FIFTH EDITION

Notices
Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

In both primary and secondary care the use of medicines is the most common intervention in healthcare. Medicines use, however, is not without risk. Drug selection and prescribing is increasingly complex and demanding, and undertaken as part of a multi-disciplinary process that involves pharmacists, some of whom are now prescribers in their own right, along with doctors, nurses and other members of the healthcare team. All must strive to promote safe, appropriate and cost-effective prescribing that respects patient choice and promotes adherence. This book has been written to help the reader understand and address many of these issues. It is unashamedly written from a pharmacy perspective, although we do hope those from other disciplines will also find it of use.

We have made considerable effort to update each chapter and ensure the content is relevant to current practice. Selected website addresses have been included to assist those who want to obtain further information and many references are now available electronically and this has been indicated where appropriate. However, knowledge in therapeutics progresses rapidly, changes to dose regimens and licensed indications are frequent, safety issues emerge with established drugs and new medicines appear at regular intervals. Yesterday another landmark study was published adding to, or perhaps altering, the evidence base for a specific treatment. Together with the ongoing publication of national guidelines and frameworks, the face of therapeutics is ever changing. It is therefore inevitable that some sections of this book will date more quickly than others.

In practice many licensed drugs are used 'off label' or "near label" when prescribed for a certain indication or used in a specific patient group such as children. To omit reference to these agents in the relevant chapter would leave an apparent gap in therapeutic management. As a consequence we have encouraged our authors to present details of all key drugs used along with details of the prescribed regimens even if not licensed for that specific indication. There is, however, a downside to this approach. The reader must always use this text critically and with caution. If this is done the book will serve as a valuable learning resource and help the reader understand some of the principles of therapeutics. We hope that, in some small way, this will also assist in achieving positive patient outcomes.

SECTION 1

GENERAL

1 Clinical pharmacy process

D. G. Webb, J. G. Davies and D. McRobbie

Key points

- Clinical pharmacy comprises a set of functions that promote the safe, effective and economic use of medicines for individual patients.
- The emergence of clinical pharmacy has allowed pharmacists to shift from a product-oriented role towards direct engagement with patients and the problems they encounter with medicines.
- The practice of clinical pharmacy is generally an essential component of pharmaceutical care.
- Pharmaceutical care is a co-operative, patient-centred system for achieving specific and positive patient outcomes from the responsible provision of medicines.
- The three key elements of the care process are patient assessment, determining the care plan and evaluating the outcome.
- The ability to consult with patients is a key process in the delivery of pharmaceutical care and requires regular review and development regardless of experience.
- The clinical pharmacy process has been incorporated into a professional development framework that can be used to enhance skills and knowledge.

Clinical pharmacy, unlike the discipline of pharmacy, is a comparatively recent and variably implemented form of practice. It encourages pharmacists and support staff to shift their focus from a solely product-oriented role towards more direct engagement with patients and the problems they encounter with medicines. Over the past 20 years there has been an emerging consensus that the practice of clinical pharmacy itself should grow from a collection of patient-related functions to a process in which all actions are undertaken with the intention of achieving explicit outcomes for the patient. In doing so, clinical pharmacy moves to embrace the philosophy of pharmaceutical care (Hepler and Strand, 1990).

This chapter provides a practical framework within which a knowledge and understanding of therapeutics and practice can be best utilised. It describes a pragmatic approach to applying both the principles of pharmaceutical care and the specific skills of clinical pharmacy in a manner that does not depend on the setting of the practitioner or patient.

Development of clinical practice in pharmacy

The emergence of clinical pharmacy as a form of practice has been attributed to the poor medicines control systems that existed in hospitals during the early 1960s (Cousins and Luscombe, 1995). Although provoked by similar hospital-centred problems, the nature of the professional response differed between the USA and the UK.

In the USA, the approach was to adopt unit dose dispensing and pursue decentralisation of pharmacy services. In the UK, the unification of the prescription and the administration record meant this document needed to remain on the hospital ward and required the pharmacist to visit the ward to order medicines. Clinical pharmacy thereby emerged from the presence of pharmacists in these patient areas and their interest in promoting safer medicines use. This was initially termed 'ward pharmacy' but participation in medical ward rounds in the late 1970s signalled the transition to clinical pharmacy.

Medication safety may have been the spur but clinical pharmacy in the 1980s grew because of its ability to promote cost-effective medicines used in hospitals. This role was recognised by the UK government, which, in 1988, endorsed the implementation of clinical pharmacy services to secure value for money from medicines. Awareness that support depended, to an extent, on the quantification of actions and cost savings led several groups to develop ways of measuring pharmacists' clinical interventions. Coding systems were necessary to aggregate large amounts of data in a reliable manner and many of these drew upon the eight steps (Table 1.1) of the drug use process (DUP) indicators (Hutchinson et al., 1986).

The data collected from these early studies revealed that interventions had very high physician acceptance rates, were made most commonly at the 'select regimen' and 'need for drug' stages of the DUP, and were influenced by hospital ward type (intensive care and paediatrics having the highest rates), pharmacist grade (rates increasing with grade) and time spent on wards (Barber et al., 1997).

Despite the level of activity that intervention monitoring revealed, together with evidence of cost containment and a broadly supportive health care system, frustrations began to appear. These, in part, stemmed from a lack of certainty about the fundamental purpose of clinical pharmacy and

Table 1.1 Drug use process (DUP) indicators

DUP stage	Action
Need for a drug	Ensure there is an appropriate indication for each drug and that all medical problems are addressed therapeutically
Select drug	Select and recommend the most appropriate drug based upon the ability to reach therapeutic goals, with consideration of patient variables, formulary status and cost of therapy
Select regimen	Select the most appropriate drug regimen for accomplishing the desired therapeutic goals at the least cost without diminishing effectiveness or causing toxicity
Provide drug	Facilitate the dispensing and supply process so that drugs are accurately prepared, dispensed in ready-to-administer form and delivered to the patient on a timely basis
Drug administration	Ensure that appropriate devices and techniques are used for drug administration
Monitor drug therapy	Monitor drug therapy for effectiveness or adverse effects in order to determine whether to maintain, modify or discontinue
Counsel patient	Counsel and educate the patient or caregiver about the patient's therapy to ensure proper use of medicines
Evaluate effectiveness	Evaluate the effectiveness of the patient's drug therapy by reviewing all the previous steps of the drug use process and taking appropriate steps to ensure that the therapeutic goals are achieved

Table 1.2 Definitions of clinical pharmacy, pharmaceutical care and medicines management

Term	Definition
Clinical pharmacy	Clinical pharmacy comprises a set of functions that promote the safe, effective and economic use of medicines for individual patients. Clinical pharmacy process requires the application of specific knowledge of pharmacology, pharmacokinetics, pharmaceutics and therapeutics to patient care
Pharmaceutical care	Pharmaceutical care is a co-operative, patient-centred system for achieving specific and positive patient outcomes from the responsible provision of medicines. The practice of clinical pharmacy is an essential component in the delivery of pharmaceutical care
Medicines management	Medicines management encompasses the way in which medicines are selected, procured, delivered, prescribed, administered and reviewed to optimise the contribution that medicines make to producing informed and desired outcomes of patient care

from tensions between the drive towards specialisation in clinical pharmacy and the need to improve services of a more general level in hospitals and other care settings.

Pharmaceutical care

The need to focus on outcomes of medicines use rather than dwelling only on the functions of clinical pharmacy became apparent (Hepler and Strand, 1990). The launch of pharmaceutical care as the 'responsible provision of drug therapy for the purpose of achieving definite outcomes that improve a patient's quality of life' was a landmark in the topography of pharmacy practice. In reality, this was an incremental step forward, rather than a revolutionary leap, since the foundations of pharmaceutical care as 'the determination of drug needs

for a given individual and the provision not only of the drug required but also the necessary services to assure optimally safe and effective therapy' had been established previously (Brodie et al., 1980).

The delivery of pharmaceutical care is dependent on the practice of clinical pharmacy but the key feature of care is that the practitioner takes responsibility for a patient's drug-related needs and is held accountable for that commitment. None of the definitions of pharmaceutical care is limited by reference to a specific professional group. Although pharmacists and pharmacy support staff would expect to, and clearly can, play a central role in pharmaceutical care, it is essentially a co-operative system that embraces the contribution of other professionals and patients (Table 1.2). The avoidance of factionalism has enabled pharmaceutical care to permeate community pharmacy, particularly in Europe, in a way that clinical pharmacy and its bedside connotations did not. It also anticipated health care policy in which certain functions, such as the prescribing of medicines, have been extended beyond their traditional professional origins to be undertaken by those trained and identified to be competent to do so.

Medication-related problems

When the outcome of medicines use is not optimal, a classification (Box 1.1) for identifying the underlying medication-related problem (MRP) has been proposed (Hepler and

Box 1.1   Categories of medication-related problems

Untreated indication
Treatment without indication
Improper drug selection
Too little drug
Too much drug
Non-compliance
Adverse drug reaction
Drug interaction

Strand, 1990). Some MRPs are associated with significant morbidity and mortality. Preventable medication-related hospital admissions in the USA have a prevalence of 4.3%, indicating that gains in public health from improved medicines management would be sizeable (Winterstein et al., 2002). In the UK too, preventable medication-related morbidity has been associated with 4.3% of admissions to a medical unit. In nearly all cases, the underlying MRP was linked to prescribing, monitoring or adherence (Howard et al., 2003).

In prospective studies, up to 28% of accident and emergency department visits have been identified as medication related, of which 70% are deemed preventable (Zed, 2005). Again, the most frequently cited causes were non-adherence and inappropriate prescribing and monitoring. The cost of drug-related morbidity and mortality in the US ambulatory care (outpatient) population was estimated in 2000 to be $177 billion. Hospital admission accounted for 70% of total costs (Ernst and Grizzle, 2001). In England, adverse drug reactions (ADRs) have been identified as the cause of 6.5% of hospital admissions for patients over 16 years of age. The median bed stay with patients admitted with an ADR was 8 days representing 4% of bed capacity. The projected annual cost to the NHS was £466 million, the equivalent of seven 800-bed hospitals occupied by patients admitted with an ADR (Pirmohamed et al., 2004).

The rate for adverse drug events among hospital inpatients in the USA has been quantified as 6.5 per 100 admissions. Overall, 28% of events were judged preventable, rising to 42% of those classified as life-threatening or serious (Bates et al., 1995). The direct cost of medication errors, defined as preventable events that may cause or lead to inappropriate medicines use or harm, in NHS hospitals has been estimated to lie between £200 and £400 million per year. To this should be added the costs arising from litigation (DH, 2004).

The scale of the misadventure that these findings reveal, coupled with increasing concerns about the costs of drug therapy, creates an opportunity for a renaissance in clinical pharmacy practice, providing that it realigns strongly with patient safety, cost-effectiveness and prevention of ill health. In practice, community pharmacists may be uniquely placed to help reduce the level of medication-related morbidity in primary care by virtue of their accessibility and existing relationships.

Benefits of pharmaceutical care

The ability to demonstrate that clinical pharmacy practice improves patient outcomes is of great importance to the pharmaceutical care model. In the USA, for example, pharmacists'

participation in physician ward rounds has been shown to reduce adverse drug events by 78% and 66% in general medical (Kucukarslan et al., 2003) and intensive care settings (Leape et al., 1999), respectively. A study covering 1029 US hospitals was the first to indicate that both centrally based and patient-specific clinical pharmacy services are associated with reduced mortality rates (Bond et al., 1999). The services involved were medicines information, clinical research performed by pharmacists, active pharmacist participation in resuscitation teams and pharmacists undertaking admission medication histories.

In the UK, the focus has been also on prevention and management of medicine-related problems. Recognition that many patients either fail to benefit or experience unwanted effects from their medicines has elicited two types of response from the pharmacy profession. The first response has been to put in place, and make use of, a range of postgraduate initiatives and programmes to meet the developmental needs of pharmacists working in clinical settings. The second has been the re-engineering of pharmaceutical services to introduce schemes for medicines management at an organisational level. These have ranged from specific initiatives to target identified areas of medication risk, such as pharmacist involvement in anticoagulation services, to more general approaches where the intention is to ensure consistency of medicines use, particularly across care interfaces. Medicines reconciliation on hospital admission ensures that medicines prescribed to in-patients correspond to those that the patient was taking prior to admission. Guidance in the UK recommends that medicines reconciliation should be part of standard care and that pharmacists should be involved as soon as possible after the patient has been admitted (NICE and NPSA, 2007). Medicines reconciliation has been defined as:

- Collecting information on medication history using the most recent and accurate sources of information to create a full, and current, list of medicines;
- Verifying this list against the hospital drug chart and ensuring that any discrepancies are identified and acted upon;
- Documenting and communicating any changes, omissions or discrepancies.

This process requires the name of medicines, dosage, frequency and route of administration to be established for all medicines taken prior to admission. The information collected as part of medicines reconciliation is a pre-requisite for medication review, which is a process which considers the appropriateness of treatment and the patient's medication-taking behaviour.

Pharmaceutical consultation

Structured postgraduate education has served to improve the knowledge of clinical pharmacists but fully achieving the goals of pharmaceutical care has proved more challenging. Part of the difficulty has been the requirement to place the patient at the heart of the system, rather than being a relatively passive recipient of drug therapy and associated

information. To deliver pharmaceutical care requires more than scientific expertise. It mandates a system that describes the role and responsibilities of the pharmacist and provides the necessary infrastructure to support them in this role and, secondly, a clear process by which the pharmacist can deliver their contribution to patient care.

Pharmaceutical care is predicated on a patient-centred approach to identifying, preventing or resolving medicine-related problems. Central to this aim is the need to establish a therapeutic relationship. This relationship must be a partnership in which the pharmacist works with the patient to resolve medication-related issues in line with the patient's wishes, expectations and priorities. Table 1.3 summarises the three key elements of the care process (Cipolle et al., 1998). Research in chronic diseases has shown that self-management is promoted when patients more fully participate in the goal-setting and planning aspects of their care (Sevick et al., 2007). These are important aspects to consider when pharmacists consult with patients. In community pharmacy, one approach to help patients used their medicines more effectively is medicines use review (MUR). This uses the skills of pharmacists to help patients understand how their medicines should be used, why they take them and to identify any problems patients have in relation to their medicines, providing feedback to the prescriber if necessary. Two goals of MUR are to improve the adherence of patients to prescribed medicines and to reduce medicines wastage.

Clinical guidance on medicines adherence emphasises the importance of patient involvement in decisions about medicines (NICE, 2009).

Recommendations include that health care professionals should:

- adapt their consultation style to the needs of individual patients
- consider any factors which may affect patients' involvement in the consultation
- establish the most effective way of communicating with each patient
- encourage patients to ask about their condition and treatment
- be aware that consultation skills can be improved to enhance patient involvement.

Table 1.3	Key elements of the care process
Element	Purpose
Assessment	The main goal is to establish a full medication history and highlight actual and potential drug-related problems
Care plan	This should clearly state the goals to optimise care and the responsibilities of both the pharmacist and the patient in attaining the stated goals
Evaluation	This reviews progress against the stated patient outcomes

Medicines-taking behaviour

The need for a care process which ensures that the patient is involved at all stages has become clearer as the extent of non-adherence has been revealed. Significant proportions (between 30% and 50%) of patients with chronic conditions do not take their prescribed medicines as directed. Many factors are thought to influence a patient's decision to adhere to a pre-scribed regimen. These include the characteristics of the disease and the treatment used to manage it, the patient's beliefs about their illness and their medicines, as well as the quality of the interaction between the patient and health care practitioner. Non-adherence can be categorised broadly into two types: intentional and unintentional. Unintentional non-adherence may be associated with physical or sensory barriers to taking medicines, for example, not being able to swallow or unable to read the labels, forgetfulness or poor comprehension. Traditionally, pharmacists have played a key role in helping patients overcome these types of problems, but have been less active in identifying and resolving intentional non-adherence.

Intentional (or deliberate) non-adherence may be due to a number of factors. Recent work in health psychology has shaped our understanding of how patients perceive health and illness and why they often decide not to take their medicines. When people receive information about illness and its treatment, it is processed in accordance with their own belief systems. Often patients' perceptions are not in tune with the medical reality and when this occurs, taking medicines may not make sense to the individual. For example, a patient diagnosed with hypertension may view the condition as one that is caused by stress and, during periods of lower stress, may not take their prescribed medicines (Baumann and Leventhal, 1985). Consequently, a patient holding this view of hypertension may be at increased risk of experiencing an adverse outcome such as a stroke.

More recent research has shown that patient beliefs about the necessity of the prescribed medication and concerns about the potential long-term effects have a strong influence on medicines-taking behaviour (Horne, 2001). However, a patient's beliefs about the benefits and risks of medicines are rarely explored during consultation, despite evidence of an association between non-adherence and the patient's satisfaction with the consultation process adopted by practitioners (Ley, 1988).

Consultation process

There are several comprehensive accounts of the functions required to satisfy each stage of the DUP, but few go on to explore how the pharmacist might create a therapeutic relationship with their patient. The ability of a pharmacist to consult effectively is fundamental to pharmaceutical care and this includes establishing a platform for achieving adherence/concordance. Nurturing a relationship with the patient is essential to understanding their medication-related needs.

Descriptions of pharmaceutical consultation have been confined largely to the use of mnemonics such as WWHAM, AS METTHOD and ENCORE (Box 1.2). These approaches

provide the pharmacist with a rigid structure to use when questioning patients about their symptoms but, although useful, serve to make the symptom or disease the focus of the consultation rather than the patient. A common misconception is that health care professionals who possess good communication skills are also able to consult effectively with patients; this relationship will not hold if there is a failure

to grasp the essential components of consultation technique. Research into patients' perceptions of their illness and treatment has demonstrated that they are more likely to adhere to their medication regimen, and be more satisfied with the consultation, if their views about illness and treatment have been taken into account and the risks and benefits of treatment discussed. The mnemonic approach to consultation does not address adequately the complex interaction that may take place between a patient and a health care practitioner.

Undertaking a pharmaceutical consultation can be considered as a series of four interlinked phases, each with a goal and set of competencies (Table 1.4). These phases follow a problem-solving pattern, embrace relevant aspects of adherence research and attempt to involve the patient at each stage in the process. For effective consultation, the practitioner also needs to draw upon a range of communication behaviours (Box 1.3). This approach serves to integrate the agendas of both patient and pharmacist. It provides the vehicle for agreeing on the issues to be addressed and the responsibilities accepted by each party in achieving the desired outcomes.

The ability to consult with patients is a key process in the delivery of pharmaceutical care and consequently requires regular review and development, regardless of experience. To ensure these core skills are developed, individuals should use trigger questions to prompt reflection on their approach to consulting (Box 1.4).

Box 1.2   Mnemonics used in the pharmacy consultation process

WWHAM
Who is it for?
What are the symptoms?
How long has it been going on?
Action taken?
Medicines taken?

AS METTHOD
Age of the patient?
Self or for someone else?
Medicines being taken?
Exactly what do you mean (by the symptom)?
Time and duration of the symptom
Taken any action (medicine or seen the doctor)?
History of any disease?
Other symptoms?
Doing anything to alleviate or worsen the symptom?

ENCORE
Evaluate the symptom, its onset, recurrence and duration.
No medication is always an option.
Care when dealing with specific patient groups, notably the elderly, the young, nursing mothers, pregnant women, those receiving specific medication such as methotrexate and anticoagulants, and those with particular disease, for example, renal impairment.
Observe the patient for signs of systemic disturbance and ask about presence of fever, loss of weight and any accompanying physiological disturbance.
Refer when in doubt.
Explain any course of action recommended.

Box 1.3   Consultation behaviours

Active listening
Appropriate use of open and closed questions
Respect patient
Avoid jargon
Demonstrate empathy
Deal sensitively with potentially embarrassing or sensitive issues

---

Table 1.4   Pharmaceutical consultation process

Element	Goal	Examples of associated competencies
Introduction	Building a therapeutic relationship	Invites patient to discuss medication or health-related issue Discusses structure and purpose of consultation Negotiates shared agenda
Data collection and problem identification	Identifying the patient's medication-related needs	Takes a full medication history Establishes patient's understanding of their illness Establishes patient's understanding of the prescribed treatment Identifies and prioritises patient's pharmaceutical problems
Actions and solutions	Establishing an acceptable management plan with the patient	Involves patient in designing management plan Tailors information to address patient's perception of illness and treatment Checks patient's understanding Refers appropriately
Closure	Negotiating safety netting strategies with the patient	Provides information to guide action when patient experiences problems with management plan Provides further appointment or contact point

Do I know more now about the patient?
Was I curious?
Did I really listen?
Did I find out what really mattered to them?
Did I explore their beliefs and expectations?
Did I identify the patient's main medication-related problems?
Did I use their thoughts when I started explaining?
Did I share the treatment options with them?
Did I help my patient to reach a decision?
Did I check that they understood what I said?
Did we agree?
Was I friendly?

Clinical pharmacy functions and knowledge

The following practical steps in the delivery of pharmaceutical care are based largely on the DUP. The 'select regimen' and 'drug administration' indicators have been amalgamated at step 3.

Step 1. Establishing the need for drug therapy

For independent prescribers this step includes establishing a diagnosis and then balancing the risks and benefits of treatment against the risks posed by the disease. Current practice for most pharmacists means that another professional, most frequently a doctor, will have diagnosed the patient's presenting condition and any co-existing disease. The pharmacist's role, therefore, is often one of providing information to the independent prescriber on the expected benefits and risks of drug therapy by evaluating both the evidence base and individual patient factors. Pharmacists also draw on these concepts as they become more involved in prescribing and adjusting therapy for patients under their care.

The evidence for one specific mode of therapy may not be conclusive. In this circumstance, the pharmacist will need to call on their understanding of the principles of pharmaceutical science and on clinical experience to provide the best advice possible.

Step 1.1. Relevant patient details

Without background information on the patient's health and social circumstances (Table 1.5) it is difficult to establish the existence of, or potential for, MRPs. When this information is

Table 1.5 Relevant patient details

Factor	Implications
Age	The very young and the very old are most at risk of medication-related problems. A patient's age may indicate their likely ability to metabolise and excrete medicines and have implications for step 2 of the drug use process
Gender	This may alter the choice of the therapy for certain indications. It may also prompt consideration of the potential for pregnancy or breast feeding
Ethnic or religious background	Racially determined predispositions to intolerance or ineffectiveness should be considered with certain classes of medicines, for example, ACE inhibitors in Afro-Caribbean people. Formulations may be problematic for other groups, for example, those based on blood products for Jehovah's Witnesses or porcine-derived products for Jewish patients
Social history	This may impact on ability to manage medicines and influence pharmaceutical care needs, for example, living alone or in a care home or availability of nursing, social or informal carers
Presenting complaint	Symptoms the patient describes and the signs identified by the doctor on examination. Pharmacists should consider whether these might be attributable to the adverse effects of prescribed or purchased medicines
Working diagnosis	This should enable the pharmacist to identify the classes of medicines that would be anticipated on the prescription based on current evidence
Previous medical history	Understanding the patient's other medical conditions and their history helps ensure that management of the current problem does not compromise a prior condition and guides the selection of appropriate therapy by identifying potential contraindications
Laboratory or physical findings	The focus should be on findings that may affect therapy, such as • renal function • liver function • full blood count • blood pressure • cardiac rhythm Results may convey a need for dosage adjustment or presence of an adverse reaction

lacking a review solely of prescribed medicines will probably be of limited value and risks making a flawed judgement on the appropriateness of therapy for that individual.

Current and co-existing conditions with which the patient presents can be established from various sources. In medical notes, the current diagnosis (Δ) or differential diagnoses (ΔΔ) will be documented, as well as any previous medical history (PMH). Other opportunities to gather information come from discussion with the patient and participation in medical rounds. In primary care, general medical practitioners' computer systems carry information on the patient's diagnosis.

Once the diagnosis and PMH are established it is then possible to identify the medicines that would be expected to be prescribed for each indication, based on contemporary evidence. This list of medicines may be compiled from appropriate national or international guidelines, local formularies and knowledge of current practice.

Step 1.2. Medication history

A medication history is the part of a pharmaceutical consultation that identifies and documents allergies or other serious adverse medication events, as well as information about how medicines are taken currently and have been taken in the past. It is the starting point for medicines reconciliation and medication review.

Obtaining accurate and complete medication histories has been shown to have a positive effect on patient care and pharmacists have demonstrated that they can compile such histories with a high degree of precision and reliability as part of medicines reconciliation. The benefit to the patient is that prescribing errors of omission or transcription are identified and corrected early, reducing the risk of harm and improving care.

Discrepancies between the history recorded by the medical team and that which the pharmacist elicits fall into two categories: intentional (where the medical team has made a decision to alter the regimen) or unintentional (where a complete record was not obtained). Discrepancies should be clarified with the prescriber or referred to a more senior pharmacist. Box 1.5 lists the key components of a medication history.

Step 2. Selecting the medicine

The issues to be tackled at this stage include clinical and cost-effective selection of a medicine in the context of individual patient care. The list of expected treatments generated at step 1 is now scrutinised for its appropriateness for the patient. This requires three separate types of interaction to be identified: drug–patient, drug–disease and drug–drug. The interactions should be prioritised in terms of likelihood of occurrence and the potential severity of outcome should they occur.

Step 2.1. Identify drug–patient interactions

Many medicines have contraindications or cautions to their use that relate to age groups or gender. Potential drug–patient interactions should be identified that may arise with any of the medicines that could be used to treat the current and pre-existing

---

Box 1.5 Key components of a medication history

1. Introduce yourself to the patient and explain the purpose of the consultation.
2. Identify any allergies or serious adverse reactions and record these on the prescription chart, care notes or patient medication record.
3. Ascertain information about prescribed and non-prescribed treatments from:
   - the patient's recall
   - medicines in the patient's possession
   - referral letter (usually from the patient's primary care doctor)
   - copy of prescriptions issued or a repeat prescription list
   - medical notes
   - contact with the appropriate community pharmacist or primary care doctor.
4. Ensure the following are recorded:
   - generic name of medicine (unless specific brand is required)
   - dose
   - frequency
   - duration of therapy.
5. Ensure items such as inhalers, eye drops, topical medicines, herbal and homeopathic remedies are included, as patients often do not consider these as medicines.
6. Ascertain the patient's medication-taking behaviour.
7. Consider practical issues such as swallowing difficulties, ability to read labels and written information, container preferences, ordering or supply problems.
8. Document the history in an appropriate format.
9. Note any discrepancies between this history and that recorded by other health care professionals.
10. Ascertain if these discrepancies are intentional (from patient, nursing staff, medical staff or medical notes).
11. Communicate non-intentional discrepancies to the prescriber.
12. Document any other important medication-related information in an appropriate manner, for example, implications of chronic renal failure, dialysis, long-term steroid treatment.

