 2006).

DMARD (combination therapy where appropriate)
+
Symptom relief using glucocorticoid, NSAID or simple analgesia

↓

Anti-TNF agent

↓

Rituximab

↓

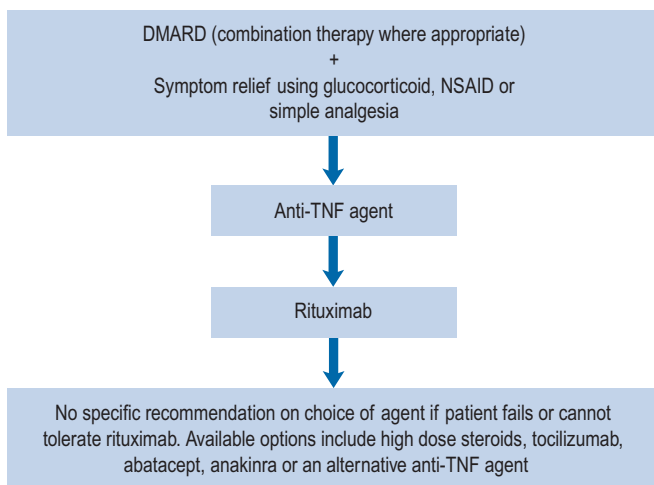
No specific recommendation on choice of agent if patient fails or cannot tolerate rituximab. Available options include high dose steroids, tocilizumab, abatacept, anakinra or an alternative anti-TNF agent


Fig. 53.2 Treatment algorithm for rheumatoid arthritis (NCCCC, 2009).

A dose-dependent increase in cardiovascular risk is associated with use of celecoxib, high-dose diclofenac (150 mg/day) and high-dose ibuprofen (2400 mg/day). There does not appear to be an increased risk of myocardial infarction in association with low-dose ibuprofen (≤1200 mg/day). Naproxen is associated with a lower risk of arterial thrombotic events than COX-2 inhibitors. There may be some increased cardiovascular risk in all patients receiving any NSAID, irrespective of their baseline risk or duration of therapy. The key message is that patients should use the lowest effective dose and the shortest duration of treatment necessary to control symptoms to minimise the risk of adverse events.

The most common adverse events of NSAIDs are those that predominantly inhibit COX-1 and cause adverse gastro-intestinal effects. These range from minor symptoms, including dyspepsia, nausea and diarrhoea, to more serious events, such as gastric erosion, bleeding and duodenal and gastric ulceration. Patients are at a higher risk of serious gastro-intestinal complications if they are over 65 years of age, have a previous history of gastro-intestinal ulceration/bleeding or peptic ulcer disease, or are taking concomitant anti-platelet, anti-coagulation or steroid therapy. There are several gastroprotective agents available which may be used to reduce adverse events, including H_2 antagonists, misoprostol and proton pump inhibitors (PPIs). PPIs, such as omeprazole and lansoprazole, have been shown to be particularly effective at preventing gastric and duodenal ulcers with NSAIDs. All patients taking a non-selective NSAID or COX-2 inhibitor should receive concomitant treatment with a PPI to minimise gastro-intestinal adverse effects.

Aspirin inhibits the COX enzyme irreversibly through a different mechanism of action to the NSAIDs. Therefore, there is an increased risk of gastro-intestinal toxicity if aspirin and non-selective NSAIDs are used concomitantly, and the gastro-intestinal advantage of using a selective COX-2 inhibitor is severely reduced. Low-dose aspirin should only be co-prescribed with NSAIDs where absolutely necessary.

All NSAIDs may potentially cause adverse cardio-renal effects such as oedema, hypertension and heart failure. The distribution of COX-1 and COX-2 differs in the kidney, but there is no evidence to suggest differing degrees of isoform inhibition have an impact on the severity of cardio-renal adverse effects. Pharmacokinetic parameters, such as half-life and metabolism, may affect both thrombotic and cardio-renal properties of NSAIDs.

Choice of agent

Evidence suggests that all non-selective NSAIDs and COX-2 inhibitors are of similar efficacy, but vary in their toxicity profiles. However, there is individual patient variability in terms of response to a given NSAID, and so some patients may need to try several agents before reaching an effective and well-tolerated agent. Non-selective NSAIDs or COX-2 inhibitors should be used at the lowest effective dose for the shortest possible period of time. There are no recommendations on which agent to use first-line as all NSAIDs have analgesic effects of similar magnitude. However, as these drugs vary in terms of potential gastro-intestinal, liver and cardio-renal toxicity, it is advised that the choice of drug should take into account the patient's individual risk factors, including age.

Disease-modifying anti-rheumatic drugs

Joint damage is known to occur early in rheumatoid arthritis and is largely irreversible. The need for early intervention with DMARDs as part of an aggressive approach to minimise disease progression has become standard practice and is associated with better patient outcome. Early introduction of DMARDs also results in fewer adverse reactions and withdrawals from therapy (NCCCC, 2009).

The DMARDs that are commonly used for rheumatoid arthritis and have clear evidence of benefit are methotrexate, sulphasalazine, leflunomide and intramuscular gold (O'Dell, 2004). There is less compelling evidence for the use of hydroxychloroquine, D-penicillamine, oral gold, ciclosporin and azathioprine, although these agents do improve symptoms and some objective measures of inflammation. The exact mechanism of action of these drugs is unknown. All DMARDs inhibit the release or reduce the activity of inflammatory cytokines, such as TNF-α, interleukin-1, interleukin-2 and interleukin-6. Activated T-lymphocytes have been implicated in the inflammatory process, and these are inhibited by methotrexate, leflunomide and ciclosporin.

Patients should be made aware that the DMARDs all have a slow onset of action. They must be taken for at least 8 weeks before any clinical effect is apparent, and it may be months before an optimal response is achieved. Whilst early initiation of DMARDs is crucial, it is important to ensure the patient is maintained on therapy to maintain disease suppression. This itself is a challenge, due to the toxicity profiles of the majority of these drugs (see Table 53.2). The majority of the DMARDs require regular blood monitoring. Guidelines are available on the action to take in the event of abnormal blood results (Chakravarty et al., 2008).

Recommendations regarding the use of DMARDs in rheumatoid arthritis are summarised in Box 53.5 (NCCCC, 2009). Patients with a new diagnosis of rheumatoid arthritis should be offered combination DMARD therapy as first-line therapy as soon as possible, ideally within 3 months of the onset of persistent disease symptoms. The combination therapy should include methotrexate and at least one other DMARD, usually sulphasalazine and/or hydroxychloroquine. Evidence suggests that combination therapy appears to be superior in terms of benefits to symptoms, quality of life, remission rates and slowing of joint damage, when compared to monotherapy. Once sustained and satisfactory levels of disease control have been achieved, the doses of drugs should be cautiously reduced to levels that continue to maintain disease control.

In patients where combination therapy is not appropriate, for example where there are contraindications to a drug due to existing co-morbidities, DMARD monotherapy should be started, placing greater emphasis on fast escalation to a clinically effective dose rather than on choice of agent (NCCCC, 2009).

Table 53.2 DMARDs used in the treatment of rheumatoid arthritis

Name	Dose	Adverse reactions	Monitoring Baseline	Monitoring Long-term	Time period to benefit
Auranofin (oral gold)	3 mg two to three times daily	Rash, oral ulceration, proteinuria, myelosuppression	FBC Urinalysis U&E LFTs	FBC and urinalysis every 4 weeks	4–6 months
Azathioprine	1–3 mg/kg/day	Myelosuppression, hepatic impairment	FBC U&E LFTs TPMT assay	FBC and LFTs weekly for 6 weeks, then every 2 weeks until dose is stable for 6 weeks, then monthly. If maintenance dose is achieved and stable for 6 months consider reducing monitoring to every 3 months U&E every 6 months	6 weeks to 3 months
Ciclosporin	2.5–4 mg/kg/day (in two divided doses)	Hypertension, renal dysfunction, gingival hyperplasia, electrolyte imbalance, hyperlipidaemia	FBC U&E LFTs Fasting lipids CrCl BP	FBC and LFTs monthly until dose and trend stable for 3 months, then every 3 months thereafter U&E every 2 weeks until dose and trend stable for 3 months, then monthly thereafter Periodic lipid check Regular BP check – maintain ≤ 140/90	3 months
D-penicillamine	Usual maintenance 500–750 mg daily	Nausea, anorexia, myelosuppression, rashes, taste disturbances	FBC U&E Urinary protein	FBC and urinalysis every 2 weeks until dose stable for 3 months, then monthly thereafter	3–6 months
Hydroxychloroquine	200–400 mg daily	Ocular toxicity, GI and visual disturbances	FBC U&E LFT Visual acuity	Annual review with optometrist	2–3 months
Leflunomide	10–20 mg daily Loading dose is not commonly used in practice due to GI side effects	Weight loss, hypertension, GI disturbances, myelosuppression	FBC U&E LFTs BP Weight	FBC and LFTs monthly for 6 months, then every 2 months thereafter if stable Monthly bloods should be continued long-term if co-prescribed with another immunosuppressant or potentially hepatotoxic agent Regular BP and weight checks	8–12 weeks, although longer if the loading dose is not given
Methotrexate	7.5–25 mg once weekly	Hepatotoxicity, myelosuppression, pneumonitis, nausea and vomiting	FBC U&E LFTs Chest X-ray	FBC, U&E, LFTs every 2 weeks until MTX dose and monitoring stable for 6 weeks, then monthly thereafter until dose and disease stable for 1 year. Following this, reduction in frequency of monitoring may be considered depending on various patient factors, for example renal impairment	6 weeks to 3 months

Table 53.2 DMARDs used in the treatment of rheumatoid arthritis—cont'd

| Name | Dose | Adverse reactions | Monitoring | | Time period to benefit |
			Baseline	Long-term	
Sodium aurothiomalate (IM gold)	10 mg test dose, then 50 mg weekly until significant response or total dose of 1000 mg has been given	Rash, oral ulceration, proteinuria, myelosuppression	FBC Urinalysis U&E LFTs	FBC and urinalysis every 4 weeks	Usually when 500 mg cumulative dose has been reached
Sulphasalazine	500 mg to 3 g daily	GI disturbances, myelosuppression, hepatotoxicity	FBC U&Es LFTs	FBC and LFTs monthly for first 3 months, then every 3 months thereafter. Reduce frequency after first year if dose and results are stable	3 months

BP, blood pressure; CrCl, creatinine clearance; FBC, full blood count; GI, gastro-intestinal; IM, intramuscular; LFTs, liver function tests; MTX, methotrexate; TPMT assay, thiopurine methyl transferase; U&E, Urea and electrolytes, including creatinine

---

Box 53.5 Key points regarding DMARD therapy (NCCCC, 2009)

Introduce DMARD therapy early (within 3 months ideally)
Use combination DMARDs involving methotrexate and at least one other DMARD
Use monotherapy where combination DMARD therapy is not appropriate, with rapid escalation to therapeutic dose
Withdraw cautiously when disease is stable to doses that maintain disease control

---

There are many factors that influence the choice of DMARD: relative efficacy, severity of disease, convenience, monitoring requirements, patient co-morbidities, cost, time period to benefit, prescriber's experience and success rates with the drug, side effects and patient adherence. Studies have shown that methotrexate has the best benefit to toxicity ratio. Both sulphasalazine and hydroxychloroquine are also favourable in terms of low incidence of serious adverse effects, although hydroxychloroquine alone does not slow radiological damage. Most patients started on a DMARD will not be taking it 3–4 years later because of adverse reactions or lack of efficacy. Despite promising results initially, some patients experience disease reactivation at a later stage and become unresponsive to treatment.

Methotrexate

Methotrexate is recognised as the gold standard DMARD in the management of rheumatoid arthritis. It is given as a once weekly dose and can be given orally or parenterally via the intramuscular or subcutaneous routes. Patients usually begin on oral therapy; parenteral methotrexate may be considered in those who do not respond adequately to the maximum tolerated oral dose, or in those who suffer from gastro-intestinal side effects. Doses used, whether administered by the parenteral or oral route, are similar, although bioavailability is greater with parenteral administration. Methotrexate is primarily excreted unchanged by the kidneys and so elderly patients or those with renal impairment may require lower doses. Methotrexate is a folic acid antagonist and acts by reversibly inhibiting dihydrofolate reductase, the enzyme that reduces folic acid to tetrahydrofolic acid. Concomitant administration of oral folic acid reduces adverse effects of methotrexate and improves continuation of therapy and adherence. Doses used range from 5 mg weekly to 5 mg daily except on the day of methotrexate administration.

Methotrexate is associated with lung, liver and bone marrow toxicities. As a consequence, strict monitoring is advised and alcohol intake should be minimised. Methotrexate pneumonitis is usually seen within the first year of treatment, but can sometimes occur after long-term therapy. Myelosuppression can cause significant falls in blood cell counts. It is more likely to occur in the elderly, patients with renal impairment or patients who are also taking anti-folate drugs. A clinically significant drop in cell count calls for immediate withdrawal of methotrexate, and folinic acid rescue therapy. Patients should be counselled to report any of the following warning symptoms immediately to a healthcare professional: blood disorders, for example sore throat, bruising, mouth ulcers; liver toxicity, for example nausea, vomiting, abdominal discomfort, dark urine; and respiratory effects, for example shortness of breath, persistent dry cough.

Following a number of patient incidents involving methotrexate toxicity, guidance on safe use was issued by the National Patient Safety Agency (Box 53.6). Methotrexate-monitoring booklets are routinely given to patients when therapy is initiated. The booklet contains information to reinforce counselling points such as warning symptoms and drug interactions, and has sections where prescribers can enter in dose details (in number and strength of tablets) and record blood results. Methotrexate tablets are available as 2.5-mg and 10-mg strengths; most pharmacies will dispense the 2.5-mg strength only for non-chemotherapy indications such as rheumatoid arthritis.

All prescriptions must specify a dose
The term 'as directed' should be avoided on prescriptions
The strength of tablets supplied should remain consistent to avoid confusion regarding dose
Issue all patients with a methotrexate monitoring booklet
Counsel patient:
- Strength and number of tablets to take
- Monitoring requirements
- Warning symptoms of methotrexate, for example sore throat, persistent cough, vomiting
- To inform other healthcare professionals that he/she is taking methotrexate

Sulphasalazine

Sulphasalazine has been shown to slow joint erosions and suppress inflammatory activity in rheumatoid arthritis. Blood dyscrasias usually occur within the first 3–6 months of treatment, therefore necessitating close monitoring in the initiation period. Patients should also be counselled to report warning symptoms of unexplained bleeding, bruising, purpura, sore throat, fever or malaise. Enteric-coated tablets are available to minimise gastro-intestinal side effects.

Hydroxychloroquine

Hydroxychloroquine is significantly less effective than other DMARDs and historically was reserved for milder cases of rheumatoid arthritis. It still has a place in therapy, particularly in combination with other DMARDs, as it seems to give some symptomatic relief to patients and is the least toxic of the DMARDs. It has also been used relatively safely in pregnancy. Regular visual assessment for retinopathy is recommended as long-term use of anti-malarial agents has been linked to ocular toxicity.

Leflunomide

Leflunomide has a long half-life of approximately 2 weeks, and consequently a loading dose may be given to achieve therapeutic drug levels more quickly. However, in practice, the loading dose is often omitted due to intolerable gastro-intestinal side effects such as diarrhoea. Leflunomide is associated with hepato- and haemato-toxicity, and should be used with caution if co-prescribed with drugs which also cause these adverse effects. Washout procedures using colestyramine or activated charcoal may be necessary when switching to another DMARD, in the event of a serious adverse effect or before conception in females.

Gold

Gold can be given via intramuscular injection as sodium aurothiomalate, or orally as auranofin. Intramuscular gold is more effective than oral. These drugs can be used over a long period of time provided the patient does not experience side effects such as proteinuria, blood disorders, rashes, gastro-intestinal side effects or bleeding.

Other DMARDs

D-Penicillamine is less commonly used, as side effects such as rashes, taste loss and vomiting, are common. It can be effective in some patients, but doses above 750 mg daily are associated with a high incidence of adverse effects. Azathioprine and ciclosporin can be used in refractory rheumatoid arthritis, but use is limited due to monitoring requirements and high incidence of side effects.

Glucocorticoids

Steroids can be given via the oral, intramuscular or intra-articular routes. They act by inhibiting cytokine release and give rapid relief of symptoms and decrease inflammation. Prednisolone is the most commonly used oral steroid. Intra-articular injections, such as triamcinolone or methylprednisolone, are administered into inflamed joints for local anti-inflammatory action, pain relief and to reduce deformity. The effects of the injection tend to last for approximately 4 weeks and should generally not be repeated more than three times a year into an affected joint. Intramuscular and, less commonly intravenous, injections are used as high-dose pulse therapy to control aggressive disease flares.

Steroids are also used as a bridging therapy and are particularly useful when introducing DMARDs which may take several months to take effect. There are various studies which demonstrate steroids are disease modifying in slowing radiological damage over 2 years. Doses of prednisolone 7.5 mg daily have been suggested to reduce the rate of joint destruction in moderate to severe rheumatoid arthritis of less than 2 years' duration (NCCCC, 2009).

Ideally, steroids should be reserved for short-term use in new-onset rheumatoid arthritis because of their long-term complications and adverse effects. However, because they exert such a potent anti-inflammatory effect, it may be difficult in some patients to withdraw therapy as the disease tends to flare with dose reductions. Gradual reducing regimens should be used with the aim to reach the lowest possible maintenance dose. A reducing rate as slow as 1 mg/month may even be necessary in some patients. Steroids can induce osteoporosis, which is a known complication associated with rheumatoid arthritis itself. Prophylactic therapy, such as calcium and vitamin D supplementation and bisphosphonates, should be considered in patients on steroids at a high dose or for an extended period of time. Gastroprotection may also be necessary in the form of H_2 antagonists or proton pump inhibitors. Other adverse effects associated with steroids are diabetes, increased risk of infection, hypertension and weight gain.

Biological therapies

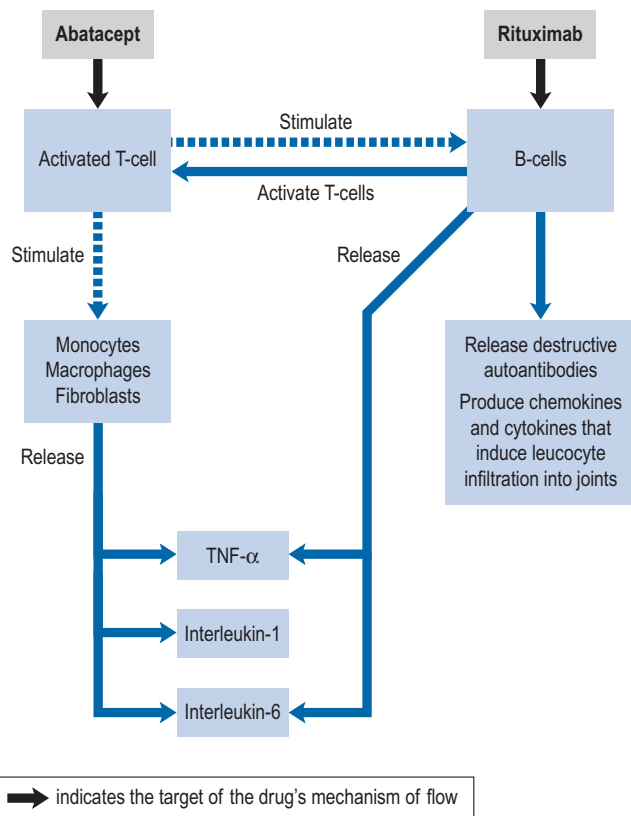
Over the past decade, there have been significant advances in the treatment of rheumatoid arthritis due to emerging biological therapies. The so-called biologics in rheumatoid arthritis are


Fig. 53.3 Biologic agents and their targets in the inflammatory pathway.

genetically engineered monoclonal antibodies which selectively target different parts of the inflammatory pathways (Fig. 53.3). Activated T-cells release pro-inflammatory cytokines including TNF-α, interleukin-1 and interleukin-6. Adalimumab, etanercept, golimumab, infliximab and certolizumab pegol target TNF-α, anakinra and tocilizumab target the interleukins, whilst abatacept and rituximab act on T-cells and B-cells, respectively.

In current practice, biologics are used after a patient has failed DMARDs, although there is emerging evidence to suggest they should be used earlier in the disease. Combination DMARD therapy is increasingly advocated and may lead to earlier use of biologics. For example, a patient may now be trialled on two DMARDs, including methotrexate, over a period of 6 months and if the response is inadequate could be eligible for an anti-TNF agent within a year of diagnosis.

Anti-TNF agents

There are five anti-TNF agents available: adalimumab, etanercept, golimumab, infliximab and certolizumab pegol. All inhibit TNF-α which is an inflammatory cytokine found in high concentrations within the joint synovium of rheumatoid arthritis patients.

Infliximab was the first anti-TNF agent licensed for the treatment of rheumatoid arthritis. It is a chimeric human-murine monoclonal antibody that binds with high affinity to TNF-α, thereby neutralising its activity. Infliximab is the only anti-TNF agent which is given by intravenous infusion and must be given concomitantly with methotrexate. It is

usually well tolerated, with the most common adverse effects being mild infusion reactions, such as headache and urticaria. Anaphylaxis and delayed hypersensitivity reactions have also been rarely reported. As infliximab is a part murine monoclonal antibody, it is thought to carry a higher risk of developing human anti-chimeric antibodies (HACAs). HACAs are associated with an increased frequency of infusion-related reactions and can be minimised by administering with an immunomodulatory therapy.

Adalimumab is a recombinant human monoclonal antibody that binds to and neutralises TNF-α. Etanercept is a human TNF fusion protein that binds to TNF cell surface receptors, thereby inhibiting interaction of TNF-α with its receptors. Certolizumab pegol is a pegylated antibody fragment which binds and neutralises TNF-α and is thought to have a relatively more rapid onset of action. Golimumab is the most recent addition to this family of agents and has the advantage of having a less frequent dosing schedule. (Table 53.3). Optimum clinical benefit is achieved when these drugs are used in combination with methotrexate. However, adalimumab, etanercept and certolizumab pegol can be used alone as monotherapy in patients for whom methotrexate is not appropriate or not tolerated.

Safety

The anti-TNF agents are generally well tolerated, with the main side effects being injection site reactions with the subcutaneous agents, and infusion-related reactions with infliximab.

Table 53.3 Biologic agents used in the treatment of rheumatoid arthritis and typical dose regimens in adults		
Drug	Usual dose	Route
Adalimumab	40 mg every 2 weeks	Subcutaneous
Certolizumab pegol	400 mg at week 0, 2 and 4, then 200 mg every 2 weeks thereafter	Subcutaneous
Etanercept	25 mg twice weekly or 50 mg weekly	Subcutaneous
Golimumab	50 mg monthly	Subcutaneous
Infliximab	3 mg/kg at week 0, 2 and 6, then every 8 weeks thereafter	Intravenous infusion
Rituximab	1 g then 1 g 2 weeks later Max 2 courses/year	Intravenous infusion
Abatacept	750 mg at week 0, 2 and 4, then every 4 weeks thereafter[a]	Intravenous infusion
Anakinra	100 mg daily	Subcutaneous
Tocilizumab	8 mg/kg every 4 weeks	Intravenous infusion

[a]For a patient weighing between 60 and 100 kg; dose modifications are necessary for patients outside this weight range.

There are fewer monitoring requirements compared to the DMARDs and less frequent dosing, making these drugs potentially more appealing. However, the long-term safety of these drugs is being monitored in the UK by the British Society of Rheumatology Biologics Registry. This database collects data on efficacy and safety outcomes of all patients on biologics in a variety of rheumatological conditions including rheumatoid arthritis.

Patients using anti-TNF agents are more susceptible to serious infections such as sepsis, and opportunistic infections. A number of serious infections, including some fatalities, have been reported. Patients should not start anti-TNF therapy in the presence of infection. Those who develop infection whilst receiving treatment should stop and wait until the infection is controlled. The anti-TNF agents have long half-lives and temporary cessation of therapy should be considered prior to and after surgery. Reactivation of hepatitis B and latent tuberculosis has been reported. All patients should be screened for tuberculosis using appropriate tests, such as the tuberculin skin test and a chest X-ray. Active tuberculosis must be treated before an anti-TNF agent is initiated.

Malignancies, including lymphoma, have been reported in studies and post-marketing surveillance of the anti-TNF agents. Caution should be exercised with the use of anti-TNF agents in patients with previous malignancy.

All the anti-TNF agents except etanercept are contraindicated in New York Heart Association (NYHA) grade III/IV heart failure, and all should be used with caution in those with mild heart failure.

Place in therapy

Guidance on the use of adalimumab, etanercept, infliximab (NICE, 2007) and certolizumab pegol (NICE, 2010a) have been published, with the appraisal of golimumab pending. Adalimumab, certolizumab, etanercept or infliximab are recommended as treatment options in adults who meet the following criteria:

- Active rheumatoid arthritis with a DAS28 greater than 5.1 on at least two occasions, 1 month apart.
- Have undergone trials with two DMARDs, including methotrexate, unless contraindicated. A trial of a DMARD is defined as being normally of 6 months, with 2 months at standard dose, unless significant toxicity has limited the dose or duration of treatment.

Patients should be assessed for treatment efficacy using DAS28 every 6 months and continue treatment only if an adequate response is demonstrated 6 months after initiation. An adequate response is currently defined as an improvement in DAS28 of 1.2 points or more.

Changes in eligibility criteria have been suggested (Deighton et al., 2010) which recommend patients should have tried two DMARDs, but those with DAS28 > 3.2 and at least three or more tender joints and three or more swollen joints should be eligible for an anti-TNF agent. Whether NICE will adapt their guidance accordingly is unclear.

Use of the anti-TNF agents above their starting doses as listed in Table 53.3 is not advocated. According to their product licences, doses of adalimumab and infliximab may be escalated according to response, but this does not generally occur in practice.

Generally, the least expensive anti-TNF agent should be used although patient aspects may also affect choice of drug. There are differences between dosing frequencies of the anti-TNF agents, which should be discussed with the patient to ensure drug administration is easily incorporated into their lifestyle, thereby improving adherence. The subcutaneous agents are also available in pen formulations, making it easier for self-administration in patients who have problems with manual dexterity. Patients who are unable to self-administer the subcutaneous anti-TNF agents may choose to receive infliximab as a hospital day case. As infliximab is only licensed to be used in combination with methotrexate, adalimumab, certolizumab and etanercept are favoured in patients where methotrexate cannot be taken.

Rituximab

Rituximab is a chimeric human-murine monoclonal antibody which binds to the C20 antigen on B-lymphocytes to mediate B-cell lysis. It causes depletion of peripheral B-cells which play a role in the pathogenesis of rheumatoid arthritis. Recovery of B-cells appears to occur 6 months after treatment, with some patients showing prolonged B-cell depletion persisting up to 2 years after treatment (Emery et al., 2004).

Rituximab in combination with methotrexate is licensed for the treatment of severe active rheumatoid arthritis in patients who have had an inadequate response or intolerance to other DMARDs including one or more anti-TNF agent. Rituximab is also licensed for non-Hodgkin's lymphoma and chronic lymphocytic leukaemia, both using a different dosing schedule to that of rheumatoid arthritis. A course of rituximab consists of two intravenous infusions administered as a day case in hospital: 1000-mg infusion followed by a second 1000-mg infusion 2 weeks later. The course may be repeated every 6 months depending on patient response. Disease response varies between patients in that some achieve disease remission after one course and do not require re-treatment, whilst others require further repeat infusions every 6–12 months.

Rituximab is generally well tolerated, and the most common adverse effects are infusion-related reactions including fever, changes in blood pressure and rash. Minor infusion-related side effects can be managed by reducing the rate of infusion and giving treatment for relief of symptoms such as paracetamol. The incidence of adverse effects is minimised by pre-medicating with methylprednisolone, paracetamol and an anti-histamine 1 h prior to the infusion. Hypersensitivity reactions and anaphylaxis are rare but serious side effects.

As with the anti-TNF agents, rituximab increases the risk of infections and should not be used in the presence of active or severe infections. Use has been associated with progressive multifocal leukoencephalopathy. It may also exacerbate

existing cardiac conditions such as angina pectoris and atrial fibrillation. Patients with a known history of cardiac disease should be closely monitored during treatment administration for changes in blood pressure and pulse. Anti-hypertensives may be omitted 12 h prior to the infusion. HACAs have been reported in some patients after the first course of rituximab. The presence of HACAs may be associated with worsening of infusion or allergic reactions, and possibly failure to deplete B-cells on further treatment.

In practice, rituximab is used in line with its product license, i.e. after failure of, or intolerance to, DMARD therapy including at least one anti-TNF agent. Patients may continue on rituximab therapy with infusions no more frequent than every 6 months, provided they demonstrate an adequate response of a DAS28 improvement of 1.2 points or more (NICE, 2010b).

Abatacept

Abatacept acts by blocking the full activation of T-cells thereby inhibiting the release of inflammatory cytokines. It is licensed for use in combination with methotrexate in the treatment of moderate to severe active rheumatoid arthritis in adults who have had an insufficient response or intolerance to other DMARDs including at least one anti-TNF agent and who cannot receive rituximab because they have a contraindication to rituximab, or when rituximab is withdrawn due to an adverse event (NICE, 2010a).

Anakinra

Anakinra blocks the binding of interleukin-1 to its receptor, thus inhibiting the inflammatory effects of interleukin-1. The evidence of its benefit in rheumatoid arthritis is weak and it is considered modestly effective. There are no trials directly comparing anakinra with other biologic agents; adjusted indirect comparisons suggest that anakinra may be significantly less effective at relieving the clinical signs and symptoms of rheumatoid arthritis than anti-TNF agents in combination with methotrexate. Anakinra is not cost effective in the treatment of rheumatoid arthritis and availability for routine use in the NHS has not been supported (NCCCC, 2009).

Tocilizumab

Tocilizumab acts by binding to interleukin-6 receptors. Interleukin-6 is a pro-inflammatory cytokine produced by a variety of cells including T- and B-cells, and has been implicated in the pathogenesis of rheumatoid arthritis and other inflammatory diseases. Tocilizumab is licensed for use in combination with methotrexate in the treatment of moderate to severe active rheumatoid arthritis in adults who have had an insufficient response or intolerance to other DMARDs including at least one anti-TNF agent. It is given as a monthly intravenous infusion at a dose of 8 mg/kg and requires regular monitoring of liver function tests and full blood count.

Tocilizumab is recommended for the treatment of rheumatoid arthritis in patients who fulfil the following criteria (NICE, 2010c):

- The patient has not responded adequately to one or more anti-TNF agents

and

- The patient cannot receive rituximab due to a contraindication or
- The patient cannot receive rituximab as they have experienced an adverse effect to treatment or
- The patient has not responded adequately to rituximab treatment.

Which biologic?

More biological therapies for the treatment of rheumatoid arthritis, with new mechanisms of action and targets in the inflammatory pathway, are expected to become available in the near future. Cost is a major factor in the use of biologics with many costing in the region of £10,000 per patient per annum. The decision as to which agent to use is further confounded by the absence of clinical trials that directly compare efficacy between the different biologics.

At present, anti-TNF agents remain the first-line biological therapy. Following failure or intolerance to one anti-TNF agent, patients should then be treated with rituximab. However, if patients cannot receive rituximab due to a contraindication, adverse effect, or intolerance to methotrexate, there remains a number of treatment options (see Fig. 53.4).

Rheumatoid arthritis and pregnancy

The management of rheumatoid arthritis during pregnancy is a common challenge, with disease activity improving in approximately 70–80% of patients. Disease activity usually decreases in the first trimester, and this lasts for a number of weeks to months into the postpartum period. Subsequently, 90% of patients will then experience a flare usually during the first 3 months.

Although case control studies of pregnancy outcome demonstrate a slight increase in spontaneous abortion in women with rheumatoid arthritis, most reports have failed to show an increase in fetal morbidity. Medication may potentially increase this risk, for example, steroids may restrict intrauterine growth. Women with active rheumatoid arthritis or other types of inflammatory arthritis may have children with lower birth weights.

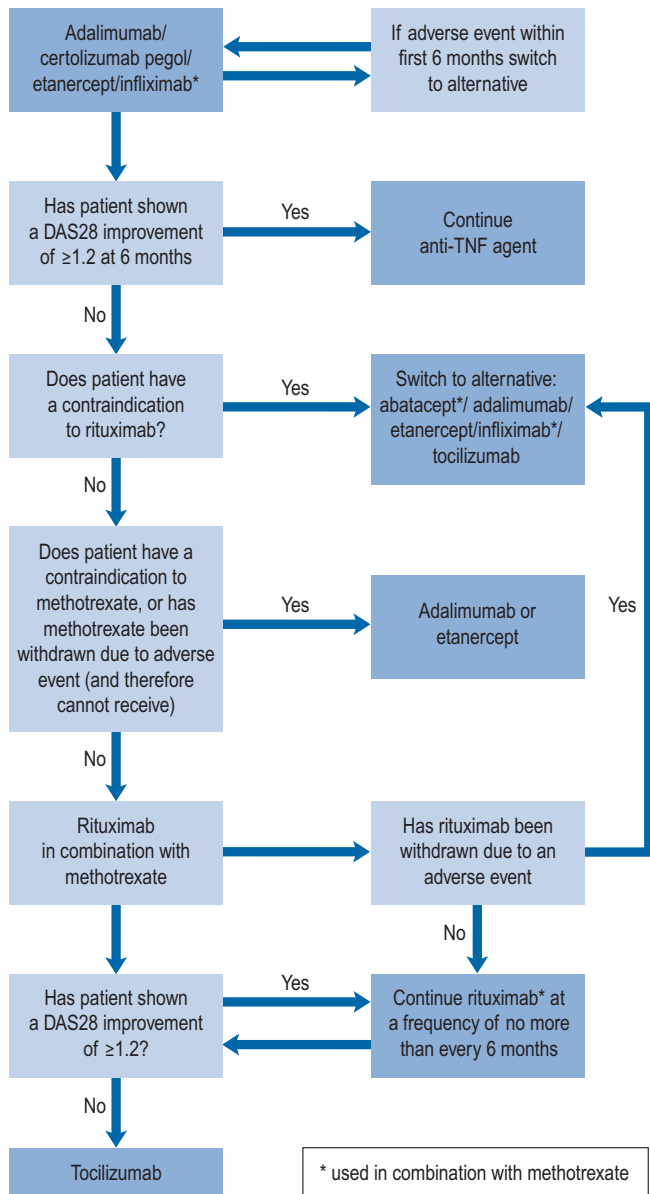
None of the available drug treatments for rheumatoid arthritis are absolutely safe in pregnancy. A prescriber must carefully assess the risks and benefits of treatment in consultation with the patient. In patients with active rheumatoid arthritis during pregnancy, prednisolone is recommended at the lowest dose (below 20 mg daily if possible) to control the disease. Sulphasalazine and hydroxychloroquine are considered safe to prescribe by most obstetric physicians. Many of the DMARDs are contraindicated in pregnancy as they are known teratogens, and some require a washout period before conception, such as leflunomide.


Fig. 53.4 Algorithm following introduction of an anti-TNF agent in the management of rheumatoid arthritis.

Patient care

Patient education and counselling are vital aspects in the management of rheumatoid arthritis. Patients should be encouraged to engage actively in their pharmacological and non-pharmacological treatment, and take responsibility for ensuring their medication regimen is safe and effective. Medicine information sheets are available from the Arthritis Research UK with further information available on their website (http://www.arthritisresearchuk.org/). Monitoring of the potentially toxic DMARDs is essential as non-adherence with the monitoring schedule may have serious consequences. Patients should be reminded of the warning symptoms that must trigger them to contact a healthcare professional. They should also be counselled to inform healthcare professionals of all the medication they are taking before starting a new

medicine, and this includes use of over-the-counter products such as ibuprofen or aspirin.

Shared care agreements between secondary and primary care are often employed for DMARD therapy. This involves a primary care clinician continuing to prescribe and monitor drug treatment which has been initiated by a hospital specialist. Clear guidelines stating responsibilities of both parties, and the action required in the event of toxicity is defined within the document. The main advantage of shared care is that the patient will not be required to attend regular hospital appointments for blood tests and will be managed in primary care.

Some of the common therapeutic problems that are encountered in the management of rheumatoid arthritis are outlined in Table 53.4.

Osteoarthritis

Osteoarthritis is a chronic disease and the most common of all rheumatological disorders. It particularly affects individuals over the age of 65 years and is the major cause of hip and knee replacements in developed countries.

Osteoarthritis was previously thought to be the consequence of ageing, thereby leading to the term degenerative joint disease. However, it is now thought to be the result of a complex interplay of multiple factors including joint integrity, genetic predisposition, local inflammation, mechanical forces and cellular and biochemical processes.

Epidemiology

The prevalence of osteoarthritis increases with age. Generally, osteoarthritis is uncommon under the age of 35 years with 0.1% of people affected between the ages of 25–34 years, but 80% of people affected above the age of 55 years. It occurs in all populations irrespective of race, climate or geographical location. Obesity is the strongest modifiable risk factor and has been shown to particularly affect the knees. Trauma or injury due to diseases, such as rheumatoid arthritis, will predispose a joint to developing osteoarthritis.

A strong genetic component is thought to be present, particularly in women with hand involvement. An inherited defect in type II collagen genes is linked to the development of early-onset polyarticular osteoarthritis.

Aetiology

Osteoarthritis is a complex disease involving bone, cartilage and the synovium. It is generally believed to be an imbalance in erosive and reparative processes. There are a wide variety of factors predisposing an individual to this condition including the following:

- Increasing age
- Gender
- Genetic predisposition
- Congenital abnormality such as Perthes disease of the hip

Table 53.4 Examples of therapeutic problems encountered in the management of rheumatoid arthritis

Problem	Solution
NSAID not providing adequate symptom control	Consider alternative NSAID Review DMARD dose If patient has been on DMARD for a sufficient time period but with no improvement, consider alternative disease-modifying agent, i.e. another DMARD or a biologic agent Consider short-term systemic steroids for rapid relief of symptoms
Patient non-adherent with DMARD monitoring regimen	Education and counselling If patient still unwilling to comply, the safest option would be to consider swapping to DMARDs that require less stringent blood monitoring, for example hydroxychloroquine or sulphasalazine However, relative drug efficacy must also be considered
Nausea and vomiting with methotrexate	Ensure patient is taking folic acid Add anti-emetic therapy Change to parenteral methotrexate
Disease flares when trying to withdraw systemic steroids	Use a slower withdrawal regimen, for example decrease by 1 mg each month If patient cannot be withdrawn completely from steroids, consider reducing to lowest dose possible as maintenance treatment
Side effects of long-term steroids	Aim to use steroids for short-term treatment only Ensure concomitant treatment of PPI, bisphosphonate and calcium and vitamin D preparations are prescribed where appropriate
Patient cannot tolerate stinging at injection site associated with adalimumab or etanercept administration	Consider switching to infliximab

- Obesity
- Previous injury either due to sport or occupation
- Previous disease such as rheumatoid arthritis or gout
- Systemic disorders such as acromegaly
- Neuropathic joint disease such as a Charcot joint

Pathogenesis

The pathogenesis of osteoarthritis has been classified into four stages:

1. Initial repair
2. Early-stage osteoarthritis
3. Intermediate-stage osteoarthritis
4. Late-stage osteoarthritis

Initial repair is characterised by proliferation of chondrocytes synthesising the extracellular matrix of bone. Early-stage osteoarthritis results in degradation of the extracellular matrix as protease enzyme activity exceeds chondrocyte activity. There is net degradation and loss of articular cartilage. Intermediate osteoarthritis is associated with a failure of extracellular matrix synthesis and increased protease activity, further increasing cartilage loss. Finally, late-stage osteoarthritis may result in complete loss of cartilage with joint space narrowing in the most severe of cases. Bone outgrowths (osteophytes) appear at the joint margins, and there is sclerosis of the adjacent bone. Deformity is common at this stage.

Clinical manifestations

Osteoarthritis is traditionally classified by aetiology into idiopathic and secondary forms. Idiopathic can be further divided into localised and generalised depending on the number of joints involved. Localised osteoarthritis most commonly affects the hands, feet, hip, knees and spine, and less commonly the shoulder, temporomandibular, sacroiliac and wrist joints. Pain is increased by movement and loading on the joint, and may radiate beyond the joint itself, as in leg pain associated with spinal disease, and knee pain radiating from the hip. Stiffness in the early morning lasts for less than 30 min, unlike that due to rheumatoid arthritis; it may also occur after periods of rest and throughout the day.

In the hands, the most commonly affected joints are the distal interphalangeal joints or Heberden's nodes, the proximal interphalangeal joints (Bouchard's nodes) and the base of the thumb, the first carpometacarpal joint. Hip pain is particularly felt in the groin. Unlike rheumatoid arthritis, there is no extra-articular disease.

Investigations

Osteoarthritis is primarily diagnosed by its clinical presentation. Confirmation and progression can be achieved by radiography with the presence of joint space narrowing, bone

sclerosis, cysts and deformity. There is a lack of conformity between symptoms and radiological findings. On arthroscopy normal cartilage is smooth, white and glistening, while osteoarthritic cartilage is yellowed, irregular and ulcerated. Synovial fluid analysis should be carried out if one suspects infection or crystal arthropathy such as gout or pseudogout. Blood tests usually reveal a normal ESR and CRP.

Treatment

The aims of treatment are pain relief, optimisation of function and minimisation of disease progression. There are three core interventions which should be considered for every person with osteoarthritis where possible:

- Education, advice and access to information
- Strengthening exercises to improve muscle strength and aerobic fitness training
- Weight loss if overweight or obese

Guidelines are available for the management of osteoarthritis (NCCCC, 2008). If the three core interventions are not sufficient, paracetamol and topical NSAIDs can be added in to the treatment regimen. Paracetamol and topical NSAIDs are deemed 'relatively safe pharmaceutical options' compared to other available agents such as oral NSAIDs, opioids and intra-articular steroids. Other interventions which may also be considered include joint arthroplasty, transcutaneous electrical nerve stimulation (TENS), supports and braces, or manual therapy involving manipulation and stretching.

Paracetamol is the first-line drug treatment and should be used alongside core treatment. Regular dosing may be required as 'when required' administration may lead to reduced efficacy.

Topical NSAIDs, capsaicin and rubefacients are widely used for local relief of pain and inflammation. Topical treatments are perceived as self-management, and this has a positive effect on a patient's perception of their disease.

Due to the recent safety concerns with non-selective NSAIDs and COX-2 inhibitors, treatment regimens have moved towards opioids for uncontrolled pain. This should be balanced against adverse effects such as constipation and drowsiness, particularly in the elderly population.

There is a large amount of evidence supporting the efficacy of NSAIDs in reducing pain and stiffness in osteoarthritis. However, there is no strong evidence to suggest a consistent benefit over paracetamol. Non-selective NSAIDs or COX-2 inhibitors may be considered in patients where paracetamol and/or topical NSAIDs do not provide adequate pain relief, based on careful consideration of the patient's risk factors, as discussed earlier in the chapter. This does not include etoricoxib which is associated with a greater risk of causing fluid retention and aggravating hypertension. NSAIDs should be used at the lowest dose for the shortest period of time possible, and patients should also be prescribed a PPI.

Intra-articular steroids may be of benefit in reducing pain and inflammation in joints. Evidence suggests that they provide short-term reduction in pain, although improvement in function is less clear. They should be considered as an adjunct to core treatment for the relief of moderate to severe pain in osteoarthritis.

Hyaluronan is an endogenous molecule found in the synovial fluid. Its key functions are to increase viscosity of synovial fluid and lubrication within the joint. Synthetic intra-articular injections of hyaluronan are thought to provide pain relief and improve joint function, although there is limited evidence to support this. The synthetic hyaluronans are expensive and not currently recommended.

Nutraceuticals is a term which describes food supplements believed to have health benefits. The most widely used of these agents in osteoarthritis are glucosamine and chondroitin. They are available in a multitude of preparations, combinations, strengths and purities and can be purchased over the counter and via the internet. There is, however, little available evidence of efficacy to support their use.

Case studies

Case study 53.1

Mrs JS is a 46-year-old woman who has been referred by her primary care doctor to the rheumatology outpatient clinic in the local hospital. Her presenting complaint is a symmetrical pattern of inflammation in the joints of her hands, knees and shoulders, and severe pain and stiffness which are worse in the morning. She is a gardener and is finding it increasingly difficult to continue her job due to limited joint function. Her investigations and X-rays confirm a diagnosis of severe seropositive rheumatoid arthritis, including a high CRP and ESR. She takes citalopram for depression and has no other remarkable medical or drug history.

Questions

1. What treatment should be introduced for Mrs JS?
2. What key counselling points should be covered regarding her DMARD therapy?

Answers

1. DMARD treatment should be initiated immediately for Mrs JS as she has seropositive disease which is associated with a poorer outcome. She has no other co-morbidities which contraindicate her to any of the DMARDs. Combination treatment should be started with methotrexate and sulphasalazine as she has severe active disease. Folic acid should be also prescribed at 5 mg weekly. Some clinicians may opt for triple combination therapy of methotrexate, sulphasalazine and hydroxychloroquine.

   Her disease activity is impacting on her life and so rapid relief of symptoms is necessary. Methotrexate and sulphasalazine will take between 6 and 12 weeks to take effect. Multiple joints have been affected, and therefore local steroid injections are inappropriate. Oral prednisolone 30 mg daily should be started, with the aim to withdraw steroids after about 3 months.

   Prednisolone will usually alleviate pain and inflammation effectively and so a NSAID should not be required. However, if additional short-term relief is necessary, an as-required regimen with an NSAID, such as ibuprofen 400 mg three times a day or

naproxen 500 mg twice a day, may be offered. A PPI should be co-prescribed, for example omeprazole 20 mg daily. Paracetamol may also be taken, and may be substituted for co-codamol if the pain is severe and uncontrolled.

Other non-pharmacological measures should be considered, such as physiotherapy. Counselling and psychological support may be particularly important for Mrs JS. Most patients find it useful to have one key healthcare professional to refer to for advice and if they have any problems – this role is usually managed by a specialist nurse.

Mrs JS is started on methotrexate 7.5 mg weekly and sulphasalazine 500 mg twice a day as her disease-modifying treatments.

2. Mrs JS should be counselled on the following:

- Her dose of methotrexate is 3 × 2.5 mg tablets and this should be taken as a single dose on the same day each week. This dose will be increased over the next few weeks.
- Folic acid is given to minimise adverse effects of methotrexate, and should be taken weekly, but not on the same day as methotrexate.
- Both DMARDs will take several weeks to take full effect.
- She will need regular blood monitoring and she should be counselled about possible adverse effects on the liver and bone marrow.
- Warning symptoms to report to a healthcare professional include any sign of infection, unexplained bleeding, bruising, purpura, sore throat, fever, malaise, dyspnoea, persistent dry cough, mouth ulcers, nausea or vomiting.
- A methotrexate-monitoring booklet should be given to Mrs JS and she should be advised that it must be shown to any healthcare professional before receiving any additional medication or treatment.

Case study 53.2

Mr TP is a 58-year-old man who has been on methotrexate 20 mg weekly for the last 2 years for rheumatoid arthritis. He has found that his symptoms are worsening, and he has been taking more regular NSAIDs and analgesia in the last month for pain relief. He has tried sulphasalazine and leflunomide in the past, but was unable to continue therapy due to gastro-intestinal side effects.

Questions

1. How would you manage Mr TP's worsening disease activity?
2. After discussion with Mr TP and consideration of other co-morbidities, the treatment plan is to add in an anti-TNF agent. What additional information is required to ensure Mr TP meets eligibility criteria for treatment?
3. Mr TP admits that he is needle-phobic and does not like the idea of giving himself weekly or fortnightly injections. What treatment options are available to him?

Answers

1. Mr TP is on DMARD monotherapy, and so an additional agent may be beneficial. However, he has not tolerated sulphasalazine and leflunomide which are regarded as the more effective DMARDs, as well as methotrexate. Hydroxychloroquine could be added in alongside methotrexate, but this is unlikely to provide adequate disease modification.

Another treatment option would be to introduce one of the biological agents. The anti-TNF agents are licensed to be used after failure of DMARDs, and would be the next logical step in Mr TP's treatment regimen.

2. Patients should demonstrate severe active disease, measured by two DAS28 assessments greater than 5.1, one month apart. A tender joint count and a swollen joint count should be carried out, ESR should be measured, and Mr TP's perception of his disease severity should be scored on a scale from 0 to 100 on a visual analogue scale. These parameters can then be used to calculate a DAS28 using an online calculator.
3. Adalimumab and etanercept are subcutaneous injections which are usually self-administered by patients. In some cases, a district nurse may be organised to administer the injection at the patient's home. For Mr TP, the thought of having such frequent injections is not desirable, and this may affect adherence to the medication regimen.