---

conditions. Types of drug–patient interactions may include allergy or previous ADR, the impact of abnormal renal or hepatic function or chronic heart failure on the systemic availability of some medicines, and patients' preferences for certain treatment options, formulations or routes of administration.

Step 2.2. Identify drug–disease interactions

A drug–disease interaction may occur when a medicine has the potential to make a pre-existing condition worse. Older people are particularly vulnerable due to the co-existence of several chronic diseases and exposure to polypharmacy. Prevention of drug–disease interactions requires an understanding of the pharmacodynamic properties of medicines and an appreciation of their contraindications.

Step 2.3. Drug–drug interactions

Medicines may affect the action of other medicines in a number of ways. Those with similar mechanisms of action may show an enhanced effect if used together whilst those with opposing actions may reduce each other's effectiveness.

Metabolism of one medicine can be affected by a second that acts as an inducer or inhibitor of the cytochrome P450 enzyme system.

The practitioner should be able to identify common drug interactions and recognise those medicines with increased risk of potential interaction, such as those with narrow therapeutic indices or involving hepatic P450 metabolic pathways. It is important to assess the clinical significance of drug interactions and consider the options for effective management.

The list of potential, evidence-based treatments should be reviewed for possible drug–patient, drug–disease and drug–drug interactions. The refined list can then be compared with the medicines that have been prescribed for the patient. The practitioner should explore any discrepancies to ensure the patient does not experience an MRP. This may necessitate consultation with medical staff or other health care professionals, or referral to a more senior pharmacist.

Step 3. Administering the medicine

Many factors influence the effect that a medicine has at its locus of action. These include the rate and extent of absorption, degree of plasma protein binding and volume of distribution, and the routes of metabolism or excretion. Factors affecting bioavailability may include the extent of absorption of the drug from the gastro-intestinal tract in relation to food and other medicines, or the amount adsorped onto intravenous infusion bags and giving sets when used to administer medicines parenterally.

The liver has extensive capacity for drug metabolism, even when damaged. Nevertheless, the degree of hepatic impairment should be assessed from liver function tests and related to potential changes in drug metabolism. This is particularly important for medicines that require activation by the liver (pro-drugs) or those whose main route of elimination is transformation into water-soluble metabolites.

Table 1.6 summarises the main pharmaceutical considerations for step 3. At this point, the practitioner needs to ensure the following tasks have been completed accurately.

Step 3.1. Calculating the appropriate dose

Where doses of oral medicines require calculation, this is usually a straightforward process based on the weight of the patient. However, medicines to be administered parenterally may require more complex calculations, including knowledge of displacement values (particularly for paediatric doses) and determination of appropriate concentrations in compatible fluids and rates of infusion.

Step 3.2. Selecting an appropriate regimen

Giving medicines via the oral route is the preferred method of administration. Parenteral routes carry significantly more risks, including infection associated with vascular access. This route, however, may be necessary when no oral formulation exists or when the oral access is either impossible or inappropriate because of the patient's condition.

Table 1.6 Pharmaceutical considerations in the administration of medicines

Dose	Is the dose appropriate, including adjustments for particular routes or formulations? Examples: differences in dose between intravenous and oral metronidazole, intramuscular and oral chlorpromazine, and digoxin tablets compared with the elixir
Route	Is the prescribed route available (is the patient nil by mouth?) and appropriate for the patient? Examples: unnecessary prescription of an intravenous medicine when the patient can swallow, or the use of a solid dosage form when the patient has dysphagia
Dosage form	Is the medicine available in a suitable form for administration via the prescribed route?
Documentation	Is documentation complete? Do nurses or carers require specific information to administer the medicine safely? Examples: appropriateness of crushing tablets for administration via nasogastric tubes, dilution requirements for medicines given parenterally, rates of administration and compatibilities in parenteral solutions (including syringe drivers)
Devices	Are devices required, such as spacers for inhalers?

Although simple regimens (once- or twice-daily administration) may facilitate adherence, some medicines possess short half-lives and may need to be given more frequently. The practitioner should be familiar with the duration of action of regularly encountered medicines to ensure dosage regimens are designed optimally.

Step 4. Providing the medicine

Ensuring that a prescription is legal, legible, accurate and unambiguous contributes in large measure to the right patient receiving the right medicine at the right time. For the majority of pharmacists this involves screening prescriptions written by other professionals, but those acting as supplementary and independent prescribers need to be cognisant of guidance on prescribing, such as that contained within the British National Formulary, when generating their prescriptions.

In providing a medicine for an individual, due account must be taken of the factors that influence the continued availability and supply of the medicine within the hospital or community setting, for example, formulary and drug tariff status, primary/secondary shared care arrangements, and whether the prescribed indication is within the product licence. This is particularly important with unlicensed or non-formulary medicines when information and agreement

on continuation of prescribing, recommended monitoring and availability of supply are transferred from a hospital to primary care setting.

Risks in the dispensing process are reduced by attention to products with similar names or packaging, patients with similar names, and when supplying several family members at the same time. Medicines should be labelled accurately, with clear dosage instructions and advisory labels, and presented appropriately for patients with specific needs, for example, the visually impaired, those unable to read English or with limited dexterity.

Step 5. Monitoring therapy

Monitoring criteria for the effectiveness of treatment and its potential adverse effects can be drawn from the characteristics of the prescribed medicines used or related to specific patient needs. Close monitoring is required for medicines with narrow therapeutic indices and for the subset of drugs where therapeutic drug monitoring may be beneficial, for example, digoxin, phenytoin, theophylline and aminoglycosides. Anticoagulant therapy, including warfarin and unfractionated heparin, is associated with much preventable medication-related morbidity and always warrants close scrutiny.

Throughout this textbook, details are presented on the monitoring criteria that may be used for a wide range of medicines. Patients with renal or hepatic impairment or an unstable clinical condition need particular attention because of the likely requirement for dosage adjustment or change in therapy.

Step 6. Patient advice and education

There is a vast quantity of information on drug therapy available to patients. The practitioner's contribution in this context is to provide accurate and reliable information in a manner that the patient can understand. This may require the pharmacist to convey the benefits and risks of therapy, as well as the consequences of not taking medicines.

Information about medicines is best provided at the time of, or as soon as possible after, the prescribing decision. In the hospital setting, this means enabling patients to access information throughout their stay, rather than waiting until discharge. With many pharmacy departments providing medicines in patient packs, the patient can be alerted to the presence of information leaflets, encouraged to read them and ask any questions they may have. This approach enables the patient to identify their own information needs and ensures the pharmacist does not create a mismatch between their own agenda and that of the patient. However, there will be a need to explain clearly the limitations of leaflets, particularly when medicines are prescribed for unlicensed indications.

Although the research on adherence indicates the primacy of information that has been tailored to the individual's needs, resources produced by national organisations, such as Diabetes UK (www.diabetes.org.uk) and British Heart Foundation (www.bhf.org.uk), may also be of help to the patient and their family or carers. In addition, patients often require specific information to support their daily routine of taking medicines. All written information, including medicines reminder charts, should be dated and include contact details of the pharmacist to encourage patients to raise further queries or seek clarification.

Step 7. Evaluating effectiveness

The provision of drug therapy for the purpose of achieving definite outcomes is a fundamental objective of pharmaceutical care. These outcomes need to be identified at the outset and form the basis for evaluating the response to treatment. Practitioners delivering pharmaceutical care have a responsibility to evaluate the effectiveness of therapy by reviewing steps 1–6 above and taking appropriate action to ensure the desired outcomes are achieved. Depending on the duration of direct engagement with a patient's care, this may be a responsibility the pharmacist can discharge in person or it may necessitate transfer of care to a colleague in a different setting where outcomes can be assessed more appropriately.

Case study

The following case is provided to illustrate the application of several steps in the delivery of pharmaceutical care. It is not intended to be a yardstick against which patient care should be judged.

Case 1.1

Mr JB, a 67-year-old retired plumber, has recently moved to your area and has come to the pharmacy to collect his first prescription. He has a PMH of coronary heart disease (CHD) and has recently had a coronary artery stent inserted. He has a long history of asthma which is well controlled with inhaled medicines.

Step 1. Establishing the need for drug therapy

What classes of medicines would you expect to be prescribed for these indications?

Mr JB gives a complete medication history that indicates he takes his medicines as prescribed, he has no medication-related allergies, but does suffer from dyspepsia associated with acute use of non-steroidal anti-inflammatory agents. He has a summary of his stent procedure from the hospital that indicates normal blood chemistry and liver function tests.

Step 2. Selecting the medicine

What drug–patient, drug–disease and drug–drug interactions can be anticipated (Table 1.7).

Steps 3 and 4. Administering and providing the medicines

What regimen and individualised doses would you recommend for Mr JB (Table 1.8).

Table 1.7   The case of Mr JB: potential drug interactions with the patient, the disease or other drugs

	Drug–patient interactions	Drug–disease interactions	Drug–drug interactions
Medicines that should be prescribed for CHD			
Aspirin	Previous history of dyspepsia	Aspirin should be used with caution in asthma	Combination of antiplatelet agents increases risk of bleeding
Clopidogrel	Previous history of dyspepsia		
Statins			Possible increased risk of myopathy if simvastatin given with diltiazem
β-Blockers		β-Blocker contraindicated in asthma	Combination of different agents to control angina may lead to hypotension
Diltiazem			Reduces metabolism of simvastatin thereby increasing the risk of side effects
Nitrates (GTN spray)	Previous history of side effects (e.g. headache, flushing) may result in patient not using spray when required		
Medicines that may be prescribed for asthma			
β2-Agonist inhalers	Patient's ability to use inhaler devices effectively	β2-Agonists can cause tachycardia	
Steroid inhalers			
Antimuscarinic inhalers		Antimuscarinic agents can cause tachycardia and atrial fibrillation	Antimuscarinics may reduce effect of sublingual nitrate tablets (failure to dissolve under tongue owing to dry mouth)

CHD, coronary heart disease.

Table 1.8   The case of Mr JB: possible therapeutic regimen

	Recommendation	Rationale
Medicines that should be prescribed for CHD		
Aspirin	75 mg daily orally after food	Benefit outweighs risk if used with PPI
Clopidogrel	75 mg daily orally after food	Benefit outweighs risk if used with PPI Length of course should be established in relation to previous stent
Lansoprazole	15 mg daily orally	Decreases risk of GI bleeds with combination antiplatelets Concerns about some PPIs reducing the effectiveness of clopidogrel makes selection of specific PPI important
Simvastatin	20 mg daily orally	Low dose selected due to diltiazem reducing the metabolism of simvastatin and increasing the risk of side effect
Nitrates	2 puffs sprayed under the tongue when required for chest pain	

This predicted regimen can be compared with the prescribed therapy and any discrepancies resolved with the prescriber. Step 4 (provision) in Mr JB's case would be relatively straightforward.

Steps 5, 6 and 7. Monitoring therapy, patient education and evaluation

What criteria would you select to monitor Mr JB's therapy and what information would you share with the patient? What indicators would convey effective management of his condition (Table 1.9).

Quality assurance of clinical practice

Quality assurance of clinical pharmacy has tended to focus on the review of performance indicators, such as intervention rates, or rely upon experienced pharmacists to observe and comment on the practice of others using local measures. The lack of generally agreed or national criteria raises questions about the consistency of these assessments, where they take place, and the overall standard of care provided to patients. Following the Bristol Royal Infirmary Inquiry (2001) into

Table 1.8 The case of Mr JB: possible therapeutic regimen—cont'd		
	Recommendation	Rationale
Diltiazem	90 mg m/r twice a day	Used for rate control as β-blockers contraindicated in asthma
Ramipril	10 mg daily	To reduce the progression of CHD and heart failure
Medicines that may have been prescribed		
Salbutamol inhaler	2 puffs (200 μcg) to be inhaled when required	Patient should follow asthma treatment plan if peak flow decreases
Beclometasone inhalers	2 puffs (400 μcg) twice a day	Asthma treatment plan which may include increasing the dose of inhaled steroids if peak flow decreases
CHD, coronary heart disease; PPI, proton pump inhibitor; GI, gastro-intestinal; m/r, modified release.		

Table 1.9 The case of Mr JB: monitoring criteria and patient advice	
	Recommendation
Drugs that should be prescribed for CHD	
Aspirin	Ask patient about any symptoms of dyspepsia or worsening asthma
Clopidogrel	Ask patient about any symptoms of dyspepsia
Lansoprazole	If PPIs don't resolve symptoms, primary care doctor should be consulted
Simvastatin	Liver function tests 3 months after any change in dose, or annually Creatine kinase only if presenting with symptoms of unexplained muscle pain Cholesterol levels 3 months after any change in dose, or annually if at target
Nitrates (GTN spray)	Frequency of use to be noted. Increasing frequency that results in a resolution of chest pain should be reported to primary care doctor and anti-anginal therapy may be increased ANY use that does not result in resolution of chest pain requires urgent medical attention
Diltiazem	Blood pressure and pulse monitored regularly
Ramipril	Renal function and blood pressure monitored within 2 weeks of any dose change, or annually
Drugs that may have been prescribed for asthma	
Salbutamol inhaler	Salbutamol use should be monitored as any increase in requirements may require increase in steroid dose
Beclometasone inhalers	Monitor for oral candidiasis

paediatric cardiac surgery, there has been much greater emphasis on the need for regulation to maintain the competence of health care professionals, the importance of periodic performance appraisal coupled with continuing professional development, and the introduction of revalidation.

The challenges for pharmacists are twofold: first, to demonstrate their capabilities in a range of clinical pharmacy functions and second, to engage with continuing professional development in a meaningful way to satisfy the expectations of pharmaceutical care and maintain registration with, for example, the General Pharmaceutical Council in the UK. The pragmatic approach to practice and the clinical pharmacy process outlined throughout this chapter has been incorporated into a professional development framework, called the General Level Framework (GLF) available at: www.codeg. org, that can be used to develop skills, knowledge and other attributes irrespective of the setting of the pharmacist and their patients.

2 Prescribing

H. Marlow and C. Whittlesea

Key points

- Prescribers need to assess and manage the potential benefits and harms of treatment.
- Patients should receive cost-effective medication appropriate to their clinical needs, in doses that meet their requirements and for an adequate period of time.
- Respect for patient autonomy, obtaining consent and sharing decision making is a fundamental part of the prescribing process.
- The consultation is a fundamental part of clinical practice and requires effective interpersonal reasoning and practical skills.
- Using a consultation framework is recommended to ensure relevant issues are covered.
- Prescribing is a complex mix of factors - evidence, external influences and cognitive biases - and these should be recognised.

To prescribe is to authorise by means of a written prescription the supply of a medicine. Prescribing incorporates the processes involved in decision making undertaken by the prescriber before the act of writing a prescription. Historically, prescribing has been the preserve of those professionals with a medical, dental or veterinary training. As the role of other health care professionals such as pharmacists and nurses has expanded, prescribing rights have in turn been extended to them. The premise for this development has been that it better utilises the training of these professional groups, is clinically appropriate and improves patient access.

Regardless of the professional background of the individual prescriber, the factors that motivate them to prescribe a particular medicine are a complex mix of evidence of effectiveness and harm, external influences and cognitive biases. A rational approach to prescribing uses evidence and has outcome goals and evaluates alternatives in partnership with the patient. With the advent of new professional groups of prescribers (non-medical prescribers), it is increasingly important to understand the components of rational and effective prescribing, and the influences on this process. There is a need for a systematic approach to prescribing, and an understanding of the factors that influence the decision to prescribe a medicine. These issues will be covered in the following sections. Initially, the fundamentals of rational and effective prescribing will be discussed, followed by a brief outline of the acquisition of prescribing rights by pharmacists and the associated legal framework. The final section will cover the prescribing process and the factors that influence this.

Rational and effective prescribing

Prescribing a medicine is one of the most common interventions in health care used to treat patients. Medicines have the potential to save lives and improve the quality of life, but they also have the potential to cause harm, which can sometimes be catastrophic. Therefore, prescribing of medicines needs to be rational and effective in order to maximise benefit and minimise harm. This is best done using a systematic process that puts the patient at the heart of the process (Fig. 2.1).

What is meant by rational and effective prescribing?

There is no universally agreed definition of good prescribing. The WHO promotes the rational use of medicines, which requires that patients receive medications appropriate to their clinical needs, in doses that meet their own individual requirements, for an adequate period of time, and at the lowest cost to them and their community. However, a more widely used framework for good prescribing has been described (Barber, 1995) and identifies what the prescriber should be trying to achieve, both at the time of prescribing and in monitoring treatment thereafter. The prescriber should have the following four aims:

- Maximise effectiveness
- Minimise risks
- Minimise costs
- Respect the patient's choices.

This model links to the four key principles of biomedical ethics: beneficence, non-maleficence, justice and veracity, and respect for autonomy, and can be applied to decision making at both an individual patient level and when making decisions about medicines for a wider population, for example in a Drug and Therapeutics Committee. One of the strengths of this model is the consideration of the patient's perspective and the recognition of the inherent tensions between the four key aims.

Another popular framework to support rational prescribing decisions is known as STEPS (Preskorn, 1994). The STEPS

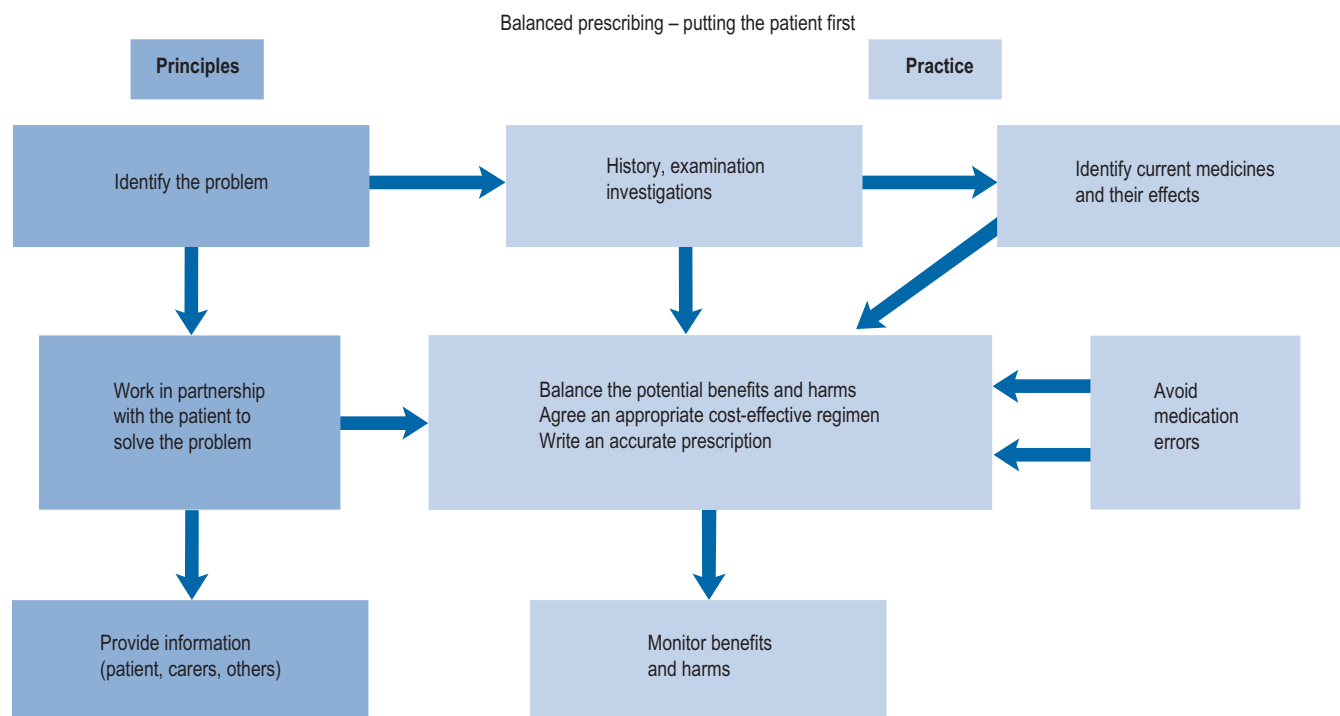
Balanced prescribing – putting the patient first


Fig. 2.1 A framework for good prescribing (from Background Briefing. A blueprint for safer prescribing 2009 © Reproduced by permission of the British Pharmacological Society.)

model includes five criteria to consider when deciding on the choice of treatment:

- Safety
- Tolerability
- Effectiveness
- Price
- Simplicity.

Inappropriate or irrational prescribing

Good prescribing is sometimes defined as the lack of irrational prescribing. Prescribing can be described as irrational for many reasons:

- Poor choice of a medicine
- Polypharmacy or co-prescribing of interacting medicine
- Prescribing for a self-limiting condition
- Continuing to prescribe for a longer period than necessary
- Prescribing too low a dose of a medicine
- Prescribing without taking account of the patient's wishes.

Inappropriate or irrational prescribing can result in serious morbidity and mortality, particularly when childhood infections or chronic diseases such as hypertension, diabetes, epilepsy and mental disorders are being treated. Inappropriate prescribing also represents a waste of resources and, as in the case of antimicrobials, may harm the health of the public by contributing to increased antimicrobial resistance. Finally, an over-willingness to prescribe stimulates inappropriate patient demand and fails to help the patient understand when they should seek out support from a health care professional.

Pharmacists as prescribers and the legal framework

Evolution of non-medical prescribing

Independent prescribing is defined as 'prescribing by a practitioner (doctor, dentist, nurse, pharmacist) who is responsible and accountable for the assessment of patients with undiagnosed or diagnosed conditions and for decisions about the clinic management required including prescribing' (DH, 2006).

In 1986, a report was published in the UK ('Cumberlage report') which recommended that community nurses should be given authority to prescribe a limited number of medicines as part of their role in patient care (Department of Health and Social Security, 1986). Up to this point, prescribing in the UK had been the sole domain of doctors, dentists and veterinarians. This was followed in 1989 by a further report (the first Crown report) which recommended that community nurses should prescribe from a limited formulary (DH, 1989). The legislation to permit this was passed in 1992.

At the end of the 1990s, in line with the then UK government's desire to widen access to medicines by giving patients quicker access to medicines, improving access to service and making better use of the skills of health care professionals, the role of prescriber was proposed for other health care professionals. This change in prescribing to include non-medical prescribers (pharmacists, nurses and optometrists) was developed following a further review (Crown, 1999).

This report suggested the introduction of supplementary prescribers, that is, non-medical health professionals who could prescribe after a diagnosis had been made and a clinical management plan drawn up for the patient by a doctor (Crown, 1999).

Supplementary prescribing

The Health and Social Care Act 2001 allowed pharmacists and other health care professionals to prescribe. Following this legislation, in 2003, the Department of Health outlined the implementation guide allowing pharmacists and nurses to qualify as supplementary prescribers (DH, 2003). In 2005, supplementary prescribing was extended to physiotherapists, chiropodists/podiatrists, radiographers and optometrists (DH, 2005).

Supplementary prescribing is defined as a voluntary prescribing partnership between an independent prescriber (doctor or dentist) and a supplementary prescriber (nurse, pharmacist, chiropodists/podiatrists, physiotherapists, radiographers and optometrists) to implement an agreed patient-specific clinical management plan with the patient's agreement. This prescribing arrangement also requires information to be shared and recorded in a common patient file. In this form of prescribing the independent prescriber, that is the doctor or if appropriate the dentist, undertakes the initial assessment of the patient, determines the diagnosis and the initial treatment plan. The elements of this patient-specific plan, which are the responsibility of the supplementary prescriber, are then documented in the patient-specific clinical management plan. The legal requirements for which are detailed in Box 2.1. Supplementary prescribers can prescribe Controlled Drugs and also both off-label and unlicensed medicines.

Box 2.1   Overview of the requirements for a clinical management plan for supplementary prescribing

Legal requirements
Patient details
- Name of the patient to whom the plan relates
- Patient allergies
- Difficulties patient has with medicines

Disease and treatment
- Condition
- Class or name of medicines
- Limitations on doses, strength or time of treatment
- When to seek advice from, or refer back to independent prescriber
- Arrangements for notification of adverse drug reactions or incidents

Prescriber information
- Name of independent prescriber (doctor or dentist)
- Name of supplementary prescriber (pharmacist, nurse, physiotherapists, chiropodists/podiatrists, radiographers and optometrists)
- Start date
- Review date

Non-medical independent prescribing

Following publication of a report on the implementation of nurse and pharmacist independent prescribing within the NHS in England (DH, 2006), pharmacists were enabled to become independent prescribers as defined under the Medicines and Human Use (Prescribing; Miscellaneous Amendments) Order of May 2006. Pharmacist independent prescribers were able to prescribe any licensed medicine for any medical condition within their competence except Controlled Drugs and unlicensed medicines. The restriction on Controlled Drugs included those in Schedule 5 (CD Inv.POM and CD Inv.P) such as co-codamol. At the same time, nurses could also become qualified as independent prescribers (formerly known as Extended Formulary Nurse Prescribers) and prescribe any licensed medicine for any medical condition within their competence, including some Controlled Drugs. Since 2008, optometrists can also qualify as independent prescribers to prescribe for eye conditions and the surrounding tissue. They cannot prescribe for parenteral administration and they are unable to prescribe Controlled Drugs.

Following a change in legislation in 2010, pharmacist and nurse, non-medical prescribers, were allowed to prescribe unlicensed medicines (DH, 2010).

From the above it should be evident that in the UK suitably qualified pharmacists can prescribe as either supplementary or independent prescribers.

Accountability

Prescribers have the authority to make prescribing decisions for which they are accountable both legally and professionally. Accountability when prescribing covers three aspects – the law, the statutory professional body and the employer.

The law of Tort, the concept of a 'civil wrong', includes clinical negligence. In such a claim, the patient needs to demonstrate that the prescriber caused them injury or damage. For this allegation to be substantiated the patient needs to prove that the prescriber owed them a duty of care, that this duty of care was breached and that this caused the injury identified, and also that the injury was foreseeable. The law of Tort also permits actions for breach of confidentiality and also for battery, should a patient be treated without consent. Therefore, prescribers (independent and supplementary) are legally and professionally accountable for their decisions. This includes decisions not to prescribe and also ensuring that the prescription is administered as directed. The legal responsibility for prescribing always lies with the individual who signed the prescription. In addition, prescribers also have a responsibility to ensure the instructions are clear and not open to misinterpretation.

If a prescriber is an employee then the employer expects the prescriber to work within the terms of his/her contract, competency and within the rules/policies, standard operating procedure and guidelines, etc. laid down by the organisation. Therefore, working as a prescriber, under these conditions, ensures that the employer has vicarious liability. So should any patient be harmed through the action of the prescriber

and he/she is found in a civil court to be negligent, then under these circumstances the employer is responsible for any compensation to the patient. Therefore, it is important to always work within these frameworks, as working outside these requirements makes the prescriber personally liable for such compensation. To reinforce this message it has been stated that the job descriptions of non-medical prescribers should incorporate a clear statement that prescribing forms part of the duties of their post (DH, 2006).

Ethical framework

Four main ethical principles of biomedical ethics have been set out for use by health care staff in patient–practitioner relationships (Beauchamp and Childress, 2001). These principles are respect for autonomy, non-maleficence, beneficence, justice and veracity and need to be considered at all points in the prescribing process.

Autonomy

Autonomy recognises an individual patient's right to self-determination in making judgements and decisions for themselves and encompasses informed patient consent. Respect for autonomy is therefore a form of personal liberty which freely permits patients to choose whether they wish to have treatment in accordance with their own plans.

Confidentiality. Confidentiality is a fundamental right with respect to patient autonomy. Therefore, patients have the right to confidentiality, and consent is required to disclose information regarding their health and treatment.

Consent. Obtaining consent from a patient for treatment can be divided into three components: voluntariness, information and competency. Consent is invalid when it is given under pressure or coercion. Therefore, it is important that consent is obtained for each act and not assumed because this is a routine assessment or procedure and therefore can be carried out automatically. It is essential the patient understands their diagnosis, the benefit and rationale of the proposed treatment and the likelihood of its success together with the associated risks and consequences, for example side effects. Therefore, a prescriber needs to discuss these aspects with the patient. In addition, potential alternative treatments should also be discussed to allow the patient to make a comparison with the proposed plan. The prognosis if no treatment is prescribed should also be discussed. Such a wide-ranging discussion may require more than one appointment and reinforces the necessity for an ongoing patient–professional relationship focused on the needs of the patient. Associated with this is the need to determine if the patient has the competency to make decisions for themselves with respect to vulnerable groups such as those who have learning disabilities, children and the elderly. Young people aged 16 and 17 are normally presumed to be able to consent to their own treatment.

Gillick competence is used to determine if children have the capacity to make health care decisions for themselves. Children under 16 years of age can give consent as long as they can satisfy the prescriber that they have capacity to make this decision.

However, with the child's consent, it is a good practice to involve the parents in the decision-making process. In addition, children under 16 may have the capacity to make some decisions relating to their treatment, but not others. So it is important that an assessment of capacity is made related to each decision. There is some confusion regarding the naming of the test used to objectively assess legal capacity to consent to treatment in children under 16, with some organisations and individuals referring to Fraser guidance and others Gillick competence. Gillick competence is the principle used to assess the capacity of children under 16, while the Fraser guidance refers specifically to contraception (Wheeler, 2006).

The Mental Capacity Act (2005) protects the rights of adults who are unable to make decisions for themselves. The fundamental concepts within this act are the presumption that every adult has capability and should be supported to make their own individual decision. The five key principles are listed in Box 2.2. Therefore, any decision made on their behalf should be as unrestrictive as possible and must be in the patient's own interest, not biased by any other individual or organisation's benefit. Advice regarding patient consent is listed in Box 2.3.

Non-maleficence

At the heart of the principle of non-maleficence is the concept of not knowingly causing harm to the patient. The principle is expressed in the Hippocratic Oath. This obligation not to harm is distinct from the obligation to help others. While

---

Box 2.2 Overview of the five principles of the Mental Capacity Act

- A person is assumed to have capacity unless it is established that he/she lacks capacity.
- A person should not be treated as unable to make a decision unless all practical steps to enable him/her to do this have been taken without success.
- A person cannot be treated as unable to make a decision because he/she makes an unwise decision.
- Acts or decisions made for or on behalf of a person who lacks capacity must be in that person's best interests.
- Before an act or decision is made, the purpose has to be reviewed to assess if it can be achieved as effectively in a way that is less restrictive of the person's rights/freedom of action.

Box 2.3 Advice on patient consent

- Take care when obtaining consent.
- Give the patient understandable information about all significant possible adverse outcomes.
- Ensure the patient has the opportunity to ask questions/consider his/her options.
- Document the advice/warnings provided in the patient's notes.
- Invite the patient to sign to say that he/she understands, and accepts the risks explained.
- Record in the patient's notes if they decline to undergo a treatment/procedure.

codes of all health care professionals outline obligations not to harm clients, many interventions result in some harm, however transitory. Sometimes one act can be described as having a 'double effect', that is, two possible effects: one good effect (intended) and one harmful effect (unintended). The harmful effect is allowed if proportionally it is less than the good effect. Therefore, it is important for prescribers to review both the potential positive effects of treatment, for example symptom control, and the negative effects, for example side effects. It is also important to consider both acts of commission and omission, as a failure to prescribe can also cause harm to the patient.

Beneficence

This is the principle of doing good and refers to the obligation to act for the benefit of others that is set out in codes of professional conduct, for example, pharmacists' code of ethics and professional standards and guidance (Royal Pharmaceutical Society of Great Britain, 2009). Beneficence is referred to both physical and psychological benefits of actions and also related to acts of both commission and omission. Standards set for professionals by their regulatory bodies such as the General Pharmaceutical Council can be higher than those required by law. Therefore, in cases of negligence the standard applied is often that set by the relevant statutory body for its members.

Justice and veracity

This last principle is related to the distribution of resources to ensure that such division or allocation is governed by equity and fairness. This is often linked to cost-effectiveness of treatment and potential inequalities if treatment options are not offered to a group of patients or an individual. However, as a prescriber it is important to consider the evidence base for the prescribed medicine and also to review the patient as an individual to ensure the treatment offered adheres to this principle. This principle of fairness and freedom from discrimination therefore encompasses Human Rights including the need for assessment of medication as part of the Disability Discrimination Act. Health care professionals have a duty under this act to make reasonable adjustments to ensure that all patients have the same opportunity for good health. Therefore, a prescriber should also assess with the patient that the medication prescribed can be accessed by them. Veracity or 'truth telling' underpins both effective communication and patient consent.

Professional frameworks for prescribing

Each professional regulatory body has standards to which their members must adhere. Members are accountable to such bodies for their practice and can be sanctioned by these bodies if their actions do not adhere to these standards. Therefore, individuals will be held accountable by their respective statutory body for their prescribing decisions.

The professional standards for pharmacists are defined within 'Medicines, Ethics and Practice' and contain additional requirements for pharmacists who are qualified as non-medical prescribers and also good practice guidance (Royal Pharmaceutical Society of Great Britain, 2009). This guidance provides advice on a wide range of areas including self-audit, promotions, gifts from drug companies, written agreement with the employing organisation describing the prescriber's scope of practice, liability and indemnity arrangements, competency to prescribe and not just prescribing and dispensing a medicine.

Off-label and unlicensed prescribing

For a medicine to be licensed for use in a specific country, the manufacturer must obtain a marketing authorisation, formerly called the product license. This details the patients, conditions and purpose under which the medicine is licensed for use. Any medicine which does not have a marketing authorisation for the specific country where it is prescribed is termed 'unlicensed'. Unlicensed medicines prescribed include new medicines undergoing clinical trial, those licensed and imported from another country but not licensed in the country where they are to be used. It also includes 'specials' manufactured to meet a specific patient's needs or produced when two licensed medicines are mixed for administration.

However, if a licensed medicine is prescribed outside that specified in the marketing authorisation then this is described as 'off-label'. This happens in practice, for example many medicines are not licensed for use in children but are prescribed for them. In addition, some established medicines are prescribed for conditions outside their marketing authorisation, for example amitriptyline for neuropathic pain and azathioprine in Crohn's disease. The British National Formulary includes information on off-label use as an annotation of 'unlicensed indication' to inform health care professionals. The details of a medicine's marketing authorisation are provided in the Summary of Product Characteristics.

The company which holds the marketing authorisation has the responsibility to compensate patients who are proven to have suffered unexpected harm caused by the medicine when prescribed and used in accordance with the marketing authorisation. Therefore, if a medicine is prescribed which is either unlicensed or off-label, the prescriber carries professional, clinical and legal responsibility and is therefore liable for any harm caused. Best practice on the use of unlicensed and off-label medicines is described in Box 2.4. In addition, all health care professionals have a responsibility to monitor the safety of medicines. Suspected adverse drug reactions should therefore be reported in accordance with the relevant reporting criteria.

Prescribing across the interface between primary and secondary care

When a patient moves between care settings, there is a risk that a 'gap' in care will take place. These 'gaps' in care are almost always as a result of poor communication and frequently involve medicines, particularly when the patient is

Box 2.4 Advice for prescribing unlicensed and off-label medicines (from Drug Safety Update, 2009; 2: 7, with kind permission from MHRA)

Consider
- Before prescribing an unlicensed medicine be satisfied that an alternative licensed medicine would not meet the patient's needs.
- Before prescribing an off-label medicine be satisfied that such use would better serve the patient's needs than an appropriately licensed alternative.
- Before prescribing an unlicensed medicine or using an off-label medicine:
  - be satisfied that there is a sufficient evidence base and/or experience of using the medicine to show its safety and efficacy;
  - take responsibility for prescribing the medicine and for overseeing the patient's care, including monitoring and follow up;
  - record the medicine prescribed and, where common practice is not being followed, the reason for prescribing the medicine; you may wish to record that you have discussed this with the patient.

Communicate
- You give patients, or those authorising treatment on their behalf, sufficient information about the proposed treatment, including known serious or common adverse drug reactions, to enable them to make an informed decision.
- Where current practice supports the use of a medicine outside the terms of its license, it may not be necessary to draw attention to the license when seeking consent. However, it is a good practice to give as much information as patients or carers require or which they see as relevant.
- You explain the reasons for prescribing an off-label medicine or prescribing an unlicensed medicine where there is little evidence to support its use, or where the use of the medicine is innovative.

discharged from hospital into a community setting. So far, there is no evidence-based solution to these problems. The primary care prescriber with the responsibility for the continuing management of the patient in the community may be required to prescribe medicines with which they are not familiar. The prescriber should be fully informed and competent to prescribe a particular medicine for his/her patient. Supporting information from the hospital, in the form of shared care guidelines, can help inform the prescriber about medicines with which they may not be very familiar. Overall, the decision about who should take responsibility for continuing care or prescribing treatment after the initial diagnosis or assessment should be based on the patient's best interests rather than on the health care professional's convenience or the cost of the medicine. However, it is legitimate for a prescriber to refuse to prescribe where they consider they have insufficient expertise to accept responsibility for the prescription or where the product is of a very specialised nature and/or requires complex ongoing monitoring. Professional bodies are developing principles for communication between health care professionals in primary and secondary care to improve patient safety.

Clinical governance

Clinical governance is defined as 'the system through which NHS organisations are accountable for continuously improving the quality of their services and safeguarding high standards of care, by creating an environment in which clinical excellence will flourish' (DH, 1998). It is a process embraced by the NHS to ensure that the quality of health care embedded within organisations is continuously monitored and improved. Clinical governance parallels corporate governance within commercial organisations and as such provides a systematic set of mechanisms such as duties, accountabilities and rules of conduct to deliver quality health care.

Clinical governance is described as having seven pillars:

- Patient, service user, carer and public involvement
- Risk management
- Clinical audit
- Staffing and management
- Education, training and continuing professional development (CPD)
- Research and clinical effectiveness
- Use of information.

Within the NHS, standards of practice have been developed and monitored to ensure risks are managed and controlled. As part of this framework the performance of staff is also assessed and remedial action taken, if required. NHS organisations have clinical governance requirements for their staff which include requirements for non-medical prescribing.

Professional bodies have also incorporated clinical governance into their codes of practice. The four tenants of clinical governance are to ensure clear lines of responsibility and accountability; a comprehensive strategy for continuous quality improvement; policies and procedures for assessing and managing risks; procedures to identify and rectify poor performance in staff. Therefore, the professional bodies such as those of pharmacists, nurses and optometrists have also identified clinical governance frameworks for independent prescribing as part of their professional codes of conduct. The General Pharmaceutical Council, the UK pharmacy regulator, code of practice provided a framework not only for the individual pharmacist, non-medical prescriber, but also for their employing organisation. Suggested indicators for good practice are detailed in Box 2.5.

Competence and competency frameworks

Competence can be described as the knowledge, skills and attributes required to undertake an activity to a specific minimum standard within a defined environment. A competency framework is a group of competencies identified as essential to effectively perform a specific task. It can be used by an individual or an organisation to assess performance in this defined area. For example, it can be used for staff selection/recruitment, training and performance review.

The National Prescribing Centre has published a competency framework for pharmacist prescribers

Box 2.5 Overview of clinical governance practice recommendations for prescribers

- Ensure effective communication with patients and carers to meet the patient's needs, so that the patient can make informed choices about their treatment.
- Prescribe within competence (scope of practice).
- Obtain patient consent for investigations and management.
- Document in the patient's medical record, a comprehensive record of the consultation and the agreed treatment plan.
- Undertake full assessment of patients competently and with consent.
- Prescribe safely, legally, appropriately, clinically and cost-effectively with reference to national and local guidelines.
- Assess and manage risk of treatment and associated investigations.
- Prescribe and refer in accordance with the clinical management plan if relevant.
- Ensure the secure storage of prescriptions and follow the relevant organisational procedures if they are lost or stolen.
- Ensure wherever possible separation of prescribing and dispensing; prescribing and administration.
- Audit prescribing practice.
- Identify and report incidents and adverse drug reactions.
- Participate in and record continuing professional development relating to prescribing.
- Follow organisational procedures for dealing with the pharmaceutical industry regarding gifts and hospitality.

(Granby and Picton, 2006) which is described in Table 2.1. This framework is composed of three areas: the consultation, prescribing effectively and prescribing in context. These three areas are further subdivided to provide nine competencies each with an overarching statement. The nine competencies are:

- Clinical and pharmaceutical knowledge
- Establishing options
- Communicating with patients
- Prescribing safety
- Prescribing professionally
- Improving prescribing practice
- Information in context
- The NHS in context (the principles apply to all health care organisations)
- The team and individual context.

Each of these competencies is supported by a series of statements/behavioural indicators, all of which an individual needs to demonstrate they have achieved the overall competency (Table 2.1). Prescribers can review their prescribing performance using the nine competencies and the associated 77 behavioural indicators using this framework as a self-assessment tool. The framework is particularly useful when structuring ongoing CPD.

Table 2.1 Overview of the National Prescribing Centre competency framework for pharmacists (Granby and Picton, 2006)

Competency area	Competency	Behaviour indicator
Consultation	Clinical and pharmaceutical knowledge	10 statements For example, understands the conditions being treated, their natural progress and how to assess their severity
	Establishing options	14 statements For example, assesses the clinical condition using appropriate techniques and equipment
	Communicating with patients	11 statements For example, explains the nature of the patient's condition, the rationale behind and potential risks and benefits of management options
Prescribing effectively	Prescribing safely	9 statements For example, only prescribes a medicine with adequate, up-to-date knowledge of its actions, indications, contraindications, interactions, cautions, dose and side effects
	Prescribing professionally	8 statements For example, accepts personal responsibility for own prescribing and understands the legal and ethical implications of doing so
	Improving prescribing practice	7 statements For example, reports prescribing errors and near misses, reviews practice to prevent recurrences
Prescribing in context	Information in context	6 statements For example, critically appraises the validity of information sources (e.g. promotional literature, research)
	The NHS in context	5 statements For example, follows relevant local and national guidance for medicines use (e.g. local formularies, care pathways, NICE guidance)
	The team and individual context	7 statements For example, establishes relationships with colleagues based on understanding, trust and respect for each other's roles

The prescribing process

Consultation

The consultation is a fundamental part of the prescribing process and the prescriber needs to understand and utilise this in order to help them practise effectively. The medical model of disease, diagnosis and prescribing is often central to practice, but an understanding of the patient's background together with their medical beliefs and anxieties is equally important in helping the prescribers understand their own role and behaviours alongside those of their patients. A broad range of practical skills are needed in the consultation:

- *Interpersonal skills:* the ability to communicate and make relationships with patients.
- *Reasoning skills:* the ability to gather appropriate information, interpret the information and then apply it both in diagnosis and management.
- *Practical skills:* the ability to perform physical examinations and use clinical instruments.

The style in which the consultation is undertaken is also important. The paternalistic prescriber–patient relationship is no longer appropriate. This has been replaced in modern health care by a more patient-centred focus that ensures patient autonomy and consent. This uses a task-orientated approach to keep consultation times to a reasonable duration and set parameters to ensure a realistic expectation from the consultation.

An example of this is the Calgary Cambridge framework which can be used to structure and guide patient consultations (Silverman et al., 2005). The framework is represented in Fig. 2.2. The five key stages of the consultation are:

- Initiating the session
- Gathering information
- Physical examination
- Explanation and planning
- Closing the session.

In addition to these stages there are two key tasks performed throughout the consultation. These are 'providing structure' and 'building the patient–prescriber relationship'. These two tasks are vital in ensuring an effective consultation. For a patient–prescriber communication to be effective, it is important that this focuses on interaction between the patient and the prescriber and is not just passive transmission of information. Feedback from the patient about the information received is essential for effective communication and will be covered in more detail below.

Building relationships

Non-verbal communication is important and can be used by the prescriber to gain information from the patient. Facial expressions and body posture can give clues about how the patient is feeling, for example anxious or tired. Proximity and

Providing structure

- Making organisation overt
- Attending to flow

Initiating the session

- Preparation
- Establishing initial rapport
- Identifying the reasons for the consultation

Gathering information

- Exploration of the patient's problems to discover the:
  - Biomedical perspective
  - Background information – context
  - Patient's perspective

Physical examination

Explanation and planning

- Providing the correct type and amount of information
- Aiding accurate recall and understanding
- Achieving a shared understanding: incorporating the patient's illness framework
- Planning: shared decision making

Closing the session

- Ensuring appropriate point of closure
- Forward planning

Building the relationship

- Using appropriate non-verbal behaviour
- Developing rapport
- Involving the patient

Fig. 2.2 Calgary Cambridge consultation framework (Silverman et al., 2005). Reproduced with kind permission from the Radcliffe Publishing Ltd, Oxford.

eye contact are also important to determine if the patient is activity engaged in the conversation or are they distracted. Such non-verbal clues, for example anxiety, tiredness and pain, can then be explored verbally with the patient.

The prescribers also need to review their own non-verbal communication to ensure this reinforces the verbal message they are giving to the patient. For example, doctors who face the patient, make eye contact and maintain an open posture were regarded by their patients to be more interested and empathic (Harrigan et al., 1985). Also health care professionals in primary care who demonstrated non-verbal intimacy (close distance, leaning forward, appropriate body orientation and touch) had increased patient satisfaction (Larsen and Smith, 1981).

As eye contact is an important non-verbal form of communication, obtaining information from patient records and documenting the consultation could undermine these skills. Therefore, it is important to read notes in advance of the consultation and avoid writing up the outcome while the patient is speaking. Indicating to the patient that references need to be made to their record or information documented ensures the patient is informed about the break in the consultation. This strategy should be adopted for both paper and computer-based records.

Developing rapport is also essential to building an effective patient–prescriber relationship. This can be achieved by providing an accepting response to the patient's concerns and expectations. This is achieved by acknowledging the patient's views and valuing their contribution and accepting this information in a non-judgemental way. This does not necessarily mean that the prescriber agrees with information but that they accept that this is a legitimate view from the patient's perspective. This can be reinforced by summarising the patient's view. The prescriber should acknowledge the patient's coping efforts and self-care. Avoiding jargon and explaining complex concepts in simple terms, to enable patients to understand the diagnosis and management, is also important.

Providing structure

This is important in the patient–prescriber consultation to enable the five key stages to be effectively completed. The prescriber needs to establish the boundaries for the consultation, that is, the time available and the topics covered and termination of the consultation. Therefore, as the power in the consultation is with the prescriber, it is his/her responsibility to guide the consultation and involve the patient. This is to ensure a patient-centred collaborative partnership is established. This can be achieved by using problem identification, screening and agenda-setting skills. The use of a logical sequence, signposting from one part of the consultation to the next and including an initial and end summary, will provide an effective structure to the consultation.

Initiating the session

During the first stage of the consultation the prescriber needs to greet the patient and confirm his/her identity. They should also ensure the environment for the consultation is appropriate for maintaining eye contact and ensuring confidentiality. The prescriber should also introduce him/herself, his/ her role and gain relevant consent. During this stage the prescriber must demonstrate respect for the patient and establish a patient-centred focus. Using initially open and then closed questions the prescriber needs to identify the patient's problem/issues. By adopting this approach and actively listening, the prescriber is able to confirm the reason for the consultation and identify other issues. This allows the prescriber to negotiate an agenda for the next stages of the consultation through agreement with the patient and taking into account both the patient and prescriber's needs. This initial stage is vital for the success of the consultation as many patients have hidden agendas which, if not identified at this stage, can lead to these concerns not being addressed. Beckman and Frankel (1984) studied doctors' listening skills and identified that even minimal interruptions by doctors to initial patients' statements at the beginning of the consultation prevented patients' concerns from being expressed. This resulted in either these issues not being identified at all or they were raised by patient's late in the consultation

Gathering information

The aim of this stage is to explore the problem identified from both the patient and prescriber's perspective to gain background information which is both accurate and complete. Britten et al. (2000) identified that lack of patient participation in the consultation led to 14 categories of misunderstanding between the prescriber and patient. These included patient information unknown to the prescriber, conflicting information from the patient and communication failure with regard to the prescriber's decision. During this stage the illness framework, identified by exploring the patient's ideas, concerns, expectations and experience of his/her condition and effect on his/her life, is combined with the information gained by the prescriber through his/her biomedical perspective. This encompasses signs, symptoms, investigations and underlying pathology. Assimilation of this information leads the prescriber to a differential diagnosis. By incorporating information from both viewpoints, a comprehensive history detailing the sequence of events can be obtained using questioning, listening and clarification. This ends with an initial summary where the prescriber invites the patient to comment and contribute to the information gathered.

Physical examination

At the start of this stage it is important to again obtain the patient's consent for any examination by explaining the process and rationale for the assessment. The environment, for example room temperature and screening for the examination, is important and the prescriber should review this to ensure the patient's comfort.

Explanation and planning

This stage of the consultation incorporates three aspects: the differential diagnosis/hypothesis, the prescriber's management plan (investigations and alternative treatments), explanation and negotiating the plan of action with the patient.

In one UK study, doctors were found to overestimate the extent to which they completed the tasks of discussing the risk of medication, checking the ability of the patient to follow the treatment plan and obtaining the patient's input and view on the medication prescribed (Makoul et al., 1995).

In order to successfully accomplish this stage of the consultation, the prescriber needs to use a number of skills and also to involve the patient. The prescriber should ensure he/she gives the correct type and amount of information. This is done by assessing the patient's prior knowledge by employing both open and closed questions. By organising the information given into chunks which can be easily assimilated the prescriber can then check the patient understands the information given. Questioning the patient regarding additional information they require also helps to ensure the patient's involvement and maintains rapport. The prescriber must determine the appropriate time to give explanations and also allow the patient time to consider the information provided. Signposting can also be a useful technique to employ during this stage. Once again the language used should be concise, easy to understand and avoid jargon. Using diagrams, models and written information can enhance and reinforce patient understanding. The explanation should be organised into discreet sections with a logical sequence so that important information can be repeated and summarised. Box 2.6 summarises the issues the prescriber should consider before prescribing a medicine.

Box 2.6   Issues the prescriber should reflect upon before prescribing a medicine (National Prescribing Centre, 1998)

- What is the drug?
  - Is it novel?
  - Is it a line extension?
- What is the drug used for?
  - Licensed indications
  - Any restrictions on initiation
  - Does first line mean first choice?
- How effective is the drug?
  - Is there good evidence for efficacy?
  - How does it compare with existing drugs?
- How safe is the drug?
  - Are there published comparative safety data?
  - Has it been widely used in other countries?
  - Are the details contained in the Summary of Product Characteristics understood?
  - Are there clinically important drug interactions?
  - Are there monitoring requirements?
  - Can it be used long term?
- Who should not receive this drug?
  - Are there patients in whom it is contraindicated?
- Does the drug provide value for money?
  - Is there good evidence of cost-effectiveness compared to other available interventions?
  - What impact will this drug have on the health care budget?
- What is its place in therapy?
  - What advantages are there?
  - Are the benefits worth the cost?
  - Are there some patients that would particularly benefit?

To achieve shared understanding and shared decision making, it is important to incorporate the patient's perspective by relating the information given to the patient's illness framework. The patients also need to have the opportunity to ask questions, raise doubts and obtain clarification. This can be undertaken effectively by taking the patient's beliefs, culture, abilities and lifestyle into account when discussing treatment options, for example fasting during Ramadan, or use of memory aids to support adherence. The prescriber should also explain his/her rationale for the management plan identified and also discuss possible alternatives. By involving and negotiating with the patient in this way, a mutually acceptable treatment plan can be identified which allows the patient to take responsibility for his/her own health.