Infliximab is given as an intravenous infusion in hospital, and he would not have to administer the drug himself. It has a less frequent dosing compared to the other anti-TNF agents, and it should be discussed with Mr TP whether he is happy to have an infusion every 8 weeks.

Case study 53.3

Mr AR is a 68-year-old man who has stable rheumatoid arthritis which is well controlled on his current drug regimen:

Sulphasalazine 1 g twice a day
Hydroxychloroquine 200 mg twice a day
Co-codamol 30/500 2 four times a day as required
Diclofenac 50 mg three times a day
Ramipril 5 mg once a day
Aspirin 75 mg once a day
Atorvastatin 40 mg once a day at night
Atenolol 50 mg once a day
He also has a history of myocardial infarction.

Question

Comment on his drug regimen.

Answer

High-dose diclofenac (150 mg/day) has been associated with an increased cardiovascular risk, and Mr AR has a history of myocardial infarction. As a consequence, his diclofenac should be stopped. In addition, Mr AR is on aspirin 75 mg daily, and so is as at a higher risk of gastro-intestinal adverse events if he is also taking an NSAID. In general, patients should not take NSAIDs concomitantly with low-dose aspirin unless absolutely necessary.

The reason for regular NSAID use should be investigated. The effectiveness of his DMARD regimen should also be considered, as his disease progression may be causing additional pain and inflammation of the joints. The next step in his disease-modifying treatment would be to consider a third DMARD, such as methotrexate. He may also be a candidate for anti-TNF therapy.

Alternative symptomatic relief that could be offered would be local steroid injections or modifications to his simple analgesia regimen, such as regular paracetamol with codeine as required. Some prescribers may consider using low-dose ibuprofen 400 mg three times a day on an as required basis, although the risk versus benefit regarding gastro-intestinal adverse effects should be considered.

54 Gout and hyperuricaemia

T. Hawkins and A. Cunnington

Key points

- Gout is the most common inflammatory joint disease in men and is strongly age related.
- The prevalence of gout has increased over recent decades.
- It is caused by the deposition of monosodium urate crystals within articular and periarticular tissue.
- The degree of elevation of uric acid levels above the saturation point for urate crystal formation is a major determinant in precipitating an attack.
- Not all people with hyperuricaemia develop gout.
- Gout is normally the result of an interaction between genetic, constitutional and environmental risk factors.
- The aim of long-term therapy is to reduce the serum uric acid level sufficiently so that crystals can no longer form and existing crystals are dissolved.
- Non-pharmacological measures such as lifestyle and dietary modification play an important role in the management of gout.
- Unmanaged recurrent attacks can result in progressive cartilage and bone erosion, deposition of tophi, secondary osteoarthritis and disability.

Introduction

Gout is the most common inflammatory joint disease in men and the most common inflammatory arthritis in older women. It is caused by deposition of monosodium urate crystals in joints and soft tissues following chronic hyperuricaemia. Chronic hyperuricaemia is associated with disorders of purine metabolism due to under excretion or over production of uric acid, the final metabolite of endogenous and dietary purine metabolism. Gout usually presents as a monoarthritis in the first metatarsophalangeal joint (big toe) of the foot and is often referred to as podagra (from the Greek 'seizing the foot'). Subsequent attacks may be polyarticular. Other commonly affected joints include the mid-foot, ankle, knee, wrist and finger joints. Although the attack is extremely painful, it is usually self-limiting resolving spontaneously in 1–2 weeks. Acute attacks are managed with rest, ice and one of the following pharmacological agents: NSAIDs, colchicine or corticosteroids. Some patients may only ever experience one attack, but often a second attack occurs within 6–12 months, with increased risk of subsequent attacks. Patients with recurrent attacks require long-term prophylaxis with drugs that lower the serum urate level. The drug of choice is usually allopurinol, however, a small percentage of patients are unable to tolerate allopurinol and require treatment with an alternative urate-lowering agent such as febuxostat or a uricosuric agent such as benzbromarone, sulphinpyrazone or probenecid. It is essential that pharmacological measures are combined with non-pharmacological measures such as dietary and lifestyle modification to prevent recurrent attacks. Inappropriate management of gout can result in chronic tophaceous gout with polyarticular, destructive low-grade joint inflammation, joint deformity and tophi.

Epidemiology

Gout is one of the oldest recognised diseases and was identified by the Egyptians in 2460 BC. Hippocrates described it as 'arthritis of the rich' due to the association with certain foods and alcohol. Gout affects 1–2% of adults in developed countries, and in recent decades there has been a significant rise in its prevalence and incidence (Zhang et al., 2006). The USA has seen a doubling in the number of cases with the rate of gout increasing to 4.1% in older males. However, unlike the rest of the world, prevalence in the UK appears not to be rising and from 2000 to 2005 remained at 1.4% (Rider and Jordan, 2010). The increasing numbers in many developed countries have been attributed to trends in lifestyle leading to increased risk of gout, for example, obesity, metabolic syndrome, hypertension, alcohol consumption and increased age of the general population. Although the Maori population have a marked genetic predisposition to gout, prior to 1700 they did not experience this inflammatory joint disease. It was changes in diet and lifestyle following European settlement that led to the appearance and increasing prevalence in the country. New Zealand now has probably the highest prevalence in the World with one in eight men affected (Richette and Bardin, 2010). A similar pattern has also been seen in Eastern China, where gout was considered a very rare disease in the 1980s. Changes in diet and lifestyle due to Western influences have seen its prevalence rise to 1.1% in Eastern China in 2008.

In the UK, the presentation of gout in men before the age of 45 years is unusual, but in those over the age of 75 years prevalence is greater than 7% in men and 4% in women (Doherty, 2009; Jordan et al., 2007; Zhang et al., 2006).

Gout is predominantly a disease of men with a male to female ratio of 3.6:1. In women, it tends to develop after menopause when levels of oestrogen, a known uricosuric, fall.

Although environmental factors are clearly implicated in the development of gout, studies have shown that inheritance also plays an important role. In recent years, research into the genetic background of gout has identified several renal urate transporters including URAT-1 and GLUT-9 and the genes that encode them, for example, *SLC22A12* and *SLC2A9*, respectively. Polymorphisms in these genes are associated with increased hyperuricaemia and gout (Dalbeth and Merriman, 2009; Doherty, 2009).

Pathophysiology

Uric acid is mainly a by-product from the breakdown of cellular nucleoproteins and purine nucleotides synthesised *de novo* with about a third coming from the breakdown of dietary purine intake (Fig. 54.1). Uric acid is a weak acid with a pK_a of 5.75, and at the physiological pH of the extra-cellular compartment 98% of uric acid is in the ionised form of urate. This is mainly present as monosodium urate due to the high concentration of sodium in the extra-cellular compartment. Human beings and higher primates lack the enzyme uricase that degrades uric acid to the highly soluble allantoin resulting in higher concentrations of urate close to the level of solubility. Monosodium urate has a solubility limit of 380 μmol/L; when the concentration exceeds 380 μmol/L, there is a risk of precipitation and the formation of monosodium urate crystals.

The production of urate is dependent upon the balance between purine ingestion, *de novo* synthesis in the cells and the actions of xanthine oxidase at the distal end of the purine pathway. Xanthine oxidase is the enzyme that catalyses the oxidation of hypoxanthine, the breakdown product from the catabolism of cellular nucleoproteins and purine nucleotides, to xanthine and xanthine to uric acid.

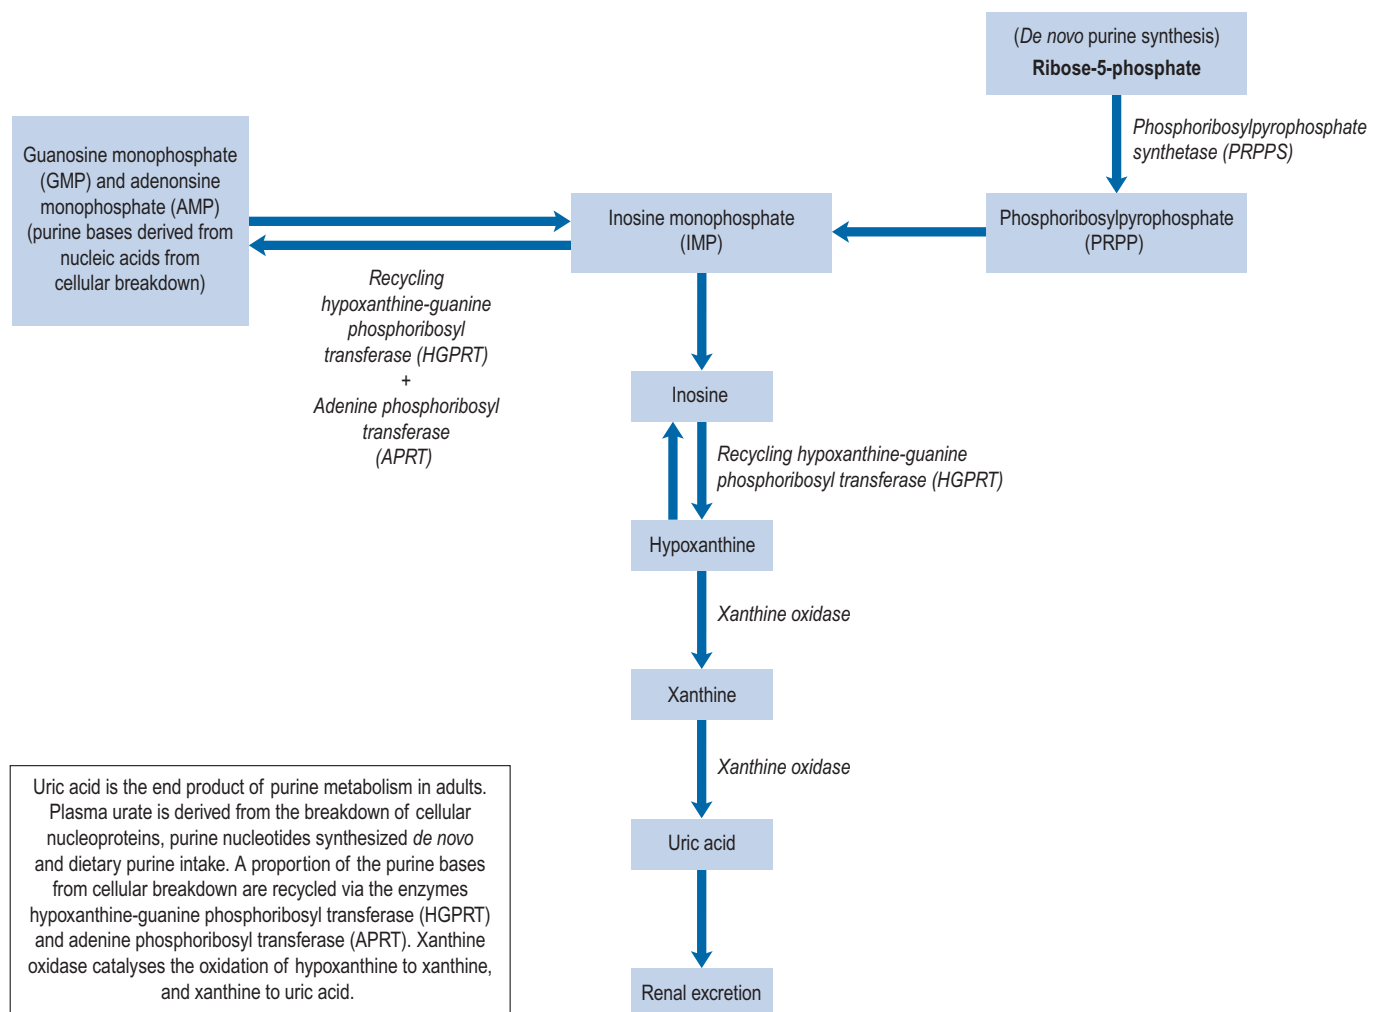
Gout can be classified as primary or secondary, depending on the presence or absence of an identified cause of hyperuricaemia.


Fig. 54.1 Purine pathway.

Primary gout is not a consequence of an acquired disorder, but is associated with rare inborn errors of metabolism and isolated renal tubular defects in the fractional clearance of uric acid. A rare group of enzyme defects result in an increased *de novo* purine synthesis such as hypoxanthine-guanine phosphoribosyl transferase deficiency (Lesch-Nyhan syndrome), phosphoribosyl pyrophosphate synthetase super activity, glucose-6 phosphatase deficiency and myogenic hyperuricaemia (Table 54.1).

Secondary gout is the consequence of the use of specific drugs or develops as a consequence of other disorders. Certain diseases are associated with enhanced nucleic acid turnover, for example, myeloproliferative and lymphoproliferative disorders, psoriasis and haemolytic anaemia, and can lead to hyperuricaemia. Renal mechanisms are responsible for the majority of hyperuricaemia in individuals with over production representing less than 10% of patients with gout. The kidney excretes about two-thirds of the uric acid produced daily with the remainder being eliminated via the biliary tract with subsequent conversion to soluble allantoin by colonic bacterial uricase. Approximately 90% of the daily load of urate filtered by the kidneys is re-absorbed. This re-absorption process is mediated by specific anion transporters such as URAT-1 which is located on the apical side of the renal proximal tubular cells and is an important determinant of urate re-absorption (Richette and Bardin, 2010). The URAT-1 transporter is targeted by a number of drugs including benzbromarone, probenecid, losartan and sulphinpyrazone.

Risk factors

Hyperuricaemia is one of the main risk factors for gout and occurs in about 15–20% of the population (Doherty, 2009). Fortunately, only a minority of individuals with increased serum uric acid levels develop gout suggesting the importance of other contributing factors (Box 54.1).

Genetics

Common primary gout in men often shows a strong familial predisposition, although the genetic basis for this is not fully understood. A polymorphism of the *SLC22A12* gene which encodes for URAT-1 has been associated with under excretion of uric acid and hyperuricaemia in German Caucasians (Graessler et al., 2006). While in a Japanese cohort, another mutation of the *SLC22A12* gene has been shown to be protective for the development of gout (Taniguchi et al., 2005).

The recently identified glucose and fructose transporter (GLU9) also acts as a high-capacity urate transporter in the proximal renal tubules (Dalbeth and Merriman, 2009). Polymorphism in the gene which encodes for this transporter (SLC2A9) has been reported to influence serum uric acid levels, and a significant association with self-reported gout has been described (Dalbeth and Merriman, 2009).

Renal disease

Gout is frequently associated with kidney disease, each being a risk factor for the other. Hyperuricaemia is associated with primary kidney disease, but kidney damage may arise secondary to gout as a consequence of the deposition of urate crystals in the interstitium and tubules of the kidney. Historically, gout was associated with significant renal impairment; however, progressive renal failure directly due to gout is now rare and mainly limited to inadequately treated patients with primary purine overproduction associated with purine enzyme defects, rare forms of inherited renal disease, chronic lead intoxication and renal disease as a consequence of uncontrolled disease states associated with gout e.g. hypertension, type 2 diabetes and congestive cardiac failure. Men with gout have a two-fold higher risk of kidney stones than patients without gout (Jordan et al., 2007). The likelihood of stones increases with serum urate concentration, extent of urinary acid secretion and low urine pH.

Table 54.1 Causes of primary and secondary gout

Primary gout	Secondary gout
Idiopathic	**Increased uric acid production**
Rare enzyme deficiencies	Lymphoproliferative/ Myeloproliferative
Hypoxanthine-guanine phosphoribosyl transferase deficiency (HPRT)	Chronic haemolytic anaemias Secondary polycythemia
Phosphoribosyl pyrophosphate synthetase super-activity	Severe exfoliative psoriasis Gaucher's disease Cytotoxic drugs
Ribose-5-phosphate	Glucose-6 phosphate deficiency
AMP-deaminase deficiency	High purine diet overproduction
	Reduced uric acid secretion
	Renal failure
	Hypertension
	Drugs (diuretics, aspirin, ciclosporin)
	Lead nephropathy
	Alcohol
	Down's Syndrome
	Myxoedema
	Beryllium poisoning

Box 54.1 Risk factors for gout

Genetics
Renal disease
Co-morbidities, for example, obesity, dyslipidaemia, glucose intolerance, hypertension
Diet
Alcohol consumption
Medication

Co-morbidities

Metabolic syndrome is a multiplex risk factor for atherosclerotic cardiovascular disease that consists of atherogenic dyslipidaemia, raised blood pressure, increased blood glucose, and both prothrombotic and pro-inflammatory states. In the USA, metabolic syndrome is present in 63% of those with gout compared to 25% of those without gout (Choi et al., 2007). Other studies have shown obesity, weight gain and hypertension all to be independent risk factors for the development of gout (Choi et al., 2005).

Diet

Gout has often been associated with a rich lifestyle and excesses in diet. In particular, gout is higher in people who consume large quantities of red meat. There is also an increased risk associated with seafood consumption, but to a lesser extent than with red meat. In contrast, a diet high in purine-rich vegetables does not increase the risk, and the consumption of low-fat dairy products reduces the relative risk of gout with each additional dairy serving. The consumption of soft drinks sweetened with sugar (not diet drinks) has also been linked to an increase in the number of gout cases particularly in USA (Choi and Curham, 2008). The mechanism of action is thought to be an increase in uric acid levels caused by an increase in adenine nucleotide degradation. Vitamin C (ascorbic acid) has been shown to have a modest uricosuric effect (Huang et al., 2005). The consumption of cherries, but no other fruits, has also been shown to decrease uric acid levels.

Alcohol

Increased daily consumption of alcohol is associated with a higher risk of gout. Beer carries the greatest risk, probably due to its high purine content, followed by spirits. However, a moderate consumption of wine is not associated with an increased risk of developing gout (Jordan et al., 2007). The mechanism of action involved is thought to be the metabolism of ethanol to acetyl coenzyme A leading to adenine nucleotide degradation, with resultant increased formation of adenosine monophosphate, a precursor of uric acid. Alcohol also raises lactic acid levels in blood, which inhibits uric acid excretion.

Medication

A number of drugs are associated with increased uric acid levels (Box 54.2). The use of both loop and thiazide diuretics is the most common modifiable risk factor for secondary gout, especially in the elderly. It is thought loop and thiazide diuretics may precipitate an attack via volume depletion and reduced renal tubular secretion of uric acid. Aspirin has a bimodal effect; low doses inhibit uric acid excretion and increase urate levels, while doses greater than 3 g/day are uricosuric.

The prescribing of ciclosporin in organ transplant patients is an independent risk factor for new-onset gout in this group. The proposed mechanism of action is the interaction

of ciclosporin with the hOAT10 transporter that mediates urate/glutathione exchange in the kidney (Bahn et al., 2008). Radiotherapy and chemotherapy in patients with neoplastic disorders can cause hyperuricaemia because of increased cell breakdown; to overcome this, prophylactic treatment may be given with allopurinol, commencing 3 days before therapy.

Presentation and diagnosis

An acute attack of gout has a rapid onset, with pain being maximal at 6–24 h of onset and spontaneously resolving within several days or weeks. The first attack usually affects a single joint in the lower limbs in 85–90% of cases, most commonly the first metatarsophalangeal joint (big toe). The next most frequent joints to be affected are the mid-tarsi, ankles, knees and arms. The affected joint is hot, red and swollen with shiny overlying skin. Even the touch of a sheet on the affected joint is too painful for the patient to bear. The patient may also have a fever, leucocytosis, raised erythrocyte sedimentation rate (ESR), and the attack may also be preceded by prodromal symptoms such as anorexia, nausea or change in mood. Following resolution of the attack, there may be pruritis and desquamation of the overlying skin on the affected joint.

Monosodium urate crystals preferentially form in cartilage and fibrous tissues where they are protected from contact with inflammatory mediators. The deposition of crystals may continue for months or years without causing symptoms; it is only when the crystals are shed into the joint space or bursa that inflammatory reaction occurs precipitating an acute attack of gout. The shedding of crystals can be triggered by a number of factors including direct trauma, dehydration, acidosis or rapid weight loss. The acute phase response associated with intercurrent illness or surgery may also precipitate an attack; during this phase, there is increased urinary urate excretion with a lowering of serum uric acid which leads to partial dissolution of monosodium urate crystals and subsequent shedding of crystals into the joint space.

The shed crystals are phagocytosed by monocytes and macrophages, activating the NACHT–LRR–PYD-containing protein-3 (NALP3) inflammasome and triggering the release of interleukin-1β (IL-1β) and other cytokines, a subsequent infiltration of neutrophils and the symptoms of an acute attack (Dalbeth and Haskard, 2005). The NALP3 inflammasome (cryopyrin) is a complex of intracellular proteins that is

activated on exposure to microbial elements, such as bacterial RNA and toxins. Activation of NALP3 leads to the release of caspase-1, which is required for cleavage of pro-IL-1β to active IL-1β (Richette and Bardin, 2009). IL-1β has been shown to be critically associated with the inflammatory response induced by monosodium urate crystals (Rider and Jordan, 2010).

A third of patients will have normal uric acid concentrations during an acute attack of gout due to increased urinary urate excretion. The most appropriate time to measure serum urate for monitoring purposes is when the attack has completely resolved. The gold standard for the diagnosis of gout is the demonstration of urate crystals in synovial fluid or in a tophus by polarised light microscopy (Zhang et al., 2006). Crystals may be found in fluid aspirated from non-inflamed joints, even in those joints which have not previously experienced an attack. The crystals are large (10–20 μm) and needle shaped with a strong, intense, characteristic light pattern under polarised light. In contrast, the calcium pyrophosphate dehydrate crystals associated with pseudo-gout are small rhomboid crystals of low intensity. Gout and septic arthritis may co-exist and in order to exclude septic arthritis synovial fluid is sent for Gram staining and culture.

Fig. 54.3 Chronic tophaceous gout.

Course of disease

The course of gout follows a number of stages; initially, the patient may be asymptomatic with a raised serum uric acid level (Fig. 54.2). Some patients may only ever experience one attack, but often a second attack occurs within 6–12 months. Subsequent attacks tend to be of longer duration, affect more than one joint and may spread to the upper limbs. Untreated disease can result in chronic tophaceous gout, with persistent low-grade inflammation in a number of joints resulting in joint damage and deformity. The disease is characterised by the presence of tophi (Fig. 54.3), monosodium urate crystals surrounded by chronic mononuclear and giant-cell reactions. Tophi deposition can occur anywhere in the body, but they are commonly seen on the helix of the ear, within and around the toe or finger joints, on the elbow, around the knees or on the Achilles tendons. The skin overlying the tophi may ulcerate and extrude white, chalky material composed of monosodium urate crystals.

Treatment

The management of gout can be split into the rapid resolution of the initial acute attack and long-term measures to prevent future episodes (see Box 54.3).

Gout is often associated with other medical problems including obesity, hypertension, excessive alcohol and the metabolic syndrome of insulin resistance, hyperinsulinaemia, impaired glucose intolerance and hypertriglyceridaemia. This contributes to the increased cardiovascular risk and deterioration of renal function seen in patients with gout. Management is not only directed at alleviating acute attacks and preventing future attacks, but also identifying and treating other co-morbid conditions such as hypertension and hyperlipidaemia. Pharmacological measures should be combined with non-pharmacological measures such as weight loss, changes in diet, increased exercise and reduced alcohol consumption.

Management of an acute attack

Drugs used in the management of an acute attack include NSAIDs, colchicine and corticosteroids. NSAIDs are the recommended first-line agents, but in a number of patients their use is contraindicated and a second-line agent is indicated

---

Reduce risk of co-morbidities, for example, cardiovascular disease
Lifestyle modification

Box 54.4   Management of an acute attack of gout

Promptly and safely resolve pain
    First line: NSAID (use maximum dose)
    Second line: Colchicine
    Third line: Corticosteroid (consider first line in mono-articular
    disease)
    (±Simple and opiate analgesia if needed, for example,
    paracetamol, codeine dihydrocodeine)
Rest the joint 1–2 days and treat with ice
Remove contributing factors
    Review medication
    Review lifestyle

(Box 54.4). Where the pain is not adequately controlled by treatment, paracetamol and weak opiate analgesics, for example, codeine or dihydrocodeine may be added to the regimen to provide additional relief. Treatment should be continued until the attack is terminated, usually between 1 and 2 weeks. The affected joints should also be rested for 1–2 days and initially treated with ice which has a significant analgesic effect during an acute attack.

A complete medication review should be performed, and ideally medication which is likely to have contributed to the attack discontinued. Where loop and thiazide diuretics are being used for the management of hypertension alone, an alternative anti-hypertensive agent should be considered according to national guidance. Losartan, an angiotensin receptor blocker effective in hypertension, has been shown to have uricosuric properties and is a suitable agent in hypertensive patients with gout (Sica and Schoolwerth, 2002; Takahashi et al., 2003). In patients with heart failure, diuretics are often essential and cannot be discontinued. Certain NSAIDs may be preferable in patients on diuretics with both indometacin and azapropazone (no longer licensed in the UK) demonstrating an increase uric acid secretion. Moreover, the diuretic effect of furosemide appears unaffected by azapropazone and azapropazone's ability to promote uric acid secretion is sustained (Williamson et al., 1984).

Allopurinol should not be commenced during an acute attack as it may prolong or precipitate another attack. However, in patients already established on allopurinol therapy, allopurinol should always be continued during the attack. Aspirin at analgesic doses (600–2400 mg/day) should be avoided as it blocks urate secretion. The continuation or initiation of low-dose aspirin (75–150 mg/day) is recommended in patients with cardiac disease as the benefits outweigh the minimal effect on serum uric acid levels.

Non-steroidal anti-inflammatory drugs

Maximum doses of an NSAID should be commenced rapidly after the onset of an attack and then tapered 24 h after the complete resolution of symptoms. The usual treatment period is 1–2 weeks. NSAIDs act by direct inhibition of cyclo-oxygenase-1 (COX-1) and cyclo-oxygenase-2 (COX-2) via blockade of the cyclo-oxgenase enzyme site. The subsequent inhibition of prostaglandin production reduces inflammation, but also results in additional activities on platelet aggregation, renal homeostasis and gastric mucosal integrity.

Although the NSAIDs differ in chemical structure, they all have similar pharmacological properties in terms of anti-inflammatory and analgesic action, and have similar drug interactions. For a number of years, indometacin was considered the NSAID of choice in gout largely because it was one of the first NSAIDs shown to be effective in the management of gout. However, it has not been shown to be of superior efficacy or safety when compared to other NSAIDs used in the management of acute gout (Jordan et al., 2007).

Azapropazone (1200–1800 mg/day) has been shown to have both anti-inflammatory and uricosuric effects during an acute attack. Unfortunately, use is associated with a higher risk of upper gastro-intestinal side effects when compared to other high-dose NSAIDs (diclofenac, ibuprofen, naproxen, indometacin and ketoprofen), and this significantly restricts its use.

Overall, there is no convincing evidence to promote the use of one NSAID over another in the management of acute gout.

In an effort to reduce the side effects of NSAIDs, and particularly the gastro-intestinal side effects, agents were developed to selectively block COX-2 and have minimal effect on COX-1. COX-2 selective agents are recommended for use in patients who are at high risk of developing gastro-intestinal side effects, but they are not recommended for routine use. It should be noted that the selective benefit of COX-2 inhibitors is lost in patients taking low dose aspirin. The selective COX-2 inhibitor etoricoxib in a daily dose of 120 mg has been shown to give comparable rapid relief of pain in acute gout to indometacin 50 mg three times daily but with fewer side effects (Schumacher et al., 2002). However, a systematic review and meta-analysis of studies involving etoricoxib have demonstrated an increased risk of cardiovascular thromboembolic events (Aldington et al., 2005). Although there are currently no data directly comparing the cardiovascular risk associated with selective and non-selective NSAIDs, it is recommended that the use of COX-2 inhibitors is avoided in patients with established heart disease, cerebrovascular disease or peripheral vascular disease.

NSAIDs should be avoided in patients with heart failure, renal insufficiency and a history of gastric ulceration. Care should also be exercised in elderly patients with multiple pathologies. When prescribing an NSAID, the need for gastric protection should be considered in patients at increased risk of a peptic ulcer, bleed or perforation.

Colchicine

Colchicine is an alkaloid derived from the autumn crocus (colchicum autumnale) and has been reported to have been used in the treatment of gout since the 6th century AD. Colchicine has a slower onset of action than NSAIDs but is recommended in patients where NSAIDs are contraindicated. It should be started as soon as possible after the onset of an attack.

Although the mode of action of colchicine in gout is not fully understood, it is thought to arrest microtubule assembly in neutrophils and inhibit many cellular functions. It suppresses

monosodium urate crystal-induced NALP3 inflammasome-driven caspase-1 activation, IL-1β processing and release, and L-selectin expression on neutrophils. Colchicine also blocks the release of a crystal-derived chemotactic factor from neutrophil lysosomes, blocks neutrophil adhesion to endothelium by modulating the distribution of adhesion molecules on the endothelial cells and inhibits monosodium urate crystal-induced production of superoxide anions from neutrophils (Nuki, 2008).

Although widely used, there are few studies that demonstrate the efficacy of colchicine. A single, randomised, controlled trial has compared the benefits of colchicine to placebo in acute gouty flare (Ahern et al., 1987). Patients were given 1 mg of colchicine followed by 500 μcg every 2 h until the attack stopped or they felt too ill to continue taking colchicine. Colchicine was found to be superior to placebo with an absolute reduction of 34% for pain and a 30% reduction in clinical symptoms such as palpation, swelling, redness and pain. The number needed to treat (NNT) with colchicine to reduce pain was 3 and the NNT to reduce clinical symptoms was 2. All participants given colchicine experienced gastro-intestinal side effects such as diarrhoea and/or vomiting. There are no studies comparing colchicine to either NSAIDs or corticosteroids in an acute flare of gout.

The current dose of colchicine licensed for the management of an acute attack of gout is 1 mg initially, followed by 500 μcg every 2–3 h until relief of pain is obtained or vomiting or diarrhoea occurs. A maximum of 6 mg should be given per course and treatment should not be repeated within 3 days. This dosage regimen frequently causes diarrhoea and other toxic side effects, particularly in elderly patients (Morris et al., 2003; Terkeltaub et al., 2008). It is therefore recommended that a dose of 500 μcg given twice or four times a day should be used to reduce toxicity. Intravenous colchicine is no longer licensed in the UK because use has been associated with a number of fatalities (2% mortality rate).

Common side effects associated with colchicine are abdominal cramps, nausea, vomiting, and rarely bone marrow suppression, neuropathy and myopathy. Side effects are more common in patients with hepatic or renal impairment. The dose of colchicine should be reduced in mild to moderate renal impairment, for example creatinine clearance 10–50 mL/min, and it should not be used in patients with severe renal impairment, for example creatinine clearance less than 10 mL/min. Care should also be exercised in patients with chronic heart failure due to colchicine's ability to constrict blood vessels and stimulate central vasomotor centres.

Colchicine is metabolised by CYP3A4 and excreted by p-glycoprotein; toxicity can be caused by drugs that interact with its metabolism and clearance, and this includes macrolides, ciclosporin and protease inhibitors. The absorption of vitamin B_{12} may be impaired by chronic administration of high doses of colchicine.

Corticosteroids

Corticosteroids are usually considered where use of an NSAID or colchicine is contraindicated or in refractory cases. They may be given intravenously, intramuscularly or direct into a joint (intra-articular) when only one or two joints are affected. In patients with a monoarthritis, an intra-articular corticosteroid injection is highly effective in treating an attack.

Intramuscular triamcinolone acetonide 60 mg has been shown to be as safe and effective as indometacin 50 mg three times daily in treating an acute attack of gout with earlier resolution of symptoms in the steroid group (Alloway et al., 1993). Common doses of intra-articular steroids are 80 mg of methylprednisolone acetate for a large joint such as a knee; 40 mg of methylprednisolone acetate or 40 mg of triamcinolone acetonide for a smaller joint such as a wrist or elbow. Oral prednisolone 30 mg daily for 5 days has also been shown to be equally efficacious to indometacin 50 mg three times a day for 2 days or 25 mg three times a day for 3 days plus paracetamol and has fewer adverse events (Man et al., 2007). Oral steroid regimens used in practice include prednisolone 30 mg daily for 1–3 days with subsequent dose tapering over 1–2 weeks. Intramuscular steroid injections (methylprednisolone acetate 80–120 mg) may sometimes be used to prevent the precipitation of a flare on initiation of prophylactic treatment for gout. Corticosteroids may have fewer adverse events than other acute treatments when used short term, particularly in the elderly.

Interleukin-1 inhibitors

IL-1β is critically associated with the inflammatory response induced by monosodium urate crystals (Rider and Jordan, 2010). Anakinra, an IL-1 receptor antagonist, has been shown to reduce the pain of gout and bring about complete resolution by day 3 in the majority of patients after a course of three 100-mg subcutaneous injections (McGonagle et al., 2007; So et al. 2007). Other IL-1 inhibitors, such as rilonacept, are under development.

Management of chronic gout

The presence of hyperuricaemia is not an indication to commence prophylactic therapy. Some patients may only experience a single episode and a change in lifestyle, diet or concurrent medication may be sufficient to prevent further attacks. Patients who suffer one or more acute attacks within 12 months of the first attack should normally be prescribed prophylactic urate-lowering therapy (see Fig. 54.4). There are, however, some groups of patients where prophylactic therapy should be instigated after a single attack. These include individuals with uric acid stones, the presence of tophi at first presentation and young patients with a family history of renal or cardiac disease. The criteria for starting prophylactic therapy for gout is detailed in Box 54.5.

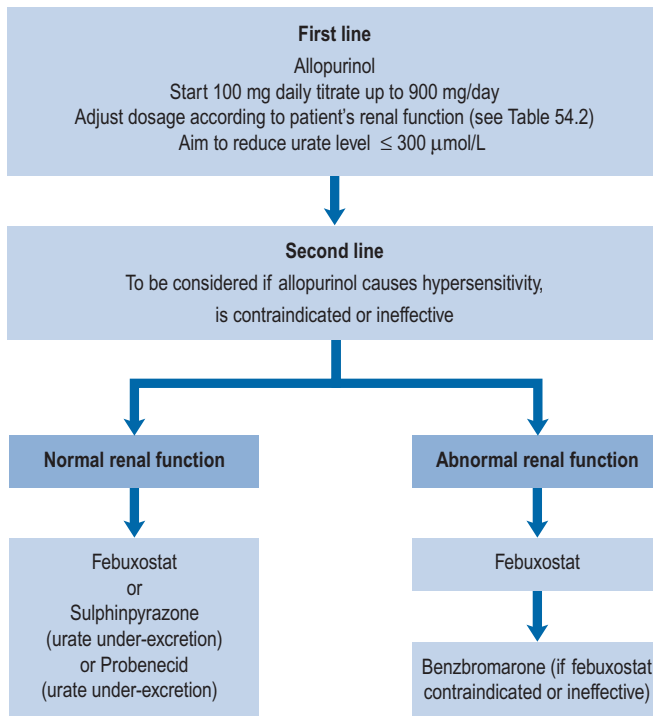
The aim of prophylactic gout treatment is to maintain the serum urate level below the saturation point of monosodium urate (300 μmol/L). If the serum urate is maintained below this level, crystal deposits dissolve and gout is controlled. Prophylactic treatment should not be initiated until an acute attack of gout has completely resolved, usually 2–3 weeks


Fig. 54.4 Management of chronic gout in patients requiring urate-lowering therapy.

Table 54.2 Recommended dose of allopurinol in patients with diminished renal function

Creatinine clearance (mL/min)	Dose
0	100 mg three times a week
10	100 mg alternate days
20	100 mg daily
40	150 mg daily
60	200 mg daily
>100	300 mg daily

after symptom resolution. Once started, prophylactic treatment should be continued indefinitely even if further acute attacks develop.

Drugs that lower serum uric acid can be classified into three groups according to their pharmacological mode of action (Box 54.6).

Uricostatic agents

Uricostatic agents act on the enzyme xanthine oxidase. Xanthine oxidase catalyses the oxidation of hypoxanthine to xanthine and subsequently xanthine to uric acid (Fig. 54.1). Hypoxanthine comes from the catabolism of cellular nucleoproteins and purine nucleotides. Blocking the action of this enzyme reduces the production of uric acid. Agents in this group include allopurinol and febuxostat.

Allopurinol. Allopurinol is the prophylactic agent of choice in the management of recurrent gout. In order to become pharmacologically active, allopurinol must be metabolised by the liver to oxypurinol. Oxypurinol has a much longer half-life than allopurinol, 14–16 h compared to 2 h. Both allopurinol and oxypurinol are renally excreted, with oxypurinol undergoing re-absorption from the renal tubule. In patients with reduced renal function, the half-life of oxypurinol is increased with the risk of accumulation and toxicity. It is, therefore, essential that a patient's renal function is checked prior to the prescribing of allopurinol and the dose adjusted accordingly (Table 54.2).

In patients with normal renal function, the starting dose is 100 mg/day; this is gradually increased in 100-mg increments every 2–3 weeks until the optimal serum urate level (<300 μmol/L) or the maximum dose is reached. The maxi-mum recommended daily dose in patients with normal renal function is 900 mg/day. A decrease in serum urate will occur within a couple of days of introducing allopurinol therapy with a peak effect at 7–10 days. The dissolution of tophi may take up to 6–12 months with effective therapy.

Approximately 3–5% of patients treated with allopurinol suffer from an adverse reaction. Intolerance usually manifests itself as a hypersensitivity reaction within the first 2 months of treatment. Adverse effects reported with allopurinol therapy include rash, fever, worsening renal failure, hepatotoxicity, vasculitis and even death. Severe toxic effects arise in less than 2% of patients. The risk of toxicity increases with renal impairment, age and concurrent drug therapy such as diuretics.

Prior to the availability of febuxostat, allopurinol desensitisation was attempted in patients with a mild hypersensitivity to allopurinol. This involved starting with a very low dose (50 μcg daily) and gradually increasing the dose over a period of several weeks to 100 mg daily. Desensitisation is now only considered where the reaction has been mild and there is an absence of alternative treatment options.

Azathioprine and mercaptopurine are metabolised by xanthine oxidase, co-administration of allopurinol reduces the metabolism of these two medicines leading to accumulation and toxicity. The dose of azathioprine or mercaptopurine

should be reduced to approximately a quarter of the normal dose when co-prescribed with allopurinol. In addition, full blood counts should be performed at regular intervals to identify potential toxicity. High-dose allopurinol (>600 mg/day) increases carbamazepine blood levels by approximately one third; the same effect is not associated with lower doses of allopurinol (<300 mg/day).

Febuxostat. Febuxostat is a more selective and potent inhibitor of xanthine oxidase than allopurinol and has no effect on other enzymes involved in purine or pyrimidine metabolism (Lawrence Edwards, 2009). It is licensed for the treatment of chronic hyperuricaemia in conditions where urate deposition has already occurred including a history, or presence of, tophus and/or gouty arthritis. It is recommended as a second-line agent in patients who are intolerant of allopurinol or for whom allopurinol is contraindicated.

Febuxostat is more effective than fixed-dose allopurinol 300 mg in lowering uric acid concentrations in trials of up to 40 months' duration (Schumacher et al., 2008, 2009). However, a reduction in the incidence of episodes of acute gout has not been demonstrated.

The recommended starting dose for febuxostat is 80 mg once daily. If the serum uric acid is greater than 357 μmol/L, after 2–4 weeks, the dose should be increased to 120 mg once daily. The increased potency and good oral bioavailability of febuxostat leads to rapid decreases in serum uric acid levels permitting the testing of levels 2 weeks after starting therapy or adjusting the dose. No dosage adjustment is necessary in patients with mild or moderate renal impairment; however, there are no current recommendations for use in patients with severe renal impairment, for example creatinine clearance <30 mL/min. In patients with mild hepatic impairment, the dose should not exceed 80 mg daily; the use of febuxostat has not been studied in patients with severe hepatic impairment. Febuxostat should not be given to patients with ischaemic heart disease or congestive heart failure because of cardiovascular side effects. When initiating therapy with febuxostat, gout flare prophylaxis should be prescribed for at least 6 months.

The most common adverse effects include respiratory infection, diarrhoea, headache and liver function abnormalities. It is recommended liver function should be tested in all patients prior to the initiation of therapy and periodically thereafter based on clinical judgement. The use of febuxostat is not recommended in patients concomitantly treated with mercaptopurine or azathioprine and in patients taking theophylline, serum levels of theophylline should be monitored.

Uricosuric agents

Uricosuric agents increase uric acid excretion primarily by inhibiting post-secretory tubular absorption of uric acid from filtered urate in the kidney. They are indicated as second-line agents in those who are urate under-excreters and are dependent on the patient having an adequate level of renal function. These agents should be avoided in patients with urate nephropathy or those who are over producers of uric acid due to the high risk of developing renal stones. Patients receiving a uricosuric agent are required to maintain an adequate fluid intake, and the need for alkalinisation of urine should be considered to prevent urate precipitation

Benzbromarone. Benzbromarone has been shown to be effective in lowering serum urate levels and reducing the time to resolution of tophi (Kumar et al., 2005; Reinders et al. 2009). However, its use was associated with hepatoxicity and it was withdrawn from the UK. It is still possible to obtain benzbromarone on a named patient basis. The risk of hepatotoxicity has been estimated to be 1:17,000 patients. For those who are prescribed benzbromarone, regular liver function tests must be performed during the first 6 months of therapy, and the hepatotoxic risk associated with the medicine should be clearly explained to the patient at the outset.

The dose ranges from 50 to 200 mg daily. It remains active in mild to moderate renal impairment and is indicated where there is a contraindication to other agents used in the management of gout such as allopurinol and febuxostat (see Fig. 54.4). Diarrhoea may be troublesome in approximately 10% of patients.

Sulphinpyrazone. Sulphinpyrazone is effective in reducing the frequency of gout attacks, tophi and plasma urate levels at doses of 200–800 mg/day. It has the same mode of action on the kidney as benzbromarone and probenecid all of which inhibit URAT-1 transporter resulting in reduced urate re-absorption. However, in addition to this, sulphinpyrazone inhibits prostaglandin synthesis resulting in a similar adverse effect profile to NSAIDs, for example gastro-intestinal ulceration, acute renal failure, fluid retention, elevated liver enzymes and blood disorders. The use of sulphinpyrazone is reserved for use in patients with adequate renal function who are underexcretors of uric acid and intolerant or resistant to treatment with allopurinol.

Probenecid. Probenecid monotherapy is less effective than the other agents in this group and generally not recommended. It may have a role as an add-on agent when allopurinol alone is insufficient. Doses of 0.5–2.0 g/day have been used. As with sulphinpyrazone, it is ineffective in renal impairment. Dyspepsia and reflux may be troublesome in some patients, and it can interact with renally excreted anionic drugs. It is no longer marketed in the UK.

Uricolytics

Uricolytic drugs convert uric acid to allantoin through the actions of the enzyme urate oxidase (uricase). Allantoin is more soluble than uric acid and readily excreted by the kidney. Uricolytics are indicated for hyperuricaemia associated with tumour lysis syndrome and are not indicated for other forms of hyperuricaemia.

Rasburicase. Rasburicase, a recombinant form of the enzyme urate oxidase (uricase), is derived from a cDNA code from a modified *Aspergillus flavus* strain expressed in a modified strain of *Saccharomyces cerevisiae*. It is licensed to treat tumour lysis syndrome and is given intravenously at a dose of 0.2 mg/kg in short courses for 5–7 days. Rasburicase has a half-life of approximately 19 h. No dosage adjustment is required in patients with renal or hepatic impairment.

Rasburicase is generally well tolerated, but adverse effects include fever, nausea, vomiting, rash, diarrhoea, headache, allergic reactions and the development of auto-antibodies.

Polyethylene glycol-uricase (PEG-uricase). PEG-uricase is a pegylated, recombinant form of uricase. Pegylation of the molecule reduces the risk of patients developing auto-antibodies and lengthens the half-life of the drug. It is effective in reducing tophi. The use of PEG-uricase has been associated with severe infusion reactions in a small minority of patients; this and its high cost are likely to limit its use. It may have a role in severe, refractory cases or as a short-term treatment to remove tophi prior to the initiation of conventional urate-lowering therapies.

Preventing gout flare

When prophylactic treatment is commenced, there is a risk of precipitating an acute gout attack, or 'mobilisation flare', for approximately 12 months. Mobilisation flares are thought to be caused by the rapid fall in serum urate following the initiation of urate lowering. The risk of precipitating an acute attack can be reduced by delaying the initiation of long-term urate-lowering therapy until the acute attack has completely resolved and prescribing colchicine or an NSAID during the treatment initiation period.

Colchicine

Colchicine is the agent of first choice to prevent the precipitation of a flare when commencing chronic gout treatment. Low doses of colchicine (500 µcg orally twice a day) should be prescribed and continued for at least 6 months. There are no randomised controlled trial data assessing the effectiveness of colchicine as a single agent to prevent recurrent gout, but it has been shown to help reduce mobilisation flares for up to 6 months after starting allopurinol.

NSAIDs

If there are no contraindications to the use of NSAIDs, they may be considered second line to colchicine in patients' intolerant to colchicine. NSAIDs should be continued for a maximum of 6 weeks.

Patient care

It is important to inform patients about the disease, its curable nature, the aims of drug therapy and how to prevent and handle flares. The need for dietary and lifestyle changes should also be stressed. The UK Gout Society website can assist in providing patients with information about the condition and how it should be managed (http://www.ukgoutsociety.org/). In over-weight patients, gradual weight loss should be encouraged, very rapid weight loss should be avoided as it can cause ketosis and result in raised uric acid levels with the likelihood of precipitating an attack. Low purine diets are difficult to

adhere to; a calorie-restricted diet with low carbohydrate (40% of energy), high protein (30% of energy) and unsaturated fat (30% of energy) should be recommended. The importance of avoiding or reducing alcohol consumption should also be emphasised.

Patients at risk of recurrent attacks should be issued with a suitable NSAID to treat the attack as soon as possible. The patient should be clear on what dose to take, when to initiate therapy, how long to take the medication for and any possible side effects to look out for. The patient should also be advised to avoid certain over-the-counter medicines which may exacerbate an attack, for example the use of aspirin as an analgesic.

Those taking long-term prophylactic therapy need to understand the importance of continuing therapy despite being asymptomatic. They should avoid running out of medication, as a short gap in therapy may precipitate an attack. Patients receiving uricosuric agents should be advised to maintain a fluid intake of at least 2 L/day to reduce the risk of uric acid stone formation in the kidneys.

Case studies

Case 54.1

Mr TH is a 50-year-old, slightly over-weight (95 kg) male who presents with an extremely painful big toe. He states that the pain started suddenly in the early hours of the morning and that he cannot even bear to put a sock over his foot. He can think of no recent trauma to his foot. He has no other symptoms and there is no previous significant medical history apart from high blood pressure for which he takes bendroflumethiazide (2.5 mg in the morning). On examination, the toe is red, hot, swollen and extremely painful on palpation. The patient also has an elevated blood pressure of 150 mm/95 mmHg. On questioning about his weekly alcohol intake, he states that he usually does not exceed 21 units/week, but that it was a friend's 50th birthday party recently and he might have had considerably more to drink than usual. Blood results show a slightly raised C-reactive protein, other parameters are normal including renal function; however, his serum urate is slightly raised (390 µmol/L). A diagnosis of acute gout is made.

Questions

1. What initial therapy would you recommend to treat the patient's acute attack of gout?
2. What risk factors could have contributed to the acute attack?
3. Should this patient be placed on therapy to prevent further attacks?
4. What lifestyle and dietary advice would you give to the patient to assist in preventing further attacks?

Answers

1. Initial therapy should be directed at promptly and safely resolving the pain. Drugs used in the management of an acute attack include NSAIDs, colchicine and corticosteroids. NSAIDs are indicated as first-line agents, but there are a number of patients

who cannot take these medicines, and this includes those with renal impairment, heart failure or a history of gastric ulceration. Caution should also be exercised in elderly patients with multiple pathologies as they are prone to develop side effects with NSAIDs, particularly gastric symptoms. Colchicine has a slower-onset action then NSAIDs (6 h vs. 2 h) and is usually indicated where NSAIDs are contraindicated. When only a single joint is affected, an intra-articular injection directly into the joint may be considered; however, this is often too painful for the patient to bear.

As the patient has no contraindications, it would be appropriate to start an NSAID at maximal dose for 2–3 days and then reduce and continue for a further 7–10 days. There is no evidence to promote the use of one NSAID over another in the management of an acute attack; the main issue is to start therapy as soon as possible at maximal dose provided there are no contraindications. When initiating an NSAID, the need for gastric protection should be considered particularly in those aged over 65 years, previous history of peptic ulcer disease or gastro-intestinal complications and other medicines associated with gastro-intestinal side effects.