Closing the session

The effectiveness of the end of a consultation is as important as the preceding stages. A number of steps are undertaken during the closing stage. These include agreeing a contract with the patient as to the next steps to be taken by both patient and prescriber, for example additional investigations and/or referral. Safety net strategies are also employed and discussed, so the patient can identify unexpected outcomes or treatment failure and also understand who and how to contact the prescriber or another health care professional if appropriate. The end summary is an essential component of this stage and is used to briefly and accurately identify the management plan established during the previous stage in the consultation. This is followed by final checking that the patient has understood and consented to this management plan. At the end of the consultation the patient is given another opportunity to ask any final questions.

Communicating risks and benefits of treatment

Explaining the risks and benefits of treatment in an effective manner is an essential skill for health care professionals. This ensures patient's consent to treatment is informed and that the patient has an opportunity to participate in shared decision making about their treatment. Before this stage of the consultation is reached, the health care professional has to know the evidence about treatment, be able to apply it to the individual patient in front of them and then be able to communicate risks and benefits in terms the patient can understand.

It is important to communicate the risks and benefits of treatment in relation to medicines. This is because many medicines are used long term to treat or prevent chronic diseases, but we know they are often not taken as intended. Sometimes these medicines do not appear to have any appreciable beneficial effect on patients' symptoms, for example medicines to treat hypertension. Most patients want to be involved in decisions about their treatment, and would like to be able to understand the risks of side effects versus the likely benefits of treatment, before they commit to the inconvenience of taking regular medication. An informed patient is more likely to be concordant with treatment, reducing waste of health care

resources including professional time and the waste of medicines which are dispensed but not taken.

Communicating risk is not simple (Paling, 2003). Many different dimensions and inherent uncertainties need to be taken into account, and patients' assessment of risk is primarily determined by emotions, beliefs and values, not facts. This is important, because patients and health care professionals may ascribe different values to the same level of risk. Health care professionals need to be able to discuss risks and benefits with patients in a context that would enable the patient to have the best chance of understanding those risks. It is also prudent to inform the patient that virtually all treatments are associated with some harm and that there is almost always a trade-off between benefit and harm. How health care professionals present risk and benefit can affect the patient's perception of risk.

Some important principles to follow when describing risks and benefit to patients:

- Remember patients' assessments of risk are primarily determined by emotions, not by facts
- Communicate the trade-off between benefits and harms
- Avoid purely descriptive terms of risk, for example 'low risk'
- Use a consistent denominator, for example 1 in 100, 5 in 100; not 1 in 100, 1 in 20
- Use absolute numbers (not relative, or percentages)
- Describe outcomes in both a negative and positive perspective
- Use visual aids and probabilities.

Visual patient decision aids are becoming increasingly popular as a tool that health care professionals can use to support discussions with patients by increasing their knowledge about expected outcomes and helping them to relate these to their personal values (National Prescribing Centre, 2008). Further information about using patient decision aids can be found at http://www.npci.org.uk/therapeutics/mastery/mast4/patient_decision_aids/patient_decision_aid1.php

Adherence

Adherence has been defined as the extent to which a patient's behaviour matches the agreed recommendation from the prescriber. When a patient is non-adherent this can be classified as intentional or unintentional non-adherence (National Institute for Health and Clinical Excellence, 2009).

Unintentional non-adherence occurs when the patient wishes to follow the treatment plan agreed with the prescriber, but is unable to do so because of circumstances beyond their control. Examples of this include forgetting to take the medicine at the defined time or an inability to use the device prescribed. Strategies to overcome such obstacles include medication reminder charts, use of multi-compartment medication dose systems, large print for those with poor eyesight, aids to improve medication delivery, for example inhaler-aids, tube squeezers for ointments and creams, and eye drop administration devices. A selection of these devices is detailed in a guide to the design of dispensed medicines (National Patient Safety Agency, 2007).

Intentional non-adherence occurs when the patient decides he/she does not wish to follow the agreed treatment plan. This may occur because of the patient's beliefs, his/her perceptions or motivation. Therefore, it is important that all of these aspects are included in the discussion between the patient and prescriber when the treatment plan is developed. The patient needs to fully appreciate his/her medical condition and its prognosis in order to understand the rationale for the treatment options discussed. Also the effect of not taking the treatment needs to be explicitly explored with the patient. The benefits of the treatment plan as well as side effects also need to be explored with the patient. The patient information leaflet (PIL) can be used to support this discussion. The patient's previous experience of medicines and associated side effects should be explored as this gives the prescriber vital information about perceptions and motivation. Adherence to existing prescribed medication should be explored non-judgementally. For example, asking the patient how often he/she has missed taking doses at the prescribed time over the previous 7 days would enable the prescriber to assess adherence but also explore lifestyle factors or side effects which may impact on the patient. These can then be discussed and strategies developed to optimise adherence.

Studies have demonstrated that between 35% and 50% of medicines prescribed for chronic conditions are not taken as recommended (National Institute for Health and Clinical Excellence, 2009). Therefore, it is the prescriber's responsibility to explore with the patient their perceptions of medicines to determine if there are any reasons why they may not want to or are unable to use the medicine. In addition, any barriers which might prevent the patient from using the treatment as agreed, for example manual dexterity, eyesight, memory, should be discussed and assessed. Such a frank discussion should enable the patient and prescriber to jointly identify the optimum treatment regimen to treat the condition. In addition, information from the patient's medical records can be used to assess adherence. For example, does the frequency of requests for repeat medication equate to the anticipated duration of use?

Review of unused medicines can be undertaken and it is also important to assess the patient's administration technique on an ongoing basis for devices, for example asthma inhalers to optimise correct technique. This can be achieved, for example, on carrying out a medicine's reconciliation on hospital admission when the patient's prescribed medicines are compared to what they were taking before admission through discussion with patients/carers and review of primary care records.

As it is likely that at some point all patients will forget to take their medicine, it is important to give all patients information on what to do should a dose be missed. For individuals taking medication for treatment of a chronic condition, adherence should not be assumed and therefore assessment of adherence should form an ongoing discussion at each consultation.

Medication review

Medication review has been defined as 'a structured, critical examination of a patient's medicines with the objective of reaching an agreement with the patient about treatment, optimising the impact of medicines, minimising the number of medication-related problems and reducing waste' (Medicines Partnership, 2002).

It is important that medicines are prescribed appropriately and that patients continue to achieve benefits from their medicines. The regular review of medicines is a key part of a good prescribing process and has many potential benefits for patients including:

- Improves the current and future management of the patient's medical condition;
- Provides an opportunity to develop a shared understanding between the patient and the health care professional about medicines and their role in the patient's treatment;
- Improves health outcomes through optimal medicines use;
- Reduces adverse events related to medicines;
- Provides an opportunity to empower the patient and carers to be actively involved in their care and treatment;
- Reduces unwanted or unused medicines.

Many medicines prescribed for patients are used to treat chronic long-term conditions and are consequently prescribed regularly on a long-term basis. Frequently, patients obtain these medicines using a repeat prescribing system. This enables the patients to obtain further supplies of their medicine without routinely having to see their primary care doctor or prescriber, thereby reducing unnecessary consultations. In the UK, repeat prescribing accounts for about 60–75% of all prescriptions and 80% of cost. Robust systems and processes are essential in primary care to ensure repeat prescribing is safe and not wasteful. Reviewing a patient's medication forms an essential element of a robust repeat prescribing process.

Medication reviews can be carried out in many different care settings, by a variety of health care professionals and in many different ways. Different types of medication review are required to meet the needs of patients for different purposes. A medication review can be from a simple review of the prescription to an in-depth clinical medication review. However, the aim of all types of medication review is to achieve the following:

- Give patients the chance to raise questions and highlight problems they are having with their medicines.
- Seek to improve or optimise the benefit of treatment for an individual patient.
- Review should be carried out in a systematic way by a competent health care professional.
- Have any proposed changes from the review agreed with the patient.
- Review should be clearly documented in the patient's medical notes.
- Monitor and record the outcome of any change in medication.

The benefits of medication review are now being recognised by health policy makers, and in the UK, community pharmacists are required to carry out different levels of medication review as part of their normal clinical activities. Medication reviews are often targeted towards patient groups who are more likely to have problems with their medicines, for example the elderly, patients taking more than four medicines regularly, patients in care homes, those on medicines with special monitoring requirements. Characteristics of different types of medication review are described in Table 2.2.

The key elements of an advanced clinical medication review are:

- Pre-planning and advance warning for the patient
- Identifying ALL medicines being taken
- Patient's understanding of treatment

Table 2.2 Characteristics of types of medication review (adapted from Clyne et al., 2008)

	Purpose of the review	Requires patient to be present	Access to patient's notes
Prescription review	Address technical issues relating to the prescription, for example anomalies, changed items, cost-effectiveness	No (any resulting changes to prescribed medicines must involve the patient/carer)	Possibly (community pharmacist may not have access to patient's clinical notes)
Concordance and compliance medication review	Address issues relating to the patient's medicine-taking behaviour and use of medicines	Usually (any resulting changes to prescribed medicines must involve the patient/carer)	Possibly (community pharmacist may not have access to patient's clinical notes)
Clinical medication review	Address issues relating to the patient's use of medicines in the context of their clinical condition	Yes	Yes

Medication reviews include all medicines, including prescription, complementary and over the counter medicines. Prescription review may relate to one therapeutic area only.

- Appropriateness of treatment
- Review of physiological tests and measurements
- Review of efficacy
- Side effects and interactions
- Practicalities of medicines usage
- Future treatment plans
- Opportunities for questions and concerns.

The NO TEARS approach (Lewis, 2004) is also a useful prompt to assist such a review (Table 2.3).

Factors that influence prescribers

A prescriber is subject to various influences which may impact upon their decision making when deciding whether to prescribe a medicine and which medicine to prescribe. Some of these influences may result in poor decision making; therefore, it is important to have an understanding of these influences and how they may impact on prescribing decisions.

A range of influences that affect the prescribing decisions made by primary care doctors have been identified (Fig. 2.3).

Patients and prescribing decisions

The prescribing and use of medicines is strongly influenced by cultural factors that affects patients and prescribers alike. Issues such as whether the patient expects a prescription or whether the prescriber thinks the patient expects a prescription both influence the decision to prescribe. Patients may want a prescription for a whole variety of reasons, some of which are more valid than others. Beyond wanting a medicine for its therapeutic effect, a prescription for a medicine may demonstrate to the patient that their illness is recognised, be seen as a symbol of care, offer legitimacy for time off work because of illness, or fit with their health beliefs. Patients who frequently consult and receive a prescription are more likely to repeat the experience, and expect a prescription at their next consultation.

A number of studies have found that doctors sometimes feel under pressure from patients to prescribe, although patients may not always expect a prescription from the doctor. However, while patients often expect to receive a medicine, they may also have more complex agendas that need to be explored in the consultation. Patients may have mixed attitudes towards medicines and reluctance to take medicines is quite common. Whilst a medicine may be prescribed for its pharmacological effect, there may be other associated reasons

| Table 2.3	The NO TEARS approach to medication review
NO TEARS	**Questions to think about**
Need and indication	Why is the patient taking the medicine, and is the indication clearly documented in the notes? Do they still need the medicine? Is the dose appropriate? Has the diagnosis been confirmed or refuted? Would a non-drug treatment be better? Does the patient know what their medicines are for?
Open questions	Use open questions to find out what the patient understands about their medicines, and what problems they may be having with them.
Tests and monitoring	Is the illness under control? Does treatment need to be adjusted to improve control? What special monitoring requirements are there for this patient's medicines? Who is responsible for checking test results?
Evidence and guidelines	Is there new evidence or guidelines that mean I need to review the patient's medicines? Is the dose still appropriate? Do I need to do any other investigations or tests?
Adverse effects	Does the patient have any side effects? Are any of the patient's symptoms likely to be caused by side effects of medicines, including OTC and complementary medicines? Are any of the patients' medicines being used to treat side effects of other medicines? Is there any new advice or warnings on side effects or interactions?
Risk reduction and prevention	If there is time, ask about alcohol use, smoking, obesity, falls risk or family history, for opportunistic screening. Is treatment optimised to reduce risks?
Simplification and switches	Can the patient's medicines regimen be simplified? Are repeat medicines synchronised for prescribing at the same time? Explain any changes in medicines to the patient.
Fig. 2.3 Influences on prescribing decisions.

to prescribe for a patient, for example to end the consultation, to avoid doing anything else or having to say 'no', to maintain contact with the patient, as a response to carer anxiety, or to fulfil the patient's expectation.

The informed patient

Health care is moving to a position of greater shared decision making with patients and development of the concept of patient autonomy. This is being supported through the better provision of information for patients about their prescribed medicines. The EU directive 2001/83 (European Commission, 2001) requires that all pharmaceutical products are packaged with an approved PIL, which provides information on how to take the medicine and possible adverse effects. Other important developments that have increased patients' access to information, albeit of variable quality, include the role of the media in general and the amount of attention they give to health and health-related matters, the emergence of the Internet, and the development of patient support groups. The reporting in the media of concerns regarding the safety of MMR vaccine and the subsequent rapid drop in MMR vaccinations rates in children is a good example of the importance of these developments in influencing patients and prescribing.

Direct advertising of medicines to patients is allowed in the USA and New Zealand, but not in Europe. Advertising medicines in this way is clearly effective in increasing sales of medicines, as evidenced by the increased spending and prescriptions for advertised drugs, compared to non-advertised drugs in these countries. This has led to concern that direct to consumer advertising encourages unnecessary and inappropriate use of medication. In the UK, education for patients may be provided by the manufacturer through sponsored disease awareness campaigns but there is concern that these encourage individuals to seek advice or treatment from their doctor for conditions that have been incorrectly self diagnosed. These campaigns may also help to raise awareness of conditions that have not been well managed in the past. However, they can also act as covert advertisements for prescription. Such campaigns, which may be established by a drug company with or without the endorsement of a patient group, often take place at the same time as a drug's launch and may involve aggressive promotion. As a consequence there have been calls to control the influence of companies on the production of disease awareness campaigns that impact on the individual patient, who then exerts pressure on the prescriber for a specific medicine.

Health care policy

National policy and guidelines, for example National Service Frameworks and guidance from NICE in the UK, have a significant influence on prescribing, although the influence may not be as great as expected for some medicines (Prescribing Support Unit, 2009).

Colleagues

Several studies have found that health care professionals in primary care (both doctors and nurses) rely on advice from trusted colleagues and opinion leaders as a key source of information on how to manage patients. It has been estimated that 40% of prescribing in primary care was strongly influenced by hospitals because the choice of medicine prescribed in general practice was often guided by hospital specialists through their precedent prescribing and educational advice (National Audit Office, 2007). The Pharmaceutical Industry recognise the value of identifying 'key opinion' leaders amongst the medical community and will try to cultivate them to influence their peers and fellow clinicians, by paying them for a consultancy, lecture fees, travel, research and articles favourable to that company's products.

Pharmacists, in both the primary and secondary care, themselves have an influence on prescribing through their roles as clinical pharmacists, or as part of their work advising on prescribing in primary care. Pharmacists are often regarded as trusted colleagues, and as such can have an important influence on prescribing. In whichever sector they are working, pharmacists need to be aware that their advice and decisions may be influenced by exactly the same factors that influence the prescriber.

Pharmaceutical industry

The pharmaceutical industry has a very wide and important influence on prescribing decisions affecting every level of health care provision, from the medicines that are initially discovered and developed through clinical trials, to the promotion of medicines to the prescriber and patient groups, the prescription of medicines and the compilation of clinical guidelines. There are over 8000 pharmaceutical company representatives in the UK trying to persuade prescribers to prescribe their company's product. This represents a ratio of about 1 representative for every 7.5 doctors (House of Commons Health Committee, 2005) with 1 representative for every 4 primary care doctors (National Audit Office, 2007). Whilst representatives from the pharmaceutical industry can provide useful and important new information to prescribers about medicines, the information presented is not without bias and rarely provides any objective discussion of available competitor products.

The influence of the pharmaceutical industry extends well beyond the traditional selling approach of using representatives, and is increasingly sophisticated. The pharmaceutical industry spends millions on advertising, company sponsored information from medical journals and supplements, sponsorship to attend conferences and meetings, and medical education. Over half of postgraduate education and training for doctors in the UK is sponsored by the pharmaceutical industry. The wide variety, volume and intensity of marketing activities the industry engage in are an important influence on prescribing by health care professionals. But on asking prescribers if they are influenced by the pharmaceutical industry, they usually deny that drug promotion affects their own prescribing practices, although they do believe that it affects other prescribers' prescribing habits. This is clearly not the case, as research has shown that even the use of modest samples, gifts and food exerts a significant influence on prescriber behaviour.

Cognitive factors

Most prescribing decisions are made using the processes our brains develop to handle large volumes of complex information quickly. This rapid decision making is aided by heuristics, strategies that provide shortcuts that allow us to make quick decisions. This type of decision making largely relies on a small number of variables that we believe are important based on information collected by brief reading in summary journals (e.g. Bandolier, Drug and Therapeutics Bulletin and articles in popular doctors' and nurses' magazines mailed free of charge) and talking to colleagues. However, it is important to recognise that cognitive biases affect these heuristics (or shortcuts) involved in rapid decision making, and that experts as well as generalists are just as fallible to cognitive biases in decision making. At least 43 cognitive biases in decision making have been described. Some examples of cognitive biases that may affect prescribing decisions are shown in Table 2.4.

Table 2.4 Examples of types of cognitive biases that influence prescribing	
Type of cognitive bias	Description
Novelty preference	The belief that the progress of science always results in improvements and that newer treatments are generally better than older treatments
Over optimism bias	Tendency of people to over-estimate the outcome of actions, events or personal attributes to a positive skew
Confirmation bias	Information that confirms one's already firmly held belief is given higher weight than refuting evidence
Mere exposure effect	More familiar ideas or objects are preferred or given greater weight in decision making
Loss aversion	To weigh the avoidance of loss more greatly than the pursuit of an equivalent gain
Illusory correlation	The tendency to perceive two events as causally related, when in fact the connection between them is coincidental or even non-existent

Strategies to influence prescribing

Health care organisations at local and national levels have been seeking to influence prescribing behaviour over many years, both to control expenditure on medicines and to improve quality of care. Medicines are one of the most well-researched interventions in health care, with a relative wealth of evidence to support their use. Despite this, there is still a wide variation in prescribing practice between clinicians and between health care organisations. This may reflect variation in clinical practice arising from the inconsistent implementation of evidence-based medicine and the impact of the many factors that influence prescribing. Strategies to improve prescribing can be managerial and process orientated, or more supportive and educationally orientated. Strategies that use a combination of different interventions on a repeat basis are more likely to be successful at influencing prescribing.

Managerial approaches to influence prescribing

Formularies are restricted lists of medicines, to which prescribers are encouraged or required to adhere. This helps consistency of prescribing, ensures that prescribers are familiar with a range of medicines, and can help contain costs. In secondary care, prescribers can usually only prescribe those medicines included within the formulary, as these are the medicines stocked in the pharmacy. In primary care a formulary is generally advisory in nature and less restrictive as community pharmacies can supply any reimbursable medicine. Medicines are included in a formulary if they are deemed to have met rational criteria based on clinical and cost-effectiveness. Health care organisations usually have a process for deciding which medicines are included within their local formulary, keeping the formulary updated, and monitoring the implementation of local formulary decisions. Some formularies are developed to cover prescribing in both primary and secondary care, which mean they can have a significant influence on prescribing patterns in the whole of a local health economy. Over recent years, formularies have developed beyond just being a list of medicines and often include useful advice for prescribers, for example about disease management.

Local and national guidelines

Guidelines for the use of a medicine, a group of medicines or the management of a clinical condition may be produced for local or national use. They can be useful tools to guide and support prescribers in choosing which medicines they should prescribe. Ideally, guidelines should make evidence-based standards of care explicit and accessible, and aid clinical decision making. The best-quality guidelines are usually those produced using systematically developed evidence-based statements to assist clinicians in making decisions about appropriate health care for specific clinical circumstances. In the UK, there is an accreditation scheme to recognise organisations who achieve high standards in producing health or social care guidance. Examples of accredited guidelines are those produced by NICE (National Institute for Health and Clinical Excellence, www.nice.org.uk) and SIGN (Scottish Intercollegiate Guideline Network, www.sign.ac.uk). Local guidelines are often developed to provide a local context and interpretation of national guidance, and offer guidance on managing patients between primary and secondary care. However, despite the availability of good quality accessible clinical guidelines, implementation in practice remains variable.

Clinical decision support systems are increasingly popular as a way of improving clinical practice, and influence prescribing. These often utilise interactive computer programs that help clinicians with decision-making tasks at the point of care, and also help them keep up-to-date, and support implementation of clinical guidelines. Clinical knowledge summaries (www.cks.nhs.uk) is a decision support system developed for use in primary care that includes PILs, helps with differential diagnosis, suggests investigations and referral criteria, and gives screens that can be shared between the patient and the prescriber in the surgery.

Incentives

In an effort to contain prescribing costs, some health care systems use direct incentives to influence clinical behaviour and, in particular, prescribing. The incentives, which are usually financial, may be direct to the prescriber or offer some benefits to the prescriber's patients. They can have a significant impact on prescribing practice. Typically, primary care doctors are given indicative prescribing budgets and are expected to meet the prescribing needs of their patients from within this budget. Financial incentive schemes to reward good fiscal management of prescribing budgets and improve the quality of prescribing are used to encourage prescribers to change their practice. Incentive schemes usually influence what is prescribed, rather than whether a prescription is written. The most effective schemes are simple to understand, have achievable targets, and require information about prescribing patterns to be readily available. However, incentives schemes for prescribing need to be managed carefully in order not to create perverse incentives, such as increasing the referral of patients to another part of the health care system, or causing an increase in overall health care costs.

Provision of comparative (benchmarking) information

The provision of benchmarked information on comparative prescribing patterns to primary care doctors is an important influence on prescribing behaviour. Using appropriate benchmarking data brings the behaviour of practices into a local and national context. Benchmarking can provide the basis for making clinicians aware of the potential for change and allows them to understand the potential outcome of any actions. Various prescribing indicators have been developed both locally and nationally to measure and compare quality and cost-effectiveness of prescribing. Ideally, indicators used should be evidence based, utilise available data sources and be validated.

Support and education

One of the challenges for modern health care organisations is to ensure consistent implementation of evidence-based interventions and influence clinical practice. Simply providing prescribers with information or education about an evidence-based intervention rarely produces a change in practice. There is a need to understand the concerns that the adopting clinician may have about the change, recognise that these concerns are often legitimate but may change over time and that the concerns must be addressed and overcome before successful adoption can occur. Interpersonal influence, particularly through the use of trusted colleagues or opinion leaders, is a powerful way to change practice. This is the basis for using pharmacists as prescribing advisers or 'academic detailers' to influence prescribing practice particularly in primary care. Prescribing advisers present evidence-based tailored messages, allow the exchange of information and try to negotiate and persuade clinicians to change practice. Clinicians see pharmacists as a trusted and credible source of prescribing information, who can be moderately successful in changing practice, particularly if linked with an incentive.

In order to change prescribing practice, pharmacists need to be aware of how to use an adoption model-based approach to convey key messages to the prescriber to help them change practice. One such model is known as AIDA (see Table 2.5)

More sophisticated multifaceted educational interventions can also be effective at changing prescribing behaviour but need to be flexible to meet the needs of individual clinicians. This sort of combination approach includes small group learning, audit and feedback, practical support to make changes in practice, and involvement and education of patients.

Table 2.5 AIDA adoption model for influencing prescribers

Awareness	Make the prescriber aware of the issues, prescribing data and evidence for the need to change
Interest	Let the prescriber ask questions and find out more about the proposed change: what the benefits are, what the prescriber's concerns are
Decision	Help the prescriber come to a decision to make a change. How can the change be applied to their patients, what support is there to overcome the barriers to change, provide further information and training to support the change
Action	Action of making a change by the prescriber. Support this with simple reminders, patient decision support, feedback data and audit

Conclusion

While medicines have the capacity to improve health, they also have the potential to cause harm. Prescribing of medicines needs to be rational and effective in order to maximise benefit and minimise harm. Good prescribing should ensure the patient's ideas, concerns and expectations are taken into account. This can be effectively managed by adopting a consultation framework and using patient decision aids to support shared decision making with the patient. Prescribers need to be aware of their responsibilities and accountability particularly when prescribing off-label or unlicensed medicines. They also need to work within their organisation's clinical governance framework. The influences and biases that affect prescribing need to be recognised and minimised by utilising trusted independent sources of information to inform prescribing decisions.

3 Practical pharmacokinetics

R. Fitzpatrick and A. Kostrzewski

Key points

- Pharmacokinetics can be applied to a range of clinical situations with or without therapeutic drug monitoring (TDM).
- TDM can improve patient outcomes but is only necessary for drugs with a low therapeutic index, where there is a good concentration response relationship, and where there is no easily measurable physiological parameter.
- Sampling before steady state is reached or before distribution is complete, leads to erroneous results.
- The volume of distribution can be used to determine the loading dose.
- The elimination half-life determines the time to steady state and the dosing interval.
- Kinetic constants determine the rate of absorption and elimination.
- Clearance determines the maintenance dose.
- Creatinine clearance can be reliably estimated from population values.
- Use of actual blood level data wherever possible to assist dose adjustment is advisable. However, population pharmacokinetic values can be used for digoxin, theophylline and gentamicin.
- Once daily dosing of gentamicin is a realistic alternative to multiple dosing.
- TDM is essential in the dose titration of lithium and phenytoin, but of little value for valproate, or the newer anticonvulsants.

Clinical pharmacokinetics may be defined as the study of the time course of the absorption, distribution, metabolism and excretion of drugs and their corresponding pharmacological response. In practice, pharmacokinetics makes it possible to model what may happen to a drug after it has been administered to a patient. Clearly, this science may be applied to a wide range of clinical situations, hence the term 'clinical pharmacokinetics'. However, no matter how elegant or precise the mathematical modelling, the relationship between concentration and effect must be established before pharmacokinetics will be of benefit to the patient.

General applications

Clinical pharmacokinetics can be applied in daily practice to drugs with a low therapeutic index, even if drug level monitoring is not required.