COX-2 inhibitors such as etoricoxib selectively block the COX-2 pathway resulting in reduced gastro-intestinal side effects. These agents are recommended for patients with high risk of gastro-intestinal side effects, but they are not recommended for routine use. Etoricoxib has been shown to be as equally effective as indometacin with fewer adverse effects. However, a systematic review and meta-analysis of etoricoxib showed an increased risk of cardiovascular and thromboembolic events associated with its use. It is recommended that COX-2 inhibitors be avoided in patients with established heart disease, cerebrovascular disease or peripheral vascular disease.

Where the patient's pain is not adequately controlled by an NSAID, simple and low-potency opiate analgesia can be added to the regimen. The affected joint should be rested for 1–2 days and the affected area treated with ice.

2. Hyperuricaemia (raised serum uric acid levels) is one of the main risk factors for the development of gout; however, not all patients with a raised serum uric acid level will go on to develop gout. Studies have shown obesity, weight gain and hypertension all to be independent risk factors for the development of gout. Mr TH is slightly over-weight and has a history of hypertension. Measurement of his serum lipid levels should be considered as dyslipidaemia is commonly associated with gout.

Loop and thiazide diuretics are one of the most common modifiable risk factors associated with gout. It is thought they exert their action via volume depletion and the reduced tubular renal secretion of uric acid. In patients with heart failure, diuretics are often essential and cannot be discontinued. Mr TH's bendroflumethiazide is being used for the management of hypertension and a change to an alternate hypertensive agent should be considered. Losartan, an angiotensin receptor blocker, has been shown to have both anti-hypertensive and urate-lowering properties and is suggested as a suitable agent in hypertensive patients with gout.

Alcohol consumption is an important risk factor for the development of gout. The mechanism of action is thought to be due to the metabolism of ethanol to acetyl coenzyme A leading to adenine nucleotide degradation and a subsequent rise in the levels of adenosine monophosphate which is a precursor of uric acid. Beer drinking is associated with the highest risk due to its high purine content. It is recommended that males restrict their alcohol consumption to less than 21 units/week and that both male and female patients have at least 3 alcohol-free days per week. Beer, stout, port and fortified wines should be avoided. Two 125-mL glasses of wine per day are considered acceptable and two pub-sized measures of spirits are considered safer than half a pint of many beers.

3. In uncomplicated gout, specific long-term treatment to reduce plasma uric acid concentration should only be given if a second attack or further attacks of gout occur within 1 year. The need for preventative therapy is not indicated in this patient; he has uncomplicated gout and his bendroflumethiazide can be switched to an alternate anti-hypertensive agent which is not linked to an increase in uric acid levels. For some patients, changes in diet and lifestyle plus the removal of medicines contributing to the attack may be sufficient to prevent further flares. Where prophylactic therapy is indicated, it should only be commenced after complete resolution of the flare.

4. Lifestyle modification can be effective in preventing further attacks. Moderate physical exercise can be beneficial; however, intense muscular exercise should be avoided as it can lead to a rise in uric acid levels. In over-weight patients, gradual weight loss should be encouraged. Rapid weight loss can precipitate ketosis and a subsequent rise in the urate pool. Mr TH should be given appropriate dietary advice. It is the regular consumption of foods containing purines rather than the absolute purine content of a particular food that is important. The UK Gout Society (http://www.ukgoutsociety.org/) provides a fact sheet with dietary recommendations and the purine content of various foods for patients. Ideally, total daily purine intake should not exceed 200 mg/day, and foods such as shellfish, offal and sardines should be avoided. Dairy products have been shown to be beneficial in lowering serum uric acid, and even the addition of yoghurt on alternate days has been shown to reduce levels. The consumption of soft drinks sweetened with fructose or sucrose (not diet drinks) should be limited. Cherries whether sweet, tart, juice or fruit have a urate-lowering potential.

As previously discussed, Mr TH should also moderate his alcohol consumption.

Case 54.2

Mr SB, a 45-year-old man, has recently been treated for his second acute attack of gout within 8 months of his first episode. The symptoms have now resolved and his primary care doctor is unsure if Mr SB should be commenced on prophylactic medication. Mr SB has no family history of renal disease, but his father died of a myocardial infarction aged 52. He takes no regular medication and has no other significant previous medical history.

Questions

1. Is it appropriate to initiate prophylactic treatment?
2. What prophylactic treatment would you recommend?

Answers

1. Patients who suffer one or more acute attacks of gout in a year should be commenced on prophylactic therapy. However, prophylactic therapy is recommended for some patients at the first acute attack. These include patients with uric acid stones, tophi and young patients with a family history of renal or cardiac disease. Mr SB is relatively young and there is a family history of cardiac disease. The initiation of prophylactic therapy should therefore be considered.

2. Allopurinol is the first-line choice for prophylactic treatment of hyperuricaemia. Patients with normal renal function should be commenced on 100 mg daily and the dose gradually increased by 100 mg increments at 2–3 week intervals until the serum urate level has been reduced to less than 300 μmol/L. Serum urate levels may be artificially low during an acute attack. The level should be checked following the acute episode and prophylactic therapy, if deemed appropriate, should not be commenced until

after the flare has resolved. Serum urate levels should fall within 2 days and peak at 7–10 days with the introduction of allopurinol and with dose increases.

Renal function should be checked prior to starting allopurinol to ensure that the correct dosage is prescribed based on the patient's creatinine clearance. Reduced renal function increases the half-life of allopurinol's active metabolite, oxypurinol. If the dose is not reduced according to renal function, the patient is at risk of oxypurinol accumulation and toxicity.

Mr SB does not take regular medication, but current medication should always be checked for interactions with allopurinol, for example azathioprine, mercaptopurine, carbamazepine.

As prophylactic treatment is being initiated, Mr SB is at risk of a mobilisation flare for approximately 12 months. Prophylaxis treatment for mobilisation flares should be recommended. First-line choice for the prevention of mobilisation flares is colchicine (500 μcg twice daily for 6 months). For patients who are intolerant to colchicines, NSAIDs offer a second-line choice, provided there are no contraindications to NSAID therapy. NSAIDs should be continued for a maximum of 6 weeks.

Case 54.3

Mrs DM, a 72-year-old woman, was admitted to hospital with dehydration and loss of consciousness, following a fall. On admission, she was taking bendroflumethiazide 2.5 mg each morning, candesartan 8 mg each morning, simvastatin 10 mg at night, paracetamol 1 g four times a day and the week before admission had been started on allopurinol 300 mg once a day for gout. On day 2 of her admission, she developed a rash and fever, her creatinine clearance was 23 mL/min and her ALT 156 international units/L. After investigation, she was diagnosed as having a hypersensitivity reaction to allopurinol. The allopurinol was stopped immediately.

Questions

1. What risk factors does this patient have for developing a hypersensitivity to allopurinol?
2. What prophylaxis treatment option would you recommend for following the allopurinol hypersensitivity reaction?

Answers

1. Severe toxic effects caused by allopurinol occur in less than 2% of patients taking allopurinol; however, the mortality risk is high in this group. The risk of allopurinol toxicity is increased for patients with renal impairment, old age and concomitant drugs. Mrs DM has all of these risk factors. Her renal function may have been impaired prior to admission due to her age, but this

may have been further exacerbated by a period of dehydration caused from extended stasis following a fall. Bendroflumethiazide may have contributed to her fall, dehydration and history of gout. Her blood pressure requires close monitoring to ensure she is not suffering from postural hypotension or that the combination of two anti-hypertensive drugs is not causing her blood pressure to drop too low. Ideally, bendroflumethiazide should be avoided in this patient and if needed an alternate anti-hypertensive prescribed. Mrs DM's starting dose of allopurinol is considerably higher than that which would normally be recommended, the high dose in combination with renal impairment may have caused an accumulation of the active metabolite of allopurinol, oxypurinol, which would have increased the risk of toxicity. Renal function should be checked in all patients prior to commencing allopurinol. For normal renal function, a starting dose of 100 mg once a day is recommended. For abnormal renal function, the product data sheet should be consulted for appropriate dose reduction. Hypersensitivity reactions usually occur up to 2 months following the initiation of allopurinol. Allopurinol should be stopped immediately in patients with symptoms of hypersensitivity reaction.

2. The choice of second-line prophylaxis treatment to replace allopurinol should be based on both renal function and pathophysiology of the disease.

Febuxostat is recommended in mild to moderate renal impairment, but there are no data in severe renal impairment. In patients with mild hepatic impairment, the dose of febuxostat must not exceed 80 mg once a day. Febuxostat is initiated at 80 mg daily but can be increased to 120 mg daily if the serum urate has not decreased adequately after 2–4 weeks of therapy. Febuxostat should not be used in patients with a history of cardiovascular disease.

In normal renal function, sulphinpyrazone or probenecid is indicated in urate under excretors when febuxostat is not appropriate. However, sulphinpyrazone can increase sodium and water retention and may worsen Mrs DM's heart failure. Probenecid is less effective than other uricosuric agents and is generally not used.

Benzbromarone is effective in moderate renal impairment and may be considered if febuxostat is contraindicated or ineffective. Baseline liver function tests must be performed as well as regular monitoring during the first 6 months of therapy. Benzbromarone is only available on a named patient basis, patients must have failed or been intolerant of other therapies and understand that the use of benzbromarone is associated with liver toxicity.

Allopurinol desensitisation should only be considered when all other prophylactic treatments have failed and is not appropriate for patients who have suffered a severe hypersensitivity reaction.

Glaucoma 55

L. C. Titcomb and S. D. Andrew

Key points

- Glaucoma is a large group of disorders with widely differing clinical features.
- Chronic open-angle glaucoma (COAG) is a chronic progressive disease of insidious onset.
- The aim of treatment in COAG is to reduce the intraocular pressure (IOP) to a target pressure, specific to the patient, preventing further damage to the nerve fibres and the development of further visual field defects.
- A wide range of drugs is used to treat COAG. Laser treatment or surgery may be undertaken if the target pressure is not attained with medical therapy.
- COAG is a symptomless disease until well advanced. Concordance with therapy is an important issue.
- Acute primary angle-closure glaucoma (PACG) is a medical emergency that must be treated rapidly to prevent blindness.
- The aim of medical treatment in acute PACG is to reduce the IOP in preparation for laser treatment or surgery.
- A wide range of drugs can provoke an attack of PACG in susceptible individuals.

The term 'glaucoma' does not represent a single pathological entity. It consists of a large group of disorders with widely differing clinical features. It is, therefore, difficult to attempt a single definition of the term. High intraocular pressure (IOP) was previously used as a diagnostic criterion for glaucoma, but more recently, it has been recognised purely as the most important risk factor for the disease. This is because glaucoma can occur even in patients with normal IOP (normal-pressure chronic open-angle glaucoma, COAG). The 'normal' IOP (10–21 mmHg) is a statistical description of the range of IOP in the population and is not applicable to an individual subject. It is thought to increase with age, at the rate of approximately 1 mmHg every decade after the age of 40 years in the Western population. There is a circadian cycle of IOP, with maximum levels often occurring between 8 and 11 a.m. and minimum levels between midnight and 2 a.m. This may affect IOP readings taken in outpatient clinics at different times of the day. The normal diurnal variation is between 3 and 5 mmHg, and this is wider in untreated glaucoma. Although a raised IOP is not the only cause of glaucoma, it is the only parameter that can currently be changed by pharmacological intervention and therefore plays an important part in the evaluation of disease progression.

Current thinking is that once the rate of disease progression has been established, a 'target IOP' can be set. The target IOP is defined as a dynamic, clinical judgement about what level of IOP is considered by the healthcare professional treating the patient to be sufficiently low to minimise or arrest disease progression or onset and avoid disability from sight loss within a person's expected lifetime.

It is, however, extremely difficult to accurately assess in advance the IOP level at which further damage will occur for any one patient. As the correct target IOP is only discovered with hindsight, one limitation is that the chosen target IOP may not be low enough and a patient must get worse before it is realised that the target IOP was inadequate. There is no single safe IOP level for all patients, but in general, the aim is to achieve at least a 25–30% reduction from the initial IOP at which damage occurred. In advanced disease, the aim is to achieve an IOP level below 18 mmHg at all times. This can be used as a good method to set an initial target IOP. However, it is essential that the patient receives regular periodic re-evaluation so that the target IOP can be adjusted according to disease progression and treatment adjusted accordingly.

Epidemiology

The World Health Organisation has estimated that globally there are 12.5 million people blind from glaucoma with the total number affected by this condition at around 66 million. Approximately 13% of UK blindness registrations are ascribed to glaucoma, and around 2% of people older than 40 years have COAG, a figure which rises to almost 10% in people older than 75 years. With changes in population demographics, the number of individuals affected by glaucoma is expected to rise. Based on these estimates, there are around 500,000 people affected by COAG in England and Wales, who receive over a million glaucoma-related outpatient visits in the hospital eye service annually. Once diagnosed, affected individuals require lifelong monitoring for disease control and to detect possible progression of visual damage. Once lost, vision cannot be restored. Disease control with prevention or at least minimisation of ongoing damage is therefore paramount to maintain sight.

The diseases which make up the group known as glaucoma are usually classified according to the manner in which aqueous humour outflow is impaired.

Chronic open-angle glaucoma

COAG, also referred to as chronic simple glaucoma, is associated with a relative obstruction to aqueous outflow through the trabecular meshwork and is a chronic progressive disease of insidious onset, usually affecting both eyes. It is frequently an inherited condition, with approximately 10% of first-degree relatives of COAG sufferers eventually developing the disease. Two conditions similar to COAG are normal-tension glaucoma, where the IOP is not raised on initial screening although signs of damage are present, and ocular hypertension (OHT), elevated IOP in the absence of visual field loss or glaucomatous optic nerve damage. It is estimated that 3–5% of those over 40 years have OHT, around one million people in England. OHT represents a major risk for future development of COAG with visual damage. Lowering IOP has been shown to protect against conversion to COAG.

Primary angle-closure glaucoma

Primary angle-closure glaucoma (PACG), or closed-angle glaucoma, is a condition in which closure of the angle by the peripheral iris results in a reduction in aqueous outflow. It occurs in predisposed eyes and is frequently unilateral. There are ethnic variations as the disease affects approximately 1 in 1000 Caucasian adults over the age of 40 years, about 1 in 100 Asians (especially mongoloids) and Hispanics, and 2–4 per 100 Inuits (Eskimos). It occurs in four times as many females as males.

Secondary glaucomas

Secondary glaucomas can arise for a number of reasons, including inflammation, intraocular tumour, raised episcleral venous pressure, or congenitally due to developmental abnormalities.

Aetiology

The factors that determine the level of IOP are the rate of aqueous humour production and the resistance encountered in the outflow channels. A fine balance between these is necessary to keep the pressure within the eye in the range of 16–21 mmHg.

Production of aqueous humour occurs in the ciliary epithelium by two mechanisms: secretion due to an active metabolic process, independent of the level of IOP, and ultrafiltration influenced by the level of blood pressure in the ciliary capillaries and the level of IOP.

Outflow of aqueous humour occurs by two routes. Approximately 80% of total outflow is through the trabecular meshwork into the canal of Schlemm and into the venous circulation via the aqueous veins. The uveoscleral pathway accounts for the remaining 20% through the ciliary body into the suprachoroidal space, to be drained into the ciliary body, choroid and sclera via the venous circulation.

Pathophysiology

The primary site of damage is thought to be the optic nerve head, rather than any other point along the nerve axon. This most easily explains the progressive loss of visual field. Studies of axoplasmic flow show a vulnerability of the nerves to elevated IOP as they pass through the optic disc.

In COAG, increased resistance within the drainage channels causes the rise in IOP. It is thought that the main route of resistance to aqueous outflow lies in the dense juxtacanalicular trabecular meshwork, or the endothelium lining the inner wall of Schlemm's canal.

In PACG, the rise in IOP is caused by a decreased outflow of aqueous humour, due to closure of the chamber angle by the peripheral iris. It occurs in predisposed eyes, and the predisposing factors can be anatomical or physiological. The anatomical characteristics are lens size, corneal diameter and axial length of the globe. The lens continues to grow throughout life. This brings the anterior surface closer to the cornea. Slackening of the suspensory ligaments increases this movement. Both factors occur very gradually and lead to a progressive shallowing of the anterior chamber. The depth of the anterior chamber and width of the chamber angle are related to corneal diameter, and those eyes predisposed to PACG are observed to have a corneal diameter less than that seen in normal eyes. A short eye, which is frequently also hypermetropic, has a small corneal diameter and a thick and relatively anteriorly located lens.

The physiological precipitating factors of PACG in predisposed eyes are not fully understood. Two theories currently exist. The dilator muscle theory suggests that contraction of the dilator muscle causes a posterior movement, which increases the apposition between the iris and anteriorly located lens and the degree of physiological pupillary block. The simultaneous dilation of the pupil renders the peripheral iris more flaccid, and causes the pressure in the posterior chamber to increase and the iris to bow anteriorly. Eventually, the peripheral iris obstructs the angle and the IOP rises (Fig. 55.1).

The sphincter muscle theory postulates that the sphincter of the pupil precipitates angle closure. The pupillary blocking force of the sphincter is greatest when the diameter of the pupil is about 4 mm.

Clinical manifestations

COAG is typically characterised by the following: an IOP greater than 21 mmHg, an open-angle, glaucomatous cupping and visual field loss. COAG, because of its insidious onset, is usually asymptomatic until it has caused a significant loss of visual field. In some eyes, subtle signs of glaucomatous retinal nerve damage can be detected prior to development of pathological cupping and detectable field loss. The earliest clinically significant field defect is a scotoma, which is an area of depressed vision within the visual field. Patients with COAG frequently show a wider swing in IOP than normal; therefore, a single pressure reading of 21 mmHg or less does not exclude
Fig. 55.1   Changes to the eye seen during closed-angle glaucoma.

the diagnosis. It may be necessary to measure IOP at different times of the day, or at periodic intervals.

Acute PACG is due to a sudden closure of the angle and a severe elevation in IOP. The symptoms include rapidly progressive visual impairment, periocular pain and congestion of the eye. In severe cases, nausea and vomiting may occur. The signs include injection of the limbal and conjunctival vessels, giving a 'ciliary flush'. The IOP usually lies between 50 and 80 mmHg and causes corneal oedema with epithelial vesicles. The anterior chamber is shallow and iridocorneal contact can be observed. The pupil is vertically oval and fixed in a semi-dilated position. It is unreactive to light and accommodation. The fellow eye usually has a shallow anterior chamber and a narrow angle. The optic nerve head is oedematous and hyperaemic.

Investigations

IOP may be measured by tonometry, such as indentation tonometry in which a plunger is applied to the cornea and the amount of indentation on the eye reflects the pressure within it. Tonography is a technique used to measure the outflow of aqueous humour from the eye, resulting from indentation of the eye, using a tonometer. Gonioscopy is used to estimate the width of the chamber angle, with the aid of a slit lamp. Perimetry is important for both the diagnosis and management of glaucoma by detecting early scotomata and larger changes in visual field. Other investigations which should be routinely offered to patients include a central corneal thickness measurement (CCT), as this has an effect on the measured IOP and may affect the efficacy of certain drug treatments (Johnson et al., 2008), and fundus examination for optic nerve assessment with dilatation using stereoscopic slit-lamp biomicroscopy. There are also guidelines for the monitoring of these patients and at what intervals their IOP, optic nerve head and visual fields should be checked (National Institute for Health and Clinical Excellence, 2009).

In patients with COAG, cupping of the optic disc becomes progressively apparent and is used in both diagnosis and assessment of the efficacy of treatment. The increased IOP appears to push the optic disc back into an excavation. This is known as glaucomatous cupping.

The colour of the optic disc will be observed to change from a creamy pink colour, due to the rich capillary network seen in the healthy eye, to increased pallor with advancing disease as the optic nerve tissue progressively atrophies.

Treatment

Chronic open-angle glaucomas

The aim of treatment in COAG is to reduce the raised IOP to the target value, preventing further damage to the nerve fibres and the development of further visual field defects to maintain the patient's visual function and quality of life. The key to effective treatment is careful and regular follow-up, including measurement of visual acuity, tonometry, gonioscopy, evaluation of the optic disc, CCT and perimetry, which is of primary importance.

The actual safe level of IOP is unknown, the importance of disc and field assessment being underlined by evidence that IOP does not rise above the 'normal' range in up to 50% of glaucomas (normal-pressure glaucomas). However, in many cases, maximal retardation of the disease process is achieved if the IOP is maintained in the lower teens. The effect on the visual field and the appearance of the optic disc are the only indications that IOP is being controlled at a safe level. A raised IOP without field or disc changes may not require treatment but will need regular review.

The initial treatment of COAG is usually medical. Topical administration is the preferred type of therapy, and there is a wide range of preparations available (Table 55.1). The chosen drug should be administered at its lowest concentration and as infrequently as possible to obtain the desired effect over the whole 24-h period as a high level of diurnal variation in IOP has been shown to be a more important factor in visual field development than the average IOP. A drug with few potential side effects should be chosen, with oral therapy retained as the final option. The prostaglandin analogues latanoprost and travoprost and the prostamide bimatoprost are indicated for first-line use, as are the β-blockers as these produce the greatest fall in IOP (Table 55.2). Carbonic anhydrase inhibitors and sympathomimetics, which result in a smaller fall in IOP, are reserved for patients unresponsive to first-line drugs, in patients in whom the first-line agents are contraindicated or as adjunctive therapy.

In most cases, the initial topical treatment is with a prostaglandin analogue or prostamide. If this is ineffective, another prostaglandin or prostamide may be substituted or a β-blocker used instead. Patients not reaching their target pressure on one first-line agent may be prescribed another concomitantly. Alternatively, a carbonic anhydrase inhibitor or a sympathomimetic may be added to one of the first-line drugs. Guidance on the treatment of people with OHT or suspected COAG has been published (National Institute for Health and Clinical Excellence, 2009). The treatment options (Table 55.3) take into account central corneal thickness and age, although age thresholds are only appropriate where vision is normal (OHT with or without suspected COAG) and the treatment is purely preventative. Pilocarpine is no longer recommended by NICE but is recommended as a second-line agent in European guidelines (European Glaucoma Society, 2008). Oral therapy with carbonic anhydrase inhibitors is usually reserved for use as the final stage of treatment in those complex glaucomas awaiting surgery (Fig. 55.2).

It has been proposed that the improved control of IOP with newer therapies has led to a reduction in surgery for glaucoma (Kenigsberg, 2007). However, some patients still require surgical intervention to reach their target pressure.

The most frequently performed surgical procedures create a fistula to act as a new route for aqueous outflow and the

Table 55.1 Drugs used in the treatment of chronic open-angle glaucoma

Therapeutic category	Primary mechanism
Topical prostaglandins	Increase aqueous outflow
Topical prostamides	Increase aqueous outflow
Topical β-blocking agents	Decrease aqueous formation
Topical miotics	Increase aqueous outflow
Topical adrenergic agonists	Increase aqueous outflow and decrease aqueous formation
Topical carbonic anhydrase inhibitors	Decrease aqueous formation
Oral carbonic anhydrase inhibitors	Decrease aqueous formation

Table 55.2 Comparison of reduction in intraocular pressure (IOP) with a range of ocular hypotensive drugs (adapted from van der Valk et al., 2009)

Drug	Relative IOP change from baseline at trough (%) (95% CI)	Relative IOP change from baseline at peak (%) (95% CI)
Bimatoprost	−28 (−29 to −27)	−33 (−35 to −31)
Travoprost	−29 (−32 to −25)	−31 (−32 to −29)
Latanoprost	−28 (−30 to −26)	−31 (−33 to −29)
Timolol	−26 (−28 to −25)	−27 (−29 to −25)
Betaxolol	−20 (−23 to −17)	−23 (−25 to −22)
Dorzolamide	−17 (−19 to −15)	−22 (−24 to −20)
Brinzolamide	−17 (−19 to −15)	−17 (−19 to −15)
Brimonidine	−18 (−21 to −14)	−25 (−28 to −22)
Placebo	−5 (−9 to −1)	−5 (−10 to 0)

Table 55.3 Treatment of people with ocular hypertension or suspected COAG (National Institute for Health and Clinical Excellence, 2009)

Central corneal thickness	More than 590 μm		555–590 μm		Less than 555 μm		
Untreated IOP (mmHg)	>21 to 25	>25 to 32	>21 to 25	>25 to 32	>21 to 25	>25 to 32	>32
Age (years)	Any	Any	Any	Treat until 60	Treat until 65	Treat until 80	Any
Treatment	No treatment	No treatment	No treatment	β-blocker	Prostaglandin analogue	Prostaglandin analogue	Prostaglandin analogue

most frequently performed surgery of this type, trabeculectomy, appears more effective in controlling IOP than laser trabeculoplasty, in which a series of laser burns is applied to the trabecular meshwork to improve the outflow of aqueous humour. (Rolim de Moura et al., 2007).

Primary angle-closure glaucoma

The medical management of acute PACG is essentially to prepare the eye for surgical treatment. The aim of treatment is to decrease the IOP and associated inflammation. Analgesics and antiemetics are sometimes needed, dependent on symptom severity, to make the patient comfortable. It is usual to treat the unaffected eye prophylactically with miotics (Fig. 55.3).

Paralysis of the iris sphincter usually occurs at an IOP of more than 60 mmHg, due to ischaemia. Therefore, intensive miotic therapy, previously the treatment of choice in many cases of PACG, is usually ineffective and the IOP needs to be lowered by drugs that reduce aqueous humour production rather than by trying to pull the peripheral iris away from the angle with miotics. An intravenous loading dose of mannitol is usually the first drug of choice with intravenous acetazolamide a possible alternative. This is followed by oral treatment, sometimes in combination with corneal indentation, to physically force aqueous humour into the peripheral anterior chamber and artificially open the angle. This should allow the IOP to drop sufficiently to relieve iris ischaemia and allow the sphincter to respond to pilocarpine therapy.

Once the IOP has been reduced medically, the condition is treated surgically, by either surgical peripheral iridectomy or laser iridotomy, to remove an area of the peripheral iris to allow flow of aqueous humour through an alternative pathway (see Fig. 55.1). Filtration surgery is indicated if a large proportion of the angle has been permanently closed by adhesions between the iris and the cornea.

Drug treatment

Ocular prostanoids: prostaglandin analogues and prostamides

The National Institute for Health and Clinical Excellence (2009) guideline does not differentiate between the prostaglandin analogues and the prostamide bimatoprost, but recommends one of this class for the treatment of COAG, certain patients with OHT and certain COAG suspects (see Table 55.4)

The prostaglandin analogues, latanoprost, travoprost and tafluprost, are ester compounds thought to achieve a fall in IOP primarily by increasing the uveoscleral outflow with no significant effect on other parameters of aqueous humour dynamics, while the prostamide bimatoprost is thought to increase outflow through both trabecular and uveoscleral outflow pathways. However, there is still debate about the precise mechanisms of action of this group (Lim et al., 2008; Toris et al., 2008).

All the drugs in this class are licensed for the reduction of elevated IOP in open-angle glaucoma and OHT, and are administered once daily in the evening.

In a meta-analysis, these drugs have been shown to have a greater effect on both peak and trough readings of IOP than timolol, betaxolol, dorzolamide, brinzolamide or brimonidine, producing falls in IOP of 28–29% at trough and 31–33% at peak as shown in Table 55.2 (van der Valk et al., 2009).

Randomised head-to-head evaluations of prostaglandin therapy demonstrate similar efficacy, but differing hyperemia effects with bimatoprost and travoprost causing more hyperaemia than latanoprost (Eyawo et al., 2009; Honrubia et al., 2009). However, these studies were conducted before the introduction of the new formulations of bimatoprost 0.01% and the benzalkonium chloride–free travoprost.

The prostanoids have some interesting local side effects (Table 55.5). Pigmentation of the iris occurs in patients with mixed colour (green-brown or blue-brown) irides after 3–6 months of use and is a result of increased deposition of melanin in the melanocytes. An increase in the length and thickness of the eyelashes and pigmentation of the palpebral skin are also known side effects. Use of these drugs may lead to disruption of the blood–aqueous barrier in patients with aphakia and pseudophakia (no or false lens, respectively) and increase the risk of developing cystoid macular oedema; they should be used with caution in such patients. Reactivation of herpes simplex infection has been reported with bimatoprost, travoprost and latanoprost.

Latanoprost

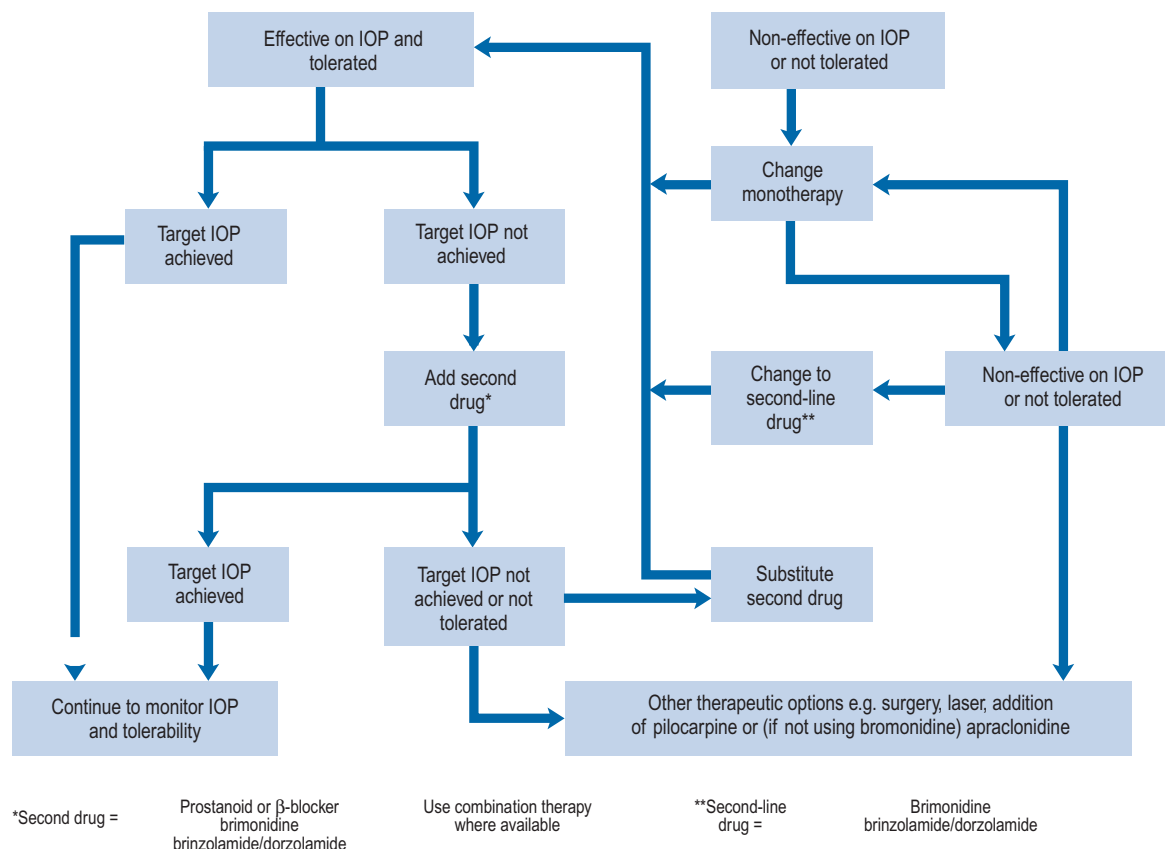
Latanoprost, which is converted to its active free acid on entering the eye, was the first of the prostanoids to be launched and is the market leader. Like timolol amongst the


Fig. 55.2 Topical therapy for chronic open-angle glaucoma (COAG) based on recommendations of European Glaucoma Society (2008).

β-blockers, latanoprost is the drug in this class against which new drugs or combinations are assessed. It must be administered in the evening for maximum effect (Stewart et al., 2008). Latanoprost is generally very well tolerated. Serious adverse drug reactions were reported in only 17/3936 (0.43%) patients using latanoprost over a 5-year period (Goldberg et al., 2008), and patient persistence with latanoprost therapy is better than that with all other frequently used monotherapies (Rahman et al., 2009). Latanoprost is not heat stable and requires refrigeration; however, it is stable enough to be stored at room temperature for the 4-week in-use period applied in the UK. The concentration of the preservative benzalkonium chloride in latanoprost eye drops and bimatoprost 0.01% may prevent their use in certain patients. The benzalkonium chloride concentration in these formulations is 0.02%, which is four times that in bimatoprost 0.03% eye drops. The current formulation of travoprost, launched in January 2011, contains polyquaternium-1 rather than benzalkonium chloride.

Travoprost

Like latanoprost, travoprost is an ester pro-drug, converted to its active acid form by corneal hydrolytic enzymes as it is absorbed through the eye. Travoprost acid is a potent full agonist for prostaglandin $F_{2\alpha}$-receptors, producing 100% efficacy, whereas the comparable efficacy for latanoprost is 92%. It is highly selective, with no significant activity at non-prostanoid receptors and low affinity for the other prostanoid receptors responsible for pain, etc. It appears to be generally well tolerated by patients and is relatively free of systemic side effects, although abdominal cramp has been reported.

Patients treated with travoprost show good diurnal fluctuation control, and an ocular hypotensive effect was shown to last for over 3 days. Patients previously treated with β-blockers, α_2-agonists, carbonic anhydrase inhibitors, latanoprost and the dorzolamide-timolol fixed combination respond to travoprost. Administration time is not as important with travoprost as with latanoprost as no statistical difference was noted in the percentage fall in IOP whether travoprost was administered in the morning or in the evening (Stewart et al., 2008). Travoprost is a stable compound throughout a range of temperatures, and the commercially available product does not require refrigeration.

Tafluprost

Tafluprost is the first of the prostanoids available in a preservative-free form. In terms of efficacy and safety, it has been shown to be equivalent to a preserved preparation of tafluprost (Hamacher et al., 2008) and useful in patients allergic to, or intolerant of, benzalkonium chloride.

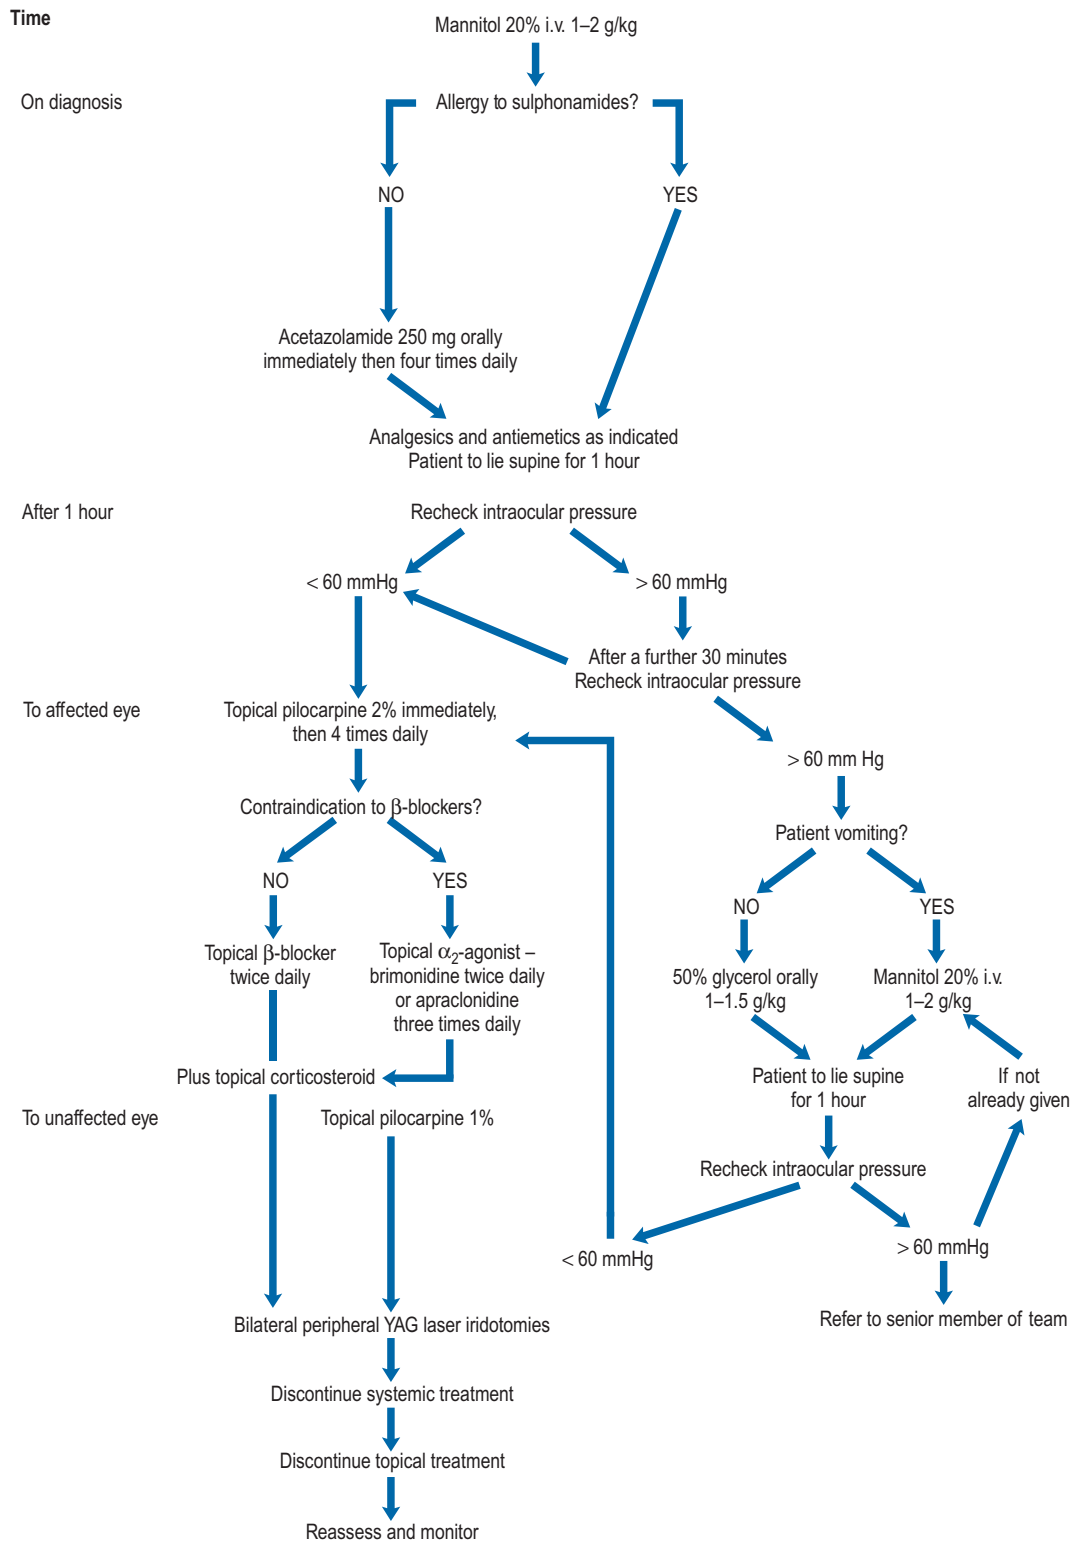
Tafluprost as adjunctive therapy to timolol results in consistently greater reductions in IOP compared with vehicle in patients with glaucoma or OHT that is inadequately controlled with timolol monotherapy (Egorov and Ropo, 2009).


Fig. 55.3 Algorithm for the treatment of primary angle-closure glaucoma (PACG). YAG, yttrium aluminium garnet.

Bimatoprost

Bimatoprost is a fatty acid amide, pharmacologically similar to prostaglandin $F_{2\alpha}$1-ethanolamide (prostamide $F_{2\alpha}$).

Several mechanisms of action have been proposed including activity of bimatoprost or its free acid, 17-phenyl PGF_{2a}, at the prostaglandin $F_{2\alpha}$ receptor, prostamide mimetic activity, and inhibition of PGF synthase which leads to an increase in endogenous $PGF_{2\alpha}$. Although the free acid has been found in human eyes, its presence alone does not explain the 24-h efficacy of bimatoprost or its hypotensive superiority over

Table 55.4 Ocular prostanoids

	Bimatoprost		Latanoprost	Tafluprost	Travoprost
Trade name	Lumigan		Xalatan	Saflutan	Travatan

Storage requirements	≤25 °C	≤25 °C	2–8 °C until opened then ≤25 °C for period of use of 4 weeks	2–8 °C	≤25 °C

latanoprost. The pharmacology of bimatoprost itself is not explained wholly by its interaction with known prostaglandin $F_{2\alpha}$ receptors. It is administered once daily in the evening; more frequent administration may lessen the IOP-lowering effect.

Bimatoprost lowers the IOP to a greater extent than any other topical ocular hypotensive (van der Valk et al., 2009), an effect (see Table 55.2) which is sustained for at least 4 years (Williams et al., 2008). It is superior to latanoprost in terms of response rate, fall in IOP and the percentage of patients reaching their target IOP. In some studies, bimatoprost is reported to be as effective as the fixed combination of latanoprost and timolol. Many patients are non-responsive to latanoprost as they do not achieve a fall in IOP greater than 10%, although a large proportion of patients show a 20% or more fall in IOP with bimatoprost. Patients not reaching their target on latanoprost achieved lower IOPs when switched to bimatoprost (Sonty et al., 2008). Such patients achieve better diurnal control with bimatoprost than with a fixed combination of dorzolamide and timolol (Sharpe et al., 2008).

Generally, bimatoprost causes similar ocular side effects to latanoprost and travoprost, but while all the ocular prostanoids cause subclinical ocular inflammation, bimatoprost and travoprost cause this to a lesser degree than latanoprost. However, bimatoprost causes hyperaemia more frequently than latanoprost, although this is described as mild. This may contribute to the higher discontinuation rate seen with bimatoprost therapy (Rahman et al., 2009). To address this issue, the manufacturers of bimatoprost have introduced a lower strength (0.01%) version containing a higher concentration of benzalkonium chloride to aid penetration of the drug. In a 12-month study, the bimatoprost 0.01% was equivalent to bimatoprost 0.03% in lowering IOP and demonstrated improved tolerability, including less frequent and severe conjunctival hyperemia (Katz et al., 2010).

β-Adrenoceptor antagonists

The exact mechanism of action of β-adrenoceptor antagonists (β-blockers) in lowering IOP has not been fully established but is thought to result from the blockade of ciliary β-receptors, preventing the cyclic AMP-induced rise in aqueous secretion, as they have been shown to reduce aqueous humour formation rather than increase outflow. Although there are both β_1- and β_2-receptors in the eye, the latter predominate and even cardioselective β-blockers are thought to work by blockade of β_2-receptors. Genetic factors have been shown to be important in patients' response to this group of drugs (Nieminen et al., 2007, Sidjanin et al., 2008).

Four drugs are available in the UK for topical administration: betaxolol, carteolol, levobunolol and timolol (Table 55.6). β-Blockers have a number of important properties in addition to β-adrenoceptor blockade. These include intrinsic sympathomimetic activity (ISA), cardioselectivity and membrane-stabilising activity, which are all of importance when considering the side effects seen with these agents (Table 55.7). The property of membrane stabilisation is relevant to the incidence of ocular side effects. The absence of anaesthetic properties reduces the number and severity of foreign body and dryness sensations, anaesthesia of the cornea and dry eye syndrome.

Ocular side effects of topically administered β-blockers are shown in Table 55.8.

It has been suggested that those β-blockers that show ISA are less likely to produce bronchospasm and peripheral vascular side effects. Carteolol is the only commercially available drug that shows ISA. The selectivity of cardioselective β-blockers diminishes with increasing dosage, even within the therapeutic range. Betaxolol is the only commercially available topical β-blocker that demonstrates cardioselectivity.

A degree of bradycardia is commonly seen with all β-blockers, and β-blocker eye drops have been identified as the cause of episodes of orthostatic hypotension and syncope in elderly patients (Müller et al., 2006). The use of topical β-blockers in patients on verapamil, diltiazem, disopyramide, quinidine or amiodarone could potentiate bradycardia and should be avoided. Topical β-blockers are generally avoided in patients with normal-tension glaucoma because the nocturnal fall in arterial pressure causes a potentially dangerous reduction in ocular perfusion.

The precipitation of bronchospasm in susceptible patients can occur with the administration of as little as one drop of timolol. Those β-blockers that show cardioselectivity or

ISA, intrinsic sympathomimetic activity.
[a]Propranolol = 1

ISA are less likely to cause bronchoconstriction, and it has been demonstrated that respiratory function improved in patients whose treatment was changed from timolol to betaxolol or an adrenergic agonist, these same patients having previously been asymptomatic.

All topical β-blockers have been reported to cause bronchospasm; hence, 'at-risk' patients with a tendency to airway disease who require therapy for glaucoma should be treated with

Table 55.8 Ocular and systemic side effects of topical β-blockers

Ocular	Systemic

extreme caution. Prescribers are advised that β-blockers, even those with apparent cardioselectivity, should not be used in patients with asthma or a history of obstructive airways disease unless no alternative treatment is available. In such cases, the risk of inducing bronchospasm should be appreciated and appropriate precautions taken. Lacrimal occlusion with intracanalicular plugs has been shown to almost completely prevent the bronchoconstriction caused by topical timolol in asthmatics by inhibiting or decreasing systemic absorption of the medication.

Ocular β-blockers are generally not contraindicated in diabetes, although a cardioselective agent may be preferable. However, they are best avoided in patients who suffer frequent hypoglycaemic attacks as they may mask the signs and symptoms of acute hypoglycaemia.

Systemic side effects of topically administered β-blockers are shown in Table 55.8.

The long-term benefits of β-blockers on visual function preservation have been shown to be less than would be expected. This may be due to adverse effects on the ocular microcirculation whereby the β-blockers interfere with endogenous vasodilation and cause optic nerve head arteriolar

vasoconstriction. The various β-blockers demonstrate marked differences in their vasoconstrictive effect, with betaxolol possibly demonstrating the least vasoconstriction.

Betaxolol

In theory, because of its cardioselectivity, betaxolol should have fewer adverse effects on the pulmonary system. It should also have fewer adverse cardiovascular effects because of comparatively lower systemic β-receptor occupancy after ocular administration. Maximum occupancies for β_1 and β_2 receptors after ophthalmic administration were 52% and 88% for carteolol, 62% and 82% for timolol, and 44% and 3% for betaxolol, respectively. The lack of systemic effects of betaxolol compared with timolol has been highlighted by Easton who reported the case of an 85-year-old lady who developed atrial fibrillation on having her β-blocker eye drops changed from timolol to betaxolol (Easton, 2007)

However, betaxolol is less effective than other β-blockers as an ocular hypotensive agent (van der Valk, 2009). On initiation of treatment, the fall in IOP is slower than with other topical β-blockers. The 0.25% suspension is as effective as the 0.5% solution and is better tolerated by the patient (Yalvac et al., 2007). Experimental studies showed the drug reaches the retina after topical administration and displays a voltage-dependent L-type calcium channel-blocking activity, which probably leads to improved retinal perfusion. This effect may explain the significant improvement in visual field performance seen with betaxolol in a comparison study with timolol in open-angle glaucoma. The significant improvement with betaxolol occurred despite the more effective reductions in IOP with timolol.

Carteolol

It has been suggested that because of the ISA of carteolol, attributable to its metabolite 8-hydroxycarteolol found in the plasma, smaller changes are seen in pulmonary and cardiovascular parameters than are seen with the non-cardioselective β-blockers without ISA. Carteolol appears to be neutral in its effect on serum lipid levels, whereas timolol adversely affects high-density lipoprotein cholesterol (HDL-C) and the total cholesterol/HDL-C ratio. Carteolol is generally well tolerated and has been shown to be as effective as timolol at lowering IOP in the majority of patients. It has a greater vasodilator effect on the retinal and choroidal vasculature than timolol and levobunolol but less than that of betaxolol. It is the least lipophilic of the topical β-blockers and consequently is likely to show a lower incidence of central nervous system side effects.

Levobunolol

Levobunolol is the potent L-isomer of bunolol. It is metabolised to dihydrolevobunolol in the eye, prolonging the drug's half-life and making it one of only two topical β-blockers licensed for once-daily use. It is as effective with once-daily dosing as the usual twice-daily regimen. It is not cardioselective,

showing greater affinity for the β$_2$-receptor, and does not possess ISA. It is reported to be as effective as timolol 0.5% and metipranolol 0.6% (now discontinued) in lowering IOP and more effective than betaxolol 0.5%. The incidence of allergic contact dermatitis is greater with levobunolol than timolol (Jappe et al., 2006), and a greater percentage of patients on levobunolol than timolol or betaxolol discontinued the drug due to adverse effects (Rahman et al., 2009). Its effect on tear volume and corneal epithelial barrier function is similar to that produced by timolol, and it has less effect on non-invasive break-up time of the precorneal tear film. This may be attributable to its formulation which includes polyvinyl alcohol. Levobunolol appears to have no effect on the retinal and choroidal vasculature.

Timolol

This non-cardioselective β-blocker without ISA was the first to be introduced, and as such is the agent against which all newer β-blockers were compared. It is effective in the long-term treatment of glaucoma, often in conjunction with other antiglaucoma therapy in terms of IOP lowering. Many patients can be placed on once-a-day therapy provided the IOP is maintained at satisfactory levels. However, the presentation of timolol in a prolonged-release formulation (a polysaccharide-based, gel-forming solution) leads to a prolonged corneal contact time and increased penetration of timolol into the eye. This is the preferred form for once-daily administration. Both timolol eye gels, 0.1% and 0.5%, have been shown to be as effective as the 0.5% solution administered twice daily. The 0.1% gel has the advantage of a much lower drug load, giving rise to plasma levels of timolol 10 times lower than achieved after twice-daily dosage of timolol 0.5% eye drops. The concentration of timolol achieved in the aqueous humour following administration of the 0.1% gel formulation, despite being approximately 40% of that following administration of the 0.5% solution is sufficient to occupy 100% of β$_1$- and β$_2$-receptors (Volotinen et al., 2009). Timolol is available in combination products with the carbonic anhydrase inhibitors brinzolamide and dorzolamide, the prostaglandin analogues latanoprost and travaprost, the prostamide bimatoprost and the sympathomimetic brimonidine (see Table 55.6).

Sympathomimetic agents

The original sympathomimetic drug used in the treatment of OHT and open-angle glaucoma, adrenaline (epinephrine) and its lipophilic pro-drug dipivefrine have been discontinued. Adrenaline (epinephrine) is an α- and β-adrenoreceptor agonist. It decreases IOP by reducing aqueous inflow via an α-mediated vasoconstriction in the ciliary body and increased outflow due to a dilation of the aqueous and episcleral veins. Adrenaline (epinephrine) is a mydriatic and therefore its use is contraindicated in PACG and in patients who show a shallow anterior chamber, because of the risk of precipitating angle closure. More selective sympathomimetics apraclonidine and brimonidine are in use today.

Apraclonidine

Apraclonidine (a derivative of clonidine) was the first of the selective adrenergic agonists to be introduced. This drug, which acts predominantly on α$_2$ but also on α$_1$-receptors, reduces the rate at which aqueous humour is produced due to ciliary vasoconstriction. Eye drops containing apraclonidine 1% are used to control or prevent postsurgical elevation of IOP following anterior segment laser surgery.

Eye drops containing a 0.5% solution are licensed for the short-term adjunctive treatment of patients on maximally tolerated medical therapy who require additional IOP reduction to delay laser treatment or glaucoma surgery, but the benefit for most patients is less than 1 month. Apraclonidine 0.5% is as effective in lowering IOP as brimonidine 0.2%, but has less effect on blood pressure and heart rate. Although an off-licence use, apraclonidine is sometimes used in children in whom brimonidine is strictly contraindicated (Wright and Freedman, 2009).

Ocular and systemic side effects of α$_2$-agonists are shown in Table 55.9.

Brimonidine

More α$_2$-selectivity is seen with brimonidine, which results in miosis rather than mydriasis. Vasoconstriction of microvessels is also not seen. It is thought to increase uveoscleral outflow as well as reducing aqueous production. Brimonidine administered twice daily is almost as effective as timolol twice a day at peak. However, bromonidine is significantly less effective at trough, and some consider it to be more efficacious when administered three times a day, the frequency used in the USA. Brimonidine may be used as monotherapy to lower IOP in patients with open-angle glaucoma or OHT who are intolerant of β-blockers or in whom β-blockers are contraindicated, as there is no effect on pulmonary function

Table 55.9 Ocular and systemic side effects of topical α$_2$-agonists

Ocular	Systemic

Miosis (reported with brimonidine)	
Uveitis	

and only minimal cardiovascular effect. It may also be used as an adjunctive therapy in those patients whose IOP is not adequately controlled with a single agent as its IOP-lowering activity has been shown to be additive to that of β-blockers and prostaglandin analogues.

A database containing details of drug use in 956 glaucoma patients over 18 years shows that brimonidine had the highest proportion of discontinuations due to adverse effects (Rahman et al., 2009). It has high allergenicity and may increase the likelihood of allergy to preparations subsequently used.

A formulation of brimonidine, brimonidine-Purite 0.15%, given twice daily, has been shown to be as effective as brimonidine 0.2% twice a day. It has a more favourable safety and tolerability profile, a reduced incidence of allergic conjunctivitis and better patient satisfaction and comfort rating. In a 4-month study, co-administration of latanoprost and brimonidine 0.15% results in a greater fall in IOP than co-administration of latanoprost and brinzolamide or dorzolamide (Bournias and Lai, 2009). This product is not available in the UK.

Brimonidine is contraindicated in patients receiving monoamine oxidase inhibitors or antidepressants which affect noradrenergic transmission, and there is the possibility of brimonidine potentiating or causing an additive effect with CNS depressants. Its use is contraindicated in children in whom it causes drowsiness, ataxia, pallor, irritability, hypotension, bradycardia, miosis and respiratory depression (Lai Becker et al., 2009).

Experimental evidence in animals has demonstrated that brimonidine is a potential neuroprotective agent. However, to date, clinical trials have failed to translate into similar efficacy in humans (Saylor et al., 2009).

Commercially available preparations of sympathomimetic agents are shown in Table 55.10.

Miotics

Miotics act to increase the outflow of aqueous humour by a stimulation of ciliary muscle and an opening of channels in the trabecular meshwork. Miotics are directly acting parasympathomimetic agents that act at muscarinic receptors. The only such drug currently available commercially in the UK is pilocarpine.

Miosis is an unwanted incidental effect and can cause considerable difficulties to patients. Reduced visual acuity, especially in the presence of central lens opacities, spasm of accommodation, accompanied by severe frontal headache

(browache) and diminished night vision may cause poor adherence in many patients.

Ocular side effects of pilocarpine are shown in Box 55.1. In eyes with narrow angles, PACG may be precipitated by an aggravation of pupillary block. Systemic side effects are due to parasympathetic stimulation and include anxiety, bradycardia, diarrhoea, nausea, vomiting and sweating (Box 55.2).

The onset of action of pilocarpine is 20 min, but its short duration of action necessitates four times daily dosing. The frequency of instillation of pilocarpine eye drops is a major disadvantage, and advances have been made to reduce the inconvenience of a four-times-daily dosage regimen. A slow-release gel preparation, Pilogel (Table 55.11), has been introduced. A single daily application, administered at bedtime, allows low IOP to be maintained for 24 h, with the patient sleeping through the more troublesome ocular side effects.

Carbonic anhydrase inhibitors

There are many forms of the enzyme carbonic anhydrase, three of which (CA-I, CA-II and CA-IV) are present in ocular tissues. In the ciliary epithelium, the inhibition of CA-II slows the formation of bicarbonate ions and their secretion into the posterior chamber of the eye. This reduces the sodium transport into the posterior chamber and decreases aqueous humour production, resulting in lower IOP. Inhibition of other forms of the enzyme results in many side effects.

Acetazolamide

This is the only systemic carbonic anhydrase inhibitor available in the UK. Although it is amongst the most potent ocular hypotensive agents available, it has limited use in the long-term management of glaucoma due to poor patient adherence following occurrence of side effects. The systemic side effects are shown in Box 55.3.

Paraesthesia occurs in almost all patients on commencement of therapy but usually disappears on continued therapy. The malaise complex can include fatigue, depression, weight loss and decreased libido.

Acetazolamide is also available in injection form, and given either intramuscularly or, preferably, intravenously. It is useful in the preoperative/emergency treatment of closed-angle glaucoma.

Topical carbonic anhydrase inhibitors

The topical carbonic anhydrase inhibitors dorzolamide and brinzolamide are useful alternatives to acetazolamide in glaucoma management. They are licensed as monotherapy for patients with OHT or open-angle glaucoma resistant to β-blockers or those in whom use of β-blockers is contraindicated. Dorzolamide is also licensed for the treatment of pseudo-exfoliative glaucoma, and limited clinical data in paediatric patients are available. Both drugs are licensed as adjunctive therapy to β-blockers and brinzolamide to prostaglandin analogues, although there is evidence to suggest that dorzolamide is as efficacious as brinzolamide when added to latanoprost (Nakamura et al., 2009).

Burning/stinging	Dyspnoea
Conjunctivitis	Headache
Eyelid pain/discomfort	Nausea
Fatigue	Taste perversion
Itching	
Nasolacrimal duct obstruction	
Ocular discharge	
Tearing	

Dorzolamide is used either alone three times a day or concurrently with a β-blocker or twice daily with a prostaglandin analogue. While the licence for brinzolamide states that the drug can be used twice a day as monotherapy, some patients may respond better to a three times daily dosage. Mean changes in IOP with brinzolamide administered twice daily and three times daily and dorzolamide administered three times daily are equivalent. However, the fall in IOP achieved with these agents is less than that seen with timolol 0.5% twice daily.

Side effects similar to those of systemic sulphonamides may occur and should be watched for. The most common side effects are shown in Table 55.12. Of the two topical carbonic anhydrase inhibitors, brinzolamide appears to cause less burning and stinging on instillation due to the neutral pH (7.5) of the formulation. This is reflected in a much greater discontinuation rate with dorzolamide (31%) than with brinzolamide (14%) (Rahman et al., 2009).

Animal studies suggested that both topical carbonic anhydrase inhibitors may improve ocular blood flow independent of the IOP; however, while this has been well established for dorzolamide in humans, data for brinzolamide are limited. It remains to be established whether this effect can help reduce visual field loss in patients with glaucoma.

Combination products

A large number of patients require more than one medication to achieve target pressure. A need for the patient to use two products concomitantly may lead to confusion, with multiple instillation of one product and non-use of the other. Also, if the second drop is instilled too soon after the first, wash-out of the first product with the second drop, overflow of the precorneal tear film and a dilution of both products may occur. In addition, the patient receives a larger dose of preservative which can irritate the eye and

is a common reason for non-tolerance of the regimen. The combination of two drugs in one topical ophthalmic preparation may improve adherence and result in a reduction in preservative load. Single rather than multi-drop combinations are recommended to improve adherence and maintain patients' quality of life.

For a combination of two drugs to be an acceptable alternative to the prescriber, the fixed combination must be more effective than either of the components used alone and at least as effective as the drugs administered separately, that is not demonstrate antagonism. In addition, adverse effects of the fixed combination must not be more numerous or more frequently encountered than with the components administered separately. There are six products in which timolol is combined with a second ocular hypotensive agent. They differ slightly in their therapeutic indications.

Fixed combination of timolol and dorzolamide

A combination of timolol 0.5% and dorzolamide 2% (Cosopt®) was the first topical ocular hypotensive combination to be marketed. It is indicated in the treatment of elevated IOP in patients with open-angle glaucoma or pseudoexfoliative glaucoma when topical β-blocker monotherapy is not sufficient. The fixed combination of dorzolamide and timolol is more effective than either timolol or dorzolamide alone, and as effective as its two components administered separately. In a review of its efficacy compared with other ocular hypotensives, an 80% response rate was reported for the fixed combination of dorzolamide and timolol (Yeh et al., 2008). It has also been reported to be a useful agent when used adjunctively with latanoprost, resulting in a further fall in IOP. Although generally well tolerated, the main problem with Cosopt® is burning and stinging on instillation. Although discontinuation of the combination in trials is low, Cosopt ® has been found to be the third most frequently discontinued eye product in practice (Rahman et al., 2009).

Fixed combination of timolol and latanoprost

A combination of timolol 0.5% and latanoprost 0.005%, marketed as Xalacom®, was first launched in the UK in 2001, shortly before the launch of travoprost and bimatoprost. Xalacom® is indicated for the reduction of IOP in patients with open-angle glaucoma and OHT who are insufficiently responsive to topical beta-blockers or prostaglandin analogues. It is administered once a day and has been shown to be more effective when administered in the evening than in the morning (Takmaz et al., 2008). It is unclear whether fixed combinations of prostaglandin analogues with timolol are superior to prostaglandin analogues alone.

Fixed combination of timolol and brimonidine

A combination of timolol 0.5% with brimonidine 0.2% is marketed as Combigan® and is indicated for the reduction of IOP in patients with COAG or OHT who are insufficiently responsive to topical beta-blockers.

The fixed combination has been shown to be superior in reducing IOP than either brimonidine or timolol alone and is as safe and effective as concomitant treatment with the individual components. Use of the combination product has been shown to result in a 24% fall in IOP (Papaconstantinou et al., 2009). Use of the brimonidine/timolol combination results in a greater number of side effects than timolol alone has fewer side effects than brimonidine alone (Sherwood et al., 2006) and fewer cases of allergy than brimonidine used alone (Motolko, 2008).

Fixed combination of timolol and travoprost

A fixed combination of travoprost 0.004% and timolol 0.5% (DuoTrav®) has been shown to be more effective than either of its components and is as efficacious as the components administered concomitantly while fewer side effects are reported with the combination product (Gross et al., 2007). The fixed combination of travoprost and timolol is indicated to decrease IOP in patients with open-angle glaucoma or OHT who are insufficiently responsive to topical β-blockers or prostaglandin analogues. Although the Summary of Product Characteristics states that the dose is one drop in the affected eye(s) once daily, in the morning or evening, it has been shown that an evening dose demonstrates better 24-h pressure control (Konstas et al., 2009).

Fixed combination of timolol and bimatoprost

A fixed combination of bimatoprost 0.03% and timolol 0.5% (Ganfort®) is available for the reduction of IOP in patients with open-angle glaucoma or OHT who are insufficiently responsive to topical β-blockers or prostaglandin analogues. The fixed combination has been shown to be more effective than either of its components used alone and as effective as the components used in their usual dosing regimen, that is bimatoprost once daily in the evening and timolol twice daily, used concomitantly. Conjunctival hyperaemia has been reported more frequently by patients on bimatoprost (39%) than the bimatoprost/timolol fixed combination (23%) with the lowest incidence in those receiving timolol (7%) (Brandt et al., 2008).

Fixed combination of timolol and brinzolamide

A fixed combination of brinzolamide 1% and timolol 0.5% (Azarga®) is a recently launched combination topical ocular hypotensive presentation. The combination is indicated to reduce IOP in adult patients with open-angle glaucoma or OHT for whom monotherapy has produced insufficient IOP reduction. It has greater IOP-lowering efficacy than brinzolamide or timolol alone (Kaback et al, 2008). Brinzolamide/timolol administration leads to a 30–33% fall in IOP at trough and 34–35% at peak and is better tolerated than, and preferred to, the dorzolamide/timolol combination, probably because of the neutral pH (7.2) of the suspension (Manni et al., 2009; Mundorf et al., 2008).

Hyperosmotic agents

Hyperosmotic agents are of great value during PACG emergencies due to their speed of action and effectiveness. The most commonly used agents are oral glycerol and intravenous mannitol, although both isosorbide and urea have been used in the past. Hyperosmotic agents act by drawing water out of the eye and therefore lower IOP. The maximal effect of glycerol is seen within 1 h and lasts for about 3 h, while mannitol acts within 30 min with effects lasting for 4–6 h.

Glycerol

Glycerol is given orally, usually as a 50% solution in water, the dose being 1–1.5 g/kg body weight given as a single dose. It is not a strong diuretic but may cause headaches, nausea and vomiting. Although it is metabolised to glucose in the body, it may be given to diabetics who are well controlled. All practitioners should be aware of the difference in dose in mL required for a 50% solution of glycerol formulated as a 50% w/v solution and one formulated as a 50% v/v solution (Table 55.13).

Mannitol

Mannitol is given as a 20% solution in water for intravenous administration. The dose is 1–2 g/kg body weight up to a maximum of 500 mL given over 30–40 min at a rate not exceeding 60 drops/min. It is a strong diuretic and as large volumes are required, it may cause problems due to cardiovascular overload, pulmonary oedema and stroke. Cerebral dehydration leads to headache and the patient may experience chills and chest pain. Mannitol is now generally preferred over acetazolamide as an initial treatment for PACG.

Patient care

Chronic open-angle glaucoma

When the condition is first diagnosed, patients should be told that the disorder cannot be cured but only controlled by the regular use of the prescribed treatment. As patients may not be aware of progression of the disease, the result of non-adherence with treatment should be made clear and the importance of regular attendance at clinics stressed.

The existence of a patient self-help group, the International Glaucoma Association (http://www.glaucoma-association.com), should be brought to the patient's attention. They will be able to put the patient in contact with their nearest support group.

The patient's technique for instillation of eye drops should be checked and corrected if necessary. Emphasis should be on the dose (one drop), the position of instillation, into the temporal side of the lower conjunctival sac, and the importance of punctal occlusion to minimise systemic side effects.

The preferred times for administration of topical medication should be discussed with the patient. Prostaglandins, prostamides and the gel form of pilocarpine are best administered at bedtime; a 12-hourly regimen should be employed for twice-daily drugs; 8-hourly for drugs given three times a day; and as near a 6-hourly regimen as practical for the

Table 55.13 Doses of hyperosmotic agents used in the treatment of POAG

aqueous formulation of pilocarpine. β-Blockers given once daily should be administered in the morning. The importance of allowing a reasonable interval between drops should be emphasised. Sometimes, the order of instillation of different types of eye drop is important for pharmacological or practical reasons. For example, the instillation of pilocarpine should always precede that of a sympathomimetic to prevent pain in the eye resulting from a strong miosis following a weak mydriasis. The instillation of aqueous eye drops, which remain in the conjunctival sac for a maximum of 10 min, should precede that of viscous eye drops, for example hypromellose eye drops, or suspensions (e.g. dexamethasone 0.1% eye drops) where the contact time is prolonged.

Eye drops containing benzalkonium chloride should not be instilled if soft contact lenses are in situ. The patient should be instructed to remove the lens immediately before instillation and replace it approximately 30 min later.

As there is a hereditary component to COAG, patients should be told to advise first-degree relatives to be screened.

Such people over the age of 40 years are entitled to free eye tests by their optometrist.

Primary angle-closure glaucoma

Patients found to have shallow anterior chambers and narrow angles are normally promptly listed for peripheral iridectomies. However, if the procedure is delayed, they should be advised of the symptoms of an attack of acute PACG and details of the factors that are likely to precipitate an attack so that they can be avoided. They should be advised that there are a number of prescription and non-prescription drugs that they should not take (Lachkar and Bouassida, 2007). When visiting the doctor and purchasing medicines from a pharmacy, the patient should always remember to mention their condition, and the prescriber should ensure that the drug is appropriate for a patient prone to angle closure. Examples of drugs contraindicated in this condition are listed in Table 55.14. Note that the absence of a drug from this list does not imply safety.

Table 55.14 Drugs contraindicated in narrow-angle glaucoma		
Therapeutic class		Examples
Antimuscarinics	Topical	Atropine, cyclopentolate, homatropine, tropicamide
	Antispasmodic	Atropine, dicycloverine, hyoscine, propantheline
	Motion sickness	Hyoscine, promethazine, cyclizine
	Bronchodilator	Ipratropium, tiotropium
	Urinary retention	Darifenacin, fesoterodine, flavoxate, oxybutynin, propiverine, solifenacin, tolterodine, trospium
Drugs used in anaesthesia		Glycopyrronium, ketamine, suxamethonium
Antidepressants		Amitriptyline, amoxapine, citalopram, clomipramine, dosulepin, doxepin,duloxetine,fluvoxamine, imipramine, lofepramine, maprotiline, mirtazapine, nortriptyline, paroxetine, phernelzine, reboxetine, sertraline, trazodone, trimipramine, venlafaxine
Antipsychotics		Chlorpromazine, clozapine, flupentixol, fluphenazine, olanzapine, pericyazine, perphenazine, pipotiazine, promazine, risperidone, sulpiride, thioridazine, trifluoperazine, zuclopentixol
Antihistamines		Alimemazine, antazoline, cetirizine, chlorphenamine, clemastine, cyproheptadine, diphenhydramine, hydroxyzine, loratidine, pizotifen
Antiarrhythmics		Disopyramide
Antiepileptics		Carbamazepine, topiramate
Sympathomimetics		Adrenaline, cocaine, dipivefrine, ephedrine, isometheptene, naphazoline, phenylephrine, pseudoephedrine, salbutamol, xylometazoline
Drugs used in the treatment of ADHD		Atomoxetine, dexamfetamine, methylphenidate, ritodrine
Drugs used in the treatment of parkinsonism		Benserazide, carbidopa, entacapone, levodopa, orphenadrine, procyclidine, selegiline, trihexyphenidyl,
Non-steroidal anti-inflammatory drugs		Mefenamic acid
Sulphonamide derived drugs		Acetazolamide, co-trimoxazole, hydrochlorothiazide, sulphasalazine
Miscellaneous		Botulinum toxin, carboprost, paracalcitol, pilocarpine

Following an attack of angle closure and surgical treatment of the disorder, the patient should be told that the drugs previously contraindicated can be safely taken provided that iridectomy/iridotomy remains patent.

Patient adherence

The patient is more likely to comply with the prescribed treatment if the drug or drugs can be administered according to a simple, infrequent dosage regimen and cause no or few, local or systemic side effects.

Thus, a patient treated with a once-daily prostaglandin analogue or prostamide or once- or twice-daily β-blocker would be expected to adhere to the regimen better than someone treated with pilocarpine, with its unfortunate side effects and inconvenient four-times-a-day dosage regimen. Common side effects of topical and systemic medication should be fully discussed with the patient so that the hyperaemia encountered with the prostanoids and the paraesthesia with acetazolamide are not unexpected, leading to premature discontinuation of therapy.

As glaucoma is predominantly a disease of elderly people, physical disability may prevent successful treatment, however conscientious the patient. For example, rheumatoid arthritis may reduce the patient's ability to squeeze the bottle of eye drops, while the tremor of Parkinson's disease can make correct positioning of instillation difficult. Various aids have been introduced to help with correct positioning and squeezing of eye drops, and these should be made available to patients so disabled.

Patients with poor visual acuity can be helped by colour coding of eye drop labels and supplying bottles labelled with large print. Some manufacturers have endeavoured to enhance adherence by including dose-reminder caps and facilitating instillation by supplying aids to open or position the bottle. Other manufacturers have made their eye drop containers easier to squeeze or supply aids to squeeze the bottle. A list of such devices, some of which are available on prescription, others free of charge from manufacturers of drugs used in the treatment of glaucoma is available on the International Glaucoma Association's website (http://www.glaucoma-association.com/).

Where self-medication is impossible, a simple infrequent dosage regimen is more likely to be achieved when a relative, a neighbour or the district nursing service becomes responsible for administration of the medication. In these cases, a drug administered once daily, such as a long-acting timolol preparation or a prostaglandin analogue or bimatoprost, has an obvious advantage over one that should be administered at 12-hourly intervals. If pilocarpine is required and bedtime administration is possible, the prescribing of pilocarpine ophthalmic gel will be more practical than pilocarpine eye drops, the administration of which is totally impractical for anyone other than someone living with the patient.

Common therapeutic problems in glaucoma are listed in Table 55.15.

Table 55.15 Common therapeutic problems in glaucoma

Problem	Comments
Lack of adherence	Treatment perceived to be worse than disease Complex multiple drug regimens Frequency of dosing Inability to differentiate between different types of medication Inability to instil medication
Contraindication to therapy	Pilocarpine in uveitis β-Blockers in asthma, bradycardia, heart block, uncontrolled heart failure Prostaglandin analogues and prostamides in aphakia Wide range of topical and systemic drugs in shallow anterior chamber α_2-agonists in depression Carbonic anhydrase inhibitors in renal failure
Intolerance to drug	Miosis and ciliary spasm with pilocarpine Red eye with prostaglandin analogues, bimatoprost Bronchospasm with β-blockers Paraesthesia with acetazolamide
Use outside licensed indications	Paediatric patients Pregnant women Nursing mothers
Hypersensitivity	To active drug To preservative in multidose formulations

Case studies

Case 55.1

Mrs SJ, a 49-year-old nurse with asthma, visits her optometrist for an annual eye check because her father has glaucoma. Although the optometrist has never detected any problem before, on this occasion he decides to refer her to an ophthalmologist because her IOPs are 27 left eye and 20 mmHg right eye, even though there are no signs of glaucomatous damage.

The ophthalmologist confirms the optometrist's findings and measures this lady's central corneal thickness at 570 μm. In accordance with National Institute for Health and Clinical Excellence (2009) guidelines, she decides to initiate ocular hypotensive therapy in the left eye.

Question

What treatment should the ophthalmologist prescribe?

Answer

It is recommended that patients under 60 years of age with OHT or suspected COAG and a central corneal thickness of between

555 and 590 μm are treated with an ocular hypotensive agent (National Institute for Health and Clinical Excellence, 2009). The recommended therapy is a topical β-blocker which typically reduces IOP by approximately 25%. However, β-blockers are contraindicated in patients with asthma and the ophthalmologist needs to choose an alternative agent with equivalent or better efficacy.

If β-blockers are contraindicated, a prostaglandin analogue could be prescribed.

The ophthalmologist initiates latanoprost eye drops 0.005%, one drop in the left eye at night and arranges to see Mrs SJ again in 3 months to assess her response to therapy.

Case 55.2

Mr FT, a 67-year-old retired bank manager, has COAG in both eyes and a history of herpes simplex infection of the right eye. His IOP has been controlled on timolol eye drops 0.5% twice a day in each eye which he tolerates well. At this appointment, the optometrist working in the hospital's clinic noted an increased IOP in the right eye and deterioration in the visual field in that eye. She feels that Mr FT requires an additional ocular hypotensive agent in his right eye and asks the ophthalmologist in the clinic for an opinion.

Question

What treatments should the ophthalmologist consider for Mr FT?

Answer

Patients with COAG would normally be offered a prostaglandin analogue as first-line treatment, but in Mr. FT's case this therapy is contraindicated because of his history of herpes simplex infection. He is already on a β-blocker, the other group of drugs recommended as first-line therapy, so the ophthalmologist should consider surgical intervention or the addition of a second ocular hypotensive agent. Mr. FT is not at all keen on the idea of surgery and expresses a preference for further medical therapy. Other classes of ocular hypotensives which have an additive effect with timolol are the carbonic anhydrase inhibitors brinzolamide and dorzolamide and the sympathomimetic brimonidine. The ophthalmologist explains to the patient that he can continue to use timolol in both eyes and an additional drop in his right eye or use timolol in his left eye and a combination drop containing timolol and a second agent in his right eye. Mr FT decides on the latter option and leaves with a prescription for timolol eye drops 0.5%, twice daily for his left eye and Azarga® eye drops, twice daily for his right eye together with a date for a review appointment in 2 months.

56 Drug-induced skin disorders

S. Walsh and D. Creamer

Key points

- Drug-induced skin reactions are common, accounting for 30% of all reported adverse drug reactions.
- Diagnosis requires a comprehensive drug history and knowledge of likely causative drugs.
- Treatment involves drug withdrawal and general supportive measures.
- All skin eruptions will cause morbidity but the severe reactions, such as Stevens–Johnson syndrome/toxic epidermal necrolysis, are associated with appreciable mortality.
- Certain individuals are at higher risk of drug eruptions, for example patients with HIV infection.
- Some types of drug reaction can cause systemic as well as skin involvement, affecting the hepatic, haematological and lymphatic systems.

Adverse drug reactions (ADRs) are an inevitable consequence of modern drug therapy. They are an important cause of iatrogenic illness in terms of morbidity and mortality. ADRs can cause serious harm to the patient, as well as carrying medico-legal and economic consequences. Fortunately, only about 2% of all drug-induced skin reactions are severe and very few are fatal. However, all drug-induced skin eruptions can cause morbidity, affect the patient's confidence in the prescriber and future adherence with medication. Therefore, it is important that all drug-associated rashes are carefully evaluated and documented. It is essential that the patient is made aware of his or her sensitivity, as subsequent exposure to the drug may cause a more severe eruption. At population level, both reporting of adverse events via the MHRA 'Yellow card scheme' and post-marketing surveillance of new drugs have a role in identifying patterns of drug eruption.

It is important to remember that the potential of an individual drug to cause a skin eruption is variable. Any drug can potentially cause any reaction pattern in the skin. Some drugs such as ferrous sulphate seldom produce a rash, while others, for example, carbamazepine, penicillin antibiotics and sulphasalazine, are far more likely to precipitate a skin eruption.

Diagnosis

It is often difficult to determine the cause of a drug-induced eruption because:

- Almost any drug can affect the skin
- Unrelated drugs produce similar reactions
- The same drug may produce different reaction patterns in different patients
- Some drug reactions are difficult to distinguish from specific skin diseases such as acne, eczema and psoriasis.

In most cases, diagnosis of a drug-induced skin eruption is based on the history and the temporal association of the onset of the rash to the commencement of the medication. Particular difficulties are presented by the patient taking combined preparations, for example co-tenidone, which contains both a diuretic and a β-blocker. Excipients contained in medication, such as preservatives, stabilisers or colours, may be the culprit rather than the drug itself. Changes in brand of medication may for this reason provoke a skin reaction in someone who appears to have been established on a drug for some time and suddenly develops a rash. Patients may be taking preparations acquired over the counter, or from an alternative practitioner, which they may not immediately volunteer when asked about current medication. If a patient presents with a rash and is currently taking, or has recently finished, medication it is important to:

- Take an accurate drug history, including over-the-counter medicines, herbal and homeopathic preparations and any injections. Record both generic and brand name of medicines.
- Ask if the patient has any history of drug sensitivity.
- Ascertain when the eruption started in relation to drug use (the latency of onset of the eruption).

Definitive diagnosis of a drug-induced dermatosis would require drug re-challenge; however, this is not recommended due to the possibility of provoking a more severe reaction on second exposure (Li Wan Po and Kendall 2001).

Drug-induced skin disorders

In this chapter, drug reactions will be considered under the following headings: drug reactions causing changes to skin function; mild drug-induced skin disorders; severe drug-induced skin disorders.

Drug reactions causing changes to skin function

Some drugs alter the ability of the skin and associated structures (hair and nails) to perform their function normally.

Abnormal photosensitivity

Drugs may induce an excessive sensitivity to sunlight. Ultraviolet wavelengths of sunlight (290–400 nm) are able to interact with certain drugs in the skin to provoke abnormal photosensitivity. An eruption occurring on all uncovered skin implicates exposure to a systemic photosensitising agent, for example, a patient who commences bendroflumethiazide and subsequently develops sunburn on a cloudy day. A localised eruption indicates a reaction to a locally applied topical photosensitiser and subsequent exposure to light. This may be seen in individuals who are sensitive to a component of sunscreens such as benzophenone, a chemical sun block.

Drug-induced photosensitivity can be either phototoxic or photoallergic (Box 56.1). Phototoxic reactions, which are more common, resemble severe sunburn and can progress to blistering. They are dose dependent for both the drug and sunlight, occur within 5–15 h of taking the drug and subside quickly on drug withdrawal. Photoallergic rashes are usually eczematous, but may be lichenoid, urticarial, bullous or purpuric. They are not dose dependent and occur following exposure to normal amounts of sunlight exposure. The onset can be delayed by weeks or months, while recovery is often slow following drug withdrawal. Rarely, a photoallergic state can persist for years after the drug responsible has been discontinued.

Patients receiving known photosensitising drugs should be advised to avoid strong sunlight. They should also be advised to use a broad-spectrum topical sunscreen, providing both UVA protection (indicated by the 'star rating' on the bottle) and UVB cover (indicated by the sun protection factor, SPF).

Pigmentary changes

The skin's colour can be altered by drugs: hyper-pigmentation, hypo-pigmentation and discoloration can all potentially be induced by a variety of medicines (see Fig. 56.1 and Table 56.1). Pigmentary changes can be widespread or localised. The most common examples of localised pigmentation are the facial blue–black pigmentation in individuals on amiodarone or minocyline, and melasma facial pigmentation occurring in some women taking the combined oral contraceptive pill. Generalised pigmentary change induced by drugs is rare, but can occur with chemotherapeutic agents such as bleomycin. This may have the appearance of generalised hyper-melanosis, or may take on a more flagellate appearance with multiple linear areas of hyper-pigmentation.

The mechanism of drug pigmentation is not always known; however, proposed pathogenetic mechanisms are:

(1) Drug or drug metabolite deposition in the dermis and epidermis. An example of this would be agyria, in which systemic absorption of silver from, for example, topical silver sulphadiazine, causes a slate-grey discolouration of the skin.

(2) Enhanced melanin production with or without an increase in the number of active melanocytes. This appears to be the pathogenetic mechanism in melasma and also bleomycin-induced pigmentation (Moncada et al., 2009)

Nail changes

The growth and colour of finger and toenails can be modified by drugs. Abnormalities of texture and architecture of the nail unit can also be drug-induced. Blue discoloration of the nails can result from therapy with mepacrine, while a blue–black pigmentation may accompany treatment with minocycline and certain cytotoxic drugs such as hydroxyurea.

Phenytoin
Tamoxifen
Verapamil

Potassium permanganate solutions will dye nails brown. White nails (leuconychia) can result from treatment with chemotherapy agents, especially, cyclophosphamide, doxorubicin and vincristine. Beau's lines, transverse depression of the nail, represent interruption to the normal growth of the nail matrix, and are caused by systemic infection, metabolic upset, or occasionally by drugs. In the drug-induced form, the most common cause is again chemotherapy agents, similar to those which cause leuconychia.

Onycholysis is characterised by separation of the nail plate from the underlying nail bed. Any cytotoxic agent may induce onycholysis by direct toxicity to the matrix. Photo-onycholysis describes lifting of the nail plate and is caused by the combination of a photosensitising drug, for example minocycline, oxytetracycline and UVA exposure.

Hair changes

Drugs may exert an effect on the hair follicle itself or on the growth cycle of hair. The cycle of hair growth involves anagen (the growth phase of the hair), catagen (the resting phase) and telogen (the shedding phase). Either loss of hair or excessive growth of hair may result.

Loss of hair. Drug-induced alopecia (Box 56.2) may be partial or complete. The temporal relationship between the introduction of the drug and the subsequent loss of hair depends on the part of the hair cycle with which the drug interferes. Cytotoxic drugs interfere with the 'anagen' or growth phase of the hair cycle, and so loss is rapid and complete; it begins shortly after administration of the drug and the effect is dose dependent and fortunately reversible, but a delay of several weeks is common before regrowth begins.

Delayed hair loss following the introduction of a drug is a more insidious process and may not be noticed immediately by the patient. In this scenario, the drug is often interfering with the 'telogen' or shedding part of the hair cycle, moving follicles through this phase more quickly. Hair is shed at a rate that exceeds that at which the follicles can produce new hair, resulting in a thinning effect. Given the length of the hair cycle, this type of hair loss can occur 2–4 months after a drug is initiated. Retinoid therapy, including isotretinoin prescribed for acne, or acitretin for psoriasis, may induce a telogen alopecia.

Androgens promote shrinking of hair follicles and shorten duration of the growth stage of the hair-follicle cycle (anagen stage). Drugs with androgen activity can induce male-pattern baldness, for example exogenously administered testosterone, which may be prescribed for hypogonadism in men and occasionally in post-menopausal women as an adjunct to hormone replacement therapy. Oestrogens are known to prolong the anagen stage and counteract androgenetic alopecia. Oestrogenic stimuli may cause the hair follicle to shift into anagen phase and vice versa. Use of the oestrogen receptor antagonist tamoxifen in women with breast cancer can exacerbate female pattern hair loss. Tamoxifen competes for the oestrogen receptor and produces an environment with relative hyperandrogenism, which may augment the androgen action on follicles.

Excessive hair. Hirsutism is excessive hairiness, especially in women, in the male pattern of hair growth, while hypertrichosis is the growth of hair at sites not normally

hairy. Both conditions can be drug induced and in some cases the same drug can produce both patterns of hair growth (see Box 56.2). The capacity of minoxidil to produce hypertrichosis was noted during early trials of this drug as an antihypertensive. It is infrequently used for its originally intended purpose, as it produces profound postural hypotension, but its most noticeable side effect has been exploited as a topical preparation for the treatment of male pattern baldness.

Changes to the skin's immune system and skin malignancy

The skin's innate immune surveillance system detects and repairs UV-induced DNA damage thus limiting the tendency to cutaneous carcinogenesis. Drug-induced immunosuppression places an individual at an increased risk of skin cancer, notably squamous cell and basal cell carcinomas. As well as a reduction in immune surveillance, immunosuppression increases susceptibility to the human papilloma virus, some strains of which may predispose to the development of squamous malignancy. Patients taking drugs such as azathioprine, ciclosporin, tacrolimus, mycophenolate mofetil and chemotherapeutic agents should be counselled about the importance of sun protection to minimise the risk of development of malignant and pre-malignant skin cancers. Certain high-risk patients on immunosuppressant drugs, particularly renal transplant recipients, should undergo formal follow-up with skin monitoring by a dermatologist on a yearly basis.

Mild drug-induced skin disorders

Mild drug reaction patterns in the skin are numerous; some of the more commonly seen morphologies are discussed in this section.

Drug-induced exanthems

A drug-induced exanthem (widespread rash) is the most common type of drug reaction in the skin. Exanthems are characterised by erythema (redness) and may be morbilliform (resembling measles) or maculopapular (a mixture of flat and raised areas) (see Fig. 56.2). Less frequently there may be blisters, which may be small (vesicles) or larger (>5 mm, bullae), and the skin may feel hot, burning or itchy.

The proportion of the body surface area (BSA) involved varies from case to case but when severe, involving more than 90% of the BSA, the presentation is referred to as 'erythroderma', which is discussed later. In theory, any drug is capable of producing a drug-induced exanthem in the skin, but in practice, common causes include antibiotics (e.g. sulphonamides, ampicillin, isoniazid), anticonvulsants (e.g. phenytoin, carbamazepine) and antimalarials (chloroquine).

Most drug-induced exanthems begin within 7 days of commencing a drug, the mechanism being a delayed (type IV) hypersensitivity (Burns et al., 2004). If the drug can be identified, it should be stopped, appropriate symptomatic relief instituted with antihistamines and topical steroids. A clear record of the reaction should be made in the patient's notes.
Fig. 56.2 Drug exanthem: maculopapular, itchy eruption appeared 4 days following the introduction of a course of co-amoxiclav for a respiratory tract infection. Note the linear marks indicating excoriation (scratching) on the left posterior shoulder.

Both the patient and his primary care doctor should be made aware of the reaction for the purposes of future avoidance.

An exanthematous reaction commonly occurs following administration of ampicillin (or its derivatives, including amoxicillin) to patients suffering from glandular fever (infectious mononucleosis). It does not usually represent a true penicillin allergy, but a complex interplay between viral factors (infectious mononucleosis being caused by Epstein Barr virus) and drug epitopes (Burns et al., 2004). This reaction to the drug would not be expected to be seen in the same patient in the absence of the virus.

Urticaria and angioedema

Urticaria, also known as hives, describes the appearance of red, itchy weals on the skin (Fig. 56.3). Angioedema is a more serious, related condition in which the patient develops deep soft-tissue swellings, mostly notably on the face. Urticaria and angioedema can be either allergic, a reaction between an antigen and specific mast cell-bound IgE, or non-allergic.

Fig. 56.3 Urticaria: patient developed the classic raised red itchy weals of urticaria following the commencement of ibuprofen for musculoskeletal pain.

Drugs are recognised triggers of urticaria and angioedema (Box 56.3) and can also exacerbate pre-existing urticaria. The most important culprits are the NSAIDs and opiates, both of which lower the threshold for mast cell degranulation. ACE inhibitors and angiotensin receptor blockers (ARBs), for example candesartan, can provoke angioedema in a susceptible individual.

Drug-induced urticaria/angioedema can be a cutaneous manifestation of anaphylaxis, and in this situation, urgent medical attention is needed with administration of adrenaline, antihistamine and intravenous corticosteroid.

Pruritus

Pruritus (itching) can accompany a drug rash, or may be an isolated symptom provoked by a medication. The most common trigger of drug-induced pruritus is the administration of opiate analgesics and their related synthetic derivatives such as tramadol. Opiate-induced pruritus is centrally mediated, rather than by peripheral nerves; therefore, antihistamines do not, in general, ameliorate the itch. This can pose a particular problem in the palliative care setting where opiate analgesics are required regularly.

Fixed drug eruptions

Fixed drug eruption is characterised by one or more inflammatory patches that recur at the same cutaneous or mucosal site(s) each time the patient is exposed to the offending drug (Fig. 56.4). The eruption usually involves the torso, hands, feet, face or genitalia, and is characterised by a deep red, circular, well-demarcated patch. They take between 2 and 24h to develop following drug ingestion. On the first drug exposure, there is usually only one lesion, but subsequent exposure can result in multiple lesions.

The group of drugs with the potential to cause a fixed drug eruption is virtually limitless, but some of the drugs more commonly responsible are listed in Box 56.4.

Once the drug has been stopped, the lesions resolve and may leave an area of post-inflammatory hyperpigmentation. This may be the only physical sign at the time the patient presents. Topical steroids may ameliorate the symptoms.

Fig. 56.4 Fixed drug eruption: female patient developed persistent macular inflamed areas on her upper chest wall 2 months after starting a new combined oral contraceptive pill. A fixed drug eruption was suspected and the lesions resolved after stopping the medicine.

Acneiform eruptions

Acne may be drug-induced or drug-exacerbated. One of the most commonly prescribed drugs to produce an acneiform eruption is corticosteroid, in either topical or oral form. Illicit use of anabolic steroids by athletes can also produce this effect, occasionally in its most severe form, acne fulminans. Other drugs which may worsen or provoke acne include ciclosporin, lithium and progesterone-only oral contraceptives.

A new class of anticancer drug, endothelial growth factor receptor antagonists, for example cetuximab, commonly produce an acneiform eruption. The papules and pustules which occur are more monomorphic than those seen in idiopathic acne. Interestingly, studies have shown that there is a positive correlation between the severity of the acneiform eruption and response of the cancer to the treatment (Saltz et al., 2003; Susman, 2004) Most drug-induced or drug-exacerbated acne can be managed with the same treatments as used in idiopathic acne, such as topical agents, oral tetracycline antibiotics, erythromycin, or in severe cases, oral retinoids. Examples of drugs which may cause an acneiform eruption are given in Box 56.5.

Phenytoin
Propylthiouracil

EGFR, Epidermal growth factor receptor.

Psoriasiform eruptions

Drugs can either exacerbate psoriasis in predisposed patients or induce psoriasiform rashes in previously unaffected patients (see Box 56.6). The psoriasiform eruptions mimic psoriasis and are characterised by itchy, scaly red patches on the elbows, forearms, knees, legs and scalp. Drugs which have a well-established effect of worsening pre-existing psoriasis include β blockers, lithium, antimalarials and ACE inhibitors.

Lichenoid eruptions

Drug-induced lichenoid eruptions (see Box 56.7) resemble lichen planus, occurring as flat mauve lesions. However, they may be atypical, showing scaling and confluence. The lesions can be seen at any site, but are found mainly on the forearms, neck and on the inner surface of the thighs. The eruption resolves with drug withdrawal, with or without topical steroids, but post-inflammatory hyperpigmentation is often long lasting.

Eczematous eruptions and contact dermatitis

Retinoid drugs (such as isotretinoin, acitretin and alitretinoin) and statins have a drying effect on the skin, and can exacerbate pre-existing eczema or precipitate eczema in a susceptible individual. Irritant contact dermatitis may be seen in preparations with an alcohol base, such as topical antibiotics, or with the application of topical preparations which are inherently irritant such as benzoyl peroxide, tar or dithranol.

Box 56.6	Drugs which exacerbate psoriasis

ACE inhibitors
Antimalarials – chloroquine, mepacrine
Biological therapy targeting tumour necrosis factor alpha (TNF-α) (occasionally – slightly paradoxical given that such drugs are also given to *treat* psoriasis)

Methyldopa
NSAIDs
Penicillamine
Phenothiazines
Quinine
Sulphonylureas

Allergic contact dermatitis is a delayed (type IV) hypersensitivity reaction which can develop to any topical preparation, for example eye drops in a sensitised individual. Most commonly, this will be to excipients contained in the preparation, such as preservatives, for example sodium metabisulphite, fragrances or stabilisers, but may be to the drug itself. In all cases of irritant or allergic contact dermatitis, the patient should be counselled to stop the preparation. Patch testing carried out by a dermatologist is a useful way of investigating patients in whom a diagnosis of allergic contact dermatitis is suspected.

Erythema nodosum

Erythema nodosum is an acute inflammatory reaction with painful subcutaneous nodules, usually but not exclusively found on the shins. Erythema nodosum is usually a complication of infection with, for example, streptococcus or tuberculosis, or is a cutaneous manifestation of an inflammatory condition such as sarcoidosis. In its drug-induced form, it may be caused by oral contraceptives, sulphonamide antibiotics, salicylates, penicillins and gold salts.

Severe drug-induced skin disorders

Erythema multiforme (EM), Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are all idiosyncratic, immunologically mediated severe drug eruptions. For our purposes, these diseases may be considered to be on a spectrum, from the mild and self-limiting at one end (EM) to the fulminating severe at the other (TEN).

Erythema multiforme

EM is an eruption of target-like lesions which are characterised by concentric red and pale rings with, in severe cases, central blistering. EM typically occurs on the limbs rather than the trunk but mucous membrane surfaces, such as the eye, the mouth and the genital tract, may also become involved. A significant proportion of EM cases are caused by infection,

Allopurinol
Antiretrovirals, for example nevirapine
Barbiturates
Carbamazepine
Cimetidine
Dapsone

NSAIDs
Penicillins
Phenytoin
Rifampicin
Sulphonamides

particularly herpes simplex virus reactivation; however, in some patients, EM is triggered by a drug (see Box 56.8). Drug-induced EM will usually present within 2 weeks of starting a new medication. Once the responsible drug has been stopped, treatment is symptomatic with paracetamol, topical steroids and appropriate topical therapy for the mouth and other involved mucosal surfaces.

Stevens–Johnson syndrome and toxic epidermal necrolysis

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are terms used to describe a life-threatening, mucocutaneous drug hypersensitivity syndrome characterised by blistering and epidermal sloughing (Fig. 56.5). In SJS, there is epidermal detachment of <10% BSA, in TEN there is detachment of >30% of the BSA, while cases with 10–30% involvement are labelled SJS/TEN overlap. The systemic

problems which accompany widespread epidermal loss such as high losses of heat and fluid, and the heightened risk of infection due to diminished barrier function can cause serious morbidity, similar to extensive burns. TEN carries a mortality rate of approximately 30%, but this can rise to 90% mortality in the presence of co-morbidities. HIV-infected patients and patients with systemic lupus erythematosus (SLE) have an enhanced risk of developing SJS/TEN. Drugs causing SJS/TEN are listed in Box 56.9.

Clinical features. A prodrome of fever, malaise, and upper respiratory tract symptoms may precede the eruption by a few days. Involvement of the mucous membranes of the eyes, mouth, and nose is a prominent early feature. Eye involvement results in blepharitis, haemorrhagic conjunctivitis, mucus secretion, and pseudomembranes. Ophthalmological input is required early if long-term sequelae such as blindness from corneal opacities and synechiae are not to occur. Urethral involvement must also be anticipated and the patient catheterised if strictures are not to complicate the disease course. Mouth involvement causes an erosive and haemorrhagic mucositis. On the skin, dusky red macules 1–3 cm in diameter appear at any site and evolve to become confluent. The skin lesions pass through vesicular and bullous phases before epidermal detachment occurs. Shearing pressure to the skin causes detachment of involved epidermis (positive Nikolsky's sign). In TEN, there is widespread epidermal loss and sloughing of the necrotic epidermis which peels back to leave large areas of exposed dermis. Denuded dermis exudes serum, becomes secondarily infected and readily bleeds. The patient is in severe pain and is usually extremely ill. The visceral manifestations that result from widespread epithelial loss include pneumonia, pancreatitis, thromboembolic disease, renal and hepatic impairment.

The patient with SJS/TEN will require full supportive care, preferably in an intensive care unit. Patients with SJS with less extensive involvement may be managed in a lower-dependency environment, but should be monitored closely

Fig. 56.5 Stevens–Johnson syndrome is a serious, idiosyncratic reaction of the skin and mucous membranes to a drug. It results in blistering and subsequently widespread epidermal loss and can have a high mortality rate.