Time to maximal response

By knowing the half-life of a drug, the time to reach a steady state may be estimated (Fig. 3.1), and also when the maximal therapeutic response is likely to occur, irrespective of whether drug level monitoring is needed.

Need for a loading dose

The same type of information can be used to determine whether the loading dose of a drug is necessary, since drugs with longer half-lives are more likely to require loading doses for acute treatment.

Dosage alterations

Clinical pharmacokinetics can be useful in determining dosage alteration if the route of elimination is impaired through end organ failure (e.g. renal failure) or drug interaction. Using limited pharmacokinetic information such as the fraction that should be excreted unchanged (f_e value), which can be found in most pharmacology textbooks, quantitative dosage changes can be estimated.

Choosing a formulation

An understanding of the pharmacokinetics of absorption may also be useful in evaluating the appropriateness of particular formulations of a drug in a patient.

Fig. 3.1 Time to steady state.

Application to therapeutic drug monitoring

Clinical pharmacokinetics is usually associated with therapeutic drug monitoring (TDM), and its subsequent utilisation. When TDM is used appropriately, it has been demonstrated that patients suffer fewer side effects than those who are not monitored (Reid et al., 1990). Although TDM is a proxy outcome measure, a study with aminoglycosides (Crist et al., 1987) demonstrated shorter hospital stays for patients where TDM was used. Furthermore, a study on the use of anticonvulsants (McFadyen et al., 1990) showed better epilepsy control in those patients where TDM was used. A literature review of the cost-effectiveness of TDM concluded that emphasis on just cost is inappropriate and clinical relevance should be sought (Touw et al., 2007). There are various levels of sophistication for the application of pharmacokinetics to TDM. Knowledge of the distribution time and an understanding of the concept of steady state can facilitate determination of appropriate sampling times.

For most drugs that undergo first-order elimination, a linear relationship exists between dose and concentration, which can be used for dose adjustment purposes. However, if the clearance of the drug changes as the concentration changes (e.g. phenytoin), then an understanding of the drug's pharmacokinetics will assist in making correct dose adjustments.

More sophisticated application of pharmacokinetics involves the use of population pharmacokinetic data to produce initial dosage guidelines, for example nomograms for digoxin and gentamicin, and to predict drug levels. Pharmacokinetics can also assist in complex dosage individualisation using actual patient specific drug level data.

Given the wide range of clinical situations in which pharmacokinetics can be applied, pharmacists must have a good understanding of the subject and of how to apply it to maximise their contribution to patient care.

Basic concepts

Volume of distribution

The apparent volume of distribution (V_d) may be defined as the size of a compartment which will account for the total amount of drug in the body (A) if it were present in the same concentration as in plasma. This means that it is the apparent volume of fluid in the body which results in the measured concentration of drug in plasma (C) for a known amount of drug given, that is:

$$C = \frac{A}{V_d}$$

This relationship assumes that the drug is evenly distributed throughout the body in the same concentration as in the plasma. However, this is not the case in practice, since many drugs are present in different concentrations in various parts of the body. Thus, some drugs which concentrate in muscle tissue have a very large apparent volume of distribution, for example digoxin. This concept is better explained in Fig. 3.2.

The apparent volume of distribution may be used to determine the plasma concentration after an intravenous loading dose:

$$C = \frac{\text{loading dose}}{V_d} \quad (1)$$

Conversely, if the desired concentration is known, the loading dose may be determined:

$$\text{loading dose} = \text{desired } C \times V_d \quad (2)$$

In the previous discussion, it has been assumed that after a given dose a drug is instantaneously distributed between the various tissues and plasma. In practice this is seldom the case. For practical purposes it is reasonable to generalise by referring to plasma as one compartment and tissue as if it were another single separate compartment. However, in reality there will be many tissue subcompartments. Thus, in pharmacokinetic terms the body may be described as if it were divided into two compartments: the plasma and the tissues.

Figure 3.3 depicts the disposition of a drug immediately after administration and relates this to the plasma concentration–time graph.

Initially, the plasma concentration falls rapidly, due to distribution and elimination (α phase). However, when an equilibrium is reached between the plasma and tissue (i.e. the distribution is complete), the change in plasma concentration is only due to elimination from the plasma (β phase), and the plasma concentration falls at a slower rate. The drug is said to follow a two-compartment model. However, if distribution

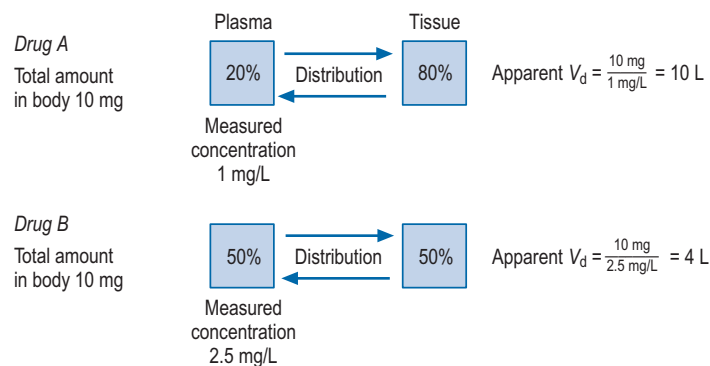

Fig. 3.2 Distribution: more of drug A is distributed in the tissue compartment resulting in a higher apparent volume of distribution than drug B, where more remains in the plasma.
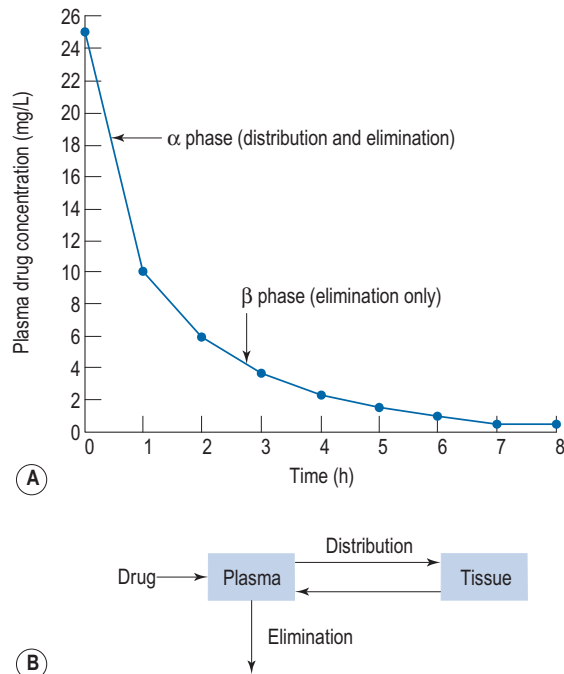

Fig. 3.3 (A) Two-compartment model showing two phases in the plasma concentration–time profile. (B) Representation of a two-compartment model showing distribution of drug between plasma and tissue compartments.

is completed quickly (within minutes), then the α phase is not seen, and the drug is said to follow a one-compartment model.

The practical implications of a two-compartment model are that any sampling for monitoring purposes should be carried out after distribution is complete. In addition, intravenous bolus doses are given slowly to avoid transient side effects caused by high peak concentrations.

Elimination

Drugs may be eliminated from the body by a number of routes. The primary routes are excretion of the unchanged drug in the kidneys, or metabolism (usually in the liver) into a more water soluble compound for subsequent excretion in the kidneys, or a combination of both.

The main pharmacokinetic parameter describing elimination is clearance (CL). This is defined as the volume of plasma completely emptied of drug per unit time. For example, if the concentration of a drug in a patient is 1 g/L and the clearance is 1 L/h, then the rate of elimination will be 1 g/h. Thus, a relationship exists:

$$\text{rate of elimination} = \text{CL} \times C \qquad (3)$$

Total body elimination is the sum of the metabolic rate of elimination and the renal rate of elimination. Therefore:

$$\text{total body clearance} = \text{CL (metabolic)} + \text{CL (renal)}$$

Thus, if the fraction eliminated by the renal route is known (f_e), then the effect of renal impairment on total body clearance can be estimated.

The clearance of most drugs remains constant for each individual. However, it may alter in cases of drug interactions, changing end-organ function or autoinduction. Therefore, it is clear from equation (Eq.) (3) that as the plasma concentration changes so will the rate of elimination. However, when the rate of administration is equal to the rate of elimination, the plasma concentration is constant (C^{ss}) and the drug is said to be at a steady state.

At steady state:

$$\text{rate in} = \text{rate out}$$

At the beginning of a dosage regimen the plasma concentration is low. Therefore, the rate of elimination from Eq. (3) is less than the rate of administration, and accumulation occurs until a steady state is reached (see Fig. 3.1).

$$\text{rate of administration} = \text{rate of elimination} = \text{CL} \times C^{ss} \qquad (4)$$

It is clear from Eq. (3) that as the plasma concentration falls (e.g. on stopping treatment or after a single dose), the rate of elimination also falls. Therefore, the plasma concentration–time graph follows a non-linear curve characteristic of this type of first-order elimination (Fig. 3.4). This is profoundly different from a constant rate of elimination irrespective of plasma concentration, which is typical of zero-order elimination.

For drugs undergoing first-order elimination, there are two other useful pharmacokinetic parameters in addition to the volume of distribution and clearance. These are the elimination rate constant and elimination half-life.

The elimination rate constant (k_e) is the fraction of the amount of drug in the body (A) eliminated per unit time. For example, if the body contains 100 mg of a drug and 10% is eliminated per unit time, then $k_e = 0.1$. In the first unit of time, 0.1×100 mg or 10 mg is eliminated, leaving 90 mg. In the second unit of time, 0.1×90 mg or 9 mg is eliminated, leaving 81 mg. Elimination continues in this manner. Therefore:

$$\text{rate of elimination} = k_e \times A \qquad (5)$$

Combining Eqs. (3) and (5) gives

$$\text{CL} \times C = k_e \times A$$

and since

$$C = \frac{A}{V_d}$$

Fig. 3.4 First-order elimination.

then

$$CL \times \frac{A}{V_d} = k_e \times A$$

Therefore,

$$CL = k_e \times V_d \tag{6}$$

Elimination half-life ($t_{1/2}$) is the time it takes for the plasma concentration to decay by half. In five half-lives the plasma concentration will fall to approximately zero (see Fig. 3.4).

The equation which is described in Fig. 3.4 is

$$C_2 = C_1 \times e^{-k_e \times t} \tag{7}$$

where C_1 and C_2 are plasma concentrations and t is time.

If half-life is substituted for time in Eq. (7), C_2 must be half of C_1.
Therefore,

$$0.5 \times C_1 = C_1 \times e^{-k_e \times t_{1/2}}$$

$$0.5 = e^{-k_e \times t_{1/2}}$$

$$\ln 0.5 = -k_e \times t_{1/2}$$

$$0.693 = -k_e \times t_{1/2}$$

$$t_{1/2} = \frac{0.693}{k_e} \tag{8}$$

There are two ways of determining k_e, either by estimating the half-life and applying Eq. (8) or by substituting two plasma concentrations in Eq. (7) and applying natural logarithms:

$$\ln C_2 = \ln C_1 - (k_e \times t)$$

$$k_e \times t = \ln C_1 - \ln C_2$$

$$k_e = \frac{\ln C_1 - \ln C_2}{t}$$

In the same way as it takes approximately five half-lives for the plasma concentration to decay to zero after a single dose, it takes approximately five half-lives for a drug to accumulate to the steady state on repeated dosing or during constant infusion (see Fig. 3.1).

This graph may be described by the equation

$$C = C^{ss}[1 - e^{-k_e \times t}] \tag{9}$$

where C is the plasma concentration at time t after the start of the infusion and C^{ss} is the steady state plasma concentration. Thus (if the appropriate pharmacokinetic parameters are known), it is possible to estimate the plasma concentration any time after a single dose or the start of a dosage regimen.

Absorption

In the preceding sections, the intravenous route has been discussed, and with this route all of the administered drug is absorbed. However, if a drug is administered by any other route it must be absorbed into the bloodstream. This process may or may not be 100% efficient.

The fraction of the administered dose which is absorbed into the bloodstream is the bioavailability (F). Therefore, when applying pharmacokinetics for oral administration, the dose or rate of administration must be multiplied by F. Bioavailability F is determined by calculating the area under the concentration time curve (AUC). The rationale for this is described below.

The rate of elimination of a drug after a single dose is given by Eq. (3). By definition the rate of elimination is amount of drug eliminated per unit time.

The amount eliminated in any one unit of time $dt = CL \times C \times dt$

The total amount of drug eliminated $= \sum_0^\infty CL \times C \times dt$

As previously explained, CL is constant. Therefore,

Total amount eliminated $= CL \times \sum C \times dt$ from start until C is zero.

$\sum C \times dt$ from start until zero is actually the area under the plasma concentration–time curve (Fig. 3.5).

After a single i.v. dose the total amount eliminated is equal to the amount administered D i.v.

Therefore, D i.v. $= CL \times AUC$ i.v. or $CL = D$ i.v. $/AUC$.

However, for an oral dose the amount administered is $F \times D$ p.o.

As CL is constant in the same individual,

$$CL = F \times D \text{ p.o.}/AUC \text{ p.o.} = D \text{ i.v.}/AUC \text{ i.v.}$$

Rearranging gives

$$F = (D \text{ i.v.} \times AUC \text{ p.o.})/(D \text{ p.o.} \times AUC \text{ i.v.})$$

In this way, F can be calculated from plasma concentration–time curves.

Dosing regimens

From the preceding sections, it is possible to derive equations which can be applied in clinical practice.

From Eq. (1) we can determine the change in plasma concentration ΔC immediately after a single dose:

$$\Delta C = \frac{S \times F \times \text{dose}}{V_d} \tag{10}$$

where F is bioavailability and S is the salt factor, which is the fraction of active drug when the dose is administered as a salt (e.g. aminophylline is 80% theophylline, therefore $S = 0.8$).

Fig. 3.5 The area under the concentration time curve (AUC) is the sum of $C \times dt$.

Conversely, to determine a loading dose:

$$\text{loading dose} = \frac{\text{desired change in } C \times V_d}{S \times F} \quad (11)$$

At the steady state it is possible to determine maintenance dose or steady state plasma concentrations from a modified Eq. (4):

$$\text{rate in} = \frac{S \times F \times \text{dose}}{T} = CL \times \text{average } C^{ss} \quad (12)$$

where T is the dosing interval.

Peak and trough levels

For oral dosing and constant intravenous infusions, it is usually adequate to use the term 'average steady state plasma concentration' (average C^{ss}). However, for some intravenous bolus injections it is sometimes necessary to determine peak and trough levels (e.g. gentamicin).

At the steady state, the change in concentration due to the administration of an intravenous dose will be equal to the change in concentration due to elimination over one dose interval:

$$\Delta C = \frac{S \times F \times \text{dose}}{V_d} = C_{max} - C_{min}$$

Within one dosing interval the maximum plasma concentration (C_{max}^{ss}) will decay to the minimum plasma concentration (C_{min}^{ss}) as in any first-order process.

Substituting C_{max}^{ss} for C_1 and C_{min}^{ss} for C_2 in Eq. (7):

$$C_{max}^{ss} = C_{max}^{ss} \times e^{-k_e \times t}$$

where t is the dosing interval.

If this is substituted into the preceding equation:

$$\frac{S \times F \times \text{dose}}{V_d} = C_{max}^{ss} - (C_{max}^{ss} \times e^{-k_e \times t})$$

Therefore,

$$C_{max}^{ss} = \frac{S \times F \times \text{dose}}{V_d[1 - e^{-k_e \times t}]} \quad (13)$$

$$C_{min}^{ss} = \frac{S \times F \times \text{dose}}{V_d(1 - e^{-k_e \times t})} \times e^{-k_e \times t} \quad (14)$$

Interpretation of drug concentration data

The availability of the technology to measure the concentration of a drug in plasma should not be the reason for monitoring. There are a number of criteria that should be fulfilled before therapeutic drug monitoring is undertaken. These are:

- the drug should have a low therapeutic index;
- there should be a good concentration–response relationship;
- there are no easily measurable physiological parameters.

In the absence of these criteria being fulfilled, the only other justification for undertaking TDM is to monitor adherence or to confirm toxicity. When interpreting TDM data, a number of factors need to be considered.

Sampling times

In the preceding sections, the time to reach the steady state has been discussed. When TDM is carried out as an aid to dose adjustment, the concentration should be at steady state. Therefore, approximately five half-lives should elapse after initiation or after changing a maintenance regimen, before sampling. The only exception to this rule is when toxicity is suspected. When the steady state has been reached, it is important to sample at the correct time. It is clear from the discussion above that this should be done when distribution is complete (see Fig. 3.3).

Dosage adjustment

Under most circumstances, provided the preceding criteria are observed, adjusting the dose of a drug is relatively simple, since a linear relationship exists between the dose and concentration if a drug follows first-order elimination (Fig. 3.6A). This is the case for most drugs.

Capacity limited clearance

If a drug is eliminated by the liver, it is possible for the metabolic pathway to become saturated, since it is an enzymatic system. Initially the elimination is first-order, but once saturation of the system occurs, elimination becomes zero-order. This results in the characteristic dose–concentration graph seen in Fig. 3.6B. For the majority of drugs eliminated by the liver, this effect is not seen at normal therapeutic doses and only occurs at very high supratherapeutic levels, which is why the kinetics of some drugs in overdose is different from normal. However, one important exception is phenytoin, where saturation of the enzymatic pathway occurs at therapeutic doses. This will be dealt with in the section on phenytoin.

Increasing clearance

The only other situation where first-order elimination is not seen is where clearance increases as the plasma concentration increases (Fig. 3.6C). Under normal circumstances, the plasma protein binding sites available to a drug far outnumber

Fig. 3.6 Dose–concentration relationships: (A) first-order elimination, (B) capacity-limited clearance, (C) increasing clearance.

the capacity of the drug to fill those binding sites, and the proportion of the total concentration of drug which is protein bound is constant. However, this situation is not seen in one or two instances (e.g. valproate and disopyramide). For these particular drugs, as the concentration increases the plasma protein binding sites become saturated and the ratio of unbound drug to bound drug increases. The elimination of these drugs increases disproportionate to the total concentration, since elimination is dependent on the unbound concentration.

Therapeutic range

Wherever TDM is carried out, a therapeutic range is usually used as a guide to the optimum concentration. The limits of these ranges should not be taken as absolute. Some patients may respond to levels above or below these ranges, whereas others may experience toxic effects within the so-called therapeutic range. These ranges are only adjuncts to dose determination, which should always be done in the light of clinical response.

Clinical applications

Estimation of creatinine clearance

Since many drugs are renally excreted, and the most practical marker of renal function is creatinine clearance, it is often necessary to estimate this in order to undertake dosage adjustment in renal impairment. The usual method is to undertake a 24-h urine collection coupled with a plasma creatinine measurement. The laboratory then estimates the patient's creatinine clearance. The formula used to determine creatinine clearance is based upon the pharmacokinetic principles in Eq. (3).

The rate of elimination is calculated from the measurement of the total amount of creatinine contained in the 24-h urine sample divided by 24, that is,

$$\frac{\text{amount of creatinine}}{24} = \text{rate of excretion (mg/h)}$$

Using this rate of excretion and substituting the measured plasma creatinine for C^{ss} in Eq. (4), the creatinine clearance can be calculated.

However, there are practical difficulties with this method. The whole process is cumbersome and there is an inevitable delay in obtaining a result. The biggest problem is the inaccuracy of the 24-h urine collection.

An alternative approach is to estimate the rate of production of creatinine (i.e. rate in) instead of the rate of elimination (rate out). Clearly this has advantages, since it does not involve 24-h urine collections and requires only a single measure of plasma creatinine. There are data in the literature relating creatinine production to age, weight and sex since the primary source of creatinine is the breakdown of muscle.

Therefore, equations have been produced which are rearrangements of Eq. (4), that is,

$$\text{creatinine clearance} = \frac{\text{rate of production}}{C^{ss}}$$

Rate of production is replaced by a formula which estimates this from physiological parameters of age, weight and sex.

It has been shown that the equation produced by Cockcroft and Gault (1976) appears to be the most satisfactory. A modified version using SI units is shown as

$$\begin{array}{c}\text{creatinine clearance}\\(\text{mL/min})\end{array} = \frac{F \times [(140 - \text{age in years}) \times \text{weight (kg)}]}{\text{plasma creatinine (}\mu\text{mol/L)}}$$

where $F = 1.04$ (females) or 1.23 (males).

There are limitations using only plasma creatinine to estimate renal function. The modification of diet in renal disease (MDRD) formula can be used to estimate glomerular filtration rate (eGFR). This formula uses plasma creatinine, age, sex and ethnicity (Department of Health, 2006).

$$\begin{aligned}\text{eGFR} = 175 &\times [\text{plasma creatinine (}\mu\text{mol/L)} \times 0.011312]^{-1.154}\\ &\times [\text{age in year}]^{-0.203} \times [1.212 \text{ if patient is black}]\\ &\times [0.742 \text{ if female}]\end{aligned}$$

eGFR = glomerular filtration rate (mL/min per 1.73m^2).

The MDRD should be used with care when calculating doses of drugs, as most of the published dosing information is based on Cockcroft and Gault formula. In patients with moderate to severe renal failure, it is best to use the Cockcroft and Gault formula to determine drug dosing.

Digoxin

Action and uses

Digoxin is the most widely used of the digitalis glycosides. Its primary actions on the heart are those of increasing the force of contraction and decreasing conduction through the atrioventricular node. Currently, its main role is in the treatment of atrial fibrillation by slowing down the ventricular response, although it is also used in the treatment of heart failure in the presence of sinus rhythm. The primary method of monitoring its clinical effect in atrial fibrillation is by measurement of heart rate but knowledge of its pharmacokinetics can be helpful in predicting a patient's dosage requirements.

Plasma concentration–response relationship

- <0.5 µcg/L: no clinical effect
- 0.7 µcg/L: some positive inotropic and conduction blocking effects
- 0.8–2 µcg/L: optimum therapeutic range (0.5–0.9 µcg/L in patients >65)
- 2–2.5 µcg/L: increased risk of toxicity, although tolerated in some patients
- >2.5 µcg/L: gastro-intestinal, cardiovascular system and central nervous system toxicity.

Distribution

Digoxin is widely distributed and extensively bound in varying degrees to tissues throughout the body. This results in a high apparent volume of distribution. Digoxin volume of distribution can be estimated using the equation 7.3 L/kg (ideal body weight (BWt)) which is derived from population data. However, distribution is altered in patients with renal impairment, and a more accurate estimate in these patients is given by:

$$V_d = 3.8 \times \text{ideal BWt} + (3.1 \times \text{creatinine clearance (mL/min)})$$

A two-compartment model best describes digoxin disposition (see Fig. 3.3), with a distribution time of 6–8 h. Clinical effects are seen earlier after intravenous doses, since the myocardium has a high blood perfusion and affinity for digoxin. Sampling for TDM must be done no sooner than 6 h postdose, otherwise an erroneous result will be obtained.

Elimination

Digoxin is eliminated primarily by renal excretion of unchanged drug (60–80%), but some hepatic metabolism occurs (20–40%). The population average value for digoxin clearance is:

$$\text{digoxin clearance (mL/min)} = 0.8 \times \text{BWt}$$
$$+ (\text{creatinine clearance (mL / min)})$$

However, patients with severe congestive heart failure have a reduced hepatic metabolism and a slight reduction in renal excretion of digoxin:

$$\text{digoxin clearance (mL/min)} = 0.33 \times \text{BWt}$$
$$+ (0.9 \times \text{creatinine clearance (mL / min)})$$

Ideal body weight should be used in these equations.

Absorption

Digoxin is poorly absorbed from the gastro-intestinal tract, and dissolution time affects the overall bioavailability. The two oral formulations of digoxin have different bioavailabilities:

$$F(\text{tablets}) = 0.65$$

$$F(\text{liquid}) = 0.8$$

Practical implications

Using population averages it is possible to predict plasma concentrations from specific dosages, particularly since the time to reach the steady state is long. Population values are only averages, and individual values may vary. In addition, a number of diseases and drugs affect digoxin disposition.

As can be seen from the preceding discussion, congestive heart failure, hepatic and renal diseases all decrease the elimination of digoxin. In addition, hypothyroidism increases the plasma concentration (decreased metabolism and renal excretion) and increases the sensitivity of the heart to digoxin. Hyperthyroidism has the opposite effect. Hypokalaemia, hypercalcaemia, hypomagnesaemia and hypoxia all increase the sensitivity of the heart to digoxin. There are numerous drug interactions reported of varying clinical significance. The usual cause is either altered absorption or clearance.

Theophylline

Theophylline is an alkaloid related to caffeine. It has a variety of clinical effects including mild diuresis, central nervous system stimulation, cerebrovascular vasodilatation, increased cardiac output and bronchodilatation. It is the last which is the major therapeutic effect of theophylline. Theophylline does have some serious toxic effects. However, there is a good plasma concentration–response relationship.

Plasma concentration–response relationship

- <5 mg/L: no bronchodilatation[1]
- 5–10 mg/L: some bronchodilatation and possible anti-inflammatory action
- 10–20 mg/L: optimum bronchodilatation, minimum side effects
- 20–30 mg/L: increased incidence of nausea, vomiting[2] and cardiac arrhythmias
- >30 mg/L: cardiac arrhythmias, seizures.

Distribution

Theophylline is extensively distributed throughout the body, with an average volume of distribution based on population data of 0.48 L/kg.

Theophylline does not distribute very well into fat, and estimations should be based on ideal body weight. A two-compartment model best describes theophylline disposition, with a distribution time of approximately 40 min.

Elimination

Elimination is a first-order process primarily by hepatic metabolism to relatively inactive metabolites.

The population average for theophylline clearance is 0.04 L/h/kg, but this is affected by a number of diseases/drugs/pollutants. Therefore, this value should be multiplied by:

- 0.5 where there is cirrhosis, or when cimetidine, erythromycin or ciprofloxacin are being taken concurrently due to enzyme inhibition in the liver;
- 0.4 where there is congestive heart failure with hepatomegaly due to reduced hepatic clearance;
- 0.8 where there is severe respiratory obstruction (FEV1 < 1 L);
- 1.6 for patients who smoke (defined as more than 10 cigarettes per day), since smoking stimulates hepatic metabolism of theophylline.