Box 56.9 Drugs causing Stevens–Johnson syndrome and toxic epidermal necrolysis

for signs of progression in the first 48 h of admission. A multidisciplinary approach, including dermatologists, ophthalmologists and intensive care physicians, is critical to a successful outcome. Following drug withdrawal, the management is supportive, including prompt treatment of infection, careful attention to thermoregulation, fluid balance and skin care, and introduction of appropriate eye and lid care. The literature has failed to identify one treatment which definitively improves outcomes, but agents which have been used include systemic steroids, ciclosporin and intravenous immunoglobulin.

Drug Reaction with Eosinophilia and Systemic Symptoms

Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS) is sometimes known as Drug-Induced Hypersensitivity Syndrome (DIHS) and is a distinct, severe and potentially fatal drug-induced skin disorder. The drugs commonly associated with this syndrome are listed in Box 56.10.

Typically, the dermatosis of DRESS is an extensive, inflammatory, maculo-papular exanthem. Other skin signs may also be present including pustules, purpura, blisters, target-like lesions and facial oedema (Fig. 56.6). To meet the diagnostic criteria, there will also be a haematological abnormality, either a raised eosinophil count ($>1.5 \times 10^9$/L) or the presence of atypical lymphocytes on the blood film. There is prominent systemic involvement in DRESS, most commonly fever, lymph node enlargement and liver function abnormalities. Less typically, there is renal, pulmonary or cardiac involvement.

Fig. 56.6 Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS): female patient developed a severe systemic reaction following commencement of phenytoin for seizure prophylaxis after brain surgery. She had an erythematous urticated eruption as seen above accompanied by lymphadenopathy, derangement of liver function, and a circulating eosinophilia.

DRESS is characterised by its long latency of onset with the syndrome usually presenting between 2 and 8 weeks after commencement of the causative drug. This is an important point to note in the medication history, as often the drug responsible may be overlooked if it is considered to have been started 'too long ago'.

DRESS is accompanied by significant morbidity while the mortality has been estimated at 10%. Systemic steroids are usually administered, and may be beneficial, but there are no randomised controlled trials to support use. Management involves stopping the suspected drug, and supportive care dictated by extent of involvement.

Acute Generalised Exanthematous Pustulosis

Acute Generalised Exanthematous Pustulosis (AGEP) describes a reaction pattern to a drug consisting of widespread sterile, monomorphic pustules studding the skin in a generalised fashion. Such patients are generally systemically unwell with a fever and the complications of generalised skin inflammation including excessive heat and fluid loss. The differential diagnosis would include pustular psoriasis. Although the condition is self-limiting, potent topical steroids may accelerate resolution. The drugs which can cause AGEP are summarised in Box 56.11.

Erythroderma and exfoliative dermatitis

Erythroderma is the term used to describe any pattern of drug reaction in the skin where more than 90% of the BSA is involved. This is usually an extension of a severe drug-induced exanthem. The erythrodermic patient often feels shivery and may have lymphadenopathy and fever. The large surface area involved in erythroderma leads to substantial losses of heat and fluid from the body. This puts the patient at risk of electrolyte imbalances, hypothermia, and with the loss of skin barrier function, infection. Admission to hospital is indicated in cases of erythroderma, and management is supportive, with intravenous fluids, warming measures, and treatment of infection. Topical corticosteroids are often prescribed but must be used with caution since significant amounts will be systemically absorbed across the erythrodermic skin. During recovery, the patient will desquamate, referred to as the exfoliative phase. Drugs commonly provoking this pattern of reaction are similar to those which cause a drug-induced exanthem (Box 56.12).

Lupus erythematosus

Syndromes indistinguishable from Lupus erythematosus (LE) may occur following drug administration (see Box 56.13) and can be accompanied by seroconversion to antinuclear antibody (ANA) positivity. Serological clearance of ANA may occur after drug withdrawal, but this may take months or years.

The cutaneous manifestations of drug-induced LE include the characteristic butterfly-shaped rash on the face, photosensitive erythema on dorsal hands and neck, and annular lesions on limbs.

Box 56.12   Drugs causing exanthemous eruptions

Amoxicillin
Ampicillin[a]
Bleomycin
Captopril
Carbamazepine
Chlorpromazine
Co-trimoxazole
Gold salts
Nalidixic acid
NSAIDs
Phenytoin
Penicillamine

[a]Ampicillin rashes do not necessarily indicate penicillin hypersensitivity, but may seen when administered to a patient with glandular fever (see text).

Box 56.11   Drugs causing acute generalised exanthematous pustulosis

Griseofulvin
Hydralazine
Isoniazid
Lithium
Methyldopa
Oral contraceptives
Penicillamine
Phenytoin
Procainamide
Propylthiouracil
Sulphasalazine
Terbinafine
Biological therapy targeting tumour necrosis factor alpha (TNF-α), for example infliximab

Biological therapy targeting tumour necrosis factor alpha (TNF-α) such as infliximab and etanercept has been found to provoke lupus both in its systemic and limited cutaneous forms.

Vasculitis

Vasculitis is characterised pathologically by inflammation in vessel walls and clinically as palpable purpuric lesions most commonly found on the lower limbs. Cutaneous vasculitis without other organ involvement is the rule, but systemic involvement, such as renal, can occasionally occur. The purpuric areas on the legs may become ulcerated and require specialist dermatology input.

Drugs are the cause of approximately 10% of cutaneous vasculitis cases and should be considered in any patient with small vessel vasculitis (Box 56.14). Withdrawal of the causative drug is often sufficient to resolve the clinical manifestations without the need for treatment with systemic corticosteroids or more powerful immunosuppressants.

Skin necrosis

The term widespread cutaneous necrosis describes extensive skin infarction which often heralds a severe systemic coagulopathy. Widespread cutaneous necrosis can be triggered by a reaction to warfarin, or less commonly to heparin. In warfarin or coumarin skin necrosis, the buttocks and breasts are the most commonly involved sites. Discontinuation of the anticoagulant responsible is essential; however, ongoing management of the coagulopathy is critical and patients need to be assessed by a haematologist.

Box 56.14   Drugs that may cause cutaneous vasculitic reactions

ACE inhibitors
Allopurinol
Amiodarone
Aspirin
Carbamazepine
Carbimazole
Diltiazem
Erythromycin
Furosemide
Gold
Haematopoietic growth factors (G-CSF and GM-CSF)
Hydralazine
Interferons
Methotrexate
Minocycline
NSAIDs
Penicillamine
Propylthiouracil
Sulphasalazine
Sulphonamides
Thiazides
Thrombolytic agents

G-CSF, Granulocyte-colony stimulating factor; GM-CSF, Granulocyte-macrophage colony-stimulating factor.

Patient care

Withdrawal of the likely offending drug should be the first intervention in cases of suspected drug eruption. This should be done in consultation with the prescribing physician, as an alternative drug may be required to control the patient's condition. General methods which will provide symptomatic relief in a mild, limited drug eruption include emollients, soap substitutes and oral antihistamines. A mild topical corticosteroid may also be appropriate. In cases where the eruption is more extensive, or if a mucosal surface is involved, specialist care provided by a dermatologist will be necessary.

Case studies

Case 56.1

A 36-year-old female patient with a long history of chronic idiopathic urticaria attends her local pharmacy for some advice. Her skin disease is usually well controlled with an occasional dose of cetirizine which she buys over the counter. She has recently begun taking ibuprofen for muscular pain associated with her marathon training, but has found to her dismay that her urticaria has become much worse and is flaring on a daily basis.

....

Questions

1. What is the likely cause of the deterioration in the control of urticaria?
2. What management should be advised?
3. What other group of drugs is likely to produce this effect?

....

Answers

1. Non-steroidal anti-inflammatory drugs (NSAIDs) are known to increase the frequency of attacks of urticaria in susceptible individuals. It is likely that the self-medicating with ibuprofen has lessened the patient's control of her urticaria.
2. In the first instance, the ibuprofen should be stopped. An alternative such as paracetamol could be advised for the musculoskeletal symptoms. An enquiry should be made as to whether or not any symptoms suggestive of angioedema, such as lip/tongue swelling, or difficulty breathing, have accompanied the urticaria, as this would imply a need for medical attention. In the acute phase, regular administration of an antihistamine such as chlorphenamine should help to relieve rapidly the symptoms. The patient should be warned that the ability of NSAIDs to worsen urticaria is a 'class effect' and that similar symptoms may be produced with drugs such as aspirin, meloxicam and naproxen.
3. Opiate analgesics lower the threshold for mast cell degranulation, which is the most important pathophysiological mechanism in the production of urticaria. Thus, morphine and related products such as codeine should be avoided.

Case 56.2

A 69-year-old male patient with a history of psoriasis attends the pharmacy looking for advice. In the past, his skin disease has always been well controlled with topical preparations. He was

recently admitted to hospital with a myocardial infarction and has noticed a marked deterioration in his psoriasis since discharge. During his admission, he was commenced on:

    Aspirin 75 mg daily
    Simvastatin 20 mg daily
    Atenolol 25 mg daily
    Enalapril 5 mg daily

Questions

1. What is the likely reason for the exacerbation of his psoriasis?
2. How should this be treated?

Answers

1. The patient's psoriasis could have worsened due to the stress of his recent illness, but it is probably secondary to the introduction of atenolol or enalapril. Both β-blockers and ACE inhibitors have been associated with the worsening of psoriasis.
2. Given the recent myocardial infarct, any interruptions or substitutions to treatment must be made in conjunction with the patient's primary care doctor or cardiologist. The worsening of psoriasis with β-blockers is likely to be a class effect, and therefore substituting a different β-blocker is unlikely to resolve the problem. The treating physician may wish to prescribe an alternative antihypertensive such as a calcium channel blocker. If this does not ameliorate the situation, then the ACE inhibitor may be suspected, and trial stoppage may be considered. An ARB (angiotensin receptor blocker) such as candesartan may be acceptable as an alternative.

Case 56.3

A 37-year-old man presents with swelling of his upper lip. He asks if this could be stress induced as he has had several previous episodes of localised swelling of the face over the last 6–12 months.
He has been taking bendroflumethazide and enalapril for hypertension for the last 3 years, but has not taken any other medications recently.

Questions

1. What condition do his symptoms suggest?
2. Could this be drug-induced?
3. How should the condition be treated?

Answers

1. This pattern of localised swelling of the face is characteristic of angioedema.
2. Angioedema is a known adverse effect of ACE inhibitors with an overall incidence of 0.5–1%. Although this commonly occurs in the first week of treatment, delayed-onset angioedema can occur even after many years of treatment.
3. Since angioedema can be life-threatening, any suspect drug should be stopped. There is a very low incidence of this occurring with an angiotensin II receptor blocker (ARB), and this may be a suitable alternative for this patient. The acute presentation of angioedema is treated with antihistamine and corticosteroids. If the patient presents with respiratory symptoms, subcutaneous epinephrine (adrenaline) is indicated.

Case 56.4

Miss AF is a 15-year-old renal transplant patient who attends the pharmacy 6 weeks following transplant. She is very distressed about the growth of facial hair and the worsening of acne.

Questions

1. What are the possible causes of Miss AF's skin complaints?
2. What other side effects should be enquired about?
3. How might these conditions be treated?

Answers

1. It is likely that Miss AF is receiving transplant immunosuppression that includes ciclosporin and prednisolone. The ciclosporin is most likely to have caused the growth of facial hair. Both the oral corticosteroid and the ciclosporin may have aggravated pre-existing acne or precipitated new-onset acne.
2. Ciclosporin may cause gingival hyperplasia, tremor, paraesthesia and nausea. Corticosteroids can cause increased appetite/weight gain, alterations of mood (euphoria, depression), sleep disturbance, gastritis and numerous other side effects.
3. Hirsutism is a side effect of ciclosporin that many young transplant patients have to cope with, and depilatory creams are commonly used. Tacrolimus is an alternative long-term immunosuppressant which is less likely to cause acne and hirsutism and which may be used in place of ciclosporin.

Case 56.5

An 85-year-old gentleman with rheumatoid arthritis, Mr DC, attends the local pharmacy with a persistent lesion on his left upper cheek, abutting the eyelid (Fig. 56.7), which has recently been bleeding. For the last 18 years, his rheumatoid arthritis has been treated with methotrexate. You know Mr DC is a retired naval officer, and his skin is severely sun damaged. He tells you he has had a number of basal cell carcinomas in the past and is concerned that this may be another.

Fig. 56.7   Case study 5 – a patient with basal cell carcinoma.

Questions

1. What is the likely diagnosis?
2. What risk factors does the patient have for this diagnosis?
3. How should he be advised?

Answers

1. This is likely to be another basal cell carcinoma (BCC). Basal cell carcinomas are the most common type of skin cancer in the western world, presenting as pearly papules with a central area of ulceration and creeping telangiectatic vessels at their surface. They usually occur on sun-exposed sites and are related to high cumulative levels of sun exposure.
2. Mr DC has a number of risk factors for developing a basal cell carcinoma:

   - Age: these lesions tend to occur in the older age group, presumably because of their high level of actinic damage accrued over many years. In addition, sunscreen was not as widely used in mid-to-late 20th century as it is today.
   - Immunosuppressed state: Mr. DC has been on an immunosuppressant for 18 years resulting in his tumour surveillance mechanisms being attenuated.
   - Occupation: it is likely that Mr DC will have served in some very sunny climates. A history of active service with the Armed Forces should always prompt health-care professionals to ask about the patient's history of sun exposure.

3. Firstly, the patient should be asked to consult his primary care doctor or dermatologist as the lesion will require treatment. If left unattended, basal cell carcinomas continue to grow and can become locally invasive. Secondly, Mr. DC should be advised of the importance of sun protection, using a high factor (30 or above) sunscreen, with good UVA protection (as indicated by the star rating system on the back of the bottle). A hat provides excellent cover for the scalp and face. The sun should be avoided completely between the hours of midday and 2 pm, when the levels of ultraviolet light are at their highest.

Case 56.6

A 56-year-old man, Mr SW, presents to the pharmacy in an alarmed state. In recent months, he has had several episodes of gout and was recently prescribed allopurinol. He has now taken four doses of the drug. Last night, Mr SW developed an unusual rash on his palms and soles, which this morning has developed blisters. The rash has now extended to involve his arms and legs. He also complains of 'mouth ulcers', a gritty feeling in the eyes, and pain on passing urine. Mr SW is not feverish now, but had a raised temperature overnight.

Questions

1. What is the likely diagnosis?
2. How should Mr SW be managed?

Answers

1. This patient is developing SJS. He has a blistering eruption which commenced peripherally, which is classical for this disorder. Mr SW now has evidence of mucosal site involvement, including the oral mucosa and conjunctivae, with urethral involvement suggested by his history of dysuria. Allopurinol is a common culprit for this condition.

2. Patients with suspected SJS need urgent dermatological assessment and often require inpatient care. The suspected drug should be withheld. Following admission to hospital, a full blood count, urinalysis, blood culture, skin swabs and a chest X-ray should be performed to screen for infection. An ophthalmological opinion should be sought to ensure that no synechiae (scarring) of the eyes forms because this can occasionally arise with the degree of inflammation seen in this patient. Catheterisation is required if urethral mucosal involvement is suspected, to prevent strictures forming due to scarring. Mr SW should not be exposed to allopurinol or related drugs again, as recurrence is likely.

Case 56.7

A 24-year-old female, Ms AM, was commenced on the combined oral contraceptive pill last month. Ms AM is concerned because she has noticed the appearance of raised red nodules on both shins, which are tender to touch, and have been becoming more numerous over the last 3 days. She has never had any such eruption before. There is no recent travel history, and Ms AM has no rashes elsewhere, nor does she have any arthralgia.

Questions

1. What is your diagnosis?
2. What is the likely cause of this eruption and what are the other possible causes?
3. What is the prognosis?

Answers

1. Ms AM has developed erythema nodosum, an inflammatory condition seen on the anterior legs, usually bilaterally. Erythema nodosum is a Latin term meaning 'red lumps', it represents a pathological process in which subcutaneous fat becomes inflamed.
2. The combined oral contraceptive pill is the most likely precipitant in this case. However, a full drug and medical history should be taken as other medicines may cause erythema nodosum, for example antibiotics or NSAIDs. A very common cause of erythema nodosum in young people is streptococcal throat infection. A travel history is important as the same clinical reaction pattern may be brought about by tuberculosis. Finally, a number of other medical problems such as ulcerative colitis and Crohn's disease, or sarcoidosis may also produce erythema nodosum.
3. The patient should see a dermatologist to have the other causes of erythema nodosum excluded. The management of erythema nodosum is supportive, with regular NSAIDs or paracetamol given for pain. The combined oral contraceptive pill should be stopped, and Ms AM switched to a different form of contraception.

Case 56.8

A 17-year-old girl, Miss AW, asks for some advice regarding a widespread itchy rash which has appeared suddenly over the last 24 h. Miss AW visited her primary care doctor 4 days ago complaining of a sore throat and a productive cough. Having auscultated the chest, the primary care doctor suspects a respiratory tract infection and prescribes amoxicillin. Five days later, Miss AW develops a widespread maculopapular rash. She attends the pharmacy for advice, and you suspect the rash to be drug-induced.

Questions

1. What is the cause of the eruption?
2. How should Miss AW be managed?
3. Should Miss AW be advised to avoid penicillin antibiotics in the future?

Answers

1. This is likely to be an amoxicillin-induced drug eruption.
2. The antibiotic should be stopped and the clinical indication for an alternative preparation assessed by the primary care doctor. An antihistamine and a mild/moderate potency topical corticosteroid should provide symptomatic relief. If the patient does not obtain relief with such treatment, if the rash is becoming widespread, or if there are any features of a systemic illness such as fever or enlarged lymph nodes, the patient should see the primary care doctor.
3. The reaction may be provoked by any antibiotic in the penicillin group, so the patient needs to be informed of the need to avoid all such antibiotics in the future.

Eczema and psoriasis 57

A. Abdul-Wahab and N. Desai

Key points

- Eczema and psoriasis are common, chronic skin diseases with significant impact on quality of life.
- Emollient therapy is the mainstay of treatment for most types of eczema.
- Active inflammation should be treated with a topical steroid of appropriate potency.
- Eczematous skin is often secondarily infected and appropriate recognition of secondary bacterial and viral infections is mandatory.
- Systemic steroids should be avoided in psoriasis.
- New effective systemic agents are now available, including biologic agents, for which careful patient selection and regular monitoring are important.
- Eczema and psoriasis are inflammatory skin conditions commonly encountered in clinical practice. Although the conditions both manifest as erythematous, pruritic rashes, their morphology, distribution, long-term treatment options and outcomes may differ significantly. Both conditions can be functionally and socially disabling. Patient education, support and guidance with topical treatments are therefore extremely important.

Eczema

The terms 'eczema' and 'dermatitis' may be used interchangeably and describe the same clinical and histological entity. Eczema is an itchy erythematous (red) eruption consisting of ill-defined erythematous patches or papules. The skin surface is usually scaly and as time progresses, constant scratching leads to thickened, 'lichenified' skin.

Pathology and clinical features

Acute eczema is an inflammatory process leading to oedema in the epidermis. The oedema is seen histologically in the epidermis as 'spongiosis'. Oedema manifests as fluid that collects into tiny blisters which may then coalesce. This is seen histologically as intraepidermal vesicles and clinically as pompholyx blisters on thicker palmar and plantar skin, and as excoriated, ruptured crusted vesicles elsewhere. Tightly packed keratinocyte cells in the epidermis usually prevent

transepidermal fluid loss and the entry of pathogens. This barrier function of the skin is lost in eczema. A schematic diagram demonstrating the normal skin epidermis and the effects on the barrier function during an acute eczema flare is shown in Fig. 57.1.

In the chronic form of eczema, prolonged rubbing and scratching results in a thickened epidermis and an increase in the upper horny cell layer of keratin, termed hyperkeratosis. Clinically, the skin appears thick, leathery, scaly and 'lichenified' with exaggerated skin markings, like tree bark (Fig. 57.2). Both acute and chronic stages are accompanied by a heavy chronic inflammatory cell infiltration of the dermis and epidermis. The main consequent symptom of these pathological processes is itch. The dictum of 'if it's not itchy, it's not eczema' holds true.

Clinical types

Atopic eczema

Atopic eczema is the commonest skin disorder of childhood, affecting between 10% and 20% of school age children in the UK. The aetiology is a combination of genetic, environmental and immunological factors.

The term 'atopy' describes an exaggerated propensity to form IgE to common allergens. In later life, approximately half of eczema patients will develop associated atopic disorders such as asthma and allergic rhinitis. The molecular pathology in atopic eczema is complex. The epidermal Langerhans cells have high-affinity IgE receptors through which the T-helper cells (T_h2 and T_h1) release cytokines and mediate skin inflammation.

Atopic eczema is diagnosed clinically and the criteria for definition include chronic itchy skin with three or more of the following: a history of flexural involvement of the skin creases, visible flexural involvement, dry skin, other atopic disease or onset within the first 2 years of life. The clinical course and distribution change through puberty and adulthood. In infants, common areas affected are face, neck and nappy area. Through childhood, flexural sites such as folds of the elbows and backs of the knees are classically involved (see Fig. 57.3). Symptoms usually improve with age and approximately 60% have resolution of symptoms by the age of 16.
Fig. 57.1 Schematic diagram demonstrating the normal skin epidermis (left) and the effects on the barrier function (right) during an acute eczema flare.

Fig. 57.2 Dry, excoriated, lichenified chronic eczema (courtesy of M. Carr).

Fig. 57.3 Flexural eczema in childhood (courtesy of M. Carr).

Exacerbating factors

A number of factors can aggravate atopic eczema:

- Extremes of temperature
- Irritants: soap, detergents, shower gels, bubble baths and water
- Stress
- Infection, either bacterial or viral
- Contact allergens
- Food allergens
- Inhaled allergens
- Airborne allergens.

The commonest trigger in the paediatric population is secondary infection, either bacterial or viral. Bacterial colonisation is common on the skin of those with atopic dermatitis and may result in the invasive infection triggering an acute flare. *Staphylococcus aureus* and *Streptococcus* spp. are most often responsible (Fig. 57.4).

Viral infections such as herpes simplex and molluscum contagiosum may also complicate atopic eczema. Eczema herpeticum is caused by the widespread dissemination of herpes simplex virus in eczematous skin and is a dermatological emergency. It requires urgent assessment and treatment with systemic aciclovir.

In some cases of severe atopic eczema, food allergy may be a contributory factor, particularly if a clear temporal relationship is detected by the parents. These cases should be referred to a paediatric allergy specialist, with access to a paediatric dietician, as unsupervised dietary restriction should be avoided in children. Most children tend to grow out of food allergies over time with the exception of nut and shellfish allergies.

Contact dermatitis

Contact dermatitis is classified as either allergic contact dermatitis (ACD) or irritant contact dermatitis (ICD).

Allergic contact dermatitis

ACD is a delayed type IV hypersensitivity reaction that develops in response to an antigen to which the host immune system has been previously sensitised. As a consequence, symptoms rarely develop on first exposure to the stimulus and

Fig. 57.4 Impetigo complicating atopic eczema (courtesy of M. Carr).

may only manifest months or years later following repeated re-exposure.

Many common compounds can lead to ACD. The most common compounds implicated are:

- Metals, for example nickel and cobalt
- Neomycin, a topical antibiotic found in over-the-counter preparations sold in some countries
- Fragrance ingredients, for example Balsam of Peru
- Rubber compounds
- Hair dyes, for example p-phenylediamine
- Plants, for example poison ivy.

Diagnosis relies heavily on a detailed patient history as well as recognising the pattern and distribution of the eczematous rash. Although the signs are usually localised to the area exposed to the allergen, secondary generalised eczema may develop.

The standard confirmatory investigation is patch testing and is used to differentiate allergic from ICD. This involves application of a standard, with or without a specialised range of compounds, to the patient's back over 72 h. This is followed by examination for a cutaneous reaction at day 2 and day 4. Identification of relevant compounds allows the patient to avoid the substance in the future, and this will hopefully reduce symptoms. Common areas of the body affected by ACD, with corresponding probable sensitisers, are listed in Table 57.1.

Irritant contact dermatitis

This is the most common form of occupational dermatitis and the commonest cause of hand eczema (Fig. 57.5). Unlike ACD, ICD is not immunologically mediated. The mechanism involves disruption of the epidermal permeability barrier and a direct cytotoxic effect depending on the irritant. Patients with pre-existing epidermal barrier dysfunction such as atopic eczema are at higher risk. The occupation of the individual may also be a risk factor, especially those working as builders, hairdressers, gardeners, healthcare workers and chefs. Irritants include detergents, oils, water, inorganic
Fig. 57.5   Contact dermatitis to cement in a building worker (courtesy of M. Carr).

acids, alcohols and plastics. Preventative skin care is key and this includes the use of barriers such as emollients or cotton gloves in addition to avoiding suspected irritants.

Seborrhoeic dermatitis

This common disorder is usually confined to areas with high sebum production. The likely aetiological mechanism is overgrowth of the commensal yeast *Malassezia furfur* (Pityosporum ovale). The clinical features are pink-yellow greasy patches with 'bran-like' scale which occur in the sebaceous-rich scalp, nasal folds, medial eyebrow, pre-sternal region and flexural sites. In the first few months of life, it manifests as coherent scaling of the scalp with inflammation and ooze, known as 'cradle cap'. In adults, the symptoms are usually mild with a chronic, relapsing course. Extensive and severe seborrhoeic dermatitis can be seen in patients with underlying HIV infection or Parkinson's disease. Treatment usually includes topical imidazoles.

Discoid eczema

Discoid eczema is also known as 'nummular dermatitis' and is a type of chronic eczema presenting with disseminated coin-shaped eczematous lesions of the extremities. Middle-aged males are most commonly affected.

Stasis eczema

Stasis eczema is also called stasis dermatitis, gravitational dermatitis or varicose eczema. It is a clinical component of chronic venous insufficiency seen in addition to other features which include varicose veins, skin discolouration, peripheral oedema, leg discomfort and non-healing ulcers. Clinical features include scaly eczematous plaques confined to the lower legs. Multiple topical medicines and dressings often lead to a secondary ACD. Management of stasis eczema should address the underlying cause.

Asteatotic eczema

Asteatotic eczema, also called eczema craquele, usually affects the lower legs and appears as dry, cracked skin likened to 'cracked paving'. This is associated with increasing age, low

Table 57.1   Common locations for allergic contact dermatitis and possible sensitisers

Location	Possible sensitising agents
Periorbital	Airborne allergens, nail polish, contact lens solution
Umbilicus	Nickel hypersensitivity to belt/jean button
Neck	Antiseptic in soap, cosmetics
Hairline	PPD in hair dye, hair perming solution
Hands	Latex or rubber accelerators in gloves, nickel, fragrances, protein contact dermatitis in food preparation, irritant contact dermatitis due to water
PPD, p-phenylediamine.	

humidity and frequent bathing. Treatment consists of emollients and mildly potent topical steroids.

Treatment

First-line treatment of eczema should include an emollient and soap substitute for washing. Topical steroids are used for anti-inflammatory effect. Systemic treatments for adult atopic eczema include oral prednisolone, ciclosporin and azathioprine. If there is a secondary bacterial infection, then this should be treated with oral antibiotics. The antibiotic(s) should be chosen based on sensitivity determined by wound swab.

Emollients

Emollients, topical hydrating agents consisting of fat or oil to soften the skin, are the mainstay of eczema management. Emollients are effective first-line treatments for all types of eczema, and regular, liberal use will reduce topical steroid requirements. The greasier products have more emollient effect (see Fig. 57.6). They are often underused and the need to educate the patient regarding use of sufficient quantities is vital. Dry skin is aggravated by soap and bath products, and therefore an emollient soap substitute for washing is advisable.

Topical corticosteroids

Topical steroids act as anti-inflammatory agents and are extremely useful and important in managing eczema. In recent years, the public have veered from overuse of topical steroids causing long-lasting side effects, to high levels of anxiety regarding possible side effects concerning their use. This can commonly lead to under treatment in children. Therefore, patient/carer education regarding appropriate topical steroid use is a crucial part of eczema management.
Fig. 57.6 Commonly used emollients used in dry skin conditions (adapted from MeReC, 1998).

Topical steroids are classified into four main groups according to potency: mild, moderately potent, potent and very potent (Table 57.2). The choice of topical steroid is dependent on the site and severity of skin disease. Potent and very potent steroids should be avoided on delicate sites such as the face, genitals and flexures. The periorbital region should be treated with caution due to the thin skin increasing the likelihood of absorption and risk of cataracts or glaucoma. Treatment should be reviewed regularly and tailored accordingly. It is also important to remember that any form of occlusion will increase the absorption of steroid applied.

Side effects are mainly local and include striae (stretch marks), telangiectasia (visible dilated small blood vessels), epidermal thinning, purpura (bruising), acne and perioral dermatitis. Lower frequency side effects include poor wound healing, spread or worsening of untreated infections and hypertrichosis. Hypopigmentation is a temporary side effect of long-term topical steroid use and is frequently

Table 57.2 Comparative potencies of topical corticosteroid preparations

UK Steroid Group	Trade name	Strength	Relative strength compared to hydrocortisone
Hydrocortisone 0.5–2.5%	Hydrocortisone	Mild	1
Fluocinolone acetonide 0.0025%	Synalar 1:10 dilution®		
Betamethasone valerate 0.025%	Betnovate RD®	Moderately potent	2.5× stronger
Clobetasone butyrate 0.05%	Eumovate®		
Fluocinolone acetonide 0.00625%	Synalar 1 in 4 dilution®		
Fludroxycortide 0.0125%	Haelan®		
Betametasone valerate 0.1%	Betnovate®	Potent	10× stronger
Mometasone furoate 0.1%	Elocon®		
Clobetasol propionate 0.05%	Dermovate®	Very potent	50× stronger

exploited in illegal 'skin bleaching' agents. Rarely, adrenal suppression or Cushing's syndrome due to systemic absorption may occur.

Local and systemic side effects are extremely rare with appropriate use and duration of topical steroid treatment. Patients should be advised to spread preparations thinly either once or twice daily. The recommended amount used can be quantified using a fingertip unit (Fig. 57.7). The quantity in this unit is sufficient to cover an area the size of two adult palms. Table 57.3 details the quantities for application to different sites required for twice-daily treatment for 1 week.

Base

Topical corticosteroids are available in ointment (oil based), cream (water based), aqueous or alcoholic solution, gel, foam or shampoo formulation for the scalp. In general, ointment preparations are preferable to creams in eczema management because they are absorbed better and have fewer preservative chemicals. Alcoholic solutions may lead to irritation and should not be applied to acutely inflamed or broken skin.
Fig. 57.7 Recommended amount of a topical steroid corresponding to one fingertip unit.

Table 57.3 Minimum quantity of topical application required for twice daily treatment for 1 week (courtesy of M. Carr).

Age	Whole body	Trunk	Both arms and legs
6 months	35	15	20
4 years	60	20	35
8 years	90	35	50
12 years	120	45	65
Adult (70 kg)	170	60	90

Allergies

Both immediate and delayed hypersensitivity reactions to topical corticosteroids can occur, although not commonly. These can be reactions to either the steroid molecule itself or the vehicle in which it is found. Allergic reactions to one topical steroid may cross-react to others. Therefore, allergy testing is mandatory for such patients. Betamethasone may be less likely to cause allergic reactions than other topical preparations.

Antibiotics and steroid combinations

Combination preparations can be useful in treating mild bacterial infection of eczematous skin. Long-term use should be limited due to the risks of sensitisation and antibiotic resistance. In general, invasive infection is best managed with oral antibiotics.

Calcineurin inhibitors

The past decade saw the introduction of topical calcineurin inhibitors for the treatment of chronic eczema. These non-steroid immunomodulators inhibit calcineurin phosphatase which is important in T-lymphocyte activation. The main side effect is burning or stinging on initial application, but this usually improves after a few days. Although a theoretical risk of increased malignancy exists with these agents, studies have not shown an association between exposure to topical calcineurin inhibitors and increased rates of cutaneous malignancy. Calcineurin inhibitors should not be used on infected skin and are generally not very useful in severely inflamed eczematous skin. Their greatest value appears to be in maintenance therapy.

Tacrolimus ointment (Protopic®) is a calcineurin inhibitor derived from the oral transplant medicine FK506. The 0.1% and 0.03% preparations are indicated in the treatment of moderate to severe atopic dermatitis in adults and children over the age of 2 years. Tacrolimus is now also used in clinical practice as a second-line agent for other steroid responsive dermatoses.

Pimecrolimus 1% cream (Elidel®) is indicated for short-term or intermittent long-term use in mild to moderate atopic dermatitis. Studies have shown that it is effective, well tolerated and has minimal adverse effects in the long-term control of eczema in children aged over 2 years (Langley et al., 2008). Furthermore, this has resulted in the reduced use of topical steroids leading to a lower risk of steroid-induced side effects (Kapp et al., 2002).

Antihistamines

Pruritis is the most distressing feature of eczema. Oral antihistamines have no direct effect on pruritis in eczema; their main effect is sedation. Sedating antihistamines may cause day time drowsiness, and caution should be taken when driving and also if prescribed to school age children.

Topical imidazoles

Ketoconazole as a shampoo or cream is effective in reduction of *Pityosporum ovale* on the skin and is therefore useful in the treatment of seborrhoeic dermatitis. As the disease runs a chronic, relapsing course regular or intermittent use is usually necessary.

Coal tar preparations

Tar creams and ointments can be used in the management of hyperkeratotic, lichenified eczema. These are less cosmetically acceptable than other topical preparations, but coal tar is an effective anti-pruritic.

Bandaging

In children with atopic eczema, occlusion with bandages is useful to prevent scratching and potentiate the action of ointments and creams on the skin. Wet wrapping involves the application of emollients and steroids under a double layer to keep the inner layer moist. Parents can be trained to apply these bandages at home.

Systemic therapies

Systemic steroids

Oral prednisolone can be used as a short-term treatment in the management of severe acute eczema that needs rapid control. Long-term treatment with oral steroids is now rarely used due to the risk of side effects including hypertension and osteoporosis.

Ciclosporin

Ciclosporin is a systemic immunosuppressant that blocks activation of T-lymphocytes. It is effective as a short-term bridging therapy in severe chronic adult eczema and has a rapid onset of action. Intermittent courses at doses of 2.5–5 mg/kg/day are useful, but dose-related renal nephrotoxicity is inevitable and limits treatment duration to a maximum of 8–12 months. Other side effects include hypertension and increased risk of malignancy. A detailed patient history is required to determine if there is a previous history of gynaecologic or prostate malignancy. During treatment with ciclosporin, patients also require close monitoring of renal function and blood pressure.

Azathioprine

Azathioprine is a purine analogue that inhibits DNA synthesis and can be effective as monotherapy in adult eczema. Bone marrow suppression and toxicity are the major concerns. A higher risk of marrow suppression occurs in individuals with low levels of thiopurine methyltransferase (TPMT), and this should be assessed at screening. Patients with borderline TPMT levels require a lower dose of azathioprine. Patients with low levels of TPMT should not be offered this treatment.

Methotrexate

Methotrexate is occasionally used in unresponsive adult atopic eczema, but randomised controlled trials are lacking. A small prospective trial has shown that methotrexate can be effective and well tolerated as a second-line therapy for the treatment of moderate to severe atopic eczema in adults (Weatherhead et al., 2007).

Mycophenolate mofetil

Mycophenolate mofetil is an oral systemic agent that prevents T- and B-cell proliferation, thereby reducing inflammatory cytokine release. This can be used as an alternative in severe adult atopic dermatitis where azathioprine or ciclosporin are contraindicated. Side effects are gastro-intestinal upset, bone marrow suppression and an increased risk of infection.

Phototherapy

Phototherapy can be effective in select cases of atopic dermatitis. Narrow-band UVB is the therapy of choice (Gambichler et al., 2005; Meduri et al., 2007). The potential side effects of all types of phototherapy include burning, premature ageing and a small increased risk of skin cancer. A small proportion of patients have photosensitive eczema, and this should be determined by taking a detailed patient history before prescribing phototherapy treatment. A treatment course requires a patient to attend two or three times a week for at least 6 weeks.

Dietary supplements

Current evidence suggests that probiotics are not an effective treatment for eczema and may carry a small risk of adverse events such as infection and small bowel ischaemia. There is no evidence for use of evening primrose oil. The use of Chinese herbal medications in atopic eczema is under close scrutiny, and conflicting results have been obtained. Liver function should be monitored as hepatitis is a known side effect of some Chinese herbal medicines.

Interactions with drugs used in the treatment of eczema and psoriasis are shown in Table 57.4.

Patient care

It is important to recognise that eczema affects many aspects of a patient's life and has considerable effects on the family. Quality-of-life factors affected include body image, irritability and loss of sleep due to profound itch and limitations to work and hobbies (Fig. 57.8). A multidisciplinary approach is often needed in overcoming these issues, and healthcare workers including primary care doctors, dermatologists, specialist nurses, pharmacists and teachers may be involved. Patients with eczema should aim to lead as normal a life as possible, and school staff and employers can play an important part in achieving this goal.

Patient and parental education is important as treatments are designed to control and manage the disease. Although atopic eczema is likely to improve throughout childhood, expectations of an immediate cure need to be addressed. Advice and support through contact with other patients and their families can be obtained from the National Eczema Society (www.eczema.org). An algorithm for the management of eczema is shown in Fig. 57.9.

Psoriasis

Psoriasis is a chronic inflammatory disorder of the skin and joints. The current prevalence in Europe and North America is estimated to be between 1% and 3%. The usual presentation is with well-demarcated red plaques with an overlying scale.

Table 57.4 Interactions with drugs used in the treatment of eczema and psoriasis (courtesy of M. Carr)

	Interacting drug	Outcome
Methotrexate	Aspirin	Increased plasma concentration and toxicity of methotrexate
	NSAIDs	Increased plasma concentration and toxicity of methotrexate
	Probenecid	Increased plasma concentration and toxicity of methotrexate
	Phenytoin	Increased bone marrow toxicity
	Sulphonamides	Increased toxicity
	Trimethoprim	Increased antifolate effect of methotrexate
Azathioprine	Allopurinol	Enhanced effect and toxicity of azathioprine
	Warfarin	Inhibition of anticoagulant effect
	Cimetidine	Enhanced myelosuppression
	Indometacin	Increased risk of leucopenia
Ciclosporin	NSAIDs	Increased risk of nephrotoxicity
	Aminoglycosides	Increased risk of nephrotoxicity
	Co-trimoxazole	Increased risk of nephrotoxicity
	Ciprofloxacin	Increased risk of nephrotoxicity
	Ketoconazole	Increased plasma concentration of ciclosporin
	Itraconazole	Increased plasma concentration of ciclosporin
	Erythromycin	Increased plasma concentration of ciclosporin
	Oral contraceptives	Increased plasma concentration of ciclosporin
	Calcium channel blockers	Increased plasma concentration of ciclosporin
	Phenytoin	Decreased plasma concentration of ciclosporin
	Carbamazepine	Decreased plasma concentration of ciclosporin
	Rifampicin	Decreased plasma concentration of ciclosporin
Acitretin	Methotrexate	Increased plasma concentration of methotrexate

Aetiology

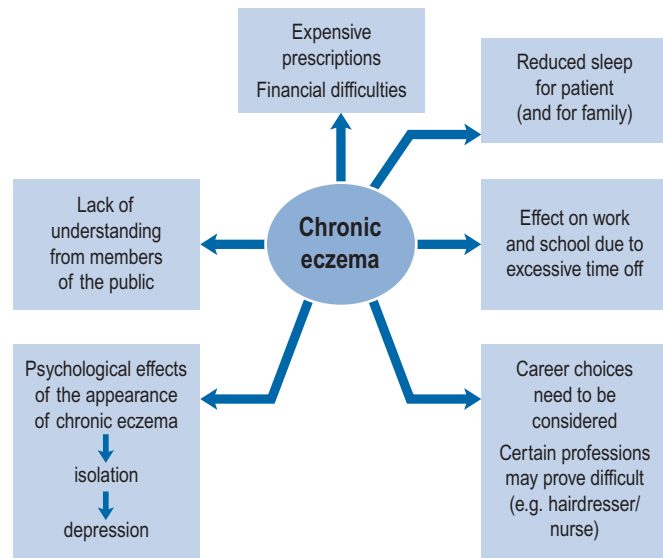
The aetiology of psoriasis is a combination of genetic and environmental factors. In most cases, there is a genetic predisposition and up to 70% of patients report a family history of psoriasis. Recent advances in genome-wide association


Fig. 57.8 The social and psychological effects of chronic eczema.

studies have led to the identification of at least nine chromosomal psoriasis susceptibility loci. Multiple genes are likely to influence disease susceptibility, severity and clinical subtype. The strongest association is with HLA-CW*06.

Precipitating factors

Non-inherited factors also have a role in triggering psoriasis in predisposed individuals. These are described as follows.

Infections

Bacterial infections have been implicated as triggers for psoriasis. Streptococcal infections, particularly pharyngitis, frequently precede the onset of guttate psoriasis. HIV infection can aggravate psoriasis. The severity of the psoriasis is greater in this patient population.

Drugs

Drugs can exacerbate or induce psoriasis in predisposed individuals. The most common causative agents are lithium, ß-blockers, anti-malarials, non-steroidal anti-inflammatory drugs (NSAIDs), tetracyclines and rapid withdrawal of systemic corticosteroids.

Alcohol and smoking

Excess alcohol consumption may exacerbate established psoriasis. Additionally, psoriasis is associated with high rates of alcoholism due to the psychological stresses of the disease.

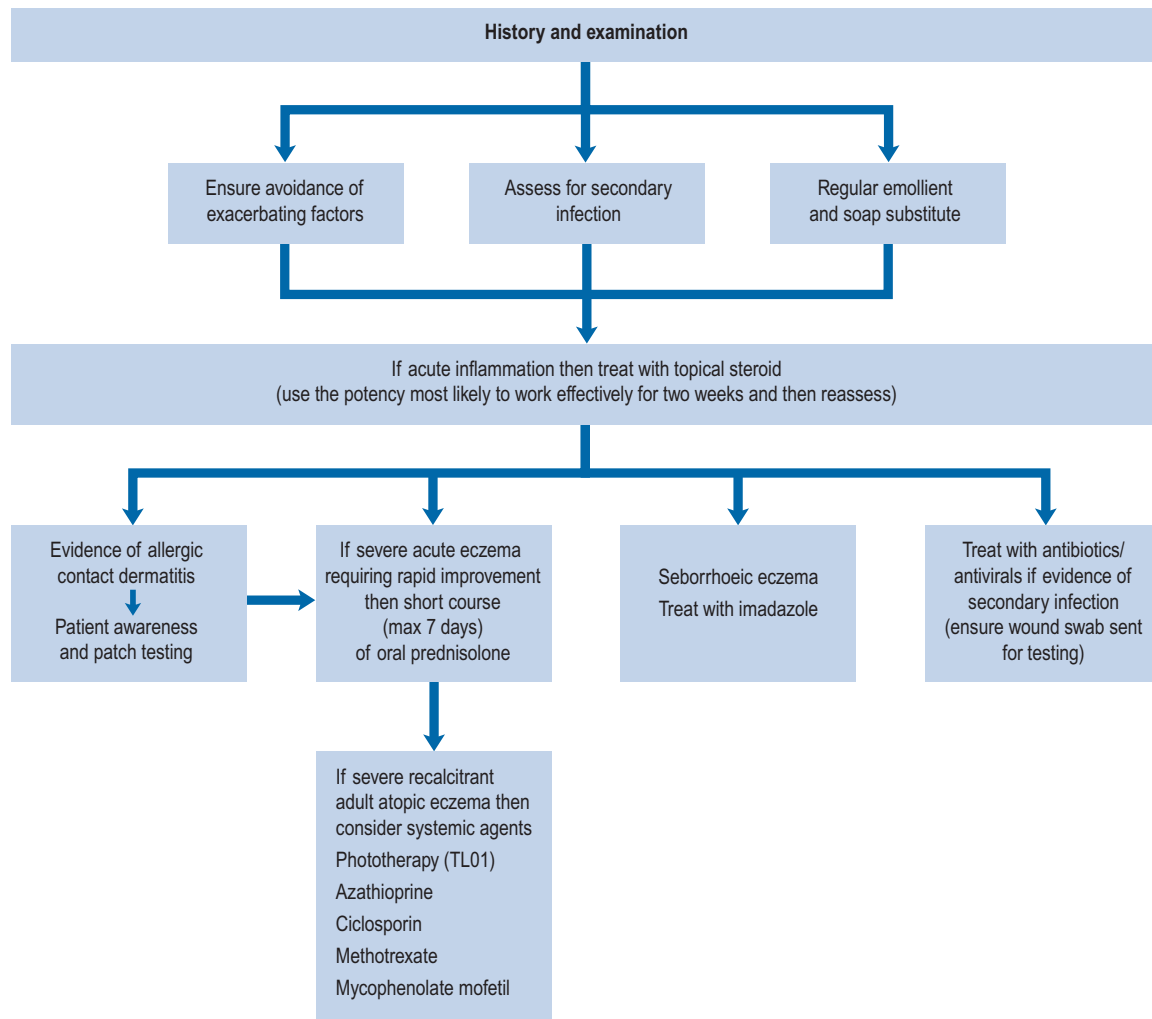
Smoking is strongly associated with palmoplantar psoriasis; up to 95% of patients with this variant are smokers at disease onset. Smoking cessation should be actively addressed due to a likely improvement in disease status and associated risk reduction of ischaemic heart disease. It has been suggested that psoriasis,


Fig. 57.9 Algorithm for the management of eczema.

particularly if severe, may be an independent risk factor for atherosclerosis, myocardial infarction and stroke (Mehta et al., 2010).

Emotional stress

Anecdotal observations and frequent patient reports identify stress as an important trigger factor for psoriasis. Clinical evidence has demonstrated that the onset and severity of psoriasis can correlate with prior stress (Kirby et al., 2008). Furthermore, psychological distress and depression can occur as a consequence of psoriasis.

Koebner phenomenon

The Koebner phenomenon refers to psoriatic lesions which occur at sites of injury to the skin, such as a cut, burn, scratch or surgical scar, in patients with psoriasis.

Pathology and clinical features

The clinical features of psoriasis, well-demarcated, erythematous scaly plaques, are explained by the histological features (Fig. 57.10). Common sites affected include the scalp, buttocks, elbows, knees and nails.

Fig. 57.10 Chronic scaly plaque psoriasis on an elbow (courtesy of M. Carr).

Histologically, the epidermis is thickened (acanthosis), with a thickened upper horny layer (hyperkeratosis) which is reflected by the clinical features of thick, scaly skin. The build of scale is due to increased epidermal turnover. The differentiation of cells through the epidermis terminating in the keratin horny layer normally takes approximately 40 days. Epidermal turnover in

psoriatic skin may be as rapid as 7 days. In the dermis, the capillaries are dilated, tortuous and closer to the surface of the skin. This explains Auspitz's sign which is the appearance of pinpoint bleeding after scraping off psoriasis scales.

Inflammatory cells are present in all layers of psoriatic skin; granulocytes are predominant and form microabscesses in the epidermis. Lymphocytes and Langerhans cells are also increased. The presence of lymphocytes in the epidermis led to hypotheses of an immunological cytokine-mediated process causing epidermal hyperproliferation and changes in vascular structure. T-cells, dendritic cells and cytokines such as tumour necrosis factor alpha (TNFα), interleukin (IL)-12 and IL-23 all contribute to its pathogenesis. This is confirmed by the therapeutic effect of drugs that suppress T-lymphocyte function, such as ciclosporin, in psoriasis.

Clinical types

Psoriasis vulgaris

Psoriasis vulgaris, also known as chronic plaque psoriasis, is the most common variant. It can occur at any age but most often begins in young adulthood and has a chronic relapsing course. The typical psoriatic lesion is a red, sharply demarcated plaque with overlying silvery scale. The distribution is usually symmetrical and involves extensor sites such as the elbows and knees. The sacrum, scalp and nails are also commonly affected. The plaques may itch but not usually to the severity of eczematous plaques. Treatment is aimed at management of disease rather than cure.

Guttate psoriasis

Guttate psoriasis is more commonly seen in children and young adults and is characterised by a widespread scaly eruption of small 'teardrop-like' scaly plaques (Fig. 57.11). The presentation is often acute and can appear 10–14 days after a streptococcal upper respiratory tract infection. Topical treatments or UVB phototherapy are usually effective. Spontaneous resolution is common; however, guttate psoriasis may be the first manifestation of psoriasis in predisposed individuals.