Neonates metabolise theophylline differently, with 50% being converted to caffeine. Therefore, when it is used to treat neonatal apnoea of prematurity, a lower therapeutic range is used (usually 5–10 mg/L), since caffeine contributes to the therapeutic response.

---

[1] Some patients exhibit a clinical effect at these levels which has been attributed to possible anti-inflammatory effects.
[2] Nausea and vomiting can occur within the therapeutic range.

Product formulation

Aminophylline (the ethylenediamine salt of theophylline) is only 80% theophylline. Therefore, the salt factor (S) is 0.8. Most sustained-release (SR) preparations show good bioavailability but not all SR preparations are the same, which is why advice in the BNF recommends patients are maintained on the same brand.

Practical implications

Intravenous bolus doses of aminophylline need to be given slowly (preferably by short infusion) to avoid side effects due to transiently high blood levels during the distribution phase. Oral doses with sustained release preparations can be estimated using population average pharmacokinetic values and titrated proportionately according to blood levels and clinical response. In most circumstances, sustained release preparations may be assumed to provide 12 h cover. However, more marked peaks and troughs are seen with fast metabolisers (smokers and children). In these cases, the sustained release preparation with the lowest k_a value may be used twice daily (e.g. Uniphyllin ($k_a = 0.22$)). Alternatively, thrice daily dosage is required if a standard ($k_a = 0.3$–0.4) sustained release product is used (e.g. Phyllocontin ($k_a = 0.37$) or Nuelin SA ($k_a = 0.33$)).

Gentamicin

Clinical use

The spectrum of activity of gentamicin is similar to other aminoglycosides but its most significant activity is against *Psuedomonas aeruginosa.* It is still regarded by many as first choice for this type of infection.

Therapeutic range

Gentamicin has a low therapeutic index, producing dose-related side effects of nephro- and ototoxicity. The use of TDM to aid dose adjustment is essential if these toxic effects which appear to be related to peak and trough plasma levels are to be avoided. It is generally accepted that the peak level (drawn 1 h post-dose after an intravenous bolus or intramuscular injection) should not exceed 12 mg/L and the trough level (drawn immediately pre-dose) should not exceed 2 mg/L.

The above recommendations relate to multiple daily dosing of gentamicin. If once daily dosing is used, then different monitoring and interpretation parameters apply as described at the end of this section.

Distribution

Gentamicin is relatively polar and distributes primarily into extracellular fluid. Thus, the apparent volume of distribution is only 0.3 L/kg. Gentamicin follows a two-compartment model with distribution being complete within 1 h.

Elimination

Elimination is by renal excretion of the unchanged drug. Gentamicin clearance is approximately equal to creatinine clearance.

Practical implications

Since the therapeutic range is based on peak (1 h post-dose to allow for distribution) and trough (pre-dose) concentrations, it is necessary to be able to predict these from any given dosage regimen.

Initial dosage. This may be based on the patient's physiological parameters. Gentamicin clearance may be determined directly from creatinine clearance. The volume of distribution may be determined from ideal body weight. The elimination constant k_e may then be estimated using these parameters in Eq. (6). By substituting k_e and the desired peak and trough levels into Eq. (7), the optimum dosage interval can be determined (add on 1 h to this value to account for sampling time). Using this value (or the nearest practical value) and the desired peak or trough value substituted into Eq. (13) or Eq. (14), it is possible to determine the appropriate dose.

Changing dosage. This is not as straightforward as for theophylline or digoxin, since increasing the dose will increase the peak and trough levels proportionately. If this is not desired, then use of pharmacokinetic equations is necessary. By substituting the measured peak and trough levels and the time between them into Eq. (7), it is possible to determine k_e (and the half-life from Eq. (8) if required). To estimate the patient's volume of distribution from actual blood level data, it is necessary to know the C_{max}^{ss} immediately after the dose (time zero), not the 1 h value which is measured. To obtain this, Eq. (7) may be used, this time substituting the trough level for C_2 and solving for C_1. Subtracting the trough level from this C_{max}^{ss} at time zero, the volume of distribution may be determined from Eq. (10). Using these values for k_e and V_d, derived from actual blood level data, a new dose and dose interval can be determined as before.

Once daily dosing. There are theoretical arguments for once daily dosing of gentamicin, since aminoglycosides display concentration-dependent bacterial killing, and a high enough concentration to minimum inhibitory concentration (MIC) ratio may not be achieved with multiple dosing. Furthermore, aminoglycosides have a long post-antibiotic effect. Aminoglycosides also accumulate in the kidneys, and once daily dosing could reduce renal tissue accumulation. There have been a number of clinical trials comparing once daily administration of aminoglycosides with conventional administration. A small number of these trials have shown less nephrotoxicity, no difference in ototoxicity, and similar efficacy with once daily administration.

Initial dosage for a once daily regimen is 5–7 mg/kg/day for patients with a creatinine clearance of >60 mL/min. This is subsequently adjusted on the basis of blood levels. However, monitoring of once daily dosing of gentamicin is different to multiple dosing. One approach is to take a blood sample 6–14 h after the first dose and plot the time and result on a standard concentration-time plot (the Hartford nomogram, Nicolau et al., 1995; Fig. 3.7). The position of the individual patient's point in relation to standard lines on the nomogram indicates what the most appropriate dose interval should be (either 24, 36 or 48 h). Once daily dosing of gentamicin has not been well studied in pregnant or breastfeeding women, patients with major burns, renal failure, endocarditis or cystic

If result available within 24 h

- Use graph below to select dose interval. Use serum concentration and time interval between start of infusion and sample to plot intercept (see example given on graph).
- Give next dose (7 mg/kg by infusion as above) after interval indicated by graph.
  If result falls above upper limit for Q48 h, abandon once daily regimen. Measure gentamicin concentration after another 24 h and adopt multiple daily dose regimen if result <2 mg/L
  If result falls on Q24 h sector it is not necessary to recheck gentamicin concentration within 5 days unless patient's condition suggests renal function may be compromised.

- **Graph:**   Use values of plasma concentration and time interval to find intercept
  (Example given of 6 mg/L after 10 h yields dose interval of 36 h)
MONITORING

- Repeat U&E daily. Calculate creatinine clearance from serum creatinine to check dose interval has not changed.
- If dose interval has to be changed, check gentamicin concentration 6 – 14 h after start of next infusion note time of start of infusion and time of sampling and use graph to verify correct dose interval.

Fig. 3.7   Nomogram for adjustment of once daily gentamicin dosage (Nicolau et al., 1995).

fibrosis. Therefore, it cannot be recommended in these groups and multiple daily dosing should be used.

Lithium

Lithium is effective in the treatment of acute mania and in the prophylaxis of manic depression. The mechanism of action is not fully understood, but it is thought that it may substitute for sodium or potassium in the central nervous system. Lithium is toxic, producing dose-dependent and dose-independent side effects. Therefore, TDM is essential in assisting in the management of the dosage.

Dose-dependent effects

The plasma concentration–response relationship derived on the basis of the 12-h standardised lithium level (measured 12 h after the evening dose of lithium) is shown below:

- <0.4 mmol/L: little therapeutic effect
- 0.4–1.0 mmol/L: optimum range for prophylaxis
- 0.8–1.2 mmol/l: optimum range for acute mania
- 1.2–1.5 mmol/L: causes possible renal impairment
- 1.5–3.0 mmol/L: causes renal impairment, ataxia, weakness, drowsiness, thirst, diarrhoea

- 3.0–5.0 mmol/L: causes confusion, spasticity, dehydration, convulsions, coma, death. (Levels above 3.5 mmol/L are regarded as a medical emergency.)

Dose-independent effects

These include tremor, hypothyroidism (approximately 10% of patients on chronic therapy), nephrogenic diabetes insipidus, gastro-intestinal upset, loss in bone density, weight gain (approximately 20% of patients gain more than 10 kg) and lethargy.

Distribution

Lithium is unevenly distributed throughout the body, with a volume of distribution of approximately 0.7 L/kg. Lithium follows a two-compartment model (see Fig. 3.3) with a distribution time of 8 h (hence, the 12-h sampling criterion).

Elimination

Lithium is excreted unchanged by the kidneys. Lithium clearance is approximately 25% of creatinine clearance, since there is extensive reabsorption in the renal tubules.

In addition to changes in renal function, dehydration, diuretics (particularly thiazides), angiotensin-converting enzyme inhibitors (ACE inhibitors) and non-steroidal anti-inflammatory drugs (NSAIDs) (except aspirin and sulindac) all decrease lithium clearance. Conversely, aminophylline and sodium loading increase lithium clearance.

Notwithstanding the above factors, there is a wide inter-individual variation in clearance, and the lithium half-life in the population varies between 8 and 35 h with an average of approximately 18 h. Lithium clearance shows a diurnal variation, being slower at night than during the day.

Practical implications

In view of the narrow therapeutic index, lithium should not be prescribed unless facilities for monitoring plasma lithium concentrations are available. Since lithium excretion is a first-order process, changes in dosage result in a proportional change in blood levels. Blood samples should be drawn 12 h after the evening dose, since this will allow for distribution and represent the slowest excretion rate. Population pharmacokinetic data (particularly the volume of distribution) cannot be relied upon to make initial dosage predictions, although renal function may give an approximate guide to clearance. Blood level measurements are reported in SI units and therefore it is useful to know the conversion factors for the various salts.

- 100 mg of lithium carbonate is equivalent to 2.7 mmol of lithium ions
- 100 mg of lithium citrate is equivalent to 1.1 mmol of lithium ions.

Phenytoin

Phenytoin is used in the treatment of epilepsy (see Chapter 31). Use is associated with dose-independent side effects which include hirsutism, acne, coarsening of facial features, gingival hyperplasia, hypocalcaemia and folic acid deficiency. However, phenytoin has a narrow therapeutic index and has serious concentration-related side effects.

Plasma concentration–response relationship

- <5 mg/L: generally no therapeutic effect
- 5–10 mg/L: some anticonvulsant action with approximately 50% of patients obtaining a therapeutic effect with concentrations of 8–10 mg/L
- 10–20 mg/L: optimum concentration for anticonvulsant effect
- 20–30 mg/L: nystagmus, blurred vision
- >30 mg/L: ataxia, dysarthria, drowsiness, coma.

Distribution

Phenytoin follows a two-compartment model with a distribution time of 30–60 min. The apparent volume of distribution is 1 L/kg.

Elimination

The main route of elimination is via hepatic metabolism. However, this metabolic route can be saturated at normal therapeutic doses. This results in the characteristic non-linear dose/concentration curve seen in Fig. 3.6B. Therefore, instead of the usual first-order pharmacokinetic model, a Michaelis–Menten model, used to describe enzyme activity, is more appropriate.

Using this model, the daily dosage of phenytoin can be described by

$$\frac{S \times F \times \text{dose}}{T} = \frac{V_{\max} \times C^{ss}}{K_m + C^{ss}} \qquad (15)$$

K_m is the plasma concentration at which metabolism proceeds at half the maximal rate. The population average for this is 5.7 mg/L, although this value varies greatly with age and race.

$V_{\max}$ is the maximum rate of metabolism of phenytoin and is more predictable at approximately 7 mg/kg/day.

Since clearance changes with blood concentration, the half-life also changes. The usual reported value is 22 h, but this increases as concentration increases. Therefore, it is difficult to predict when the steady state will be reached. However, as a rule of thumb, 1–2 weeks should be allowed to elapse before sampling after a dosage change.

In overdose, it can be assumed that metabolism of the drug is occurring at the maximum rate of $V_{\max}$. Therefore, the decline in plasma concentration is linear (zero-order) at approximately 7 mg/L/day.

Practical implications

Since the dose/concentration relationship is non-linear, changes in dose do not result in proportional changes in plasma concentration (see Fig. 3.6B). Using the Michaelis–Menten model, if the plasma concentration is known at one dosage, then $V_{\max}$ may be assumed to be the population average (7 mg/kg/day), since this is the more predictable parameter, and K_m calculated using Eq. (15). The revised values of K_m can then be used in Eq. (15) to estimate the new dosage required to produce a desired concentration. Alternatively, a nomogram may be used to assist in dose adjustments (Fig. 3.8).

Care is needed when interpreting TDM data and making dosage adjustments when phenytoin is given concurrently with other anticonvulsants, since these affect distribution and metabolism of phenytoin. Since phenytoin is approximately 90% protein bound, in patients with a low plasma albumin and or uraemia, the free fraction increases and therefore an adjusted total phenytoin should be calculated or a free salivary level taken. To adjust the observed concentration in hypoalbuminaemia the following equation can be applied:

$$C_{\text{adjusted}} = \frac{C_{\text{observed}}}{0.9 \times (C_{\text{albumin}}/44) + 0.1}$$
Albumin concentration is in g/L.

Fig. 3.8 Orbit graph. The most probable values of V_{max} and k_m for a patient may be estimated using a single steady-state phenytoin concentration and a known dosing regimen. The eccentric circles or 'orbits' represent the fraction of the sample patient population whose k_m and V_{max} values are within that orbit. (1) Plot the daily dose of phenytoin (mg/kg/day) on the vertical line (rate of elimination). (2) Plot the steady-state concentration (C^{ss}) on the horizontal line. (3) Draw a straight line connecting C^{ss} and daily dose through the orbits (line A). (4) The coordinates of the mid point of the line crossing the innermost orbit through which the line passes are the most probable values for the patient's V_{max} and k_m. (5) To calculate a new maintenance dose, draw a line from the point determined in Step 4 to the new desired C^{ss} (line B). The point at which line B crosses the vertical line (rate of elimination) is the new maintenance dose (mg/kg/day). The line A represents a C^{ss} of 8 mg/l on 276 mg/day of phenytoin acid (300 mg/day of sodium phenytoin) for a 70 kg patient. Line B has been drawn assuming the new desired steady-state concentration was 15 mg/L (μg/mL). The original figure is modified so that R and V_{max} are in mg/kg/day of phenytoin acid (modified from Evans et al., 1992).

In ureamic patients with severe renal failure, the unbound fraction is approximately doubled, so the target concentration needs to be half the normal concentration or apply the adjusted concentration equation if albumin level is known.

The oral formulations of phenytoin show good bioavailability. However, tablets and capsules contain the sodium salt ($S = 0.9$), whereas the suspension and infatabs are phenytoin base ($S = 1$). Intramuscular phenytoin is slowly and unpredictably absorbed, due to crystallisation in the muscle tissue, and is therefore not recommended. Fosphenytoin, a prodrug of phenytoin, is better absorbed from the intramuscular site. Doses should be expressed as phenytoin equivalent. Fosphenytoin sodium 1.5 mg is equivalent to phenytoin sodium 1 mg.

Carbamazepine

Carbamazepine is indicated for the treatment of partial and secondary generalised tonic-clonic seizures, primary generalised tonic-clonic seizures, trigeminal neuralgia, and prophylaxis of bipolar disorder unresponsive to lithium. There are a number of dose-independent side effects, including various dermatological reactions and, more rarely, aplastic anaemia

and Stevens–Johnson syndrome. However, the more common side effects are concentration related.

Plasma concentration–response relationship when used in the treatment of epilepsy

- <4 mg/L: little therapeutic benefit
- 4–12 mg/L: optimum therapeutic range for monotherapy
- >9 mg/L: possible side effects of nystagmus, diplopia, drowsiness and ataxia, particularly if patients are on other anticonvulsant therapy
- >12 mg/L: side effects common, even on monotherapy.

Distribution

Carbamazepine is distributed widely in various organs, with the highest concentration found in liver and kidneys. Carbamazepine is 70–80% protein bound and shows a wide variation in the population average apparent volume of distribution (0.8–1.9 L/kg). This wide variation is thought to be due to variations in absorption (since there is no parenteral form) and protein binding.

Elimination

Carbamazepine is eliminated almost exclusively by metabolism, with less than 2% being excreted unchanged in the urine. Elimination is a first-order process, but carbamazepine induces its own metabolism (auto-induction). Therefore, at the beginning of therapy, clearance is 0.01–0.03 L/h/kg, rising to 0.05–0.1 L/h/kg on chronic therapy. Auto-induction begins in the first few days of commencing therapy and is maximal at 2–4 weeks.

Since clearance changes with time, so does half-life, with reported values as long as 35 h after a single dose, decreasing to 5–7 h on regular dosing.

Absorption

Absorption after oral administration is slow, with peak concentrations being reached 2–24 h post-dose (average 6 h). Absorption is incomplete, with bioavailability estimated at approximately 80% ($F = 0.8$).

Practical implications

Use of pharmacokinetic equations is limited, due to the auto-induction effect. However, there are a number of important practical points:

- Blood samples should not be drawn before the steady state, which will not be achieved until 2–4 weeks after starting therapy to allow for auto-induction, or 3–4 days after subsequent dose adjustments.
- When sampling, the trough level should be measured because of the variable absorption pattern.
- Complex calculations are not helpful, but as a rule of thumb each 100 mg dose will increase the plasma concentration at the steady state by approximately 1 mg/L in adults.

- A number of other drugs (including phenytoin) when given concurrently will affect carbamazepine metabolism and subsequent blood levels.

Phenobarbital

Phenobarbital is indicated in all forms of epilepsy except absence seizures. Although there is a clear concentration–response relationship, routine plasma concentration monitoring is less useful than for other drugs, since tolerance occurs.

Plasma concentration–response relationship

- <15 mg/L: little therapeutic effect
- 15–40 mg/L: optimum range
- 40–50 mg/L: sedation, confusion (elderly), although may be tolerated by some patients
- >60 mg/L: serious toxic effect of ataxia, lethargy, stupor, coma.

The sedation which commonly manifests early on in therapy becomes less with continued therapy.

Distribution

Phenobarbital readily distributes into most body tissues and is 50% protein bound. The population-average volume of distribution is 0.7–1 L/kg.

Elimination

Phenobarbital is primarily (80%) metabolised by the liver, with approximately 20% being excreted unchanged in the urine. Elimination is a first-order process, but is relatively slow with a population average clearance of approximately 0.004 L/h/kg. However, as with theophylline, clearance in children is increased and is approximately twice the adult clearance. Applying Eqs. (6) and (8) to these population values gives an estimate of the half-life of the order of 5 days. This is much shorter in children and longer in the elderly.

Practical application

In view of the long half-life, single daily dosage is possible with phenobarbital. Samples for therapeutic monitoring may be drawn any time during a dose interval, since concentration fluctuation between doses is minimal. However, the patient should be at the steady state, which takes 2–4 weeks (1–2 weeks in children). The pharmacokinetics of phenobarbital may be altered by liver and (less markedly) renal disease, but are not affected by the concurrent administration of other anticonvulsants.

Primidone

Like phenobarbital, primidone is effective in the treatment of tonic–clonic and partial seizures. Much of the anticonvulsant activity of primidone is due to the metabolites phenobarbital and phenylethylmalonamide. Therefore, primidone plasma concentrations are only useful to confirm transient toxicity.

Toxic manifestations such as sedation, nausea and ataxia are seen at concentrations greater than 15 mg/L. The plasma concentration should be drawn approximately 3 h post dose, which corresponds to the peak concentration.

Phenylethylmalonamide assays are not routinely available, although this metabolite probably contributes to anticonvulsant activity. Measurement of phenobarbital levels is of limited value, since conversion of primidone to phenobarbital is variable between individuals. However, phenobarbital levels may be helpful in dosage selection, where seizures are not adequately controlled despite regular dosage, or where there is suspected toxicity.

Valproate

Sodium valproate as valproic acid in the bloodstream has a broad spectrum of anticonvulsant activity, being useful in generalised absence, generalised tonic–colonic and partial seizures.

Plasma concentration–response relationship

There is no clear concentration–response relationship for valproate, although a range of 50–100 mg/L is often quoted as being optimal, with 50% of patients showing a response at levels above 80 mg/L. Levels above 100 mg/L do not confer any additional therapeutic benefits. Although there is no clear relationship between plasma levels and toxic effects, the rare hepatotoxicity associated with valproate appears to be related to very high levels of over 150 mg/L.

Distribution

Valproate is extensively bound to plasma protein (90–95%), and unlike other drugs, it can saturate protein binding sites at concentrations greater than 50 mg/L, altering the free fraction of drug. Therefore, the apparent volume of distribution of valproate varies from 0.1 to 0.5 L/kg.

Elimination

Elimination of valproate is almost entirely by hepatic metabolism, with less than 5% being eliminated by the kidneys.

As a result of the saturation of protein binding sites and the subsequent increase in the free fraction of the drug, clearance of the drug increases at higher concentrations. Therefore, there is a non-linear change in plasma concentration with dose (illustrated in Fig. 3.6C).

Practical implications

In view of the lack of a clear concentration–response relationship and the variable pharmacokinetics, there are limited indications for the measurement of valproate levels. In most cases, dosage should be based on clinical response. Valproic acid can take several weeks to become fully active, so adjustment of doses must not be made quickly.

In a few cases where seizures are not controlled at high dosage, a plasma level may be helpful in confirming treatment failure. If monitoring is to be undertaken, levels should be drawn at steady state (2–3 days). A trough sample will be the most useful, since wide fluctuations of blood levels may occur during a dose interval.

Lamotrigine, vigabatrin, gabapentin, tiagabine, topiramate, pregabalin, lacosamide and levetiracetam

These newer medicines are indicated for the treatment of a range of types of epilepsy and some with additional indications. All are used as adjunctive treatment with other anticonvulsants, and some indicated for monotherapy.

Plasma concentration–response relationship

There is no clear relationship between plasma concentration and response for these newer anticonvulsants. The situation is further complicated by the fact that these preparations are usually used as add-on therapy with other anticonvulsants.

Practical implications

While these newer anticonvulsants have narrow therapeutic indices and inter- and intra-individual variation in pharmacokinetics, there is not enough evidence to support routine TDM, and dosage should be titrated to clinical response.

Ciclosporin

Ciclosporin is a neutral lipophilic cyclic endecapeptide extracted from the fungus *Tolypocladium inflatum gams*. It is a potent immunosuppressive agent, used principally to reduce graft rejection after organ and tissue transplantation. The drug has a low therapeutic index, with a number of toxic effects including nephrotoxicity, hepatotoxicity, gastro-intestinal intolerance, hypertrichosis and neurological problems. Efficacy in reducing graft rejection as well as the main toxic effect of nephro- and hepatotoxicity appear to be concentration related.

Plasma concentration–response relationship

With all drugs that are monitored the therapeutic range is a window with limits, which are not absolute. It is even more difficult to define a therapeutic range for ciclosporin, since there are a number of influencing factors. First, the measured concentration varies depending on sampling matrix (i.e. whole blood or plasma). Second, it depends on whether the assay is specific for ciclosporin alone or non-specific to include metabolites. A target concentration varies between centres, but is commonly around 100–200 ng/mL in the first 6 months after transplantation and 80–150 ng/mL from 6 months onwards. Levels below the lower limit

of this window are associated with an increased incidence of graft rejection. Levels above the upper limit are associated with an increased incidence of nephrotoxicity and hepatotoxicity.

Distribution

Ciclosporin is highly lipophilic and is distributed widely throughout the body with a volume of distribution of 4–8 L/kg. There is variable distribution of ciclosporin within blood, since the whole blood concentration is approximately twice the plasma concentration. Within plasma, ciclosporin is 98% protein bound.

Elimination

Ciclosporin is eliminated primarily by hepatic metabolism, with wide inter-individual variation in clearance (0.1–2 L/h/kg). In children these values are approximately 40% higher, with a resulting increased dosage requirement on a milligram per kilogram basis. In elderly patients or patients with hepatic impairment a lower clearance rate has been observed.

Practical implications

In addition to the wide inter-patient variability in distribution and elimination pharmacokinetic parameters, absorption of standard formulations of ciclosporin is variable and incomplete ($F = 0.2$–0.5 in normal subjects). In transplant patients this variation in bioavailability is even greater, and increases during the first few months after transplant. Furthermore, a number of drugs are known to interact with ciclosporin. All these factors suggest that therapeutic drug monitoring will assist in optimum dose selection, but the use of population averages in dose prediction is of little benefit, due to wide inter-patient variation. When using TDM with ciclosporin a number of practical points need to be considered:

- The sampling matrix should be whole blood, since there is a variable distribution of ciclosporin between blood and plasma.
- Samples should represent trough levels and be drawn at the steady state, which is achieved 2–3 days after initiating or changing the dosage (average half-life is 9 h).
- Ciclosporin concentration monitoring should be undertaken every 2–3 days in the immediate postoperative phase until the patient's clinical condition is stable. Thereafter, monitoring can be undertaken every 1–2 months.
- TDM should be performed when changing brands of ciclosporin, since there are marked differences in the bioavailability of different brands.

Summary pharmacokinetic data for drugs with therapeutic plasma concentrations are listed in Table 3.1.

Table 3.1 Summary of pharmacokinetic data

Drug	Therapeutic range of plasma concentrations	V_d (L/kg)	CL (L/h/kg)	Half-life (h)
Digoxin	0.8–2.0 μcg/L (0.5–0.9 μcg/L in patients >65) 1–2.6 nmol/L (0.625 nmol/L – 1.1 nmol/L in patients >65)	7.3	See text	36
Theophylline	10–20 mg/L 55–110 μmol/L	0.48	0.04	8
Gentamicin	Peak 5–12 mg/L, trough <2 mg/L	0.3	1 × CL (creatinine)	2
Lithium	0.4–0.8 mmol/L	0.5–1	0.2 × CL (creatinine)	18
Phenytoin	10–20 mg/L 40–80 μmol/L	1	K_m = 5.7 mg/L V'_{max} = 7 mg/kg/day	
Carbamazepine	4–12 mg/L 17–50 μmol/L	0.8–1.9	0.05–1	
Phenobarbital	15–40 mg/L 65–172 μmol/L	0.7–1	0.004	120
Primidone	<15 mg/L <69 μmol/L	0.6		
Valproate	<100 mg/L <693 μmol/L			
Ciclosporin	Varies between centres 100–200 ng/mL (first 6 months after transplantation) 80–150 ng/mL (from 6 months onwards)			9

Population pharmacokinetic parameters are based on averages. The degree of variability around the average is different for each drug. See text for variability.

Case studies

Case 3.1

You are reviewing a formulary submission for a new formulation of a product, which has reportedly an improved side effect profile due to better absorption characteristics. However, there is conflicting evidence in the literature over the absorption of the new preparation. One paper, which is available to you, shows a concentration-time profile for the oral formulation after a single oral dose of 250 mg as in Table 3.2.

The paper also quotes an area under the curve (AUC) after a single i.v. dose of 200 mg as 87 mg/L/h.

Table 3.2 Concentration-time profile for the oral formulation after a single oral dose of 250 mg

Time after administration	1 h	2 h	3 h	4 h	5 h	6 h	7 h	8 h	9 h	10 h	11 h	12 h
Concentration (mg/L)	10	18	12.7	9	6.4	4.5	3.2	2.25	1.6	1.1	0.78	0.55

Questions

1. What is the AUC after the single oral dose of 250 mg?
2. What is the bioavailability of the new formulation?

Answers

1. Draw the concentration-time profile on a piece of paper; try to do it reasonably accurately but it does not have to be exact. Draw down vertical lines from the curve at each 1-h time interval to create a series of trapeziums (the first one is actually a triangle). Calculate the area of each trapezium from the formula

   Area of trapezium = (sum of the height of each side/2) × width (1h)

   Then add all the areas together (assume a value of 0 after 12 h)

   AUC p.o. = 69.99 mg/L/h

2. From the equation $F = \dfrac{D\,\text{i.v.} \times \text{AUC p.o.}}{D\,\text{p.o.} \times \text{AUC i.v.}}$

   $F = 200 \times 69.99 / 250 \times 87$

   $F = 0.64$

Case 3.2

An 86-year-old lady is admitted to hospital by her primary care doctor, with increasing shortness of breath. She lives alone, is independent and has a flat on the 5th floor of a block of flats. She has a stable plasma creatinine of 150 μmol/L

She is 55 kg, 4′ 11″ tall.

She is known to have recently diagnosed atrial fibrillation, osteoporosis and ischaemic heart disease.

Her current medication is:

Aspirin	300 mg daily
Adcal D3	Two tablets daily
Imdur	60 mg daily
Simvastatin	40 mg daily
Senna	7.5 mg daily
Digoxin	62.5 μcg daily

She has been taking digoxin in a dose of 62.5 μcg daily for the last 3 weeks.

Questions

1. Calculate the predicted digoxin level for this lady.
2. A digoxin blood level is reported to be 1.0 μcg/L. List the reasons for the difference between the measured and predicted digoxin levels.
3. The hospital doctor queries if he should increase the dose of digoxin as the blood level is on the low side. Use an evidence-based approach to reply to the clinician.

Answers

1. Her predicted glomerular filtration rate is calculated from Cockcroft-Gault equation:

$$\text{Creatinine clearance (mL/min)} = \frac{F \times [(140 - \text{age in years}) \times \text{weight (kg)}]}{\text{plasma creatinine (μmol/L)}}$$

$$\text{Creatinine clearance (CL}_{cr}) = \frac{1.04(140 - 86)55}{150} = 20.6 \text{ mL/min}$$

On the assumption that the patient has severe congestive heart failure, the predicted digoxin level is calculated using the equation:

$$CL_{dig} = 0.33 \times IBW + 0.9 \times CL_{cr}$$
$$= (0.33 \times 55) + (0.9 \times 20.6) = 36.69 \text{ mL/min} = 2.2 \text{ L/h}$$

Ideal body weight (IBW (kg)):

$$\text{Male} = 50 + (2.3 \times \text{height in inches over 5 feet})$$

$$\text{Female} = 45.5 + (2.3 \times \text{height in inches over 5 feet})$$

Equation (4)   rate of administration = rate of elimination = $CL \times C^{ss}$

Rearranging Eq. (4):

$$C_{ssave} = \frac{\text{Dose} \times S \times F}{CL_{dig} \times \tau} = \frac{62.5 \times 1 \times 0.63}{2.2 \times 2.4} = 0.75 \text{ μcg/L}$$

2. The predicted level is less than the measured level, this may be because:
   - The level has been taken less than 6 h after the oral dose
   - Suspected non-adherence
   - Congestive heart failure has affected the renal function
3. A subgroup analysis of the Digitalis Investigation Group suggested that participants >65 years who had low blood levels (0.5–0.9 μcg/L) had reductions in all – cause mortality. It has also been suggested that digoxin may be associated with an increased risk of problems in patients with atrial fibrillation (Gjesdal et al., 2008).
   Therefore, the dose of digoxin should not be increased.

Case 3.3

A 68-year-old man (72 kg, 5′ 2″ tall) is admitted to the medical ward from intensive care as he is in a stable condition. He was admitted 2 days ago with Gram negative sepsis identified from a blood culture. He was commenced on gentamicin 5 mg/kg once daily as per the hospital protocol.

Current laboratory results are:

Urea	31.6 mmol/L (3.2–7.5 mmol/L)
Creatinine	168 μmol/L (71–133 μmol/L)

Gentamicin levels were taken 1 and 8 h after the first dose and reported as 19 and 10 mg/L, respectively.

Questions

1. Calculate the patient's elimination constant k_e.
2. Calculate the plasma concentration at C° immediately after the injection.
3. Using the plasma concentration at C° calculate the level you would expect the patient to achieve immediately prior to his next dose.
4. Calculate the dosage interval you would recommend aiming for a trough of 1 mg/L.

Answers

1. As the two plasma levels are known the elimination constant k_e is calculated from the following equation.

$$k_e = \frac{\ln C_1 - \ln C_2}{t}$$

Using the plasma levels reported:

$$k_e = \frac{\ln 19 - \ln 10}{7}$$

$$k_e = 0.092 \text{ h}^{-1}$$

2. The plasma concentration at C° immediately after the injection is calculated as:

$$C^t = C^{\circ} \times e^{-k_e \times t}$$

$$19 = C^{\circ} \times e^{-0.092 \times 1}$$

$$C^{\circ} = 20.8 \text{ mg/L}$$

3. The plasma concentration at C° is then used to calculate the expected level to be achieved immediately prior to his next dose.

$$C^t = C^{\circ} \times e^{-k_e \times t}$$

$$C^t = 20.8 \times e^{-0.092 \times 24}$$

$$= 2.2 \text{ mg/L}$$

4. The dosage interval can then be calculated for a trough of 0.5 mg/L

$$Cp^t = Cp^{\circ} \times e^{-k_e \times t}$$

$$\ln 0.5 = \ln 20.8 \times (-0.092 \times t)$$

$$-0.693 = 3.03 \times (-0.092 \times t)$$

$$t = 40.52 \text{ h}$$

As this time interval is more than 24 h and could potentially become nephrotoxic/ototoxic, an alternative antibiotic should be prescribed.

Case 3.4

A 68-year-old Argentinean man (69 kg) was found wandering in the street. A neighbour alerted the police. He was described as being confused and agitated. The patient could not speak English and on admission to hospital could not give a history. The neighbour told the ambulance staff the patient was normally well, but known to be taking medicines for a mental disorder. The ambulance staff found lithium and amisulpride in the man's pockets.

A sample of lithium was taken and reported as 2.5 mmol/L (0.6–1 mmol/L). His plasma creatinine was 160 µmol/L so the lithium was stopped.

Questions

1. Calculate the patient's pharmacokinetic parameters clearance (CL), volume of distribution (V_d), elimination constant (k_e) using population data.
2. Estimate the time for the lithium level to decrease to the middle of the normal range.
3. Briefly describe the symptoms of lithium toxicity.

Answers

1. Population data suggests that the clearance of lithium can be calculated using the following equation:

$$\text{Clearance} = 0.25 \times \text{CrCL} \, (\text{L/h})$$

The patient's creatinine clearance (CrCL) is calculated using the Cockcroft and Gault equation:

$$\text{Creatinine clearance (CrCL)} = \frac{1.23 \times (140 - \text{age}) \times \text{weight in kg}}{\text{Plasma creatinine (µmol/L)}}$$

$$\text{Creatinine clearance (CrCL)} = \frac{1.23 \times (140 - 68) \times 69}{160} = 38.2 \text{ mL/min}$$

Convert 38.2 mL/min to L/h

$$\frac{38.2 \times 60}{1000} = 2.29 \text{ L/h}$$

Lithium clearance = $0.25 \times 2.29 = 0.573$ L/h

Population data suggests that the volume of distribution (V_d) for lithium is 0.7 L/Kg.

Therefore, for this patient the volume of distribution:

$$V_d = 0.7 \times 69$$

$$V_d = 48.3 \text{ L}$$

The elimination rate constant k_e is calculated:

$$CL = k_e \times V_d \quad \text{to give } k_e = \frac{CL}{V_d}$$

$$k_e = \frac{0.573}{48.3}$$

$$k_e = 0.01186 \text{ h}^{-1}$$

2. The time it will take for this man's lithium level to return to the middle of the normal range (0.6-1 mmol/L), that is, 0.7 mmol/L is calculated using:

$$\text{Time to decay} = \frac{\ln Cp^1 - \ln Cp^2}{k_e}$$

$$\text{Time to decay} = \frac{\ln 2.5 - \ln 0.7}{0.01186}$$

$$\text{Time to decay} = 107.3 \text{ h} = 4.5 \text{ days}$$

3. Acute lithium toxicity tends to present with gastro-intestinal symptoms. If the toxicity is due to an increase in dose, symptoms will include neuromuscular signs, for example, ataxia and tremor. This is sometimes referred to as acute on chronic toxicity. Chronic toxicity is harder to treat due to tissue deposition and involves neurological problems.

Case 3.5

Mr B is a 38-year old, 63 kg man who suffers from asthma. He has been admitted to hospital and Nuelin S.A. 500 mg 12 hourly (6 am and 6 pm) has been added to his regimen. He responds well to this treatment but unfortunately after 2 days of treatment two doses are missed (evening dose and following morning dose). The clinical team is anxious to discharge him, so it is decided to give him a loading dose of aminophylline at 10 am before restarting him on maintainence therapy.

Questions

1. Was the patient at steady state before the medication was omitted?
2. What is the estimated theophylline level at 10 am?
3. The levels were then checked and the theophylline level was reported as 4 mg/L. What loading dose of i.v. aminophylline would you recommend?

Answers

1. His pharmacokinetic parameters can be calculated from population data

$$\text{Clearance} = 63 \text{ kg} \times 0.04 \text{ L/h/kg} = 2.52 \text{ L/h}$$

$$V_d = 63 \text{ kg} \times 0.45 \text{ L/kg} = 28.3 \text{ L}$$

$$k_e = \frac{CL}{V_d}$$

$$k_e = 0.089 \text{ h}^{-1}$$

Using Eq. (8), $t_{1/2} = 0.693/k_e$

The patient's half-life ($t_{1/2}$) = 7.8 h.
It can therefore be assumed he was at steady state after 48 h of treatment (more than 5 × half-life).
2. To calculate his levels at 10 am it is assumed that S.R. theophylline behaves like an i.v. infusion ($F = 1.0$). Although this is not strictly true, Nuelin S.A. has a good slow release profile.
From Eq. (12)

$$\frac{S \times F \times \text{dose}}{T} = \text{Average } C^{ss} \times CL$$

$$\text{Average } C^{ss} = \frac{S \times F \times \text{dose}}{T \times CL}$$

$$\text{Average } C^{ss} = \frac{500 \times 1}{12 \times 2.52}$$

$$\text{Average } C^{ss} = 16.5 \text{ mg/L}$$

To calculate theophylline concentration at 10 am, $C^{10\,am}$ need to delay this for 16 h as the morning dose from the previous day will have provided a steady dose of theophylline until the evening (first missed dose), so starting dose is C^{ss}.
Using Eq. (7)

$$C_2 = C_1 \times e^{-k_e \times t}$$

$$C^{10\,am} = 16.5 \times e^{-k_e \times 16}$$

$$C^{10\,am} = 16.5 \times e^{-0.089 \times 16}$$

$$C^{10\,am} = 3.97 \text{ mg/L}$$

3. To calculate a loading dose the change in theophylline concentration (C) to be achieved needs to be calculated:

$$C = \text{desired } C \ (15 \text{ mg/L}) - \text{actual} \ (4 \text{ mg/L})$$

From Eq. (1):

$$\text{Loading dose} = C \times V_d$$

$$\text{Loading dose} = 11 \times 28.3 \text{ L}$$

$$\text{Loading dose} = 311 \text{ mg of theophylline}$$

Aminophylline is only 80% theophylline, therefore

$$\text{Loading dose} = \frac{311}{0.8}$$

Aminophylline loading dose = 390 mg aminophylline to be administered by slow i.v. bolus.

Case 3.6

A 29-year-old man (70 kg) was diagnosed with TB meningitis 2 months ago. He is currently in hospital because of social issues. His liver function and other biochemical results are within the normal range. He was started on phenytoin capsules 350 mg daily at the time of diagnosis.

His current medication is:

Pyridoxine	12.5 mg daily
Rifater	four tablets daily
Phenytoin capsules	350 mg daily

One month after being started on this medication his phenytoin plasma level is measured as 7 mg/L

Questions

1. Using population data, calculate this man's predicted phenytoin plasma level.
2. Explain the difference between the predicted and actual phenytoin level
3. Using the phenytoin plasma level reported, assume steady state. Calculate this patient's V_{max}.
4. Calculate the dose required to obtain a plasma level of 10 mg/L at steady state.
5. Compare your answer using the orbit plot.

Answers

1. Using population data, calculate this man's predicted plasma level.
F, bioavailabilty; S, salt factor; V_{max}, maximum rate of metabolism; K_m, Michaelis-Menten constant.
$V_{max} = 7$ mg/kg/day, $K_m = 5.7$ mg/L, $D = 350$ mg, $F = 1$, $S = 0.92$.
Rearranging Eq. (15):

$$\frac{S \times F \times \text{dose}}{T} = \frac{V_{max} \times C^{ss}}{K_m + C^{ss}}$$

$$C^{ss} = \frac{K_m \times (S \times F \times \text{dose})}{(V_{max} \times T) - (S \times F \times \text{dose})}$$

$$C^{ss} = \frac{5.7 \times 0.92 \times 350}{70 \times 7 \times 1 - (0.92 \times 350)}$$

$$C^{ss} = \frac{1835.4}{490 - 322}$$

$$C^{ss} = 10.93 \text{ mg/L}$$

2. There are a number of potential reasons for the difference between the predicted and actual level:
   - The patient is not at steady state. This is unlikely as he has been on this medication from diagnosis 2 months ago.
   - The patient is not taking the phenytoin prescribed. This is also unlikely because as a hospital inpatient the nursing staff have been giving him his medication.
   - There is an interaction between the rifampacin and phenytoin. This is the most likely reason.
3. Using the plasma level reported, assume steady state. Calculate this patient's actual V_{max}.
Using $K_m = 5.7$ mg/L

$$\text{Current phenytoin plasma level } 7 = \frac{5.7 \times (350 \times 1 \times 0.92)}{V_{max} - (350 \times 1 \times 0.92)}$$

$$7 = \frac{1834.4}{V_{max} - 322}$$

$$V_{max} - 322 = \frac{1834.4}{7}$$

$$V_{max} = 262.2 + 322$$

$$V_{max} = 584 \text{ mg/day}$$

4. Calculate the dose required to obtain a plasma level of 10 mg/L at steady state:

$$\frac{S \times F \times \text{dose}}{T} = \frac{V_{max} \times C^{ss}}{K_m + C^{ss}}$$

$$\frac{S \times F \times \text{dose}}{1} = \frac{584 \times 10}{5.7 + 10}$$

$$\text{Dose} = \frac{371.97}{0.92}$$

$$\text{Dose} = 404 \text{ mg/day}$$

The nearest practical dose would be 400 mg per day and a level checked again in 2 weeks.

Drug interactions

H. K. R. Thanacoody

Key points

- Drug interactions can cause significant patient harm and are an important cause of morbidity.
- Most clinically important drug interactions occur as a result of either decreased drug activity with diminished efficacy or increased drug activity with exaggerated or unusual effects. Drugs with a narrow therapeutic range, such as theophylline, lithium and digoxin, or a steep dose–response curve, such as anticoagulants, oral contraceptives and anti-epileptics, are often implicated.
- The most important pharmacokinetic interactions involve drugs that can induce or inhibit enzymes in the hepatic cytochrome P450 system.
- Pharmacodynamic interactions are difficult to classify but their effects can often be predicted when the pharmacology of co-administered drugs is known.
- In many cases, potentially interacting drugs can be given concurrently provided the possibility of interaction is kept in mind and any necessary changes to dose or therapy are initiated promptly. In some situations, however, concurrent use of potentially interacting drugs should be avoided altogether.
- Suspected adverse drug interactions should be reported to the appropriate regulatory authority as for other adverse drug reactions.

The increasing availability and non-prescription use of herbal and complementary medicines has also led to greater awareness of their potential for adverse interactions. St John's wort, a herbal extract used for treatment of depression, can cause serious interactions as a result of its enzyme-inducing effects. Drug interactions with food and drink are also known to occur, exemplified by the well-known interaction between monoamine oxidase inhibitor antidepressants (MAOIs) and tyramine-containing foodstuffs. Grapefruit juice is a potent inhibitor of cytochrome P450 3A4 and causes clinically relevant interactions with a number of drugs including simvastatin and atorvastatin, thereby increasing the risk of statin-induced adverse reactions such as myopathy and myositis.

Although medical literature is awash with drug interaction studies and case reports of adverse drug interactions, only a relatively small number of these are likely to cause clinically significant consequences for patients. The recognition of clinically significant interactions requires knowledge of the pharmacological mechanisms of drug interactions and a thorough understanding of high-risk drugs and vulnerable patient groups.

Drug interactions have been recognised for over 100 years. Today, with the increasing availability of complex therapeutic agents and widespread polypharmacy, the potential for drug interactions is enormous and they have become an increasingly important cause of adverse drug reactions (ADR).

Despite regulatory requirements to define the safety profile of new medicines including their potential for drug–drug interactions before marketing, the potential for adverse interactions is not always evident. This was illustrated by the worldwide withdrawal of the calcium channel blocker mibefradil, within months of launch, following reports of serious drug interactions (Li Wan Po and Zhang, 1998). In the past decade, a number of medicines have been either withdrawn from the market, for example, terfenadine, grepafloxacin and cisapride, or had their use restricted because of prolongation of the QT interval on the electrocardiogram, for example, thioridazine. Drug interactions are an important cause of QT prolongation which increases the risk of developing a life-threatening ventricular arrhythmia known as torsade de pointes (Roden, 2004).

Definition

An interaction is said to occur when the effects of one drug are altered by the co-administration of another drug, herbal medicine, food, drink or other environmental chemical agents (Baxter, 2010). The net effect of the combination may manifest as an additive or enhanced effect of one or more drugs, antagonism of the effect of one or more drugs, or any other alteration in the effect of one or more drugs.

Clinically significant interactions refer to a combination of therapeutic agents which have direct consequences on the patient's condition. Therapeutic benefit can be obtained from certain drug interactions, for example, a combination of different antihypertensive drugs may be used to improve blood pressure control or an opioid antagonist may be use to reverse the effect of an overdose of morphine. In this chapter, we will concentrate on clinically significant interactions which have the potential for undesirable effects on patient care.

Epidemiology

Accurate estimates of the incidence of drug interactions are difficult to obtain as published studies frequently use different criteria for defining a drug interaction, and for distinguishing between clinically significant and non-significant interactions. Some of the early studies uncritically compared prescribed drugs with lists of possible drug interactions without taking into account their potential clinical significance.

The reported incidence of drug–drug interactions in hospital admissions ranged from 0% to 2.8% in a review which included nine studies, all of which had some design flaws (Jankel and Fitterman, 1993). In the Harvard Medical Practice Study of adverse events, 20% of events in acute hospital inpatients were drug related. Of these, 8% were considered to be due to a drug interaction, suggesting that interactions are responsible for less than 2% of adverse events in this patient group (Leape et al., 1992).

In a 1-year prospective study of patients attending an Emergency Department, 3.8% resulted from a drug–drug interaction and most of these led to hospital admissions (Raschett et al., 1999). In a prospective UK study carried out on hospital inpatients, ADR were responsible for hospital admission in 6.5% of cases. Drug interactions were involved in 16.6% of adverse reactions, therefore being directly responsible for leading to hospital admission in approximately 1% of cases (Pirmohamed et al., 2004).

Few studies have attempted to quantify the incidence of drug–drug interactions in the outpatient hospital setting and in the community. In the early 1990s, a community pharmacy study in the USA revealed a 4.1% incidence of interactions, while a Swedish study reported an incidence of 1.9%. In the outpatient setting, the availability of newer drugs for a variety of chronic conditions has increased the risk of drug–drug interactions in this patient group.

Although the overall incidence of serious adverse drug interactions is low, it remains a potentially preventable cause of morbidity and mortality.

Susceptible patients

The risk of drug interactions increases with the number of drugs used. In a hospital study, the rate of ADR in patients taking 6–10 drugs was 7%, rising to 40% in those taking 16–20 drugs, with the exponential rise being largely attributable to drug interactions (Smith et al., 1969). In a high-risk group of emergency department patients, the risk of potential adverse drug interaction was 13% in patients taking 2 drugs and 82% in those taking 7 or more drugs (Goldberg et al., 1996).

Although polypharmacy is common and often unavoidable, it places certain patient groups at increased risk of drug interactions. Patients at particular risk include those with hepatic or renal disease, those on long-term therapy for chronic disease, for example, HIV infection, epilepsy, diabetes, patients in intensive care, transplant recipients, patients undergoing complicated surgical procedures and those with more than one prescriber. Critically ill and elderly patients are

at increased risk not only because they take more medicines but also because of impaired homeostatic mechanisms that might otherwise counteract some of the unwanted effects. Interactions may occur in some individuals but not in others. The effects of interactions involving drug metabolism may vary greatly in individual patients because of differences in the rates of drug metabolism and in susceptibility to microsomal enzyme induction. Certain drugs are frequently implicated in drug interactions and require careful attention (Box 4.1).

Mechanisms of drug interactions

Drug interactions are conventionally discussed according to the mechanisms involved. These mechanisms can be conveniently divided into those with a pharmacokinetic basis and those with a pharmacodynamic basis. Drug interactions often involve more than one mechanism. There are some situations where drugs interact by unique mechanisms, but the most common mechanisms are discussed in this section.

Pharmacokinetic interactions

Pharmacokinetic interactions are those that affect the processes by which drugs are absorbed, distributed, metabolised or excreted. Due to marked interindividual variability in these processes, these interactions may be expected but their extent cannot be easily predicted. Such interactions may result in a change in the drug concentration at the site of action with subsequent toxicity or decreased efficacy.

Absorption

Following oral administration, drugs are absorbed through the mucous membranes of the gastro-intestinal tract. A number of factors can affect the rate of absorption or the extent of absorption (i.e. the total amount of drug absorbed).

Changes in gastro-intestinal pH. The absorption of a drug across mucous membranes depends on the extent to which it exists in the non-ionised, lipid-soluble form. The ionisation state depends on the pH of its milieu, the pK_a of the drug and formulation factors. Weakly acidic drugs, such as the salicylates, are better absorbed at low pH because the non-ionised form predominates.

An alteration in gastric pH due to antacids, histamine H_2 antagonists or proton pump inhibitors therefore has the potential to affect the absorption of other drugs. The clinical significance of antacid-induced changes in gastric pH is not certain, particularly since relatively little drug absorption occurs in the stomach. Changes in gastric pH tend to affect the rate of absorption rather than the extent of absorption, provided that the drug is acid labile. Although antacids could theoretically be expected to markedly influence the absorption of other drugs via this mechanism, in practice, there are very few clinically significant examples. Antacids, histamine H_2 antagonists and omeprazole can significantly decrease the bioavailability of ketoconazole and itraconazole, which require gastric acidity for optimal absorption, but the absorption of fluconazole and voriconazole is not significantly altered by changes in gastric pH.

The alkalinising effects of antacids on the gastro-intestinal tract are transient and the potential for interaction may be minimised by leaving an interval of 2–3 h between the antacid and the potentially interacting drug.

Adsorption, chelation and other complexing mechanisms. Certain drugs react directly within the gastro-intestinal tract to form chelates and complexes which are not absorbed. The drugs most commonly implicated in this type of interaction include tetracyclines and the quinolone antibiotics that can complex with iron, and antacids containing calcium, magnesium and aluminium. Tetracyclines can chelate with divalent or trivalent metal cations such as calcium, aluminium, bismuth and iron to form insoluble complexes, resulting in greatly reduced plasma tetracycline concentrations.

Bisphosphonates are often co-prescribed with calcium supplements in the treatment of osteoporosis. If these are taken concomitantly, however, the bioavailability of both is significantly reduced, with the possibility of therapeutic failure.

The absorption of some drugs may be reduced if they are given with adsorbents such as charcoal or kaolin, or anionic exchange resins such as colestyramine or colestipol. The absorption of propranolol, digoxin, warfarin, tricyclic antidepressants, ciclosporin and levothyroxine is reduced by colestyramine.

Most chelation and adsorption interactions can be avoided if an interval of 2–3 h is allowed between doses of the interacting drugs.

Effects on gastro-intestinal motility. Since most drugs are largely absorbed in the upper part of the small intestine, drugs that alter the rate at which the stomach empties its contents can affect absorption. Drugs with anticholinergic effects, such as tricyclic antidepressants, phenothiazines and some antihistamines, decrease gut motility and delay gastric emptying. The outcome of the reduced gut motility can either be an increase or a decrease in drugs given concomitantly. For example, tricyclic antidepressants can increase dicoumarol absorption, probably as a result of increasing the time available for its dissolution and absorption. Anticholinergic agents used in the management of movement disorders have been shown to reduce the bioavailability of levodopa by as much as 50%, possibly as a result of increased metabolism in the intestinal mucosa.

Opioids such as diamorphine and pethidine strongly inhibit gastric emptying and greatly reduce the absorption rate of paracetamol, without affecting the extent of absorption. Codeine, however, has no significant effect on paracetamol absorption. Metoclopramide increases gastric emptying and increases the absorption rate of paracetamol, an effect which is used to therapeutic advantage in the treatment of migraine to ensure rapid analgesic effect. It also accelerates the absorption of propranolol, mefloquine, lithium and ciclosporin. This type of interaction is rarely clinically significant.