Scalp psoriasis

Involvement of the scalp may be the only manifestation of psoriasis in some patients, but may also occur in psoriasis vulgaris. This appears as scaly demarcated plaques extending to the hairline and around the ears. Hair loss is rare.

Psoriatic nail disease

The nails are frequently affected in psoriasis. In a small proportion of patients, the nails are the only area affected. Changes include nail pitting, nail ridging, onycholysis (separation of the nail from the nail bed), hyperkeratosis under the nail and complete nail destruction. These symptoms can be cosmetically disfiguring. Topical treatments are rarely effective for psoriatic nail disease. Systemic treatments such as methotrexate, when prescribed for generalised psoriasis, may also improve nail disease.

Palmoplantar psoriasis

At these sites on the palms and soles, there is sharp demarcation of the involved areas (Fig. 57.12). Palmoplantar psoriasis can take two forms: either inflamed hyperkeratotic fissured skin which can be very painful or sterile pustules on an erythematous base which dry to leave small brown macules (palmoplantar pustulosis). The pustular form is much commoner in smokers.

Flexural psoriasis

Psoriasis can occur at flexural sites such as the axillae, groin, submammary areas and genitalia. Due to friction and moisture within skin folds, lesions differ in appearance from classical psoriasis and tend to be red and glazed rather than scaly. Affected areas tend to be clearly demarcated. Secondary infections,

Fig. 57.11   Guttate psoriasis showing Koebner phenomenon in scratch mark (courtesy of M. Carr).

Fig. 57.12   Pustular psoriasis of sole (courtesy of M. Carr).

and general malaise. Pustular psoriasis may be precipitated by the withdrawal of systemic or very potent topical steroid. Therefore, oral steroids are avoided in the management of stable psoriasis.

Psoriatic arthropathy

Approximately 25% of psoriatic patients suffer with an associated arthropathy. There are five patterns of psoriatic arthropathy; monoarthopathy, rheumatoid arthritis-like, osteoarthritis-like, sacroiliitis-like and arthritis mutilans. Rheumatoid factor is negative in these patients. Some treatments effective for skin psoriasis are also effective in psoriatic arthropathy including methotrexate, and biological agents with action against TNFα.

Treatment

Many patients with psoriasis have mild disease and require only emollient therapy to prevent drying and fissuring of the elbows and knees. Other treatment options should take into account the type of psoriasis, patient occupation and lifestyle factors as well as disease severity. This will ensure improved patient compliance and better outcome.

Topical therapy

First-line treatment of mild to moderate psoriasis should include an emollient as well as a topical treatment. Mild to moderate topical steroids are useful for delicate skin sites such as the face and flexures. Dithranol and tar products are effective, but limitations of use include irritation, messy application and potent odour. Topical treatments may be technically difficult to apply to the scalp area; patient education and demonstration is key. Topical vitamin D analogues are well tolerated.

Vitamin D analogues

Vitamin D analogues inhibit keratinocyte differentiation and production. The most commonly prescribed Vitamin D analogue is calcipotriol. This is commonly used within primary care for mild localised psoriasis and is available as a lotion, ointment, cream or scalp treatment. Patients should be advised to avoid use on delicate skin sites such as the face and flexures due to irritation. Hypercalcaemia due to systemic absorption can occur if the maximum weekly dose exceeds 100 g. Efficacy may be enhanced when used in combination with a topical steroid.

Steroids

Topical steroids are cosmetically acceptable and easy to apply. Mild to moderately potent steroids are of greatest value in acutely inflamed psoriasis to reduce inflammation. Reduction of inflammation is important as it then allows other treatments to be introduced that would otherwise irritate acutely inflamed plaques. Topical steroids have a number of limitations. The use of potent steroids on large areas of psoriasis is associated with

Fig. 57.13 Erythrodermic psoriasis, courtesy of St John's Institute of Dermatology, London.

particularly with *Candida* are common. Potent steroids are not advised at these sites due to the high risk of skin atrophy.

Erythrodermic psoriasis

Erythroderma, or exfoliative dermatitis, is a severe, potentially life-threatening condition in which more than 90% of the body surface is red and scaly (see Fig. 57.13). This can occur as a consequence of either eczema or psoriasis. Skin function is impaired and patients suffer dehydration, electrolyte imbalance, temperature dysregulation and serious secondary infection. These patients need urgent hospital admission, medical supportive therapy and topical treatment. Initially, bland emollients such as white soft paraffin and mild to moderate topical steroids should be used. Underlying conditions, such as psoriasis, can then be treated with appropriate systemic agents.

Generalised pustular psoriasis

This is an acute, unstable form of psoriasis manifesting as widespread sheets of tiny sterile pustules on an erythematous base. The patient is usually systemically unwell with fever

risks of local atrophy and systemic absorption. Furthermore, there is a rebound effect on withdrawal. Potent steroids should be reserved for localised disease, such as thicker acral sites, often in combination with salicylic acid if there is hyperkeratosis. In general, very potent steroids should be avoided.

Coal tar

Along with dithranol, coal tar is one of the oldest topical treatments for psoriasis. Coal tar has anti-inflammatory, antibacterial, anti-pruritic and antimitotic effects. A variety of preparations are available including bath preparations, shampoos, creams and ointment. Coal tar concentrations of 1–10% can be used, but use of higher concentrations should occur in a supervised setting. Coal tar in combination with topical steroids can be effective, for example Alphosyl HC®. The efficacy of tar is enhanced when used with UVB light therapy (Goerkerman regimen). The main limitations of tar are irritation of delicate skin sites, odour and temporary staining of skin and clothing. The theoretical risk of carcinogenesis due to polycyclic aromatic hydrocarbons has not been demonstrated in long-term clinical practice.

Dithranol

Dithranol (anthralin in the USA) is a synthetic anthracene derivative which has an anti-proliferative and anti-inflammatory effect on the skin. It is one of the older treatments used for stable, chronic plaque psoriasis. Although effective, practical drawbacks include burning and irritation of normal skin, staining of clothes as well as a strong odour. In current practice, dithranol is most commonly used as a short contact regimen within a dermatology day centre setting. The starting concentration of dithranol is usually 0.5% which can be increased slowly if tolerated up to 3%.

Salicylic acid

This is useful to reduce scale, particularly while treating hyperkeratosis of the palms and soles. It can be mixed with coal tar, steroid or urea.

Topical retinoids

Retinoids are less effective than vitamin D analogues in the treatment of psoriasis. Irritation is a possible side effect to therapy.

Topical treatment of psoriasis at special sites

Scalp

Tar shampoo is effective in mild scalp psoriasis. However, a descaling agent is required as part of therapy for thicker plaques. Coconut oil compounds, peanut oil and greasy emollient with salicylic acid can be used as descaling agents. A topical steroid can then be applied for inflammatory disease. Treatment does require considerable time and commitment from the patient.

Genitals

The genital regions are prone to irritation and mild to moderate topical steroids can be used. In addition, it is also important to inform patients that treatments used on other parts of the body may be too potent and irritant for genital areas.

Nails

Before treatment of psoriasis, fungal infections of the nails should be excluded. Topical treatments often have poor efficacy in psoriasis affecting the nail, and systemic therapy is preferred.

Phototherapy

The majority of psoriatic patients exhibit improvement of symptoms on sunny holidays, with only 10% of patients reporting deterioration in symptoms on sun exposure. Phototherapy has an immunosuppressive effect on skin and has been used in the treatment of psoriasis for over 80 years. Narrow-band UVB (311–313 nm) is preferable to broadband UVB (290–320 nm) due to increased safety and reduced risk of burning.

PUVA

PUVA (psoralens plus UVA light) has a valuable role in the treatment of stable moderate to severe psoriasis. Psoralens are drugs that are activated by long-wave ultraviolet light (320–400 nm), thereby interfering with DNA synthesis and reducing epidermal turnover. The two psoralens available in the UK are 8-MOP (methoxypsoralen) and 5-MOP. These are taken orally 2 h before exposure to UVA light. The eyes are always protected due to the risk of cataracts and patients are given sunglasses to wear for 12 h after treatment. The treatment is usually given twice a week for a 6-week period. Total cumulative dosage is carefully monitored.

The commonest adverse effect is nausea due to ingestion of oral psoralens. The most serious adverse effect is an increased risk of long-term cutaneous malignancy. Those with fair skin types and on past or present immunosuppresion are at greatest risk. Due to these risks, PUVA is usually reserved for patients resistant to UVB therapy.

Systemic therapy

Systemic therapy is indicated in severe widespread psoriasis, intolerant of or rapidly relapsing after topical therapy and phototherapy. Objective measures of disease severity and impact on quality of life are used routinely to assess need for systemic therapy and treatment response and include the Psoriasis Area and Severity Index (PASI) and the Dermatology Quality of Life Index (DLQI). Systemic treatments commonly prescribed in psoriasis include methotrexate, acitretin and ciclosporin. Drug interactions are important and a detailed patient drug history is important. New biologic agents are used in severe disease which is unresponsive to oral immunosuppressant treatment. Common adverse effects and monitoring requirements of systemic treatments of eczema and psoriasis are presented in Table 57.5.

Table 57.5 Common adverse effects and monitoring requirements for systemic treatments of eczema and psoriasis

Therapy	Adverse Effects	Monitoring requirements
Methotrexate	Hepatic fibrosis; myelosuppression; nausea; pulmonary fibrosis; teratogenic (contraindicated in both males and females for 4 weeks before and 3 months after treatment)	FBC U&E LFT Pro-collagen III peptide (P3NP) ±Liver biopsy Chest X-Ray (screening)
Hydroxyurea	Myelosuppression; skin reaction; teratogenic; liver toxicity (narrow therapeutic window)	FBC U&Es LFT
Ciclosporin	Renal nephrotoxicity Hypertension Gingival hypertrophy	FBC U&E LFT Lipid profile Blood pressure Urinalysis
Acitretin	Teratogenic (including up to 2 years post-treatment) Dryness of mucous membranes and skin Hyperostoses, increased serum triglyceride Occasional hepatotoxic reaction	FBC U&E LFT Lipid profile
Fumaric Acid Esters	Gastro-intestinal side effects Flushing Lymphopenia Proteinuria Renal failure	FBC U&E LFT Urinalysis
Azathioprine	Myelosuppression Deranged liver function Gastro-intestinal effects	TPMT pre-treatment FBC/U&E/LFT

U&Es, urea and electrolytes; LFTs, liver function tests; FBC, full blood count; TPMT, thiopurine methyl transferase genetic polymorphism screening.

Methotrexate

Methotrexate is a folic acid antagonist used in moderate to severe psoriasis. In males and females of non-childbearing potential, this tends to be the first-line systemic agent. It is also effective in psoriatic arthropathy. Methotrexate is given as a once weekly oral low dose regimen, with an initial test dose of 5 mg increasing up to 30 mg weekly. Acute toxicity occurs due to the effect of methotrexate on folic acid metabolism of rapidly dividing cells in the bone marrow and gastro-intestinal tract. This can cause myelosuppression or gastro-intestinal bleeding. In such cases, folinic acid rescue can be used to oppose the folate antagonist effect at a dose of 120 mg folinic acid over 12–24 h intravenously or intramuscularly in divided doses, followed by 15 mg/kg orally every 6 h for 48 h. Hepatic fibrosis is the commonest long-term risk and regular monitoring of liver function is necessary. Some patients complain of nausea and other gastro-intestinal side effects as well as lethargy. Folic acid 5 mg taken on the days methotrexate is not prescribed can reduce these adverse effects.

Patient monitoring in methotrexate therapy is detailed in Table 57.5. Liver function tests do not reliably predict hepatic fibrosis; supportive investigations are therefore required. Liver biopsy remains the gold standard. Recently, the measurement of serum pro-collagen three peptide levels has led to a reduction of liver biopsies for detection of hepatic fibrosis in these patients (Chalmers et al., 2005).

Acitretin

Acitretin, a vitamin A derivative that inhibits epidermal proliferation, is effective for disorders of keratinisation including chronic plaque psoriasis. The starting dose is usually 25–30 mg daily for 2–4 weeks increasing to 75 mg daily for short periods and according to clinical response. Mucocutaneous side effects, hair loss and lethargy are common. Acitretin should be avoided in women of childbearing potential because of the teratogenic risk. However, it is a safer option for patients with chronic infection for whom immunosuppression is contraindicated. Patients should be warned that a rebound response is occasionally seen when stopping treatment, and therefore a long-term maintenance dose is usually advised.

Ciclosporin

Ciclosporin is an effective treatment for all variants of psoriasis with a fairly rapid mode of action. The dose is 2–5 mg/kg. Similar to eczema management, continuous ciclosporin treatment for more than 1 year is not advised due to renal nephrotoxicity. Adverse events include hypertension, hypertrichosis, paraesthesia, tremor and increased risk of infections. There is also of an increased risk of skin cancer in conjunction with ciclosporin use in patients who have previously had phototherapy.

Hydroxyurea/hydroxycarbamide

Hydroxyurea/hydroxycarbamide is a drug with similar effects on bone marrow and germ cells to methotrexate but without the hepatotoxic effects. Relapse occurs on stopping treatment.

Fumaric acid esters

Fumaric acid esters have been used since the early 1960s and affect both keratinocytes and T-cell activity. It is licensed in Europe, but not in the UK, for severe, relapsing, chronic, plaque psoriasis. The main side effects are gastro-intestinal upset and flushing.

Biologic therapy

Biologic therapies or 'biologics' are drugs designed to block specific molecular steps important in immune-mediated disease. They have been used successfully in rheumatoid arthritis, inflammatory bowel disease and are now licensed for use in chronic plaque psoriasis. Their use is recommended for patients with severe plaque psoriasis defined as a PASI ≥ 10 and DLQI > 10 who have failed at least two standard systemic agents including methotrexate, ciclosporin and acitretin or one systemic agent and phototherapy (Smith et al., 2009).

TNFα antagonists

TNFα is a pro-inflammatory cytokine that plays a central role in the pathogenesis of psoriasis. The tumour necrosis factor antagonists: infliximab, adalimumab and etanercept all have potent immunosuppressant action and have proven efficacy in severe psoriasis. Serious adverse effects include infection, in particular reactivation of tuberculosis, exacerbation of severe cardiac failure, demyelinating disease and a potential risk of malignancy (solid organ tumours and lymphoma). Careful patient selection and regular monitoring are important.

Etanercept is a genetically engineered receptor fusion protein with affinity for soluble TNFα. The dose is 25 mg twice weekly via subcutaneous injection. Higher doses of 50 mg twice a week are used in psoriatic arthropathy. The most frequent side effects are injection site reactions.

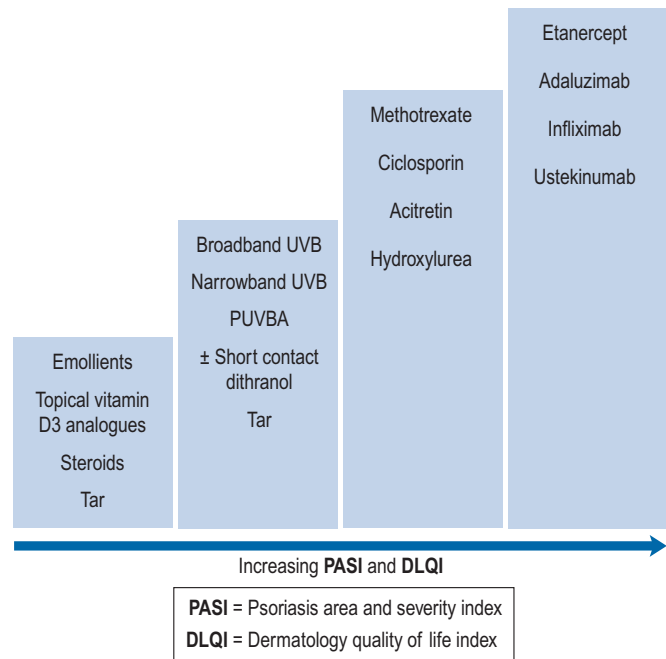
Infliximab is a chimeric monoclonal antibody against TNFα. It is also used in Crohn's disease, ulcerative colitis, ankylosing spondylitis and rheumatoid arthritis. Clinical trials have demonstrated rapid onset and good efficacy in psoriasis.


Fig. 57.14   Treatment algorithm for psoriasis.

Infliximab is administered at a dose of 5 mg/kg by intravenous infusion every 8 weeks after a loading dose at weeks 0, 2 and 6. Observation and nursing care on a day unit are therefore required.

Adalimumab is humanised monoclonal antibody against TNFα that is administered in a bolus of 80 mg subcutaneously and then 40 mg on alternate weeks.

Other biologic agents used in psoriasis

Ustekinumab is the newest available biologic agent used in the treatment of psoriasis. It is a fully human monoclonal antibody that prevents IL-12 and IL-23 from binding receptor proteins. A dose of 45 mg (or 90 mg in patients weighing >100 kg) is administered subcutaneously at week 0, 4 then every 12 weeks. In light of the limited patient exposure to this treatment, ustekinumab is reserved for use as a second-line biologic agent where TNF therapy has failed or cannot be used.

Efaluzimab, a T-cell modulator, was withdrawn in 2009 due to an increased risk of progressive multifocal leucoencephalopathy.

A treatment algorithm for psoriasis is shown in Fig. 57.14.

Patient care

Psoriasis is a chronic disease associated with significant psychosocial disability and reduction in quality of life. As well as effects related to depression; impact on body image and sexual relationships should be considered. Coexistent psoriatic arthropathy may have a severe impact on function and lead to significant time away from work or education. Support and

understanding of individual patients' needs and lifestyles will improve adherence to treatment. Psoriasis can be associated with alcohol misuse, and a drug and alcohol history should always be sought. Systemic and biologic treatments require regular attendance and blood tests, and therefore patients with poor attendance records may not be suitable for such treatment. Ultimately, responsibility lies with the patient to ensure regular treatment.

The chronicity of this disease may lead to treatment 'fatigue' and frustration with messy topical therapies. There are numerous alternatives and newer formulations are generally less messy. Treatments can be expensive and information on the entitlement to benefits to replace clothing ruined by ointments or washing machines worn out by constant use is available. The Psoriasis Association (www.psoriasis-association.org.uk) provides an excellent service for this, together with practical advice from fellow sufferers about day-to-day problems.

Case studies

Case 57.1

A 3-year-old child with known atopic eczema is seen in clinic with a widespread, excoriated, dry rash (see Fig. 57.15). Her eczema symptoms started at the age of 6 weeks. Her sleep has always been poor due to the marked itch symptoms at night. She has had two recent courses of oral antibiotics for presumed bacterial skin infection. Her normal skin treatment involves hydrocortisone 1% ointment to affected areas twice daily. Her parents are concerned regarding the possible triggers of her eczema flares and are keen to pursue possible allergy testing.

Fig. 57.15 Case study 1 – a young child with moderate/severe atopic eczema courtesy of St John's Institute of Dermatology, London.

Question

What advice could be given to the child's parents?

Answer

Fig. 57.15 shows a young child with moderate/severe atopic eczema. Ill-defined, dry, erythematous patches of eczema are visible. A few of the patches around her ankles appear crusty and eroded. This may represent secondary infection.

Management should include regular topical emollient therapy. The correct quantities should be emphasised. A regular soap substitute should be prescribed.

Wound swabs should always be taken before prescribing an oral antibiotic for presumed infected eczema.

A moderately potent steroid ointment should be administered daily, along with a regular, greasy topical emollient. When a moderately potent or potent topical steroid is prescribed for a child, medical follow-up must be arranged. Regular use of potent steroids is not advised and will lead to local side effects including skin atrophy. If the treatment is ineffective, a short admission to hospital or regular day care should be arranged for further intensive topical treatments or dressings.

Time should be spent explaining to the parents the aetiology of atopic eczema. Although eczema is usually a chronic disease with no 'cure', it should also be explained that approximately 60% of children will have minimal or no symptoms after the age of 16.

Allergy testing is commonly requested by parents, but as most children will grow out of their symptoms as well as food sensitivities, formal testing is not always appropriate. Allergy testing may involve blood tests, including RAST tests, and skin prick tests. These may not be a pleasant experience for a young child. A positive result does not directly correlate with the effect of allergen avoidance on the course of atopic eczema. High street or internet allergy tests have no benefit in atopic eczema.

Case 57.2

A 22-year-old male nurse attends outpatients complaining of dry, painful eczema affecting his hands. He had previously suffered with childhood eczema and asthma. Since starting his new job, his symptoms have developed causing severe pain, fissures, itch and dry skin. His finger pulps are particularly affected. He attended occupational health and was then advised to see a dermatologist.

Question

What is the likely cause of his symptoms and what advice should be given?

Answer

The aetiology of hand dermatitis is often complex and multifactorial. An atopic predisposition, irritant factors as well as allergic contact type IV hypersensitivity may all play a part. In view of his atopic eczema during childhood, he is at greater risk of irritant and ACD than the general population. The need for this patient to constantly wash his hands with antiseptic hand wash and excessive contact with water is likely to be an exacerbating factor. Alternatives to antiseptic washes include a moisturising soap substitute, for example Dermol 500®.

A potent topical steroid and emollient with a good barrier effect should be prescribed. Tape impregnated with a steroid preparation,

for example Haelan® tape may be useful to protect fissured areas on his hands. Patch testing would be the next step to investigate a possible allergic contact component to his symptoms.

Young adults with moderate or severe eczema should be given career guidance to avoid occupations at higher risk of leading to ICD, for instance hairdressing, domestic cleaning or working in a healthcare environment that requires constant hand washing.

Case 57.3

A 28-year-old male management executive with lifelong atopic eczema has attended with worsening severity of his eczema. He has been using emollients and moderately potent topical steroids for many years and feels that these are no longer having an effect. Over the past year, he has required two short courses of oral steroids. His sleep is affected and he cannot afford to take any further time off work.

Question

What are the treatment options for this man?

Answer

This patient needs effective treatment before he becomes erythrodermic. High-dose systemic steroids over a 2-week period may have a rapid effect but are not a long-term option. His topical regime should be explored to ensure adequate quantities of emollient are being used. In addition, his aims, expectations and medical issues should be explored with a view to possible systemic treatment.

If more than a few weeks of treatment are anticipated, ciclosporin is a possible treatment option. Pre-treatment screening should include blood pressure, urinalysis and blood tests including renal function. A short course of ciclosporin treatment no longer than 12 months would alleviate his symptoms, improve his mental well being and give him a break from his chronic skin disease. If longer-term systemic management is anticipated, azathioprine would be an option, but efficacy would only be evident after approximately 8 weeks of treatment.

Case 57.4

A 9-year-old boy with known atopic eczema presented with a vesicular, blistering eruption over his face and trunk (see Fig. 57.16). His mother noticed the blisters 48 h ago and brought him to hospital as he was unwell and feverish. He had been using topical steroids and emollients regularly for his moderate atopic eczema. His sister has recently been suffering with cold sores.

Question

Fig. 57.16 shows the young patient with eczema herpeticum. What advice would you give this patient and his mother?

Answer

Eczema herpeticum, Kaposi's varicelliform eruption, is an important and serious complication that can occur in eczema patients. This is a medical emergency and early treatment with aciclovir may prove lifesaving. This widespread eruption occurs following inoculation of herpes simplex virus to skin damaged by eczema. This then spreads rapidly and can affect the eyes and lungs. It usually

Fig. 57.16 Case study 4 – a young patient with eczema herpeticum courtesy of St John's Institute of Dermatology, London.

manifests in young children with atopic eczema. Typically, the tiny blisters, vesicles, develop in large numbers on eczematous skin and patients are systemically unwell. The blisters or erosions appear 'punched out' and may be pustular. Eye involvement, as suggested in Fig. 57.16, necessitates urgent ophthalmological review as herpes simplex ocular infection can lead to corneal ulceration, stromal keratitis, iritis and permanent visual loss.

Children with atopic eczema and their parents should be educated to recognise the signs and symptoms of eczema herpeticum.

Case 57.5

A 33-year-old electrician presents to clinic with a 5-month history of a mildly itchy eruption occurring around the nasal area and eyebrows (see Fig. 57.17). He describes it as occasionally scaly and is very concerned regarding the cosmetic appearance. On examination, he also has mild scale and erythema affecting the scalp. The dandruff shampoos he usually purchases from his local community pharmacy have been ineffective. The diagnosis is seborrheic dermatitis.

Fig. 57.17 Case study 5 – man with seborrheic dermatitis, courtesy of St John's Institute of Dermatology, London.

Question

What options would you offer for topical treatment?

Answer

Ketoconazole shampoo and ketoconazole 2% cream will reduce the population of *Pityosporum ovale* on the skin which may benefit symptoms. If symptomatic and itchy, a mild topical steroid with antifungal may be an option. In addition, patients should be counselled that seborrheic dermatitis is a common condition which may be chronic and periodic exacerbations may occur.

Case 57.6

A 55-year-old woman presents with a history of longstanding chronic plaque psoriasis. Since the age of 16, she has had numerous topical treatments which have not adequately managed her symptoms. Over the past 18 months, she has noticed swelling and pain over the proximal joints of both hands, which is much worse in the morning. On examination, she has early signs of deformity. NSAIDs have not alleviated her symptoms, and her function at work is now affected.

Question

What management options should be offered for this patient?

Answer

Psoriatic arthopathy affects up to 30% of patients with psoriasis. The resulting pain and functional disability of this arthropathy can be debilitating. However, non-steroidal anti-inflammatory medicines improve symptom control. Other treatment options include methotrexate, ciclosporin and TNFα antagonists. These medicines would also have a beneficial effect on this patient's psoriasis. Both rheumatology and dermatology services are required in the management of such patients.

Case 57.7

A 45-year-old man with psorasis has been complaining of an itchy scaly scalp for the last 8 months. He has seen his primary care doctor who as prescribed a topical steroid preparation (Betacap®), but this treatment has had little effect. He is troubled by thick scale and severe itch at night.

Question

What treatment options could be considered?

Answer

Treatment of scalp psoriasis differs from other forms of psoriasis because of the presence of thick hair. Topical treatments can be difficult and messy to apply. In addition, phototherapy is not usually effective at this site. Almost all topical preparations used to treat psoriasis on the body have equivalent scalp preparations, although the application method varies. Coal tar shampoos are usually suitable first-line treatments for scalp psoriasis. Aqueous and alcoholic scalp preparations will not penetrate thick scale which needs to be softened with emollient preparations first.

Arachis oil, provided the patient is not peanut allergic, or coconut oil are commonly used for this. Salicylic acid and coal tar preparations are often effective, and sometimes these are mixed with a coconut oil base (Sebco®, Cocois®). These preparations should be left on for approximately 1 h and then washed off. Topical steroids may be effective for inflamed skin, but will not penetrate thick scale. Intermittent rather than prolonged use of topical steroids is advised.

Case 57.8

A 45-year-old man has become increasingly disabled with palmoplantar pustular psoriasis. He has had frequent crops of inflamed pustules on the palms and soles which dry up to form crusts and scaling followed by painful fissuring of the skin. This has made his job as a joiner increasingly difficult, and he has had prolonged periods of absences through illness. He has tried emollients, topical steroid applications and steroid combinations but with only temporary relief.

Question

What are the best options for the treatment of this man?

Answer

Firstly, the patient should be advised to use regular emollient therapy. A topical treatment should also be prescribed such as a potent topical steroid in combination with a base such as propylene glycol or salicylic acid. Occlusion with either cotton gloves or cling film can improve skin penetration. However, this condition can be chronic and very disabling for manual workers, and therefore systemic therapy may be advised. In such cases, oral acitretin may be given for long-term use. The patient's fasting lipids and liver function should be monitored. If oral acitretin is contraindicated, hand and foot PUVA can be used. Patients diagnosed with palmoplantar pustulosis should be advised to stop smoking and be provided with appropriate support. This is because palmoplantar pustulosis has been found to improve after cessation of smoking (Michaëlsson et al., 2006).

Case 57.9

A 24-year-old man presents at the clinic with a 10-year history of plaque psoriasis affecting his elbows, knees and sacral area, with a few small plaques elsewhere. He is otherwise fit and well. He regularly plays football and is embarrassed by the appearance of his skin. He has tried Betnovate RD® ointment (0.025%), which smoothed the plaques a little, and calcipotriol ointment, which removed the scale from the plaques but did not clear them.

Question

What treatment could this patient try next?

Answer

As the patient only has a few localised plaques, a treatment course of short contact dithranol creams may be suitable. A starting concentration of 0.5% dithranol is tolerated by most patients. The dithranol strength can then be increased every 5–7 days. The effect can be enhanced by UVB treatment twice

weekly at a dermatology department. The usual staining and burning with dithranol is minimised by short contact therapy, and any discolouration fades quickly after the treatment has stopped.

Case 57.10

A 35-year-old male patient with chronic plaque psoriasis has been reviewed. He has severe plaque psoriasis occurring on more than 50% of his body surface area. He has tried topical treatments and has also had UVB and PUVA therapy with little improvement. A course of methotrexate has failed to improve his symptoms and his work and psychological wellbeing are suffering. His PASI score is 25 and DLQI is 13.

Question

What treatment options could now be offered?

Answer

This patient would be considered eligible to receive treatment with any of the licensed biologic agents. Eligibility is based on having severe disease. This is defined as PASI score greater than 10 and a DLQI greater than 10 in addition to being unresponsive/intolerant to standard systemic therapy. Pre-treatment screening for infection including active or latent tuberculosis, congestive cardiac failure, demyelination and malignancy is required.

58 Wounds

S. Holloway and K. Harding

Key points

- Acute wound healing should progress through an orderly sequence of events to re-establish tissue integrity.
- A functional blood vessel network is fundamental for wound healing.
- Changes occur in the repaired tissue for up to 2 years with the scar tissue becoming stronger with time.
- A number of intrinsic and extrinsic factors can affect the healing process and include age, diabetes, infection, nutrition, smoking and drugs.
- Wounds are costly to treat and therefore accurate assessment of a patient and his/her wound is important.
- Assessment should be part of an ongoing process with opportunity for regular re-assessment.
- Acute wounds such as surgical incisions heal quickly with minimal complications; chronic wounds such as diabetic foot ulcers, leg ulcers and pressure ulcers take longer to heal.
- The management of patients with diabetic foot ulcers needs to include treatment of their diabetes as well as local wound management and off-loading techniques to reduce foot pressures.
- Venous leg ulcers are the most common cause of ulceration in the population and require the external application of compression bandages/hosiery to aid healing. These ulcers can be complicated by gravitational eczema; therefore, treatment of the surrounding skin is of equal importance.
- The majority of pressure ulcers are preventable. Management of patients requires a multi-disciplinary approach with the use of pressure-reducing/pressure-relieving support surfaces and repositioning as adjunctive measures to ensure appropriate care.

A wound can be thought of as any break in the integrity of the skin (Enoch and Leaper, 2005), although when this is due to minor trauma it might be termed a cut or an abrasion. Such wounds tend to heal fairly quickly by the process of regeneration of tissue and cells and generally do not pose any long-term problems. However, the time it takes for a wound to heal will depend on a number of factors related to the nature of the wound, the individual and environment. Many of these factors will be dealt with at different points throughout this chapter.

Structure of the skin

The skin is made up of the epidermis and dermis below which is the sub-cutis, muscle and bone. Within the epidermis, there are four layers:

- Stratum corneum
- Stratum granulosum
- Stratum spinosum
- Stratum basale.

Within the very thin structure of the epidermis, some of the key cells required for healing are present, in particular keratinocytes, dendritic cells and melanocytes.

The dermis is separated into the papillary and reticular dermis and is thicker than the epidermis. It is joined to the epidermis by structures known as rete ridges or 'pegs'. In uninjured tissue, this arrangement helps the skin to maintain its normal function, something which can be affected when a wound occurs or as an individual's skin changes with age. Like the epidermis, the dermis also contains many of the key cells/structures that are required for the normal healing response to occur; these include:

- Fibroblasts; for the production of collagen
- Endothelial cells; to stimulate blood vessel growth
- Leucocytes; such as lymphocytes, neutrophils and macrophages
- Smooth muscle cells
- Extracellular matrix.

The functions of the skin and factors that affect skin condition are listed in Table 58.1. How these roles link to wounds and wound healing will be explored in more detail later.

Wound healing

In adults, a scar is the normal end product of most injuries, with occasionally excessive scarring, that is hypertrophic or keloid complicating matters. However, wound healing can also be scarless, such as in fetal skin or the oral mucosa

Table 58.1 Functions of the skin and factors affecting skin condition	
Functions of the skin	Factors affecting skin condition
Protective covering	Dryness
Moisture retention	Age
Sensation	Environment
Regulation of body temperature	Nutrition
Release of waste	Hydration
Absorption of nutrients, that is Vitamin D	

(Desai, 1997a; Wysocki, 2007). This type of healing presents an interesting concept and may offer some significant developments in the future. There are also many individuals for whom healing is delayed, and includes wounds often referred to as 'chronic' or 'non-healing'. Other terminology is used in clinical practice to describe how wounds heal and includes:

- Primary intention
- Delayed primary closure
- Secondary intention.

Essentially, healing by primary intention (Fig. 58.1) describes where the wound edges are opposed, that is brought together by sutures, staples or glue and wound healing occurs mainly by connective tissue formation. Delayed primary healing is used where there may be a risk of contamination or infection, that is if the patient has undergone emergency abdominal surgery. In this instance, some of the layers of tissue are stitched, and the sutures are placed in readiness for the remainder of the wound to be closed after 48 h when the risk of infection is less. In contrast, secondary healing (Fig. 58.2) describes a situation where the wound is left open to heal by the normal processes. This type of healing is relevant to many of the types of wounds that will be discussed later.

Any injury to the skin will result in a sequence of events aimed at repairing the defect. Figure 58.3 shows the process of wound healing and is divided into four phases:

- Haemostasis
- Inflammation
- Proliferation
- Remodelling or maturation.

Fig. 58.1   Example of wound healing by primary intention.

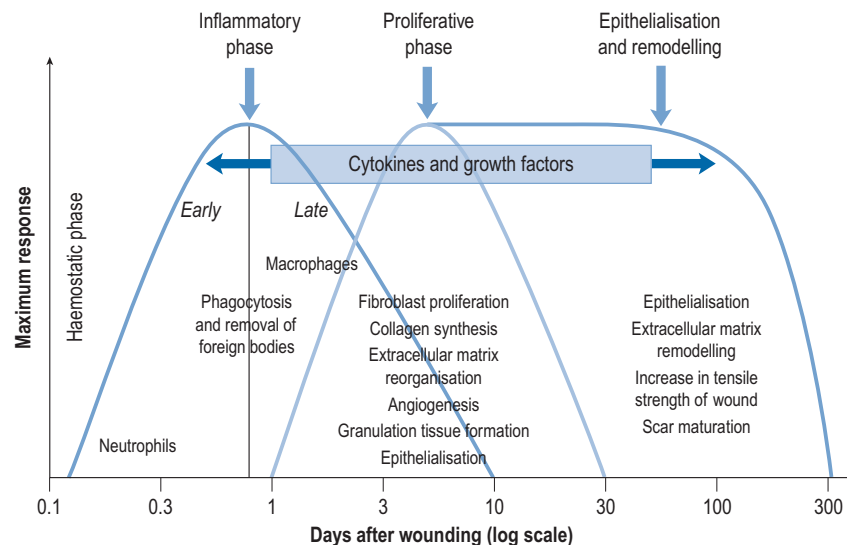
Fig. 58.2   Example of wound healing by secondary intention. Wound bed shows healthy granulation tissue and epithelial tissue can be seen at the wound edges.


Fig. 58.3 Phases of wound healing (from Enoch et al 2008).

An insult to the tissues causes a number of systemic processes to occur simultaneously. Platelets aggregate and adhere to the sub-endothelium; coagulation factors as well as growth factors are also released. Through changes in the platelet structure and function, thrombin and fibrin are released to aid clot formation and reduce excess blood loss. Once this has occurred, haemostasis is said to have been established. The initial fibrin matrix provides the scaffold for the subsequent structure. This process relies on the individual having a normal clotting response and may be affected by drugs or systemic disease.

Following haemostasis, the inflammatory phase extends from day 0 through to about day 10 in normal healing and involves neutrophils (early inflammation), and macrophages (late inflammation). Neutrophils phagocytose bacteria and kill foreign bodies by producing oxygen metabolites such as hydroxyl radicals, hydrogen peroxide and superoxide ion. In normal healing, the numbers of neutrophils decrease in number over time leading to an increase in the number of macrophages present. The key function of macrophage is to digest bacteria, dead tissue and old neutrophils. There is some evidence to suggest that in wounds which are not healing it may be the inflammatory phase and its related cells that are at fault. The classic signs of inflammation are well reported and include:

- Redness
- Swelling
- Heat
- Pain.

These signs are normal and should not be considered as indicating the presence of infection.

The proliferative phase begins approximately 1 day post-injury and should be resolving by about day 30. There are three main activities that occur during this time and include:

- Granulation tissue formation – requires new blood vessels and formation of collagen
- Contraction of the wound
- Epithelialisation.

The presence of a functional blood vessel network is fundamental for wound healing to progress. Angiogenesis, the formation of blood vessels, is required to supply oxygen to the wound environment and it is through the migration of capillaries through the provisional matrix that the vasculature is re-established. Endothelial cells migrate and proliferate to eventually join the existing blood supply to the injured area. Once this has occurred, granulation tissue can form to begin to repair the defect. The provisional tissue laid down (Fig. 58.2) is made up of fibrin, fibronectin, collagen and glycosaminoglycans. Through the action of fibroblasts, collagen is produced and the continued presence of macrophages ensures the wound is kept 'clean'. Collagen production is essential for healing to progress and in particular Types I, III and IV are required.

In conjunction with the laying down of granulation tissue, the wound edges begin to contract at around day 8, and this process assists wound closure. The key cell involved is the myofibroblast which applies tension to the surrounding matrix to induce contraction. The normal process of contraction should not be confused with contracture, which is an abnormal feature of scarring.

Around the same time, it may also be possible to see signs of epithelialisation occurring (Fig. 58.2). Keratinocytes, the cell associated with this process, are initiated hours after injury; they migrate from the edge of a wound over the provisional matrix laid down or they dissect through it. Hair follicles can act as islands of regenerating epithelium in some areas. The wound bed can be easily damaged during the proliferative phase, with simple things like incorrect dressing choice causing significant damage. Moist wound healing (MWH) principles (Winter, 1962) are encouraged to support the normal physiological process of healing.

The final phase of the healing process is termed remodelling or maturation. During this time, the initial collagen that has been laid down is synthesised by enzymes ultimately leading to a more ordered network that increases in structure and strength over time. However, this repaired area is never as strong as normal tissue and is always at risk of breakdown should circumstances occur. These final changes can take place for up to a year or more after the initial insult.

Factors affecting wound healing

Generally, wound healing should progress as described above; however, a number of factors that affect healing have been identified (Grey and Harding, 2008). A summary of these is provided in Table 58.2, some of which include:

- Age
- Diabetes
- Infection
- Nutrition
- Smoking
- Drugs.

Age

Younger patients appear to have an increased rate of healing, and there are differences in fetal healing that mean the regeneration process is superior with little or no inflammation or scarring (Desai, 1997b). In comparison, wound repair in the elderly is slower (Ashcroft et al., 2002), and management may be more challenging because of concurrent disease processes. This is a particular problem in the proliferative and remodelling phases where tissue appears to be more friable and fragile. The overall effects of age on wound healing appear to be:

- Decreased inflammatory response
- Delayed angiogenesis
- Decreased collagen synthesis and degradation
- Slower epithelialisation.

Diabetes

Diabetes poses many problems for patients with wounds and management is often challenging because of concurrent peripheral neuropathy (PN), peripheral arterial disease (PAD), neuro-ischaemia and infection (Table 58.3).

Infection

Bacterial invasion of wounds is very common. In fact, any break in the skin integrity places the wound at risk of local contamination or infection and if untreated can lead to systemic infection. The spectrum of infection from colonisation through to infection is demonstrated in Fig. 58.4. The difficulty may be in recognising when such circumstances are present. The normal inflammatory signs were discussed earlier, and these should be borne in mind when examining a patient's wound. However, there are additional local signs that may be present in wounds healing by primary or secondary intention (Fig. 58.5) that suggest an infective process; these include:

- Increased pain
- Delayed wound healing
- Wound bleeds easily
- Friable, fragile tissue
- Pocketing/bridging of tissue
- Wound breakdown (dehiscence).

Infection in a wound can often be diagnosed by clinical signs and symptoms alone and unless a systemic infection is suspected, that is the patient complains of flu-like symptoms, can

Table 58.2 Intrinsic and extrinsic factors affecting wound healing

Intrinsic factors systemic	local	Extrinsic factors
Age	Blood supply	Nutrition
Uraemia	Changes in oxygen tension	Smoking
Jaundice	Vessel trauma	Radiotherapy
Diabetes	Abnormal scarring	Infection
Anaemia	Haematoma	Drugs
Hormones	Local infection	Iatrogenic influences
Malignant disease		Wound dressings

Table 58.3 Complications of diabetes

Peripheral neuropathy	Causes damage to nerves that leads to a lack of the protective pain sensation, but the blood supply remains good. Very common and can lead to foot deformities and abnormal walking patterns. Neuropathy should be considered in terms of sensory, autonomic and motor changes. The foot is usually warm, numb and dry with palpable foot pulses
Peripheral arterial disease	Often develops as a result of atherosclerosis but develops at a faster rate in diabetic patients. Can affect the large (macro) and small (micro) vessels leading to decreased blood flow to the legs and feet, which can ultimately lead to minor or major amputations. The foot is often cool, clammy with absent or reduced foot pulses
Neuro-ischaemia	A combination of peripheral neuropathy and peripheral arterial disease
Infection	More common in diabetic patients, probably because they have an associated defective immunity. The neutrophil and lymphocyte response is slow (partly due to vascular problems); therefore, the inflammatory and subsequent phases are impaired. Hence, these patients have an increased tendency to develop infections
Fig. 58.4 Schematic representation for the outcome of bacterial invasion.

Fig. 58.5 Infection in a granulating wound.

be treated locally with topical antimicrobial dressings rather than oral antibiotics.

In recent years, there has been increased recognition that bacteria have the ability to build up colonies that present a challenge in terms of the management of bacterial load. Known as biofilms, they have the ability to resist removal and have been implicated in delayed healing of a number of wound types. The removal of dead and devitalised tissue from the wound bed seems to have some effect in preventing the growth of biofilms (Wolcott and Rhoads, 2008); however, this method is not suitable for all wounds; hence, other approaches are being sought.

The choice of topical treatment for the management of local wound infection will be dealt with in a later section.

Nutrition

The nutritional requirements for wound healing have been the subject of debate with limited evidence as to the exact dietary components for individual wound types. In general, if the patient has a balanced diet, this should be sufficient for the normal processes to take place. However, a diet that is lacking in vital nutrients can lead to delayed wound healing and wound breakdown. In the extreme, the patient can become malnourished with surgical patients most at risk of protein energy malnutrition (PEM). Box 58.1 outlines the nutritional factors that should be considered in the assessment of individuals, many of which have been incorporated in nutritional risk assessment tools. Individuals at most risk of nutritional deficiencies are those affected by:

- Ill-health in old age
- Cancer
- Chronic neurological disease

Box 58.1 Nutritional assessment and treatment options
General nutritional assessment to include Current appetite Food intake Patient's ability to eat/chew/swallow Presence of dentures
Specialist nutritional assessment Anthropometric measurements such as: Body Mass Index (BMI), % weight loss, haemoglobin, skin fold thickness, grip strength, serum albumin Gut function Total energy requirements
Nutrients required for healing Protein Zinc Copper Iron
Vitamins required for healing A B complex C E
Treatment options Modified normal diet: increase high energy/protein foods Modified normal diet plus nutritional supplementation Total enteral support Naso-gastric feeding Total parenteral nutrition Percutaneous endoscopic gastrostomy (PEG)

- Chronic inflammatory bowel disease
- Surgery (pre- and post-operatively)
- Stroke
- Acute and chronic pain
- Immuno-deficiency disease such as HIV and AIDS.

Smoking

Smoking is known to be detrimental to health generally, and in addition the effect of nicotine and carbon monoxide on skin and muscles is well documented (Møller et al., 2002). These substances reduce the oxygen levels in the tissues and can lead to the formation of thrombi. A good blood supply and adequate vascularisation is important for normal wound healing. There has been debate about the period of time patients should abstain from smoking to reduce relevant, potential complications. This has been suggested to vary from 4 (Sorensen et al., 2003) to 8 weeks (Møller et al., 2002). However, the role of nicotine replacement interventions in further reducing complications is less clear.

Drugs

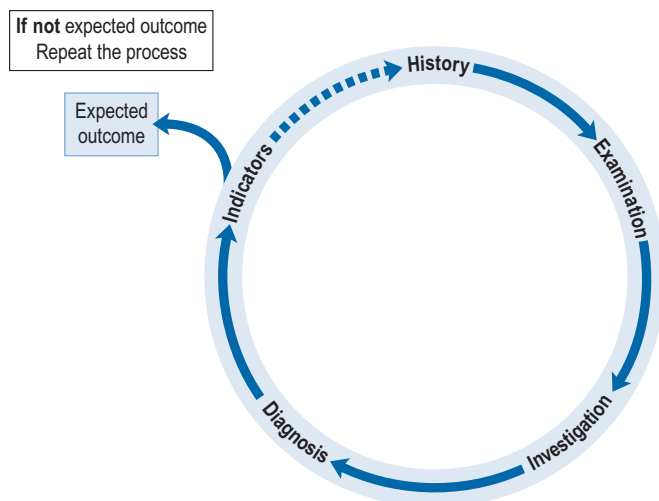
There are certain drugs that are suggested to have an effect on the healing process. These include NSAIDs, corticosteroids and immunosuppressive agents (Grey and Harding, 2008),


Fig. 58.6 Assessment of a patient with a wound.

which affect the inflammatory response, collagen synthesis and mitosis, respectively. Whilst drugs do not generally cause wounds, there have been recent reports that nicorandil, used for the treatment of angina, may cause peri-anal wounds that resolve on cessation of the medication (Baker et al., 2007).

Wound assessment

Wounds are costly to treat; therefore, it is important to appreciate the various considerations that need to be taken into account when assessing a patient. Assessment should not be viewed as a one-off occurrence but instead should be undertaken as part of an ongoing process with the emphasis on the patient, not just their wound.

A structured approach to the assessment of a patient with a wound is required. The six key elements of the original wound healing matrix are listed here and the key concepts depicted in Fig. 58.6:

- Phase of wound healing
- Aetiology
    - Acute, that is surgical, trauma, burns
    - Chronic, that is leg ulcers, diabetic foot ulcers, pressure ulcers
- Clinical manifestation
    - Size
    - Shape
    - Characteristics, that is exudate, odour, tissue type
- Environment and care
    - Primary care
    - Secondary care
- Healthcare system and resources
- Site of the wound.

Diabetic foot ulcers

Epidemiology

It was estimated that there were 1.4 million people diagnosed as diabetic in 2002 with these figures expected to double by 2010 (Cradock and Shaw, 2002). The cost of treating individuals

with diabetes accounts for at least 9% of the acute health-care costs in the UK. These costs, however, do not take into account the personal cost to the individual, such as a reduction in the ability to work and time they may need to take off work (Waters and Holloway, 2009). Diabetic foot problems are the most common cause for admission, and patients admitted to hospital for in-patient care are often hospitalised for 4–6 weeks, which obviously increases the financial costs considerably.

One of the major risks to patients with diabetic foot disease is that of amputation, which could be minor, that is mid-foot to toe; or major, that is mid-foot and above. National Service Frameworks for diabetes (Department of Health, 2001) have emerged to address this and, in turn, have been built upon (Department of Health, 2007a,b). Of concern is that up to 85% of amputations are preceded by foot ulcers. Therefore, if the incidence of foot ulcers can be reduced, this might lead to a reduction in amputations.

Aetiology

Individuals with diabetes are at risk of a number of systemic complications (see Chapter 44).

The two main causes of foot ulceration in patients with diabetes are:

- Neuropathy
- Ischaemia

PN causes damage to the nerves that leads to a lack of the protective pain sensation and is present in 75% of patients with diabetes. In this group of individuals, the blood supply to the extremities remains good, but the foot becomes insensate and can subsequently become deformed. This leads to an abnormal walking pattern and potentially tissue breakdown from abnormal pressures placed upon the foot. The characteristics of the diabetic foot are set out in Table 58.4. Unfortunately, the early systemic changes associated with the onset of diabetes may be present for up to 12 years before a diagnosis is

Table 58.4 Clinical features of a diabetic foot with neuropathy or arterial disease

Characteristic	Peripheral neuropathy	Peripheral arterial disease
Temperature	Warm	Cool
Foot pulse	Present/'bounding'	Absent/reduced
Pain	Commonly no pain NB Painful diabetic neuropathy is a rare but potential feature	Pain on walking (intermittent claudication) Depends on degree of neuropathy
Site of ulcers	Toes and metatarsal heads	Lateral (outer) border of foot
Callus (hard skin)	Present	Absent

made, by which time damage has already begun to occur and is often irreversible.

PAD usually occurs as a result of atherosclerosis. This often results in a reduction in blood flow to the lower limbs and pain on walking (claudication), pain at rest with possible progression to gangrene and amputation. PAD is common in the elderly and is not just a complication of diabetes, although people who have diabetes are at an increased risk of developing it. Foot ulceration due to PAD is less common, accounting for approximately 5% of cases.

Neuropathy can be related to lack of sensation (sensory neuropathy) and may also cause atrophy and weakness of muscles in the foot (motor neuropathy). In addition, there are effects on the autonomic nervous system which can cause changes in blood flow and sweat secretion (autonomic neuropathy). Each of these elements needs to be considered as each has significant effects on the lower limb in individuals with diabetes.

Clinical signs

The clinical features of a diabetic foot with PN and PAD are summarised in Table 58.4 and their typical presentations shown in Fig. 58.7 and Fig. 58.8, respectively. There are a number of factors that place patients at increased risk of ulceration including foot deformity; ill-fitting footwear; mechanical injury, for example treading on a sharp object; thermal injury, for example heat from a fire, or stepping into a hot bath; and chemical trauma typically caused by an over-the-counter preparation purchased to remove hard skin. National guidelines outline the processes that should be in place to ensure the monitoring of patients deemed at risk (Department of Health, 2001, 2007a,b; National Institute of Health and Clinical Excellence, 2004). One of the key issues

Fig. 58.8 Peripheral arterial disease in a patient with diabetes.

to consider is that the feet of patients with diabetes do not ulcerate spontaneously, instead any one, or combination, of the factors discussed could be to blame.

Diagnosis

It is essential that individuals with diabetes are cared for within a multi-disciplinary framework with the responsibilities for management of the patient clearly defined.

Initial assessment should include a clinical examination of the foot and may also require objective testing, for example an X-ray. The key features of this examination are set out in Table 58.5. In addition, further tests such as a full blood count, examination of urine, alternate imaging methods,

Fig. 58.7 Diabetic foot ulcer caused by peripheral neuropathy.

Table 58.5 Examination of the diabetic foot		
Clinical examination		**Objective test**
Shape and deformities	Toe deformities Foot deformities Callus	X-ray
Sensory function	Vibration Protective sensation	Biothesiometry Semmes–Weinstein filament
Motor function	Wasting Weakness Ankle reflexes	Electrophysiological tests
Autonomic function	Reduced sweating Callus Warmth Appearance of veins on the foot	Quantitative sweat test
Vascular status	Foot pulses Temperature Swelling	Non-invasive Doppler studies, ankle brachial pressure index and/ or toe pressure indices

that is magnetic resonance imaging, colour duplex scans and angiograms, may be indicated.

Infection in the diabetic foot is a real risk and a common complication. It has been estimated that 20–50% of diabetic ulcers are infected. The severity of the infection will depend on the nature of the bacteria, but commonly cellulitis and osteomyelitis occur in patients with neuropathic ulcers with gangrene being more associated with PAD. Bacterial cultures from ulcers are usually polymicrobial with both Gram-positive and Gram-negative organisms as well as anaerobic bacteria. There should be concern if any of the following features occur:

- Difficulty walking and/or applying shoes
- Swelling in part or all of the foot
- Redness or other discolouration
- Foot becomes hotter than normal
- Discharge or unusual odour
- Open sores or blisters
- Nausea, vomiting or high temperature
- Difficulty maintaining blood glucose control.

Treatment

Infection

The signs of infection are often delayed or insidious in patients with diabetes. Virtually all diabetic foot infections require antimicrobial therapy, but this alone is rarely sufficient. If soft-tissue infection is superficial, then oral, relatively narrow spectrum antibiotics for 1–2 weeks are indicated (Lipsky and Berendt, 2006); however, if there is cellulitis and spreading infection, parenteral antibiotic therapy may be required for up to 4 weeks. In addition to antibiotics, the patient may require hospitalisation if removal of dead or devitalised tissue is required. An X-ray of the foot may also be advisable if the tissue loss is over the bone, and referral to a vascular or orthopaedic specialist may be necessary for surgery.

Other considerations

Treatment of a diabetic foot ulcer should also include:

- Podiatry
- Skin and wound care
- Provision of footwear to remove/redistribute weight
- Offloading options to include orthoses/custom-made insoles
- Patient education
- Pain relief
- Control of diabetes
- Multidisciplinary team approach.

The range of treatment options will be determined by whether there is neuropathy and/or PAD present, as well as the presence of ulcers and/or infection. The debridement of callus and devitalised tissue is essential as it enables the true dimensions of the ulcer to be established (Edmonds and Foster, 2000). Dressings are important but should not be viewed in isolation to the other essential aspects of treatment listed above. Key aspects in the choice of dressing for diabetic foot ulcers are how it will perform in a shoe, whether it will withstand pressure and shear forces, how well it will absorb any fluid from the wound and how often the dressing needs to be changed and cost effectiveness.

Prevention of recurrence

Many of the considerations discussed above are also important in terms of preventing a recurrence of ulceration and should be borne in mind when planning the management of individuals with diabetes. Ideally, ulceration should be prevented via intensive screening programmes, although unfortunately this is not always achievable. In addition, the maintenance of tight control over blood glucose and blood pressure is required together with the monitoring of cholesterol and initiation of antiplatelet therapy. Guidelines (National Institute of Health and Clinical Excellence, 2008) recommend the following:

- Blood pressure ≤140/80
- Blood glucose <7 mmol/L or $HbA1_c$ <6.5%
- Total cholesterol <5.0 mmol/L
- Antiplatelet therapy for those with or at risk of cardiovascular disease.

Leg ulcers

Epidemiology

The prevalence of leg ulcers in the Western world is 0.11–0.18% (Briggs and Closs, 2003). There is a preponderance of 2.8:1 female to male ratio, with venous disease being the main cause of ulceration. The risk of leg ulceration increases with age.

The estimated cost in the UK of all leg ulcers is between £200–600 million pounds with the costs of individual ulcer treatment between £557–1366 over a year (Tennvall and Hjelmgren, 2005). Between 60% and 90% of patients are managed in the community.

Aetiology

Leg ulcers can be classified as follows:

- Venous
- Arterial
- Mixed, that is ulcers that have a venous and arterial component
- Diabetic; typically on the foot, rather than the leg
- Autoimmune, for example rheumatoid arthritis.

Venous ulcers

Ulcers of venous origin account for the majority of all leg ulcers. There are a number of reasons why they occur and include failure of the calf muscle pump to work effectively, which leads to pooling of fluid in the lower limb and oedema. This can lead to high pressures in the lower limb on walking, known as venous hypertension. This swelling can lead to poor

oxygenation of the tissues and trapping of harmful substances such as growth factors and enzymes. Ultimately, this can lead to tissue breakdown precipitated by simple trauma such as knocking the leg.

The calf muscle pump relies on an adequate level of mobility; therefore, anything that might affect this such as increasing age, obesity and trauma predisposes the individual to a sequence of events if they also have poor venous return.

Risk factors associated with the development of venous ulcers include deep vein thrombosis (DVT), varicose veins, or surgery/trauma to the leg.

Clinical signs

Venous disease. As a result of venous hypertension and leakage of fluid, red blood cells are deposited in the tissues causing discolouration known as haemosiderin. This can often be seen on the lower limb and may be red or brown in colour. Varicose veins may also be visible as will oedema (swelling) and a characteristic change known as lipodermatosclerosis (LDS). Over time, the limb may develop a typical inverted 'champagne bottle' appearance. Venous ulcers are typically shallow and develop in the gaiter area (Fig. 58.9). Patients may also have associated gravitational eczema.

Diagnosis

The key element is the accuracy of the assessment and should include:

• Clinical history
• Clinical investigation
• Assessment of the limb
• Assessment of the ulcer.

Table 58.6 summarises the key aspects of the assessment of an individual with a leg ulcer.

Assessment of ankle brachial pressure index (ABPI). The use of a hand-held Doppler device is used to assess the arterial blood flow. Ideally, this test should be undertaken on any patient presenting with a leg ulcer. Furthermore, it should

Fig. 58.9 Venous leg ulceration.

be carried out on first presentation as well as at subsequent intervals depending on whether the ulcer is improving or not. Essentially, the ankle brachial pressure index compares the patient's brachial (arm) and ankle systolic pressures:

$$ABPI = \frac{\text{highest ankle systolic pressure}}{\text{highest brachial systolic pressure}}$$

The patient should rest for 20 min before the assessment and the pressures should be measured supine (lying down). Two measurements should be taken from the foot and the highest value used in the calculation.

The ankle brachial pressure index is not a definitive measure of arterial status but merely serves as an indicator of blood flow. Other clinical signs and symptoms also need to be taken into account.

As a general principle, the ankle brachial pressure index or ratio should be ≥ 1.0 in individuals with no arterial disease. However, this should not be relied upon in the presence of diabetes as calcification of arteries can occur and lead to falsely high ABPI readings. In this instance, a Duplex scan would be a more reliable indicator of vascular status. Furthermore, both hypo- and hypertension can affect the readings.

Table 58.6 Factors to be taken into account in the assessment of an individual with a leg ulcer

Clinical history	Clinical investigations	Assessment of both limbs	Assessment of the ulcer
Family history	Blood pressure	Oedema	Year first ulcer occurred
Varicose veins	Ankle brachial pressure index	Site of ulcer	Site of ulcer/previous ulcers
Deep vein thrombosis/pulmonary embolus	Full blood count	Depth of wound	Size of ulcer(s)
Phlebitis		Appearance of wound bed	Number of previous episodes
Surgery or fracture of the leg		Surrounding skin	Time free of ulcers
Heart disease/stroke		Perfusion of feet	Past treatment (successful or not)
		Presence of pulses	Previous/current uses of compression bandaging
Diabetes		Ankle brachial pressure index	
Peripheral arterial disease			
Chest pain/angina			
Smoker			
Rheumatoid arthritis			
Medication			
Allergies			

Treatment

The mainstay of treatment for confirmed venous ulceration is compression bandaging. Known as graduated compression, specific bandage systems are used to apply external pressure to aid venous return. The ABPI must be ≥ 0.8 for this treatment to be used. Although there is much debate about which bandage system is preferable, the choice should be based on an individual patient assessment and may include:

- Short stretch systems
- Multi-layer systems

The aim of most systems is to create pressures of 40 mmHg at the ankle decreasing up to the knee to assist in venous return. In addition to bandaging, the patient should be encouraged to keep mobile, which could be as simple as undertaking ankle exercises to improve blood flow. Leg elevation and rest should also form part of overall management.

Even where arterial disease has been excluded as a complication, the patient should be monitored carefully for signs of compromised blood flow as serious injury such as skin necrosis or in the extreme amputation may be required.

Other treatment options may include antibiotics if systemic infection is suspected or topical antimicrobial dressings for local infection which include iodine- or silver-based products.

Intermittent pneumatic compression, surgery, skin grafting, bioengineered skin and pharmacological treatments such as oxypentifylline have all been suggested as adjuvant therapies to compression therapy (Robson et al., 2006).

General wound care should include cleansing of the ulcerated area with saline or tap water to maintain cleanliness and hygiene as well as debridement of any dead or devitalised tissue. Dressings should be simple and as low adherent as possible as they have to perform well under the bandage system. There is a need to be aware of the potential of contact sensitivity to the dressings, bandages, or skin treatments used.

Gravitational eczema is commonplace in patients with venous disease and is related to the changes caused by venous hypertension. The patient may complain of intense itching, and scratch marks may be visible on examination. It is important to distinguish eczema from contact sensitivity and cellulitis as each of these requires a different treatment. Treatment of eczema will include a combination of a topical corticosteroid such as clobetasone butyrate (Eumovate®) or mometasone furoate (Elocon®) creams and emollients such as Epaderm® or similar mixtures of white soft paraffin and liquid paraffin to manage this inflammatory condition.

Prevention of recurrence

Once a venous ulcer is healed, compression hosiery (in the form of stockings) are required. This hosiery is classed as 1, 2 or 3 depending on the level of pressure applied. Class 3 stockings and tights provide strong support (25–35 mmHg at the ankle) and are the preferred choice to prevent recurrence of venous ulcers. Table 58.7 provides the compression values for hosiery. Ideally, they will need to be worn for life or at least a minimum

Table 58.7 British national formulary compression values for hosiery

Compression class	Level of support	Compression hosiery (British Standard)
Class 1	Light	14-17 mm Hg*
Class 2	Medium'	18-24 mm Hg*
Class 3	Strong	25-35 mm Hg*

*compression provided at the ankle

of 5 years. Unfortunately, recurrence is common often because of the inconvenience associated with the wearing of stockings. Patient education and follow-up is essential. Community leg ulcer clinics have been established in many areas of the UK and have shown to be effective in supporting patients.

Arterial ulcers

Arterial ulceration is commonly associated with atherosclerosis and peripheral artery disease, much of which has been discussed previously in relation to diabetic foot disease. Both macro- and micro-disease may be present.

Clinical signs

The classic clinical features of arterial insufficiency are:

- Intermittent claudication/rest pain
- Colour changes, for example pallor
- Muscle atrophy/weakness
- Poor perfusion, for example cool limb
- Loss of skin hair
- Thickening/hardening of the nails
- Ulceration
- Gangrene.

Arterial ulcers often appear 'punched out' (Fig. 58.10) and have a pale wound bed. The significant feature is pain, with many patients reporting pain on walking known as intermittent claudication. As the disease progresses, patients may also report that their pain is worse at rest, particularly when their legs are elevated. This feature affects their ability to sleep, eat and keep mobile which can ultimately mean they are unable to leave the house.

Diagnosis

A simple test known as Buerger's Test (see glossary) is normally used to look for positive signs of disease. If it is possible, a Doppler test should also be undertaken to calculate the patient's ankle brachial pressure index. Typically, an ankle brachial pressure index of 0.6–0.8 indicates a degree of arterial disease, whilst a value ≤0.6 is considered to be indicative of considerable disease. In addition, a colour Duplex scan is usually required to ascertain the extent of the disease. If treatment is required, an angiogram will usually be undertaken to examine the affected vessels.

Fig. 58.10 Arterial leg ulceration.

Treatment

An angioplasty may be carried out to improve the blood supply. Where this is not possible, vascular reconstruction may be advised to try and prevent further progression. Treatment will also include pain relief, prevention of infection and nutritional support. In addition, smoking cessation advice may be needed as might pharmaceutical intervention for cholesterol or lipid lowering purposes.

Prevention of recurrence

The main risk for individuals with arterial disease is amputation (minor or major). The patient plays a key role in prevention as many of the predisposing factors are lifestyle issues such as giving up smoking, eating a healthy diet and exercise. It may also be necessary to continue taking medication as discussed previously.

Mixed ulcers

While the term 'mixed ulceration' is used in clinical practice to describe ulcers with an element of venous and arterial disease, technically it is not a diagnosis. Patients present with venous and arterial symptoms, and an ankle brachial pressure index is likely to be between 0.6 and 0.8. Treatment is directed at the symptoms causing most concern, with compression bandaging only used under close supervision. The management options are as discussed previously for venous and arterial ulcers.

Pressure ulcers

Epidemiology

Previously referred to as *bed sores* or *pressure sores*, this wound type is now generally referred to as a pressure ulcer (National Institute of Health and Clinical Excellence, 2005) and defined as:

localised injury to the skin and/or underlying tissue usually over a bony prominence, as a result of pressure, or pressure in combination with shear. A number of

contributing or confounding factors are also associated with pressure ulcers, the significance of these factors is yet to be elucidated.

(European Pressure Ulcer Advisory Panel and National Pressure Ulcer Advisory Panel, 2009)

The prevalence of pressure ulcers across five European countries was 18.1% (Clark et al., 2004). This helps us establish the burden of pressure ulcers perhaps locally, nationally and globally but does not necessarily provide information on the quality of care (European Pressure Ulcer Advisory Panel and National Pressure Ulcer Advisory Panel, 2009). Table 58.8 provides the most recent data on incidence.

Common sites of pressure ulcers

Pressure ulcer damage can occur anywhere on the body, but are most common over bony prominences including:

• Sacrum
• Heels
• Buttock
• Trochanter.

Sacral damage often occurs from the patient slipping down the bed or whilst sitting in a chair with shear forces causing the most damage. Injury to other areas is more likely to be due to direct pressure over a bony prominence. In acutely ill patients, equipment such as nasal cannula can even cause pressure damage to the nose.

Aetiology

As the name implies, this sort of wound is caused by external pressure on the tissues which, if sustained, leads to decreased capillary flow, ischaemia and capillary thrombosis. In turn, fluid escapes from the vasculature into the surrounding tissues causing oedema, accumulation of metabolic waste and cell death.

There are different types of pressure that may be implicated in the onset of damage, and it is both the type and duration of pressure that is of importance. The types of pressure are listed as follows:

• Capillary closing pressure
• Vertical pressure
• Tissue interface pressure
• Shear and friction forces.

Table 58.8 Incidence of pressure ulcers in UK

	Grade distribution	Annual incidence
Grade I	34.9%	140,000
Grade II	41.2%	170,000
Grade III	12.9%	50,000
Grade IV	11.0%	50,000

In addition to pressure, other factors that may influence the development of the damage are:

- Reactive hyperaemia
- Reperfusion injury
- Patient age: extremes of age most at risk
- Nutritional status: extremes of weight most at risk
- Mobility status
- Condition of peripheral circulation
- Continence status.

Clinical signs

Early signs of damage may present as a red area on the skin that remains even after the pressure has been relieved, or damage may present as broken skin or an abrasion. Pressure ulcers are now classified using four categories or stages (rather than grades):

Category/stage I: Non-blanchable redness of intact skin

Intact skin with non-blanchable erythema (in normal tissue if you use light finger pressure on an area it turns white, once the pressure is released it returns to the normal colour very quickly; where damage is present the tissue does not 'blanch', i.e. turn white) of a localised area usually over a bony prominence. Discolouration of the skin, warmth, oedema, hardness or pain may also be present. Darkly pigmented skin may not have visible blanching but may be painful, firm, soft, warmer or cooler as compared to adjacent tissue.

Category/stage II: Partial skin loss or blister

Partial thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed, without slough. May also present as an intact or open/ruptured serum-filled or serosanguinous filled blister.

Category/stage III: Full thickness skin loss (fat visible)

Full thickness tissue loss. Sub-cutaneous fat may be visible but bone, tendon or muscle is not exposed. Some slough may be present. May include undermining and tunnelling.

Category/stage IV: Full thickness tissue loss (muscle/ bone visible)

Full thickness tissue loss with exposed bone, tendon or muscle. Slough or eschar may be present. Often includes undermining and tunnelling.

Diagnosis

Pressure ulcers are usually diagnosed on clinical appearance and presenting history. Using the classification system outlined above, it is also possible to determine the stage of ulcer.

X-rays of the ulcer may be required, especially if it is over a bony area, to exclude any underlying infection in the bone (osteomyelitis). In addition, blood tests to examine inflammatory markers may also be useful in determining the presence of infection.

If undermining or tunnelling is present, further ultrasound scans may be required to examine the full extent of the wound and to identify any collection of fluid.

Treatment

The care of patients with pressure ulcers will depend on the category/stage of the damage, but there are interventions common to all patients and these include (National Institute of Health and Clinical Excellence, 2003, 2005):

- Appropriate support surface (mattress and seating/cushions) to redistribute pressure and reduce shear forces
- Repositioning (turning) schedule to meet the needs of the individual
- Wound cleansing with normal saline or potable water
- Debridement of dead or devitalised tissue using an appropriate method
- Dressings that meet the wound characteristics
- Treatment of infection via local or systemic route as appropriate
- Skin care and hygiene, particularly if the patient is incontinent
- Negative pressure wound therapy may be a suitable adjuvant therapy
- Surgical reconstructive intervention in complex cases.

Other therapeutic interventions include electrical stimulation, laser therapy and ultrasound.

Prevention of pressure ulcers

The majority of pressure ulcers are preventable. Prevention strategies should take into account the aetiology of the ulcer and also the risk factors discussed. Important considerations in terms of prevention include:

- Patient repositioning
- Use of equipment
- Skin care
- Nutritional support.

An individual's potential risk of developing damage should be assessed with a view to identifying those that are vulnerable. Once an individual is deemed to be at risk of skin breakdown, the aim should be to improve tissue tolerance which can be achieved using the elements described above.

Principles of wound management

There are a number of principles to wound management including:

- Knowledge of wound healing physiology
- Assessment of the patient
- Assessment of the wound/ulcer
- Assessment of the tissue type
- Recognition of factors affecting healing
- Knowledge of dressings available
- Availability of resources.

The health care professional needs to be clear about the aim of management, and the expected outcome before the most appropriate treatment can be selected. Table 58.9 outlines the main considerations to be taken into account. Whilst wound healing is often viewed as the eventual outcome in some instances this may not be feasible; therefore, alternative aims should be identified to demonstrate success.

Assessment of the tissue type should include examination of the following:

- Dead, devitalised tissue, that is slough, necrosis
- Infected tissue
- Granulating, that is pink
- Epithelial tissue, that is pink, silvery tissue at the edges of a wound.

Once this information has been established, then the choice of local treatment should be more apparent. The selection of a dressing will depend on:

- Treatment objective
- Stage of healing
- Tissue type
- Site and size of the wound
- Frequency of the dressing change
- Comfort/cosmetic appearance
- Where/by whom the dressing is to be changed
- If the dressing is available.

Table 58.9 Criteria to consider in choosing appropriate wound management

Aim	Criteria
Protect from	Drying out Infection Further damage
Debride using	Autolytic methods Mechanically Sharp/Surgical Larvae
Control	Bleeding Exudate Pain Odour

Box 58.2 lists the main types of dressings available. Dressings alone will not heal a wound, and other aspects of care may need to be taken into account including:

- Compression bandages for patients with venous ulcers
- Pressure relieving equipment for individuals with or at risk of pressure ulcers
- Footwear and off-loading devices for patients with diabetic foot disease

---

Box 58.2 Wound management products

Basic wound contact dressings, that is knitted viscose/polymer dressings
Low adherent dressings – indicated for clean granulating wounds with a light amount of exudate. NB Dressing may stick so be cautious of trauma on removal
Absorbent dressings – are also low adherent and suitable for mild and moderate (but not viscous) exudate

Advanced wound dressings
Hydrogel – generally donates liquid to aid autolytic debridement of sloughy, necrotic wounds. Available in amorphous or sheet form depending on the size and shape of the wound. Choice will depend on the amount of exudate present.
Vapour permeable films and membranes – also allow the passage of water vapour and oxygen but remain impermeable to water and bacteria. They allow viewing of the wound and are flexible and conform to awkward wound shapes. Mainly suitable for partial thickness wounds and formulated with and without an absorbent pad for exudate management. Use would be avoided in infected and highly exuding wounds.
Soft polymer – often with added silicone. Designed to be non-adherent and are useful if the skin/wound is fragile and where further damage is to be avoided. They can be used on wounds that have light to moderate exudate but may require a secondary absorbent dressing if large amounts of exudate are present.
Hydrocolloids – semi-permeable to water vapour and oxygen, and gel in the presence of exudate. Promote autolytic debridement and are also useful on granulating wounds as they can be left in place for a number of days. Generally, these dressings are indicated for moderate to heavy exudate, careful monitoring for maceration of the wound edges and surrounding skin would be important.
Foam – suitable for most types of wounds but requires a moist wound interface. Can absorb various levels of exudate with some having better fluid handling capacity than others. Presented in adhesive and non-adhesive forms, the choice of which is often based on the integrity of the patient's surrounding skin.
Alginate – usually fibrous dressings, made from seaweed, some have haemostatic properties. Require moisture so are not suitable for dry wounds. They are suitable for exuding wounds and can aid autolytic debridement. Available as packing material (ropes) or flat sheets, the choice of which depends on the size and shape of the wound. May require a secondary dressing to hold in place.
Capillary action – contraindicated in bleeding wounds but useful for exuding wounds, particularly when slough is present. Absorbent core absorbs and contains the exudate which minimises the risk of maceration. A secondary dressing is also required.
Odour absorbent – utilise activated charcoal to absorb odour from wounds. Some require a suitable primary contact layer whilst others are layered and provide a non-adherent wound contact interface. The cause of the odour should always be established as underlying infection may require additional treatment.

Box 58.2	Wound management products—cont'd

Antimicrobial – used to treat local rather than spreading or systemic infection. Can be used to reduce the levels of bacteria in the wound. The amount of exudate should be a consideration when choosing an antimicrobial dressing.

Honey – medical honey is anti-inflammatory as well as antimicrobial and can aid with debridement of the wound and combating odour. Caution should be exercised in diabetic patients and its use should be avoided if a patient is allergic to bees/bee stings.

Iodine – available as povidone-iodine or cadexomer-iodine, preparations are useful in clinically infected wounds. Iodine is effective against a wide range of bacteria, but its effect can be diluted if large amounts of exudate are present. Cadexomer-iodine is effective at debriding wounds. Iodine can cause sensitivity and systemic absorption can occur especially from large wounds or prolonged use.

Silver – used when infection is suspected. Available in different presentations and can be used on all wound types that have clinical signs of infection and where exudate is present. Skin discoloration can occur and systemic absorption can occur therefore use is contraindicated in pregnancy and neonates.

Specialised dressings
Protease-modulating matrix – acts on the proteolytic enzymes in chronic wounds and re-establishes normal enzymatic activity. Can be used on non-healing wounds that do not seem to be progressing.

Silicone keloid dressings – used to reduce hypertrophic and keloid scarring, therefore are not appropriate for open wounds. A staged approach to application is advised with increasing wear time being indicated. Dressings can be washed and re-used.

Adjunct dressings and appliances
Surgical absorbents – useful as secondary layer over a primary wound contact layer. Absorb exudate but allow leakage of exudate ('strike-through'). Can adhere to the wound bed and fibres may be shed, therefore should be used cautiously.

Wound drainage pouches – use when other exudate absorbing dressings are not sufficient to manage the fluid levels; wound drainage bags may be useful as a means to containing the leakage.

Complex adjunct therapies
Topical negative pressure – useful for acute and chronic cavity wounds and shallower wounds healing by secondary intention; topical negative pressure or vacuum-assisted closure aims to stimulate angiogenesis, remove excess exudate, reduce the bacterial burden and stimulate the production of granulation tissue.

Sterile larvae (maggots) – useful for debridement of sloughy wounds. Once applied they can remain *in situ* for 3 days before replacing. Now available contained within a net bag to simplify application.

Growth factors – Becalpermin (Regranex®) licensed for full thickness, diabetic neuropathic foot ulcers.

Bandages
Compression (multi-layer) – provide compression for treatment of venous ulcers. Correct application of bandage is essential as the incorrect application technique can be hazardous. A Doppler assessment to establish the patient's ankle brachial pressure index (ABPI) is essential prior to application. Systems include high compression, short stretch and multi-layer (4 layer and 2 layer). Choice is often dependent on patient preference.

Compression hosiery – prevents recurrence of venous ulcers. Ankle brachial pressure index should be established prior to application. Class III is preferred.

Compression garments – for management of lymphoedema. Used in conjunction with intermittent pneumatic compression systems.

Skin care
Skin barriers that protect the peri-wound area are important as wound exudate contains enzymes that can cause damage to tissues. Simple silicone-based creams or petroleum-based ointments can be useful in providing a protective layer for fragile skin.

- Topical negative pressure for cavity wounds healing by secondary intention.
- Nutritional supplementation
- Drugs to influence healing
- Surgical interventions.

Case studies

Case 58.1

A 64-year-old diabetic man has an ulcer on the sole of his foot. He cannot recall how he sustained the injury and the wound is not painful. The patient feels otherwise well (Fig. 58.11).

Questions

1. What is the most likely cause of the ulceration?
2. What are the key concerns in ensuring appropriate management?
3. What are the options for assessment and treatment?

Answers

1. From the position and the appearance, this is likely to be a neuropathic diabetic foot ulcer as these commonly present on the plantar (sole) aspect of the foot. They are usually painless and can leak large amounts of exudate if they are deep. Note the signs of macerated tissue around the edges of the wound.

Fig. 58.11 Case 58.1

2. The most common complication of this sort of ulcer is infection. Local infection of the wound bed can quickly lead to spread of infection (cellulitis) in patients with diabetes as they have a slower immune response and do not mount a defence mechanism quickly. In addition, an assessment of the patient's glucose control should be undertaken as poor glucose management can exacerbate complications. Finally, a review of the patient's footwear should be considered as the patient may require further off-loading techniques to assist wound healing.
3. Assessment of the foot should be undertaken to establish the extent of the neuropathy. Vascular assessment is also required to examine the blood flow to the limb. Local wound assessment should include a description of the tissue present, the size of the wound (to include depth) and the amount of exudate as this will determine not only the topical dressing to be applied but also whether further investigations are required.

   As the ulcer has some depth, the wound will need packing gently with a dressing that has good fluid handling capacity. A secondary dressing will be needed to secure the contact layer, and the footwear should be suitable enough to accommodate the dressing without causing further pressure.

Case 58.2

A 71-year-old lady has ulceration on the gaiter area of her lower leg (Fig. 58.12).

Questions

1. What is the likely cause and how would this be established?
2. What treatment does the patient require?
3. What advice would be required in the short and long-term?

Fig. 58.12 Case 58.2

Answers

1. The ulcer is typical of a venous ulcer, caused by venous hypertension which damages the veins and causes leakage of cells and fluid ultimately leading to tissue breakdown often caused by minor trauma. A medical history should be taken to establish likely predisposing factors; the limb should be assessed for colour, oedema and the presence of pain. The ulcer is likely to be shallow, with irregular edges and surrounding skin may demonstrate changes associated with venous disease such as haemosiderin, LDS or gravitational eczema.
2. Local treatment will include a non-adherent dressing if the wound bed is clean and granulating. Surrounding skin will require emollients for hydration and/or topical steroids if eczema is present. The most important treatment will be the application of graduated compression using a multi-layer bandage system.
3. The patient should be encouraged to take gentle exercise (sufficient to ensure ankle flexion) and also elevate the leg when sitting. The patient must continue to wear the compression bandages (day and night) until healed unless pain, discomfort or skin colour changes occur, in which case they should seek medical attention. In the long-term, the patient should be assessed for compression hosiery which should be continued for at least 5 years post-healing to prevent recurrence.

Case 58.3

A 59-year-old spinally injured, wheelchair-bound patient has a pressure ulcer extending into the underlying tissues (Fig. 58.13).

Questions

1. What is the likely stage/category of the ulcer?
2. What are the factors that have led to the development of the ulcer?
3. What are the key concerns in selecting the most appropriate product (s) to manage (a) the ulcer (b) the patient?

Answers

1. This is likely to be a Stage/Category III ulcer as on further examination no bone can be felt at the base of the wound (bleeding noted in the image is due to probing of the ulcer and is also due to the presence of local infection in the tissues).

Fig. 58.13 Case 58.3

2. The patient has sustained a spinal injury and as a consequence their mobility will be limited, and they will not sense the need to change position regularly as they have lost

the sensory clues to undertake this. The ulcer has probably been caused by direct pressure over a bony prominence which has led to the compression of tissue and vessels leading to damage.

(a) An assessment of the ulcer should be undertaken to include the size of the ulcer, presence of undermining or tunnelling, the type of tissue in the wound bed (to include presence of bone) and the amount of exudate. A cavity wound such as this should be packed gently and secured with a non-adhesive type dressing as skin stripping may occur on dressing removal otherwise. An antimicrobial dressing could be used.

(b) The patient's wheelchair and cushion should be assessed to determine whether they are suitable. The patient should also be asked about how often they relieve the pressure when sitting and be reminded that ideally this should be every 15 min. The patient should be encouraged to remain off the affected area until it has healed and the use of an appropriate mattress should be discussed. Other aspects such as skin care (to include the peri-wound area), skin hygiene and nutrition should also be reviewed.

abd.	abdomen (abdominal)
	abduction
ABE	acute bacterial endocarditis
ABG	arterial blood gases
ABMT	autologous bone marrow transplant
ABP	acute bacterial prostatitis
ABVD	adriamycin (doxorubicin), bleomycin, vinblastine, dacarbazine
ACAT	acylcholesterol acyltransferase
ACBS	aortocoronary bypass surgery
ACD	allergic contact dermatitis
ACE	angiotensin-converting enzyme
Acid phos.	acid phosphatase
ACR	albumin:creatinine ratio
ACT	activated clotting time
AD	Alzheimer's disease
ADC	AIDS dementia complex
ADH	antidiuretic hormone
ADL	activities of daily living
ADP	adenosine diphosphate
ADR	adverse drug reaction
ADT	androgen deprivation therapy
ADU	acute duodenal ulcer
AED	antiepileptic drug
AF	atrial fibrillation
AFB	acid-fast bacillus
AFP	a-fetoprotein
AGEP	acute generalised exanthematous pustulosis
AGL	acute granulocytic leukaemia
AGN	acute glomerulonephritis

AHA	autoimmune haemolytic anaemia
AHD	autoimmune haemolytic disease
AIDS	acquired immune deficiency syndrome
AIP	asymptomatic inflammatory prostatitis
AIT	amiodarone induced thyrotoxicosis
AK	above knee
ALA	aminolaevulinic acid
ALD	alcoholic liver disease
ALF	acute liver failure
ALG	antilymphocyte globulin
ALL	acute lymphocytic leukaemia
ALP	alkaline phosphatise
ALT	alanine transaminase
	argon laser trabeculopasty
AMA	against medical advice
AMI	acute myocardial infarction
AML	acute myeloid leukaemia
AMP	adenosine monophosphate
ANA	antinuclear antibody
ANC	absolute neutrophil count
ANF	antinuclear factor
ANP	atrial natriuretic peptide
Anti-HbAb	anti-hepatitis B antibody
AOB	alcohol on breath
AP	alkaline phosphatase
	angina pectoris
	antepartum
	anterior pituitary
	anteroposterior
	aortic pressure
	apical pulse
	appendectomy
	artificial pneumothorax
APB	atrial premature beat
APC	activated protein C
	atrial premature contraction
APD	action potential duration
APKD	adult polycystic kidney disease
APP	amyloid precursor protein
APSAC	anisoylated plasminogen streptokinase activated complex
APTT	activated partial thromboplastin time
AR	aortic regurgitation
	apical/radial (pulse)
ARB	angiotensin receptor blocker

ARDS	adult respiratory distress syndrome		**Bx.**	biopsy
ARF	acute renal failure		**C**	complement
AS	aortic stenosis		**C & P**	cystoscopy and pyelogram
	arteriosclerosis		**C & S**	culture and sensitivity
A–S attack	Adams–Stokes attack		**c/o**	complains of
ASB	asymptomatic bacteriuria		**C₁, C₂, …**	cervical vertebrae 1, 2, …
ASCA	anti-*Saccharomycs cerevisiae* antibodies		**CA**	cancer
ASD	atrial septal defect			carcinoma
ASLO titre	antistreptolysin-O titre			cardiac arrest
AST	aspartate transaminase			coronary artery
ATG	antithymocyte globulin		**Ca**	carcinoma
ATN	acute tubular necrosis		**CABG**	coronary artery bypass graft
AUC	area under the curve		**CAD**	coronary artery disease
AUR	acute urinary retention		**CAH**	chronic active hepatitis
AV	aortic valve		**CAP**	community-acquired pneumonia
	atrioventricular		**CAPD**	continuous ambulatory peritoneal dialysis
A-V	arteriovenous		**CAT**	computed axial tomography
AVNRT	atrioventricular nodal re-entry tachycardia		**CAVH**	continuous arteriovenous haemofiltration
AVR	aortic valve replacement		**CBA**	cost–benefit analysis
	augmented V lead, right arm (ECG)		**CBP**	chronic bacterial prostatitis
AVRT	atrioventricular re-entry tachycardia		**CBT**	cognitive behaviour therapy
AVS	arteriovenous shunt		**CC**	chief complaint
AXR	abdominal X-ray			current complaint
B Bx.	breast biopsy		**CCF**	congestive cardiac failure
BACUP	British Association of Cancer United Patients		**CCU**	coronary care unit
BBB	bundle branch block		**CEA**	cost-effectiveness analysis
BBBB	bilateral bundle branch block (ECG)		**CF**	cardiac failure
BCAA	branched-chain amino acid			complement fixation
BCC	basal cell carcinoma			cystic fibrosis
BCG	bacille Calmette–Guérin		**CFT**	complement fixation test
BDA	British Diabetic Association		**CGL**	chronic granulocytic leukaemia
BE	base excess		**CGN**	chronic glomerulonephritis
BEACOPP	bleomycin, etoposide, adriamycin (doxorubicin), cyclophosphomide, Oncovin (vincristine), procarbazine, prednisolone		**CHB**	complete heart block
			CHD	coronary heart disease
			CHF	congestive heart failure
BEAM	carmustine, etoposide, cytarabine, melphalan		**CHM**	Commision on Human Medicines
BG	blood glucose		**CHO**	carbohydrate
BHS	beta haemolytic streptococci		**CHOP**	cyclophosphamide, hydroxydaunorubicin (doxorubicin), Oncovin (vincristine), prednisolone
BIA	bioelectrical impedance analysis			
BJ protein	Bence-Jones protein		**CHOP-R**	cyclophosphamide, hydroxydaunorubicin (doxorubicin), Oncovin (vincristine), prednisolone, rituximab
BKA	below knee amputation			
BM	bowel movement			
BMI	body mass index		**CI**	cardiac index
BMT	bone marrow transplant			cerebral infarction
BNO	bowels not open		**CINV**	chemotherapy-induced nausea and vomiting
BOR	bowels open regularly		**CIVA**	centralized intravenous additive
BP	bypass, blood pressure		**CK**	creatine kinase (same as CPK)
BPA	British Paediatric Association		**CKD**	chronic kidney disease
BPD	bronchopulmonary dysplasia		**CL**	clubbing
BPE	benign prostatic enlargement		**ClCr**	creatinine clearance
BPH	benign prostatic hyperplasia		**CLD**	chronic liver disease
BS	blood sugar			chronic lung disease
	bowel sounds		**CLL**	chronic lymphocytic leukaemia
	breath sounds		**CMA**	cost minimization analysis
BSA	body surface area		**CML**	chronic myelocytic leukaemia
BW	body water		**CMV**	cytomegalovirus
	body weight		**CNS**	central nervous system

CNS	coagulase negative staphylococci
CO	cardiac output
CoA	co-enzyme A
COAD	chronic obstructive airways disease
COC	combined oral contraceptive
COD	cause of death
COG	closed angle glaucoma
COLD	chronic obstructive lung disease
COP	capillary osmotic pressure
COPD	chronic obstructive pulmonary disease
COX	cyclo-oxygenase
CP	cor pulmonale
	creatine phosphate
CP	chronic prostatitis
CPA	cardiopulmonary arrest
	cerebellar pontine angle
CPAP	continuous positive airway pressure
CPD	continuous peritoneal dialysis
CPK	creatine phosphokinase
CPN	chronic pyelonephritis
CPPS	chronic pelvic pain syndrome
CPPV	continuous positive pressure ventilation
CPR	cardiopulmonary resuscitation
CPSI	chronic prostatitis symptom index
CPZ	chlorpromazine
CR	cardiorespiratory
	clot retraction
	colon resection
	complete remission
	conditional reflex
	crown-rump
CRD	chronic renal disease
CRF	chronic renal failure
	corticotrophin-releasing factor
CRP	C-reactive protein
CSAP	cryosurgical ablation of prostate
CSF	cerebrospinal fluid
CSH	chronic subdural haematoma
CSM	carotid sinus massage
	cerebrospinal meningitis
CSP	carotid sinus pressure
CSR	Cheyne–Stokes respiration
	correct sedimentation rate
CSS	carotid sinus stimulation
	central sterile supply
CSU	catheter specimen of urine
CT	circulation time
	clotting time
	computer tomography
	Coombs' test
	coronary thrombosis
cTnI	cardiac troponin I
cTnT	cardiac troponin T
CTZ	chemoreceptor trigger zone
CUA	cost–utility analysis
CUG	cystourethrogram

CV	cardiovascular
	central venous
	cerebrovascular
	contingent valuation
CVA	cerebrovascular accident (stroke)
	costovertebral angle
CVD	cardiovascular disease
CVP	central venous pressure
CVVH	continuous venovenous haemofiltration
Cx	cervical, cervix
CXR	chest X-ray
d	dead
	deceased
D & C	dilation and curettage
D & V	diarrhoea and vomiting
D/C	discontinue
D/S	dextrose and saline
D5W	dextrose 5%
DADs	delayed after depolarisation
DAFNE	(insulin) dose adjustment for normal eating
DBP	diastolic blood pressure
DDx.	differential diagnosis
DES	diethylstilboestrol
DEXA	dual energy X-ray absorptiometry
DH	drug history
DIC	disseminated intravascular coagulation
DILD	drug-induced liver disease
DILI	drug-induced liver injury
DIP	drug-induced parkinsonism
DIT	di-iodotyrosine
DKA	diabetic ketoacidosis
DLBCL	diffuse large B cell lymphoma
DLE	discoid lupus erythematosus
	disseminated lupus erythematosus
DM	diabetes mellitus
	diastolic murmur
DMARDS	disease-modifying antirheumatic drugs
DNA	did not attend (outpatients)
DOA	dead on arrival
DOB	date of birth
DOD	date of death
DOE	dyspnoea on exertion
DOTS	Directly Observed Treatment Short course TB programme
DRE	digital rectal examination
DROP	dyslipidaemia, insulin resistance, obesity and high blood pressure
DSM	*Diagnostic and Statistical Manual of Mental Disorders*
DTI	direct thrombus imaging
DTP	diphtheria, tetanus, pertussis (vaccine)
DTs	delirium tremens
DU	diagnosis undetermined
	duodenal ulcer
DUB	dysfunctional uterine bleeding
DUE	drug use evaluation

DVT	deep vein thrombosis		**FRC**	functional reserve capacity
Dx.	diagnosis			functional residual capacity
DXT	deep X-ray therapy		**FSH**	follicle-stimulating hormone
E/I	expiration–inspiration ratio		**FSNGN**	focal segmental necrotising glomerulonephritis
EADs	early after depolarisations		**FT4**	free thyroxine
EBV	Epstein–Barr virus		**FTI**	free thyroxine index
ECBV	effective circulating blood volume		**FUO**	fever of unknown origin
ECF	extracellular fluid		**FVC**	forced vital capacity
ECFV	extracellular fluid volume		**Fx.**	fracture
ECG	electrocardiogram		**G6PD**	glucose-6-phosphate dehydrogenase
ECHO	echocardiogram		**GA**	general anaesthesia
	echoencephalogram			general appearance
ECMO	extracorporeal membrane oxygenation		**GABA**	g-aminobutyric acid
ECT	electroconvulsive therapy		**GABAA**	g-aminobutyric acid A
EDD	expected date of delivery		**GAD**	glutamic acid decarboxylase
EDV	end-diastolic volume		**GAD**	generalised anxiety disorder
EEG	electroencephalogram		**Gamma-GT**	g-glutamyl transferase
EENT	eyes, ears, nose and throat		**GB**	gallbladder
EGFR	epidermal growth factor receptor			Guillain–Barré (syndrome)
ELBW	extremely low birth weight		**GBM**	glomerular basement membrane
ELISA	enzyme-linked immunosorbent assay		**GBS**	Glasgow-Blatchford score
EM	ejection murmur		**G-CSF**	granulocyte-colony stimulating factor
EM	erythema multiforme		**GDM**	gastro-intestinal diabetes mellitus
EMG	electromyogram		**GF**	glomerular filtration
EN	erythema nodosum			gluten-free
ENT	ears, nose and throat		**GFR**	glomerular filtration rate
EP	ectopic pregnancy		**GGT**	g-glutamyl transpeptidase (transferase)
ER	(o)estrogen receptor		**GI**	gastro-intestinal
ERCP	endoscopic retrograde cholangiopancreatography		**GIK**	glucose, insulin and potassium
			GLA	g-linolenic acid
ERP	effective refractory period		**GM seizure**	grand mal seizure
ESBL	extended spectrum beta lactamase		**GM-CSF**	granulocyte macrophage colony stimulating factor
ESHAP	etoposide, methylprednisolone, cytarabine, cisplatin		**GN**	glomerulonephritis
ESM	ejection systolic murmur		**GNDC**	Gram-negative diplococci
ESN	educationally subnormal		**GnRH**	gonadotrophin-releasing hormone
ESP	end-systolic pressure		**GORD**	gastro-oesophageal reflux disease
ESR	erythrocyte sedimentation rate		**grav.**	gravid (pregnant)
ESRF	end-stage renal failure		**GRE**	glycopeptide-resistant enterococci
ET	endotracheal tube		**GS**	general surgery
ETT	exercise tolerance test			genital system
FAS	fetal alcohol syndrome		**GTN**	glyceryl trinitrate
FB	finger breadths		**GTT**	glucose tolerance test
FBS	fasting blood sugar		**GU**	gastric ulcer
FCE	finished consultant episode			genitourinary
FeNa	fractional excretion of sodium			gonococcal urethritis
FEV	forced expiratory volume		**GUS**	genitourinary system
FEV1	forced expiratory volume in 1 second		**GVHD**	graft-versus-host disease
FFA	free fatty acids		**H & L**	heart and lungs
FFP	fresh frozen plasma		**h/o**	history of
FH	familial hypercholesterolaemia		**HAA**	hepatitis-associated antigen
	family history		**HACAs**	human anti-chimeric antibodies
FHH	familial hypocalciuric hypercalcaemia		**HAP**	hospital-acquired pneumonia
FMD	fludarabine, mitoxantrone, dexametasone		**HAS**	human albumin solution
FOB	faecal occult blood		**HAV**	hepatitis A virus
FP	frozen plasma		**HB**	heart block

Hb (Hgb)	haemoglobin
HbA$_1$	glycated haemoglobin
HbA$_{1c}$	glycated haemoglobin
HbA$_2$	haemoglobin found in b-thalassaemia carriers
HBAg	hepatitis B antigen
HBD	hydroxybutyrate dehydrogenase
HBDH	hydroxybutyrate dehydrogenase
HBGM	home blood glucose monitoring
HbS	sickle haemoglobin in sickle cell disease
HBsAG	hepatitis B surface antigen
HBV	hepatitis B virus
HCAI	healthcare-associated infections
Hct. (hct.)	haematocrit
HCV	hepatitis C virus
HDL	high-density lipoprotein
HDL-C	high-density lipoprotein cholesterol
HDT	high-dose therapy
HER1	human epidermal growth factor receptor type 1
HER2	human epidermal growth factor receptor type 2
HF	heart failure
HHV	human herpes virus
Hib	*Haemophilus influenzae* type b
HIE	hypoxic-ischaemic encephalopathy
HIFU	high intensity focussed ultrasound
HIT	heparin induced thrombocytopaenia
HIV	human immunodeficiency virus
HLA	human lymphocyte antibody
HMD	hyaline membrane disease
HMMA	4-hydroxy-3-methoxymandelic acid
hMPV	human metapneumovirus
HO	house officer
HONK	hyperosmolar non-ketotic hyperglycaemia
HPEN	home parenteral and enteral nutrition
HPI	history of present illness
HPN	home parenteral nutrition
HPRT	hypoxanthine-guanine phosphoribosyl transferase deficiency
HPV	human papilloma virus
HR	heart rate
HRS	hepatorenal syndrome
HRT	hormone replacement therapy
HS	half strength
	Hartmann's solution
	heart sounds
HSA	human serum albumin
HSCT	hematopoietic stem cell transplantation
HSV	herpes simplex virus
HT, HTN	hypertension
HUS	haemolytic uraemic syndrome
HVA	homovanillic acid
HVD	hypertensive vascular disease
Hx.	history
i.v.	intravenous
IADHS	inappropriate antidiuretic hormone syndrome
IBC	iron binding capacity
IBD	inflammatory bowel disease
IBS	irritable bowel syndrome

IC	intercostal
	intracerebral
	intracranial
ICA	islet cell antibody
ICD	*International Classification of Diseases*
ICD	implantable cardioverter-defibrillator
ICD	impulse control disorder
ICE	ifosfamide, carboplatin, etoposide
ICF	intracellular fluid
ICH	intracerebral haemorrhage
ICM	intracostal margin
ICS	intercostal space
ICS	inhaled cortocosteroids
ICU	intensive care unit
ID	intradermal
IDDM	insulin-dependent diabetes mellitus
IDL	intermediate-density lipoprotein
IDL-C	intermediate-density lipoprotein cholesterol
IDP	intradialytic parenteral nutrition
IEP	immunoelectrophoresis
IFRT	involved field radiotherapy
Ig	immunoglobulin
iGAS	invasive group A streptococcal infection
IGT	impaired glucose tolerance
IHC	immunohistochemistry
IHD	ischaemic heart disease
IHR	intrinsic heart rate
IMI	inferior myocardial infarction
IMP	impression
Inf. MI	inferior myocardial infarction
INR	international normalized ratio
IOP	intraocular pressure
IPCN	International Prostatitis Collaborative Network
IPF	idiopathic pulmonary fibrosis
IPI	International Prognostic Index
IPP	intermittent positive-pressure inflation with oxygen
IPPB	intermittent positive-pressure breathing
IPPV	intermittent positive-pressure ventilation
IRDS	idiopathic respiratory distress syndrome
ISA	intrinsic sympathomimetic activity
ISDN	isosorbide dinitrate
ISI	International Sensitivity Index
ISMN	isosorbide mononitrate
IT	intrathecal(ly)
ITT	insulin tolerance test
IUCD	intrauterine contraceptive device
IUD	intrauterine death
	intrauterine device
IVD	intervertebral disc
IVH	intraventricular haemorrhage
IVP	intravenous push
	intravenous pyelography
IVSD	interventricular septal defect
IVU	intravenous urography
J	jaundice
JVD	jugular venous distension
JVP	jugular venous pressure

KA	ketoacidosis
KCCT	kaolin-cephalin clotting time
KLS	kidney, liver, spleen
KS	Kaposi's sarcoma
KUB	kidneys, ureters, bladder
L	left
	lower
	lumber
L & A	light and accommodation
L & U	lower and upper
L & W	living and well
L$_1$, L$_2$, …	lumbar vertebrae 1, 2, …
LA	left arm
	left atrium
	local anaesthesia
LABA	long-acting β$_2$-adrenoceptor agonist
LAD	left anterior descending
LADA	latent autoimmune diabetes in adults
LAMA	long acting antimuscarinic
LBBB	left bundle branch block
LBM	lean body mass
LBW	low birth weight
LCAT	lecithin-cholesterol acyltransferase
LCT	long-chain triglyceride
LD, LDH	lactate dehydrogenase
LDL	low-density lipoprotein
LDL-C	low-density lipoprotein cholesterol
LDS	lipodermatosclerosis
LE	lupus erythematosus
LFT	liver function test
LH	luteinizing hormone
LHRH	luteinizing hormone-releasing hormone
LIF	left iliac fossa
LK	left kidney
LKKS	liver, kidneys, spleen
LKS	liver, kidney, spleen
LL	left leg
	left lower
	lower lobe
LLL	left lower lobe
	left lower lid
LLQ	left lower quadrant
LMN	lower motor neurone
LMP	last menstrual period
LMWH	low molecular weight heparin
LN	lymph node
LNG-IUS	levonorgestrel intrauterine system
LNMP	last normal menstrual period
LOM	limitation of movement
LP	lumbar puncture
Lp(a)	lipoprotein a
LPA	left pulmonary artery
LS	left side
	liver and spleen
	lumbosacral
	lymphosarcoma
LSD	lysergic acid diethylamide
LSK	liver, spleen, kidneys

LSM	late systolic murmur
LT	leukotriene
LTBI	latent tuberculosis infection
LTC	long-term care
LTOT	long-term oxygen therapy
LUL	left upper lobe
LUQ	left upper quadrant
LV	left ventricle
LVDP	left ventricular diastolic pressure
LVE	left ventricular enlargement
LVEDP	left ventricular end-diastolic pressure
LVEDV	left ventricular end-diastolic volume
LVET	left ventricular ejection time
LVF	left ventricular failure
LVH	left ventricular hypertrophy
LVP	left ventricular pressure
M	male
	married
	metre
	mother
	molar
	murmur
M:P	milk-to-plasma ratio
MABP	mean arterial blood pressure
MAC	*Mycobacterium avium* complex
MAI	*Mycobacterium avium-intracellulare*
MALT	mucosal-associated lymphoid tissue
MAMC	mid-arm muscle circumference
MAO-A	monoamine oxidase A
MAO-B	monoamine oxidase B
MAOI	monoamine oxidase inhibitor
MAP	mean arterial pressure
MARS	molecular adsorbent recycling system
MBC	minimum bactericidal concentration
MBP	mean blood pressure
MCH	mean corpuscular cell haemoglobin
MCHC	mean corpuscular cell haemoglobin concentration
MCP	metacarpophalangeal (joint)
MCT	medium-chain triglycerides
MCV	mean corpuscular cell volume
MD	mitral disease
	muscular dystrophy
MDI	metered-dose inhaler
MDM	mid-diastolic murmur
MDMA	methylene dioxymethamphetamine, ecstasy
MDRD	modification of diet in renal disease formula for GFR estimation
MDRST	multidrug-resistant *S. enterica* serovar typhi
MDRTB	multidrug-resistant tuberculosis
MDR-TB	multidrug-resistant tuberculosis
MDS	myelodydysplastic syndrome
MEN	multiple endocrine neoplasia
met.	metastatic (metastasis)
MGN	membranous glomerulonephritis
MH	medical history
	menstrual history
MHPG	methoxyhydroxyphenylglycerol

933

MHRA	Medicines and Healthcare products Regulatory Agency		**NaSSA**	noradrenergic and specifc serotonergic antidepressant
MI	myocardial infarction		**NBM**	nil by mouth
	mitral incompetence		**NEC**	necrotizing enterocolitis
MIC	minimum inhibitory concentration		**NG**	nasogastric
MID	multi-infarct dementia		**NHL**	non-Hodgkin's lymphoma
MIRU	mycobacterial interspersed repetitive unit typing		**NIDDM**	non-insulin-dependent diabetes mellitus
MIT	monoiodotyrosine		**NKHA**	non-ketotic hyperosmolar acidosis
ML	middle lobe		**NLPHL**	nodular lymphocyte-predominant Hodgkin's lymphoma
	midline		**NMR**	nuclear magnetic resonance
MMR	measles, mumps, rubella		**NMS**	neuroleptic malignant syndrome
MMSE	mini mental state examination		**NNRTI**	non-nucleoside reverse transcriptase inhibitor
MODY	maturity-onset diabetes of the young		**NOF**	neck of femur
MOPP	mustine, Oncovin (vincristine), procarbazine, prednisolone		**NS**	nephrotic syndrome
				nervous system
MOTT	mycobacteria other than tuberculosis			normal saline
MPJ	metacarpophalangeal joint			no specimen
MR	mitral regurgitation		**NSAID**	non-steroidal anti-inflammatory drug
MRA	magnetic resonance angiography		**NSFTD**	normal spontaneous full-term delivery
MRD	minimal residual disease		**NSR**	normal sinus rhythm
MRDM	malnutrition-related diabetes mellitus		**NSTEMI**	non-ST-elevated myocardial infarction
MRI	magnetic resonance imaging		**NSU**	non-specific urethritis
MRSA	methicillin-resistant *Staphylococcus aureus*		**NT**	nasotracheal (tube)
MS	mitral stenosis		**NTS**	nucleus tractus solitarius
	multiple sclerosis		**NVD**	nausea, vomiting, diarrhoea
	musculoskeletal		**O**	oedema
MSL	midsternal line		**O & A**	observation and assessment
MSSA	methicillin-sensitive *Staphylococcus aureus*		**O & E**	observation and examination
MSU	midstream urine specimen		**O/A**	on admission
MTB	*Mycobacterium tuberculosis*		**O/E**	on examination
MTI	minimum time interval		**OA**	osteoarthritis
MTP	metatarsophalangeal		**OAD**	obstructive airway disease
MUD	matched unrelated donor		**OAG**	open angle glaucoma
MV	minute volume		**OB**	occult blood
	mitral valve		**OCD**	obsessive compulsive disorder
MVP	mitral valve prolapse		**OD**	overdose
MVPP	mustine, vinblastine, procarbazine, prednisolone		**OGTT**	oral glucose tolerance test
			OH	occupational history
MVR	mitral valve replacement		**OHT**	ocular hypertension
MWH	moist wound healing		**OI**	opportunistic infection
N	normal		**OKGA**	ornithine salt of a-ketoglutaric acid
N & T	nose and throat		**OLT**	orthoptic liver transplantation
N & V	nausea and vomiting		**OPA**	outpatient appointment
NAAT	nucleic acid amplification techniques		**OPD**	outpatient department
NAD	no appreciable disease		**OSAHS**	obstructive sleep apnoea hypopnoea syndrome
	normal axis deviation		**OT**	occupational therapy
	nothing abnormal detected		**P & A**	percussion and auscultation
NADPH	nicotinamide adenine dinucleotide phosphate hydrogen		**P & V**	pyloroplasty and vagotomy
			PA	pernicious anaemia
NAFLD	non-alcoholic fatty liver disease			pulmonary artery
NAG	narrow angle glaucoma		**PACG**	primary angle-closure glaucoma
NAI	neuraminidase inhibitor		**PaCO$_2$**	arterial carbon dioxide tension
NAPQI	*N*-acetyl-*p*-benzoquinoneimine		**PAD**	peripheral arterial disease
NARI	noradrenergic reuptake inhibitor		**PAF**	platelet-activating factor
NARTI	nucleoside analogue reverse transcriptase inhibitor		**PAH**	pulmonary artery hypertension
			pANCA	perinuclear antineutrophil cytoplasmic antibodies
NASH	non-alcoholic steatohepatitis			

934

PaO₂	arterial oxygen tension
PAPS	primary antiphospholipid syndrome
PAS	*P*-aminosalicylic acid
	pulmonary artery stenosis
PAT	paroxysmal atrial tachycardia
PAWP	pulmonary artery wedge pressure
PB	premature beats
PBC	primary biliary cirrhosis
PBI	protein-bound iodine
PBSCT	peripheral blood stem cell transplantion
PC	prostate cancer
PCA	patient-controlled analgesia
PCAS	patient-controlled analgesia system
PCI	percutaneous coronary intervention
PCO₂	partial pressure of carbon dioxide
PCR	polymerase chain reaction
PCS	portocaval shunt
PCV	packed cell volume
PD	peritoneal dialysis
PDA	patent ductus arteriosus
PE	physical examination
	pleural effusion
	pulmonary embolism
PEARLA	pupils equal and react to light and accommodation
PEF	peak expiratory flow
PEFR	peak expiratory flow rate
PEG	percutaneous endoscopic gastrostomy
PEJ	percutaneous endoscopic jejunostomy
PEM	prescription event monitoring
PEM	protein energy malnutrition
PEP	post exposure prophylaxis
PERLA	pupils equal, react to light and accommodation
PERRLA	pupils equal, round, react to light and accommodation
PET	position emission tomography
PF	peak flow
PF4	platelet factor 4
PFR	peak flow rate
PFT	pulmonary function test
PG	prostaglandin
P-gp	P-glycoprotein
PH	past history
	patient history
	personal history
	prostatic hypertrophy
	pulmonary hypertension
PHI	primary HIV infection
PI	present illness
	protease inhibitor
PICC	peripherally inserted central catheter
PID	pelvic inflammatory disease
PIN	prostatic intra-epithelial neoplasia
PIP	proximal interphalangeal joint
PIVD	protruded intervertebral disc
PJB	premature junctional beat
PJC	premature junctional contraction
PJP	*Pneumocystis jiroveci* pneumonia
PKU	phenylketonuria

PL	product licence
PLL	prolymphocytic leukaemia
PMDD	premenstrual dysphoric disorder
PMH	past medical history
PMI	past medical illness
PMN	polymorphonucleocyte
PMS	premenstrual syndrome
	postmenopausal syndrome
PMT	premenstrual tension
PMV	prolapsed mitral valve
PN	percussion note
	peripheral nerve
	peripheral neuropathy
PND	paroxysmal nocturnal dyspnoea
	postnasal drip
PO₂	partial pressure of oxygen
POAG	primary open-angle glaucoma
POMR	problem-oriented medical record
PONV	postoperative nausea and vomiting
PPAR-g	proliferative-activated receptor-g
PPD	purified protein derivative
PPH	postpartum haemorrhage
PPI	proton pump inhibitor
PPNG	penicillinase-producing *Neisseria gonorrhoeae*
PPV	positive-pressure ventilation
PR	per rectum
	progestogen receptor
PRCA	pure red cell aplasia
PREP	pre-exposure prophylaxis
PROM	premature rupture of membranes
PS	pulmonary stenosis
	pyloric stenosis
PSA	prostate-specific antigen
PSG	presystolic gallop
PSGN	poststreptococcal glomerulonephritis
PSVT	paroxysmal supraventricular tachycardia
PT	parathyroid
	paroxysmal tachycardia
	physical therapy
	physical training
	posterior tibial (pulse)
	prothrombin time
PTC	percutaneous cholangiogram
PTH	parathyroid hormone
PTLD	post-transplant lymphoproliferative disorder
PTSD	post traumatic stress disorder
PTT	partial thromboplastin time
PTTK	partial thromboplastin time kaolin
PTU	propylthiouracil
PU	pass urine
	per urethra
	peptic ulcer
PUD	peptic ulcer disease
	pulmonary disease
PUO	pyrexia (fever) of unknown origin
PUVA	psoralen and ultraviolet A radiation
PV	vaginal examination (per vagina)
PVB	premature ventricular beat

PVC	premature ventricular contraction
PVD	peripheral vascular disease
PVP	pulmonary venous pressure
PVR	post-void residual
PVT	paroxysmal ventricular tachycardia
Px.	past history
	prognosis
QALY	quality-adjusted life-year
R	respiration
RA	renal artery
	rheumatoid arthritis
	right arm
	right atrial (atrium)
RAST	radio-allergosorbent test
RBBB	right bundle branch block
RBC	red blood cell
	red blood (cell) count
RBS	random blood sugar
R-CVP	rituximab, cyclophosphamide, vincristine, prednisolone
RDS	respiratory distress syndrome
REMS	rapid eye movement sleep
Re-PUVA	PUVA treatment with retinoids
RF	renal failure
	rheumatic fever
	rheumatoid factor
RFT	respiratory function tests
Rh factor	rhesus factor
RHF	right heart failure
RHL	right hepatic lobe
rhuEPO	recombinant human erythropoietin
rhuGM-CSF	recombinant human granulocyte-macrophage colony-stimulating factor
RIF	right iliac fossa
RIMA	reversible inhibitor of monoamine oxidase type A
RITA	radiofrequency interstitial tumour ablation
RK	right kidney
RL	right leg
	right lung
RLC	residual lung capacity
RLD	related living donor
RLL	right lower lobe (lung)
RLQ	right lower quadrant (abdomen)
RP	radial pulse
RPGN	rapidly progressive glomerulonephritis
RPI	resting pressure index
RQ	respiratory quotient
RR	respiratory rate
RR & E	round, regular and equal (pupils)
RRT	renal replacement therapy
RS	respiratory system
RSF	rheumatoid serum factor
RSV	respiratory syncytial virus
RTA	road traffic accident
rt-PA	recombinant plasminogen activator
RUL	right upper lobe
RUQ	right upper quadrant

RV	residual volume
	right ventricle
RVH	right ventricular hypertrophy
RVOT	right ventricular outflow tract
SA	sinoatrial (node)
	Stokes–Adams (attacks)
	surface area
SAH	subarachnoid haemorrhage
SARS	severe acute respiratory syndrome
SARS CoV	severe acute respiratory syndrome-associated coronovirus
SB	seen by
	shortness of breath
SBE	subacute bacterial endocarditis
	shortness of breath on exertion
SBO	small bowel obstruction
SBP	spontaneous bacterial peritonitis
sCT	spiral computed tomography
SCU	*see* SCUF
SCUF	slow continuous ultrafiltration
SDD	selective decontamination of the digestive tract
SEM	systolic ejection murmur
SERM	selective estrogen receptor modulator
SGOT	serum glutamate-oxaloacetate transaminase
SGPT	serum glutamate-pyruvate transaminase
SH	social history
SIADH	syndrome of inappropriate antidiuretic hormone
SIDS	sudden infant death syndrome
SJS	Stevens–Johnson syndrome
SLE	systemic lupus erythematosus
SmPC	summary of product characteristics
SNRI	serotonin-noradrenaline reuptake inhibitor
SOA	swelling of ankle(s)
SOAP	subjective, objective, assessment, plan
SOB	short of breath
SOBOE	short of breath on exertion
SP	systolic pressure
SPA	suprapubic aspiration
SPC	Summary of Product Characteristics
SR	sinus rhythm
	sustained release
SS	serotonin syndrome
SSI	surgical site infection
SSRI	selective serotonin reuptake inhibitor
ST	sinus tachycardia
stat.	immediately (Latin: statim)
STD	sexually transmitted disease
STS	sodium tetradecyl sulphate
STS	serological tests for syphilis
SV	stroke volume
SVI	stroke volume index
SVT	supraventricular tachycardia
SWS	slow-wave sleep
Sx.	symptoms
T	temperature
T & C	type and cross-match

T & X	type and cross-match
T$_3$	tri-iodothyronine
T$_4$	thyroxine
TAGvHD	transfusion-assisted graft-versus-host disease
TB	tuberculosis
TBA	to be administered
	to be arranged
TBG	thyroid-binding globulin
TBI	total body irradiation
TBM	tuberculous meningitis
TBW	total body weight
TC	total capacity
	total cholesterol
	tricarboxylic acid cycle
TCA	tricyclic antidepressant
TDM	therapeutic drug monitoring
TEN	toxic epidermal necrolysis (Lyell's syndrome)
TENS	transcutaneous electrical nerve stimulation
TF	tissue factor
TFTs	thyroid function tests
TGF	tubuloglomerular feedback
TGs	triglycerides
TH	thyroid hormone (thyroxine)
THA	tetrahydroaminoacridine
THC	tetrahydrocannabinol
TIA	transient ischaemic attack
TIBC	total iron-binding capacity
TIMP	tissue inhibitor of metalloproteinases
TIPSS	transjugular intrahepatic portosystemic shunting
TKI	tyrosine kinase inhibitor
TLC	total lung capacity
	tender loving care
TLCO	transfer factor of the lung for carbon monoxide
TLS	tumour lysis syndrome
TNF	tumour necrosis factor
TNF-α	tumour necrosis factor alpha
TNM	tumour node metastasis
TP & P	time, place and person
t-PA	tissue plasminogen factor
TPMT	thiopurine methyl transferase
TPMT	thiopurine methyltransferase testing
TPN	total parenteral nutrition
TPR	temperature, pulse, respiration
tPSA	total prostate specific antigen
TRABs	thyroid receptor antibodies
TRH	thyrotrophin-releasing hormone
TRUS	transrectal ultrasonography
TSF	triceps skinfold thickness
TSH	thyroid-stimulating hormone
TTA	transtracheal aspiration
TTO	to take out (to take home)
TUIP	transurethral incision of the prostate

TUMT	transurethral microwave heat treatment
TUR	transurethral resection
TURB	transurethral resection of the bladder
TURP	transurethral resection of the prostate
TV	tidal volume
TVN	tissue viability nurse
TWOC	trial without catheter
Tx.	transfusion
	treatment
U & E	urea and electrolytes
UBIC	unsaturated iron-binding capacity
UC	ulcerative colitis
UFH	unfractionated heparin
UPCR	urine protein creatinine ratio
URTI	upper respiratory tract infection
US	ultrasound
UTI	urinary tract infection
UVA	ultraviolet A
UVB	ultraviolet B
V/Q	ventilation-perfusion ratio
VaD	vascular dementia
VC	vital capacity
	vulvovaginal candidiasis
VD	venereal disease
VDRL	Venereal Disease Research Laboratory (test for syphilis)
VEGF	vascular endothelial growth factor
VF	ventricular fibrillation
VHD	valvular heart disease
VKA	vitamin K antagonist
VLBW	very low birth weight
VLDL	very low-density lipoprotein
VMA	vanillyl mandelic acid
VNTR	variable number of tandem repeats typing
VP	venous pressure
VPC	ventricular premature contraction
VS	vital signs
VT	ventricular tachycardia
VTE	venous thromboembolism
VTEC	verotoxin-producing *E. coli*
VUR	vesicoureteric reflux
VVC	vulvo vaginal candidiasis
WBC	white blood cell
	white blood count
WCC	white cell count
WHO	World Health Organization
WPW	Wolff–Parkinson–White (syndrome)
WR	Wassermann reaction
WTA	willingness to accept
WTP	willingness to pay
XDR-TB	extensively drug resistant tuberculosis
ZE	Zollinger–Ellison (syndrome)
ZIG	zoster immune globulin
ZPP	zinc protoporphyrin

Glossary

Acanthosis nigricans Diffuse velvety acanthosis with grey, brown or black pigmentation, chiefly in axilla and other body folds, occurring in an adult form, often associated with an internal carcinoma and in a benign, nevoid form, more or less generalised.

Achlohydria Absence of hydrochloric acid from maximally stimulated gastric secretion.

Acral Pertaining to or affecting a limb or other extremity.

Acropachy Clubbing of the fingers and toes with distal periosteal bone changes and swelling of the overlying soft tissues.

Addisonian crisis The symptoms that accompany an acute onset or worsening of Addison's disease, including fatigue, nausea and vomiting, loss of weight, hypotension, fever and collapse.

Adenomyosis Penetration of an endometrial tissue into the myometrium.

Agenesis Absence of an organ.

Agyria Congenital malformation or absence of the convolutions of the cerebral cortex.

Alloimmunity Immunity to an alloantigen.

Alport syndrome Hereditary disease of the kidneys that primarily affects men. Heterogeneous group of conditions may manifest including glomerulonephritis, hematuria, proteinuria, hypertension, nephrotic syndrome, end-stage renal disease, and variably accompanied by sensorineural deafness, coloured urine, swelling, cough, poor vision. Eventually, kidney dialysis or transplant may be necessary.

Amphipathic Molecules containing groups with characteristically different properties, for example both hydrophilic and hydrophobic properties.

Amphoteric Having opposite characters, that is capable of acting as an acid and a base.

Anoxaemia Reduction of blood oxygen content below physiological levels.

Anthropometry The science which deals with the measurement of the size, weight and proportions of the human body.

Aphakia No lens.

Aplasia cutis Localised failure of development of skin.

Apnoea Cessation of breathing.

Apoptosis Programmed destruction of cells; mechanism that keeps cell numbers in check by eliminating senescent cells or those without useful cell function.

Arachnoiditis Inflammation of the arachnoidea, a delicate membrane inter-posed between the dura mater and the pia mater.

Ataxia telangectasia Hereditary disorder with severe progressive cerebellar ataxia, associated with oculocutaneous telangectasia, sinopulmonary disease with frequent respiratory infections and abnormal eye movements.

Atelectasis Incomplete expansion of a lung.

Atretic Without an opening; characterised by atresia.

Auspitz's sign Removal of a yellow-white, sharply demarcated plaque of psoriasis, results in pinpoint hemorrhage.

Azoospermia Absence of spermatozoa in the semen, or failure of formation of spermatozoa.

Bacteriuria The presence of bacteria in the urine.

Barrett's oesophagus A precancerous condition in which normal cells lining the oesophagus are replaced with abnormal cells that may develop into an adenocarcinoma.

Beau's lines Transverse depression of the nail that represents interruption to the normal growth of the nail matrix.

BK virus A human polyomavirus that causes widespread infection in childhood and remains latent in the host; believed to cause hemorrhagic cystitis and nephritis in immunocompromised patients.

Bronchiectasis Characterised by dilation of the small bronchi and bronchioles, associated with the presence of chronic pulmonary sepsis. It presents as a chronic cough, often with the production of large amounts of purulent, foul-smelling sputum, and may eventually lead to repeated episodes of pneumonia and respiratory failure.

Bronchoalveolar lavage A procedure performed during bronchoscopy in which the bronchial tree is literally washed (lavaged) with a small volume of sterile saline. The saline is then collected and sent for microbiological or cytological examination.

Bronchoscopy The procedure in which a flexible fibreoptic endoscope is inserted into the bronchial tree to allow direct visualization of the bronchi and, if required, the collection of specimens for microbiology or histology.

Brugada syndrome A genetic disease characterised by an abnormal electrocardiogram and an increased risk of sudden cardiac death. More prevalent in those from South East Asia.

Bruxism Tooth grinding.

Budd–Chiari syndrome Symptomatic obstruction or occlusion of the hepatic veins, usually of unknown origin but probably caused by neoplasms, strictures, liver disease, trauma, systemic infections or haematological disorders.

Buerger's test Two part test to assess adequacy of the arterial supply to the leg.

Cachectic A profound and marked state of general ill health and malnutrition.

Cardiogenic emboli Emboli originating from the heart; caused by abnormal function of the heart.

Carpal tunnel syndrome A complex of symptoms resulting from compression of the median nerve in the carpal tunnel, with pain and burning or tingling paraesthesias in the fingers and hand, sometimes extending to the elbow.

Catamenia Term used to designate age at onset of menses.

Cataract An opacity of the crystalline lens of the eye.

Cavitation Formation of cavities. For example, in the lungs when the liquefied centre of a tuberculous lesion drains (usually into a bronchus).

Charcot's arthropathy A destructive arthropathy (disease of any joint) with impaired pain perception or position sense.

Cholelithiasis The presence or formation of gallstones.

Chondrocyte A mature cartilage cell embedded in a lacuna (a small pit or hollow cavity) within the cartilage matrix.

Christmas disease Haemophilia B.

Churg–Strauss syndrome Allergic granulomatosis.

Chvostek's sign Spasm of the facial muscles elicited by tapping the facial nerve in the region of the parotid gland, seen in tetany.

Coarctation of the aorta A localised malformation characterised by deformity of the aortic media, causing narrowing, usually severe, of the lumen of the vessel.

Cognitive Pertaining to cognition; that operation of the mind by which we become aware of objects of thought or perception; it includes all aspects of perceiving, thinking and remembering.

Corneal arcus Crescentic deposition of lipids in the cornea.

Cor pulmonale Persistent lung damage, eventually leads to increased blood pressure in the pulmonary arteries (pulmonary hypertension), which in turn leads to stress on the right ventricle, right ventricular hypertrophy and heart failure. This process is known as cor pulmonale.

Cryptogenic Obscure, doubtful or unascertainable origin.

Cytotoxin A toxin or antibody that has a specific toxic action upon cells of special organs.

Denudation Removal of the epithelial covering from any surface.

Diarthrodial joint A joint characterised by mobility in a rotary direction.

Dimorphic Occurring in two distinct forms.

Disseminated intravascular coagulation (DIC) In this condition vigorous activation of the clotting cascade causes widespread intravascular deposition of fibrin and consumption of clotting factors and platelets. There are numerous potential triggers for this process, including severe sepsis, burns, massive transfusion and placental abruption.

Diverticulosis The presence of circumscribed pouches or sacs of variable size called diverticula that occur normally or are created by herniation of the lining mucous membrane through a defect in the muscular coat of a tubular organ such as the gastro-intestinal tract.

Ductopenia Absence/shortage of ducts; typically absence of interlobular bile ducts.

Dubin–Johnson syndrome Familial chronic form of non-haemolytic jaundice due to a defect in the excretion of conjugated bilirubin and other organic anions.

Dupuytren's contracture Shortening, thickening and fibrosis of the palmar fascia, producing a flexion deformity of a finger. The term also applies to a flexion deformity of a toe.

Dyschezia Difficult or painful evacuation of faeces from the rectum.

Dyskinesia Impairment of the power of voluntary movement, resulting in fragmentary or incomplete movements.

Dyspareunia Difficult or painful intercourse.

Dyspnoea Difficult or laboured breathing.

Dystonia Disordered tonicity of muscle.

Dysuria Painful or difficult urination.

Eclampsia Convulsions and coma occurring in a pregnant or puerperal woman, associated with hypertension, oedema and/or proteinuria.

Electrodiathermy Heating of the body tissues due to their resistance to the passage of an electric current.

Elliptocytosis A hereditary disorder in which the majority of erythrocytes are elliptical in shape, and characterised by varying degrees of increased red cell destruction and anaemia.

Emphysema A state in which the alveoli of the lung become dilated, possibly with destruction of the alveolar walls, leading to large empty air spaces which are useless for gas exchange. It is often seen accompanying chronic bronchitis but may be due to inherited disorders such as a_1-antitrypsin deficiency.

Encephalopathy Any degenerative disease of the brain.

Endophthalmitis Inflammation involving the ocular cavities and their adjacent structures.

Enterostomy The formation of a permanent opening into the intestine through the abdominal wall.

Enterotoxin A toxin arising in the intestine.

Episcleritis Inflammation of the loose connective tissue forming the external surface of the sclera.

Epstein–Barr virus A herpes virus originally isolated from Burkitt lymphomas and believed to be the aetiological agent in infectious mono-nucleosis or closely related to it.

Euthymic Normal state of thymus.

Exanthema Widespread rash usually occurring in children caused by toxins, drugs, micro-organisms or autoimmune disease.

Faecal Occult blood in the stools. Called 'occult' because it is partly digested and therefore no longer red in colour. Usually detected by means of a chemical test.

Fanconi's anaemia A rare hereditary disorder, transmitted in a recessive manner and having a poor prognosis, characterised by pancytopenia, hypoplasia of the bone marrow, and patchy brown discoloration of the skin due to the deposition of melanin, and associated with multiple congenital anomalies of the musculoskeletal and genitourinary systems.

Fastidious organism Organism which will only grow with specialist culture media or under certain physiological conditions.

Feculent Having dregs or a sediment.

Felty's syndrome Combination of chronic rheumatoid arthritis, splenomegaly, leucopenia, pigmented spots on the skin of the lower extremities.

Fibroadenoma Benign tumour that is made of glandular and fibrous tissue and typically occurs in breast tissue.

Fibromuscular Composed of fibrous and muscular tissue.

Fistula An abnormal passage or communication, usually between two internal organs or from an internal organ to the surface of the body.

Foreign body giant cells Giant cells resembling Langhan's giant cells, having clusters of nuclei scattered in an irregular pattern throughout the cytoplasm, characteristic of granulomatous inflammation due to invasion of the tissue by a foreign body.

Gastroschisis Congenital fissure of the abdominal wall not involving the site of insertion of the umbilical cord, and usually accompanied by protrusion of the small and part of the large intestine.

Gaucher's disease Group of hereditary disorders of glucocerebroside metabolism characterised by accumulation of glucocerebroside in the spleen, liver, lungs, bone marrow, and sometimes the brain leading to splenomegaly, hepatomegaly, erosion of the cortices of the long bones and pelvis, and CNS impairment.

Glasgow-Blatchford score Screening tool to assess likelihood that a patient with an acute upper gastro-intestinal bleed will require medical intervention.

Glomerulonephritis Nephritis characterised by inflammation of the capillary loops in the glomeruli of the kidney.

Glossitis Inflammation of the tongue.

Goerkerman regimen Combination of coal tar and UVB light to bombard the skin with anti-psoriasis treatment.

Gonioscopy Estimate of the width of the eye chamber angle, measured using a slit-lamp.

Goodpasture's disease Autoimmune disease characterised by glomerulonephritis and hemorrhaging from the lung.

Granuloma A tumour-like mass or nodule of granulation tissue, with actively growing fibroblasts and capillary buds; it is due to a chronic inflammatory process associated with infectious disease or with invasion by a foreign body.

Guillain–Barré syndrome Acute febrile polyneuritis.

Haematuria Blood in the urine.

Haem(at)opoiesis The formation and development of blood cells.

Harris Benedict equation Equation first developed in 1919 to predict basal energy expenditure.

Hasenclever score Prognostic score for Hodgkins disease.

Haustral Pertaining to the haustra of the colon, denoting sacculations in the wall of the colon produced by adaptation of its length.

Heberden's nodes Gelatinous cysts or bony outgrowths on the dorsal aspects of the distal interphalangeal joints.

Heinz bodies Inclusion bodies in red blood cells resulting from oxidative injury to and precipitation of haemoglobin, seen in the presence of certain abnormal haemoglobins and erythrocytes with enzyme deficiencies.

Henoch–Schönlein purpura An acute or chronic vasculitis primarily affecting skin, joints and the gastro-intestinal and renal systems.

Hepatorenal syndrome Development of renal failure secondary to liver disease.

Hirschsprung's disease Congenital megacolon.

Horner's syndrome Sinking in of the eyeball, ptosis of the upper eyelid, slight elevation of the lower lid, constriction of the pupil, narrowing of the palpebral fissure, anhidrosis and flushing of the affected side of the face; caused by paralysis of the cervical sympathetic nerves.

Horton's syndrome Migrainous neuralgia; also called paroxysmal nocturnal cephalalgia.

Huntington's chorea A rare hereditary disease characterised by chronic progressive chorea and mental deterioration terminating in dementia. The age of onset is variable but usually occurs in the fourth decade of life.

Hyaline membrane A layer of eosinophilic hyaline material lining the alveoli, alveolar ducts and bronchioles, found at autopsy in infants who have died of respiratory distress syndrome of the newborn.

Hypermelanosis Excessive deposition of melanin.

Hypersplenism A condition characterised by exaggeration of the inhibitory or destructive functions of the spleen, resulting in deficiency of the peripheral blood elements, singly or in combination, hypercellularity of the bone marrow, and usually splenomegaly.

Hypertrichosis Growth of hair at sites not normally hairy.

Hypophonic Reduced volume of speech.

Hypovolaemia Abnormally reduced volume of circulating fluid in the body/plasma.

Ileus Obstruction or lack of smooth muscle tone in the intestines.

Immunoblastic Pertaining to or involving the stem cells (immunoblasts) of lymphoid tissue.

Index case The first detected case in a particular series that prompts investigation into other patients.

Interstitial nephritis Inflammation of the renal interstitial tissue resulting from arterial, arteriolar, glomerular or tubular disease which destroys individual nephrons.

Intussusception The prolapse of one part of the intestine into the lumen of an immediately adjoining part.

Jod–Basedow syndrome Thyrotoxicosis produced in a patient with goitre, when given a bolus of iodine.

Kayser–Fleischer ring A grey-green to red-gold pigmented ring at the outer margin of the cornea, seen in progressive lenticular degeneration and pseudosclerosis.

Koebner phenomenon Induction of new psoriasis skin lesions following local trauma or injury to the skin.

Koilonychia Dystrophy of the fingernails, in which they are thin and concave, with edges raised.

Kussmaul's respiration Air hunger.

Kwashiorkor Insufficient protein provision.

Kyphosis Abnormally increased convex curvature of the spinal column.

Labyrinthitis Inflammation of the labyrinth; otitis interna.

Lacunar syndrome Small infarct or small cavity in brain tissue that develops after the necrotic tissue of a deep infarct is resorbed.

Laminectomy Excision of the posterior arch of a vertebra.

Laparoscopy Examination of the interior of the abdomen by means of a laparoscope.

Lesch–Nyhan syndrome Rare disorder of purine metabolism due to deficiency of the enzyme hypoxanthine-guanine phosphoribosyl-transferase and characterised by physical and mental retardation, self-mutilation of fingers and lips by biting, choreoathetosis, spastic cerebral palsy and impaired renal function.

Leucocytosis Total white cell count in excess of 11×10^9 L^{-1}.

Leuconychia White nails.

Lichenoid Resembling the skin lesions designated as 'lichen' – the name applied to many different kinds of papular skin.

Liddle's Syndrome Autosomal dominant disorder in which the kidneys excrete potassium but retain too much sodium and water, leading to high blood pressure diseases in which the lesions are typically small, firm papules that are usually set very close together.

Lipaemia retinalis Retinal deposition of lipid.

Lipohypertrophy Thickening of subcutaneous tissues at injection sites because of recurrent injection in the same area.

Livedo reticularis A peripheral vascular condition characterised by a reddish blue netlike mottling of the skin and extremities.

Lyme disease A multisystem tick-borne disorder caused by the spirochaete *Borrelia burgdorferi*. Clinical manifestation includes an erythematous macule followed by systemic disorders such as arthralgias, myalgias and headache followed by neurological manifestations, cardiac involvement and a migratory polyarthritis.

Lymphadenopathy Disease of the lymph nodes.

Lymphoblastic Pertaining to a lymphoblast.

Maculopapular An eruption consisting of both macules (areas distinguishable by colour from their surroundings, e.g. spots) and papules (small circumscribed, superficial, solid elevations of the skin).

Malleolus medialis The rounded protruberance on the medial surface of the ankle joint.

Malrotation Abnormal or pathological rotation.

Marasmus Insufficient energy provision.

Melaena The passage of dark stools stained with blood pigments or with altered blood.

Menorrhagia Excessive and prolonged uterine bleeding occurring at the regular intervals of menstruation.

Microalbuminuria Small amounts of albumin present in the urine.

Miliary Literally, resembling small round millet seeds. Miliary tuberculosis is so called because the chest radiograph usually shows miliary speckling.

Morbilliform Resembling the eruption of measles.

Mucositis Inflammation of a mucous membrane.

Mycosis fungoides A rare, chronic, malignant, lymphoreticular neoplasm of the skin and, in the late stages, the lymph nodes and viscera, marked by the development of firm, reddish, painful tumours that ulcerate.

Myelofibrosis Replacement of the bone marrow by fibrous tissue occurring in association with a myeloproliferative disorder or secondary to another disorder.

Myoclonus Shock like contractions of a group of muscles.

Myoglobulinuria Presence of myoglobin in the urine.

Myomas Fibroids, common benign tumours of the myometrium.

Myometrium The muscular layers of the uterus that contract spontaneously throughout the menstrual cycle.

Myopathy Unexplained muscle soreness or weakness.

Myositis Inflammation of a voluntary muscle.

Necrobiosis lipoidica A dermatosis usually occurring in diabetics characterised by necrobiosis (swelling and distortion of collagen bundles in the dermis) of the elastic and connective tissue of the skin, with degenerated collagen occurring in irregular patches, especially in the upper dermis.

Nephrolithiasis Formation of uric acid calculi in the kidneys.

Nikolsky's sign Easy separation of the outer portion of the epidermis from the basal layer on exertion of firm sliding pressure by the finger or thumb.

Nocturia Waking at night to pass urine.

Nystagmus Involuntary rapid movement of the eyeball, which may be horizontal, vertical, rotatory or mixed.

Obligate intracellular pathogen An organism that cannot be cultured using artificial media since it requires living cells for growth.

Oligohydramnios Presence of less than 300ml of amniotic fluid at term.

Oliguria Diminished urine output.

Onycholysis Separation of the nail from its bed.

Oophorectomy Removal of an ovary or ovaries.

Ophthalmopathy Any disease of the eye.

Opsonization The rendering of bacteria and other cells subject to phagocytosis.

Orchiectomy Excision of one or both testis(es).

Orosomucoid a_1-acid glycoprotein, a glycoprotein occurring in blood plasma

Orthopnoea Difficult breathing except in an upright position.

Orthoptic Correcting obliquity of one or more visual axis.

Osler's nodes Small, raised, swollen tender areas, about the size of a pea and often bluish in colour but sometimes pink or red, occurring most commonly in the pads of the fingers or toes, in the palm or the soles of the feet.

Osteomalacia Reduced mineralization.

Osteophyte A bony or osseous outgrowth.

Pallidotomy A stereotaxic surgical technique for producing lesions in the globus pallidus or extirpation of it by other means.

Palmar striae Yellow raised streaks across the palms of the hands.

Pancytopenia Deficiency of all cell elements of the blood.

Panmyelopathy A pathological condition of all the elements of the bone marrow.

Paroxysmal nocturnal dyspnoea Difficult or laboured breathing at night that recurs in paroxysms.

Pericarditis Inflammation of the fibrous sac (pericardium) that surrounds the heart and the roots of the great vessels.

Petechial Characterised by pinpoint, non-raised, round, purplish red spots caused by intradermal or submucous haemorrhage.

Phaeochromocytoma A tumour of chromaffin tissue of the adrenal medulla or sympathetic paraganglia. The cardinal

symptom that represents the increased secretion of adrenaline and noradrenaline is hypertension, which may be persistent or intermittent.

Phagocytosis The engulfing of micro-organisms, cells and foreign particles by phagocytes.

Phlebitis Inflammation of a vein.

Pica A craving for unnatural articles of food.

Pneumaturia Passage of urine charged with air.

Polycythaemia rubra vera A myeloproliferative disorder in which the abnormal bone marrow overproduces red blood cells (white cells and platelets may also be raised).

Polymorphic Occurring in several or many forms.

Polyp A protruding growth from a mucous membrane.

Pompholyx A skin eruption on the sides of the fingers, toes, palms or soles, consisting of discrete round intraepidermal vesicles 1 or 2 mm in diameter, accompanied by intense itching and occurring in repeated self-limited attacks lasting 1 or 2 weeks.

Porphyria Any of a group of disturbances of porphyrin metabolism, characterised by marked increase in formation and excretion of porphyrins or their precursors.

Pretibial myxoedema Localised myxoedema associated with preceding hyperthyroidism and exopthalmus, occurring typically on the anterior (pretibial) surface of the legs where mucin deposits as plaques and papules.

Priapism Persistent, abnormal erection of the penis, usually without sexual desire, and accompanied by pain and discomfort.

Prinzmetal's angina A variant of angina pectoris in which the attacks occur during rest.

Proptosis A forward displacement or bulging, especially of the eye.

Pseudophakia False lens.

Pyruvate kinase deficiency A deficiency in the glycolytic (metabolic) pathway of red blood cells that results in haemolysis.

Pyuria Presence of pus in the urine.

Raeder's syndrome A syndrome consisting of the Horner syndrome but without loss of sweating on the affected side of the face.

Reed–Sternberg cells Giant histiocytic cells, typically multinucleate, most often binucleate; the nuclei are enclosed in abundant amphophilic cytoplasm and contain prominent nucleoli.

Retinopathy Any non-inflammatory disease of the retina.

Retroperitoneal fibrosis Deposition of fibrous tissue in the retroperitoneal space, producing vague abdominal discomfort, and often causing blockage of the ureters with resultant hydronephrosis and impaired renal function.

Retrosternal Situated or occurring behind the sternum.

Reiter's syndrome Triad of nongonococcal urethritis, conjunctivitis, and arthritis frequently with mucocutaneos lesions.

Reye's syndrome An acute and often fatal childhood syndrome of encephalopathy and fatty degeneration of the liver, marked by rapid development of brain swelling and hepatomegaly and by disturbed consciousness and seizures.

Rhabdomyolysis Dissolution of muscle associated with excretion of myoglobin in the urine.

Rockall score Scoring system to identify patients at risk of adverse outcome following acute upper gastro-intestinal bleed.

Roth's spots Round or oval white spots sometimes seen in the retina early in the course of subacute bacterial endocarditis.

Rotor's syndrome Chronic familial non-haemolytic jaundice differing from Dubin–Johnson syndrome in the lack of liver pigmentation.

Sarcoidosis A chronic, progressive, generalised granulomatous reticulosis of unknown aetiology, involving almost any organ or tissue.

Schofield equation An equation to predict basal metabolic rate; may be used to estimate the total calorie intake required to maintain current body weight.

Sclerotherapy The injection of sclerosing solutions in the treatment of haemorrhoids or varicose veins.

Scotoma An area of depressed vision within the visual field, surrounded by an area of less depressed or of normal vision.

Sézary syndrome Generalised exfoliative erythroderma produced by cutaneous infiltration of reticular lymphocytes and associated with intense pruritus, alopecia, oedema, hyperkeratosis, pigment and nail changes.

Shy–Drager syndrome Orthostatic hypotension, urinary and rectal incontinence, anhidrosis, atrophy of the iris, external ophthalmoplegia, rigidity, tremor, loss of associated movements, impotence, atonic bladder, generalised weakness, fasciculations, and neuropathic muscle wasting.

Sickle cell anaemia A hereditary haemolytic anaemia occurring almost exclusively in black people, characterised by arthralgia, acute attacks of abdominal pain, ulcerations of the lower extremities and with sickle-shaped erythrocytes in the blood.

Sjögren's syndrome A symptom complex of unknown aetiology, usually occurring in middle-aged or older women, in which keratoconjunctivitis is associated with pharyngitis sicca, enlargement of the parotid glands, chronic polyarthritis and xerostomia.

Sloughing material Soft, gel-like material often found in ulcer bases. Composed of tissue exudate and cellular debris.

Spherocytosis The presence of spherocytes (thick, almost spherical, red blood cells) characterised by abnormal fragility of erythrocytes, jaundice and splenomegaly.

Splinter haemorrhages Linear haemorrhages beneath the nail.

Steatosis Fatty degeneration.

Stenosis Narrowing or stricture of a duct or canal.

Stevens–Johnson syndrome A severe form of erythema multiforme in which the lesions may involve the oral and anogenital mucous membranes in association with constitutional symptoms, including malaise, prostration, headache, fever, arthralgia and conjunctivitis.

Stromal keratitis Immune-mediated nonsuppurative stromal inflammation with an intact epithelium usually linked to a causative disorder such as Epstein Barr virus, herpes zoster and simplex, mumps, measles, Lyme disease, tuberculosis.

Subchondral Beneath a cartilage.

Subluxation An incomplete or partial dislocation.

Supranuclear palsy Pseudobulbar paralysis.

Sweet's syndrome Acute febrile neutrophillic dermatosis.

Sympathetic ileus Failure of gastro-intestinal motility secondary to acute non-gastro-intestinal illness, for example hyaline membrane disease or septicaemia.

Tamponade Surgical use of the tampon; also pathological compression of a part, as compression of the heart by pericardial fluid.

Telangiectasia Prominent surface blood vessels.

Tendon xanthomas Yellow papules or nodules or lipids deposited in tendons.

Tenesmus Straining, especially ineffectual and painful straining at stool or in urination.

Tenosynovitis Inflammation of a tendon sheath.

Thalassaemia A heterogeneous group of hereditary haemolytic anaemias that have in common a decreased rate of synthesis of one or more haemoglobin polypeptide chains and are classified according to the chain involved (a, b, g). The homozygous form (thalassaemia major) is incompatible with life. The heterozygous form (thalassaemia minor) may be asymptomatic or marked by mild anaemia.

Thrombocytopenia Decrease in the number of blood platelets.

Thrombocytosis Increased number of platelets in blood.

Thrombophilia A tendency to the occurrence of thrombosis.

Thromboplastin Phospholipid-protein extract of tissue that promotes the activation of factor X by factor VIII.

Tonometry Measurement of intraocular pressure.

Tophi Deposits of monosodium urate crystals, typically in subcutaneous and periarticular areas.

Trephine Biopsy examination of an intact core of tissue (e.g. liver, bone marrow) obtained through a wide-bore needle.

Tropical sprue A malabsorption syndrome occurring in the tropics and subtropics. Protein malnutrition is usually precipitated by the malabsorption, and anaemia due to folic acid deficiency is particularly common.

Trousseau's sign Spasmodic contractions of muscles provoked by pressure upon the nerves which go to them; seen in tetany.

Tuberoeruptive xanthomas Groups of flat or yellowish raised nodules on the skin over joints, especially the elbows and knees.

Tuberous sclerosis Congenital familial disease characterised by tumours on the surfaces of the lateral ventricles and sclerotic patches on the surface of the brain and marked clinically by progressive mental deterioration and epileptic convulsions.

Tubular cast A cast formed from gelled protein precipitated in the renal tubules and moulded to the tubular lumen; pieces of these casts break off and are washed out with the urine.

Uraemic frost Crystalline area deposited on the skin.

Urethral Pertaining to the urethra, the membranous canal conveying urine from the bladder to the exterior of the body.

Variant angina *See* Prinzmetal's angina.

Volvulus Intestinal obstruction due to a knotting and twisting of the bowel.

Von Willebrand's disease A lack of or a defective plasma protein (von Willebrand factor) necessary for the adhesion of platelets to vascular elements when a blood vessel is damaged.

Wernicke–Korsakoff syndrome The co-existence of Wernicke's disease (acute onset of mental confusion, nystagmus, ophthalmoplegia and gait ataxia, due to thiamine deficiency) with Korsakoff's syndrome (a gross disturbance in recent memory, sometimes compensated for by confabulation).

West's syndrome A form of myoclonus epilepsy with onset in infancy or early childhood and characterised by seizures involving the muscles of the neck, trunk and limbs, with nodding of the head and flexion and abduction of the arms. Mental retardation is common.

Wilson's disease Characterised by progressive accumulation of copper within body tissues, particularly erythrocytes, kidney, liver and brain, and associated with liver and lenticular degeneration.

Xanthelasma Yellow plaques or nodules of lipids deposited on eyelids.

Xenotransplantation Transplantation of tissue from another species.

Xerosis Dry skin.