Induction or inhibition of drug transport proteins. The oral bioavailability of some drugs is limited by the action of drug transporter proteins, which eject drugs that have diffused across the gut lining back into the gut. At present, the most well-characterised drug transporter is P-glycoprotein. Digoxin is a substrate of P-glycoprotein and drugs that inhibit P-glycoprotein, such as verapamil, may increase digoxin bioavailability with the potential for digoxin toxicity (DuBuske, 2005).

Malabsorption. Drugs such as neomycin may cause a malabsorption syndrome leading to reduced absorption of drugs such as digoxin. Orlistat is a specific long-acting inhibitor of gastric and pancreatic lipases, thereby preventing the hydrolysis of dietary fat to free fatty acids and triglycerides. This can theoretically lead to reduced absorption of fat-soluble drugs co-administered with orlistat. There has been recent concern about potential decreased absorption of levothyroxine and anti-epileptic drugs such as valproate sodium and lamotrigine, although the exact mechanism for the postulated interactions is presently unclear.

Most of the interactions that occur within the gut result in reduced rather than increased absorption. It is important to recognise that the majority result in changes in absorption rate, although in some instances the total amount (i.e. extent) of drug absorbed is affected. For drugs that are given chronically on a multiple dose regimen, the rate of absorption is usually unimportant provided the total amount of drug absorbed is not markedly altered. On the other hand, delayed absorption can be clinically significant where the drug affected has a short half-life or where it is important to achieve high plasma concentrations rapidly, as may be the case with analgesics or hypnotics. Absorption interactions can often be avoided by allowing an interval of 2–3 h between administration of the interacting drugs.

Drug distribution

Following absorption, a drug undergoes distribution to various tissues including to its site of action. Many drugs and their metabolites are highly bound to plasma proteins. Albumin is the main plasma protein to which acidic drugs such as warfarin are bound, while basic drugs such as tricyclic antidepressants, lidocaine, disopyramide and propranolol are generally bound to α_1-acid glycoprotein. During the process of distribution, drug interactions may occur, principally as a result of displacement from protein-binding sites. A drug displacement interaction is defined as a reduction in the extent of plasma protein binding of one drug caused by the presence of another drug, resulting in an increased free or unbound fraction of the displaced drug. Displacement from plasma proteins can be demonstrated in vitro for many drugs and has been thought to be an important mechanism underlying many interactions in the past. However, clinical pharmacokinetic studies suggest that, for most drugs, once displacement from plasma proteins occurs, the concentration of free drug rises temporarily, but falls rapidly back to its previous steady-state concentration due to metabolism and distribution. The time this takes will depend on the half-life of the displaced drug. The short-term rise in the free drug concentration is generally of little clinical significance but may need to be taken into account in therapeutic drug monitoring. For example, if a patient taking phenytoin is given a drug which displaces phenytoin from its binding sites, the total (i.e. free plus bound) plasma phenytoin concentration will fall even though the free (active) concentration remains the same.

There are few examples of clinically important interactions which are entirely due to protein-binding displacement. It has been postulated that a sustained change in steady-state free plasma concentration could arise with the parenteral administration of some drugs which are extensively bound to plasma proteins and non-restrictively cleared, that is, the efficiency of the eliminating organ is high. Lidocaine has been given as an example of a drug fitting these criteria.

Drug metabolism

Most clinically important interactions involve the effect of one drug on the metabolism of another. Metabolism refers to the process by which drugs and other compounds are biochemically modified to facilitate their degradation and subsequent removal from the body. The liver is the principal site of drug metabolism, although other organs such as the gut, kidneys, lung, skin and placenta are involved. Drug metabolism consists of phase I reactions such as oxidation, hydrolysis and reduction, and phase II reactions, which primarily involve conjugation of the drug with substances such as glucuronic acid and sulphuric acid. Phase I metabolism generally involves the cytochrome P450 (CYP450) mixed function oxidase system. The liver is the major site of cytochrome 450-mediated metabolism, but the enterocytes in the small intestinal epithelium are also potentially important.

CYP450 isoenzymes. The CYP450 system comprises 57 isoenzymes, each derived from the expression of an individual gene. As there are many different isoforms of these enzymes, a classification for nomenclature has been developed, comprising a family number, a subfamily letter and a number for an individual enzyme within the subfamily (Wilkinson, 2005). Four main subfamilies of P450 isoenzymes are thought to be responsible for most (about 90%) of the metabolism of commonly used drugs in humans: CYP1, CYP2, CYP3 and CYP4. The most extensively studied isoenzyme is CYP2D6, also known as debrisoquine hydroxylase. Although there is overlap, each cytochrome 450 isoenzyme tends to metabolise a discrete range of substrates. Of the many isoenzymes, a few (CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1 and CYP3A4) appear to be responsible for the human metabolism of most commonly used drugs.

The genes that encode specific cytochrome 450 isoenzymes can vary between individuals and, sometimes, ethnic groups. These variations (polymorphisms) may affect metabolism of substrate drugs. Interindividual variability in CYP2D6 activity is well recognised (see Chapter 5). It shows a polymodal distribution and people may be described according to their ability to metabolise debrisoquine. Poor metabolisers tend to have reduced first-pass metabolism, increased plasma levels and exaggerated pharmacological response to this drug, resulting in postural hypotension. By contrast, ultra-rapid metabolisers may require considerably higher doses for a standard effect. About 5–10% of white Caucasians and up to 2% of Asians and black people are poor metabolisers.

The CYP3A family of P450 enzymes comprises two isoenzymes, CYP3A4 and CYP3A5, so similar that they cannot be easily distinguished. CYP3A is probably the most important of all drug-metabolising enzymes because it is abundant in both the intestinal epithelium and the liver and it has the ability to metabolise a multitude of chemically unrelated drugs from almost every drug class. It is likely that CYP3A is involved in the metabolism of more than half the therapeutic agents that undergo alteration by oxidation. In contrast to other cytochrome 450 enzymes, CYP3A shows continuous unimodal distribution, suggesting that genetic factors play a minor role in its regulation. Nevertheless, the activity of the enzyme can vary markedly among members of a given population.

The effect of a cytochrome 450 isoenzyme on a particular substrate can be altered by interaction with other drugs. Drugs may be themselves substrates for a cytochrome 450 isoenzyme and/or may inhibit or induce the isoenzyme. In most instances, oxidation of a particular drug is brought about by several CYP isoenzymes and results in the production of several metabolites. So, inhibition or induction of a single isoenzyme would have little effect on plasma levels of the drug. However, if a drug is metabolised primarily by a single cytochrome 450 isoenzyme, inhibition or induction of this enzyme would have a major effect on the plasma concentrations of the drug. For example, if erythromycin (an inhibitor of CYP3A4) is taken by a patient being given carbamazepine (which is extensively metabolised by CYP3A4), this may lead to toxicity due to higher concentrations of carbamazepine. Table 4.1 gives examples of some drug substrates, inducers and inhibitors of the major cytochrome 450 isoenzymes.

Table 4.1 Examples of drug substrates, inducers and inhibitors of the major cytochrome P450 enzymes

P450 isoform	Substrate	Inducer	Inhibitor
CYP1A2	Caffeine Clozapine Imipramine Olanzapine Theophylline Tricyclic antide- pressants R-warfarin	Omeprazole Lansoprazole Phenytoin Tobacco smoke	Amiodarone Cimetidine Fluoroquinolones Fluvoxamine
CYP2C9	Diazepam Diclofenac Losartan Statins SSRIs S-warfarin	Barbiturates Rifampicin	Amiodarone Azole antifungals Isoniazid
CYP2C19	Cilostazol Diazepam Lansoprazole	Carbamazepine Rifampicin Omeprazole	Cimetidine Fluoxetine Tranylcypromine

Enzyme induction. The most powerful enzyme inducers in clinical use are the antibiotic rifampicin and antiepileptic agents such as barbiturates, phenytoin and carbamazepine. Some enzyme inducers, notably barbiturates and carbamazepine, can induce their own metabolism (autoinduction). Cigarette smoking, chronic alcohol use and the herbal preparation St John's wort can also induce drug-metabolising enzymes. Since the process of enzyme induction requires new protein synthesis, the effect usually develops over several days or weeks after starting an enzyme-inducing agent. Similarly, the effect generally persists for a similar period following drug withdrawal. Enzyme-inducing drugs with short half-lives such as rifampicin will induce metabolism more rapidly than inducers with longer half-lives, for example, phenytoin, because they reach steady-state concentrations more rapidly. There is evidence that the enzyme induction process is dose dependent, although some drugs may induce enzymes at any dose.

Enzyme induction usually results in a decreased pharmacological effect of the affected drug. St John's wort is now known to be a potent inducer of CYP3A (Mannel, 2004). Thus, when a patient receiving ciclosporin, tacrolimus, HIV-protease inhibitors, irinotecan or imatinib takes St John's wort, there is a risk of therapeutic failure with the affected drug. However, if the affected drug has active metabolites, this may lead to an increased pharmacological effect. The effects of enzyme induction vary considerably between patients and are dependent upon age, genetic factors, concurrent drug treatment and disease state. Some examples of interactions due to enzyme induction are shown in Table 4.2.

Enzyme inhibition. Enzyme inhibition is responsible for many clinically significant interactions. Many drugs act as inhibitors of cytochrome 450 enzymes (see Box 4.2). A strong inhibitor is one that can cause ≥5-fold increase in the plasma area-under-the-curve (AUC) value or more than 80% decrease in clearance of CYP3A substrates. A moderate inhibitor is one that can cause ≥2- but <5-fold increase in the AUC value or

Table 4.2 Examples of interactions due to enzyme induction

Drug affected	Inducing agent	Clinical outcome
Oral contraceptives	Rifampicin Rifabutin Modafinil	Therapeutic failure of contraceptives Additional contraceptive precautions required Increased oestrogen dose required
Ciclosporin	Phenytoin Carbamazepine St John's wort	Decreased ciclosporin levels with possibility of transplant rejection
Paracetamol	Alcohol (chronic)	In overdose, hepatotoxicity may occur at lower doses
Corticosteroids	Phenytoin Rifampicin	Increased metabolism with possibility of therapeutic failure

Drug affected	Inhibiting agent	Clinical outcome
Anticoagulants (oral)	Ciprofloxacin Clarithromycin	Anticoagulant effect increased and risk of bleeding
Azathioprine	Allopurinol	Enhancement of effect with increased toxicity
Clopidogrel	Lansoprazole	Reduced anti-platelet effect
Carbamazepine Phenytoin Sodium valproate	Cimetidine	Antiepileptic levels increased with risk of toxicity
Sildenafil	Ritonavir	Enhancement of sildenafil effect with risk of hypotension

50–80% decrease in clearance of sensitive CYP3A substrates when the inhibitor is given at the highest approved dose and the shortest dosing interval. A weak inhibitor is one that can cause ≥1.25- but <2-fold increase in the AUC values or 20–50% decrease in clearance of sensitive CYP3A substrates when the inhibitor is given at the highest approved dose and the shortest dosing interval.

Concurrent administration of an enzyme inhibitor leads to reduced metabolism of the drug and hence an increase in the steady-state drug concentration. Enzyme inhibition appears to be dose related. Inhibition of hepatic metabolism of the affected drug occurs when sufficient concentrations of the inhibitor are achieved in the liver, and the effects are usually maximal when the new steady-state plasma concentration is achieved. Thus, for drugs with a short half-life, the effects may be seen within a few days of administration of the inhibitor. Maximal effects may be delayed for drugs with a long half-life.

The clinical significance of this type of interaction depends on various factors, including dosage (of both drugs), alterations in pharmacokinetic properties of the affected drug such as half-life and patient characteristics such as disease state. Interactions of this type are again most likely to affect drugs with a narrow therapeutic range such as theophylline, ciclosporin, oral anticoagulants and phenytoin. For example, starting treatment with an enzyme inhibitor such as ritonavir in a patient taking sildenafil could result in a marked increase in sildenafil plasma concentrations. Some examples of interactions due to enzyme inhibition are shown in Table 4.3.

The isoenzyme CYP3A4, in particular, is present in the enterocytes. Thus, after oral administration of a drug, cytochrome 450 enzymes in the intestine and the liver may reduce the portion of a dose that reaches the systemic circulation, that is, the bioavailability of the drug. Drug interactions resulting in inhibition or induction of enzymes in the intestinal epithelium can have significant consequences. For example, by selectively inhibiting CYP3A4 in the enterocyte, grapefruit juice can markedly increase the bioavailability of some oral calcium channel blockers, including felodipine (Wilkinson, 2005). Such an interaction is usually considered to be a drug metabolism interaction, even though the mechanism involves an alteration in drug absorption. A single glass of grapefruit juice can cause CYP3A inhibition for 24–48 h and regular consumption may continuously inhibit enzyme activity. Consumption of grapefruit juice is therefore not recommended in patients receiving drugs that are extensively metabolised by CYP3A such as simvastatin, tacrolimus and vardenafil.

Enzyme inhibition usually results in an increased pharmacological effect of the affected drug, but in cases where the affected drug is a pro-drug which requires enzymatic metabolism to active metabolites, a reduced pharmacological effect may result. For example, clopidogrel is metabolised via CYP2C19 to an active metabolite which is responsible for its anti-platelet effect. Proton pump inhibitors such as lansoprazole are inhibitors of CYP2C19 and may lead to reduced effectiveness of clopidogrel when used in combination

Predicting interactions involving metabolism. Predicting drug interactions is not easy for many reasons. First, individual drugs within a therapeutic class may have different effects on an isoenzyme. For example, the quinolone antibiotics ciprofloxacin and norfloxacin inhibit CYP1A2 and have been reported to increase plasma theophylline levels, whereas moxifloxacin is a much weaker inhibitor and appears not to interact in this way. While atorvastatin and simvastatin are metabolised predominantly by the CYP3A4 enzyme, fluvastatin is metabolised by CYP2C9 and pravastatin is not metabolised by the CYP450 system to any significant extent.

Identification of cytochrome P450 isoenzymes involved in drug metabolism using in vitro techniques are now an important step in the drug development process. However, findings

of in vitro studies are not always replicated in vivo and more detailed drug interaction studies may be required to allow early identification of potential interactions. Nevertheless, some interactions affect only a small proportion of individuals and may not be identified unless large numbers of volunteers or patients are studied.

Suspected drug interactions are often described initially in published case reports and are then subsequently evaluated in formal studies. For example, published case reports indicate that some antibiotics reduce the effect of oral contraceptives, although this interaction has not been demonstrated in formal studies. Another factor complicating the understanding of metabolic drug interactions is the finding that there is a large overlap between the inhibitors/inducers and substrates of the drug transporter protein P-glycoprotein and those of CYP3A4. Therefore, both mechanisms may be involved in many of the drug interactions previously thought to be due to effects on CYP3A4.

Elimination interactions

Most drugs are excreted in either the bile or urine. Blood entering the kidneys is delivered to the glomeruli of the tubules where molecules small enough to pass across the pores of the glomerular membrane are filtered through into the lumen of the tubules. Larger molecules, such as plasma proteins and blood cells, are retained. The blood then flows to other parts of the kidney tubules where drugs and their metabolites are removed, secreted or reabsorbed into the tubular filtrate by active and passive transport systems. Interactions can occur when drugs interfere with kidney tubule fluid pH, active transport systems or blood flow to the kidney, thereby altering the excretion of other drugs.

Changes in urinary pH. As with drug absorption in the gut, passive reabsorption of drugs depends on the extent to which the drug exists in the non-ionised lipid-soluble form. Only the non-ionised form is lipid soluble and able to diffuse back through the tubular cell membrane. Thus, at alkaline pH, weakly acidic drugs (pK_a 3.0–7.5) largely exist as ionised lipid-insoluble molecules which are unable to diffuse into the tubule cells and will therefore be lost in the urine. The renal clearance of these drugs is increased if the urine is made more alkaline. Conversely, the clearance of weak bases (pK_a 7.5–10) is higher in acid urine. Strong acids and bases are virtually completely ionised over the physiological range of urinary pH and their clearance is unaffected by pH changes.

This mechanism of interaction is of very minor clinical significance because most weak acids and bases are inactivated by hepatic metabolism rather than renal excretion. Furthermore, drugs that produce large changes in urine pH are rarely used clinically. Urine alkalinisation or acidification has been used as a means of increasing drug elimination in poisoning with salicylates and amphetamines, respectively.

Changes in active renal tubule excretion. Drugs that use the same active transport system in the kidney tubules can compete with one another for excretion. Such competition between drugs can be used to therapeutic advantage. For example, probenecid may be given to increase the plasma concentration of penicillins

by delaying renal excretion. With the increasing understanding of drug transporter proteins in the kidneys, it is now known that probenecid inhibits the renal secretion of many other anionic drugs via organic anion transporters (OATs; Lee and Kim, 2004). Increased methotrexate toxicity, sometimes life-threatening, has been seen in some patients concurrently treated with salicylates and some other non-steroidal anti-inflammatory drugs (NSAIDs). The development of toxicity is more likely in patients treated with high-dose methotrexate and those with impaired renal function. The mechanism of this interaction may be multifactorial but competitive inhibition of methotrexate's renal tubular secretion is likely to be involved. If patients taking methotrexate are given salicylates or NSAIDs concomitantly, the dose of methotrexate should be closely monitored.

Changes in renal blood flow. Blood flow through the kidney is partially controlled by the production of renal vasodilatory prostaglandins. If the synthesis of these prostaglandins is inhibited by drugs such as indometacin, the renal excretion of lithium is reduced with a subsequent rise in plasma levels. The mechanism underlying this interaction is not entirely clear, as plasma lithium levels are unaffected by other potent prostaglandin synthetase inhibitors, for example, aspirin. If an NSAID is prescribed for a patient taking lithium, the plasma levels should be closely monitored.

Biliary excretion and the enterohepatic shunt. A number of drugs are excreted in the bile, either unchanged or conjugated, for example, as the glucuronide, to make them more water soluble. Some of the conjugates are metabolised to the parent compound by the gut flora and are then reabsorbed. This recycling process prolongs the stay of the drug within the body but if the gut flora are diminished by the presence of an antibacterial, the drug is not recycled and is lost more quickly. This mechanism has been postulated as the basis of an interaction between broad-spectrum antibiotics and oral contraceptives. Antibiotics may reduce the enterohepatic circulation of ethinyloestradiol conjugates, leading to reduced circulating oestrogen levels with the potential for therapeutic failure. There is considerable debate about the nature of this interaction as the evidence from pharmacokinetic studies is not convincing. However, due to the potential adverse consequences of pill failure, most authorities recommend a conservative approach, including the use of additional contraceptive precautions to cover the short-term use of broad-spectrum antibiotics.

Drug transporter proteins. Drugs and endogenous substances are now known to cross biological membranes not just by passive diffusion but by carrier-mediated processes, often known as transporters. Significant advances in the identification of various transporters have been made and although their contribution to drug interactions is not yet clear, they are now thought to play a role in many interactions formerly attributed to cytochrome 450 enzymes (DuBuske, 2005).

P-glycoprotein (P-gp) is a large cell membrane protein that is responsible for the transport of many substrates, including drugs. It is a product of the ABCB1 gene (previously known as the multidrug resistance gene, MDR1) and a member of the adenosine triphosphate (ATP)-binding cassette family of transport proteins (ABC transporters). P-glycoprotein is found in high levels in various tissues including the renal

proximal tubule, hepatocytes, intestinal mucosa, the pancreas and the blood–brain barrier. P-glycoprotein acts as an efflux pump, exporting substances into urine, bile and the intestinal lumen. Its activity in the blood–brain barrier limits drug accumulation in the central nervous system (CNS). Examples of some possible inhibitors and inducers of P-glycoprotein are shown in Table 4.4. The pumping actions of P-glycoprotein can be induced or inhibited by some drugs. For example, concomitant administration of digoxin and verapamil, a P-glycoprotein inhibitor, is associated with increased digoxin levels with the potential for digoxin toxicity. There is an overlap between CYP3A4 and P-glycoprotein inhibitors, inducers and substrates. Many drugs that are substrates for CYP3A4 are also substrates for P-glycoprotein. Therefore, both mechanisms may be involved in many of the drug interactions initially thought to be due to changes in CYP3A4. Digoxin is an example of the few drugs that are substrates for P-glycoprotein but not CYP3A4.

Pharmacodynamic interactions

Pharmacodynamic interactions are those where the effects of one drug are changed by the presence of another drug at its site of action. Sometimes these interactions involve competition for specific receptor sites but often they are indirect and involve interference with physiological systems. They are much less easy to classify than interactions with a pharmacokinetic basis.

Antagonistic interactions

It is to be expected that a drug with an agonist action at a particular receptor type will interact with antagonists at that receptor. For example, the bronchodilator action of a selective β_2-adrenoreceptor agonist such as salbutamol will be antagonised by β-adrenoreceptor antagonists. There are numerous examples of interactions occurring at receptor sites, many of which are used to therapeutic advantage. Specific antagonists may be used to reverse the effect of another drug at receptor sites; examples include the opioid antagonist naloxone and the benzodiazepine antagonist flumazenil. α-Adrenergic agonists such as metaraminol may be used in the management of priapism induced by α-adrenergic antagonists such as phentolamine. There are many other examples of drug classes that have opposing pharmacological actions, such as anticoagulants and vitamin K and levodopa and dopamine antagonist antipsychotics.

Additive or synergistic interactions

If two drugs with similar pharmacological effects are given together, the effects can be additive (see Table 4.5). Although not strictly drug interactions, the mechanism frequently contributes to ADR. For example, the concurrent use of drugs with CNS-depressant effects such as antidepressants, hypnotics, antiepileptics and antihistamines may lead to excessive drowsiness, yet such combinations are frequently encountered. Combinations of drugs with arrhythmogenic potential such as antiarrhythmics, neuroleptics, tricyclic antidepressants and those producing electrolyte imbalance (e.g. diuretics) may lead to ventricular arrhythmias and should be avoided. Another example which has assumed greater importance of late is the risk of ventricular tachycardia and torsade de pointes associated with the concurrent use of more than one drug with the potential to prolong the QT interval on the electrocardiogram (Roden, 2004).

Serotonin syndrome

Serotonin syndrome (SS) is associated with an excess of serotonin that results from therapeutic drug use, overdose or inadvertent interactions between drugs. Although severe cases are uncommon, it is becoming increasingly well recognised in patients receiving combinations of serotonergic drugs (Boyer and Shannon, 2005). It can occur when two or more drugs affecting serotonin are given at the same time or after one serotonergic drug is stopped and another started. The

Table 4.4 Examples of inhibitors and inducers of P-glycoprotein

Inhibitors	Atorvastatin Ciclosporin Clarithromycin Dipyridamole Erythromycin Itraconazole Ketoconazole Propafenone Quinidine Ritonavir Valspodar Verapamil
Inducers	Rifampicin St John's wort

Table 4.5 Examples of additive or synergistic interactions

Interacting drugs	Pharmacological effect
NSAID, warfarin, clopidogrel	Increased risk of bleeding
ACE inhibitors and K-sparing diuretic	Increased risk of hyperkalaemia
Verapamil and β-adrenergic antagonists	Bradycardia and asystole
Neuromuscular blockers and aminoglycosides	Increased neuromuscular blockade
Alcohol and benzodiazepines	Increased sedation
Pimozide and sotalol	Increased risk of QT interval prolongation
Clozapine and co-trimoxazole	Increased risk of bone marrow suppression

syndrome is characterised by symptoms including confusion, disorientation, abnormal movements, exaggerated reflexes, fever, sweating, diarrhoea and hypotension or hypertension. Diagnosis is made when three or more of these symptoms are present and no other cause can be found. Symptoms usually develop within hours of starting the second drug but occasionally they can occur later. Drug-induced SS is generally mild and resolves when the offending drugs are stopped. Severe cases occur infrequently and fatalities have been reported.

SS is best prevented by avoiding the use of combinations of several serotonergic drugs. Special care is needed when changing from a selective serotonin reuptake inhibitor (SSRI) to an MAOI and vice versa. The SSRIs, particularly fluoxetine, have long half-lives and SS may occur if a sufficient wash-out period is not allowed before switching from one to the other. When patients are being switched between these two groups of drugs, the guidance in manufacturers' Summaries of Product Characteristics should be followed. Many drugs have serotonergic activity as their secondary pharmacology and their potential for causing the SS may not be readily recognised, for example linezolid, an antibacterial with monoamine oxidase inhibitory activity has been implicated in several case reports of SS.

Many recreational drugs such as amfetamines and their derivatives have serotonin agonist activity and the SS may ensue following the use of other serotonergic drugs.

Drug or neurotransmitter uptake interactions

Although seldom prescribed nowadays, the MAOIs have significant potential for interactions with other drugs and foods. MAOIs reduce the breakdown of noradrenaline in the adrenergic nerve ending. Large stores of noradrenaline can then be released into the synaptic cleft in response to either a neuronal discharge or an indirectly acting amine. The action of the directly acting amines adrenaline, isoprenaline and noradrenaline appears to be only moderately increased in patients taking MAOIs. In contrast, the concurrent use of MAOIs and indirectly acting sympathomimetic amines such as amphetamines, tyramine, MDMA (ecstasy), phenylpropanolamine and pseudoephedrine can result in a potentially fatal hypertensive crisis. Some of these compounds are contained in proprietary cough and cold remedies. Tyramine, contained in some foods, for example cheese and red wine, is normally metabolised in the gut wall by monoamine oxidase to inactive metabolites. In patients taking MAOI, however, tyramine will be absorbed intact. If patients taking MAOIs also take these amines, there may be a massive release of noradrenaline from adrenergic nerve endings, causing a sympathetic overactivity syndrome, characterised by hypertension, headache, excitement, hyperpyrexia and cardiac arrhythmias. Fatal intracranial haemorrhage and cardiac arrest may result. The risk of interactions continues for several weeks after the MAOI is stopped as new monoamine oxidase enzyme must be synthesised. Patients taking irreversible MAOIs should not take any indirectly acting sympathomimetic amines. All patients must be strongly warned about the risks of cough and cold remedies, illicit drug use and the necessary dietary restrictions.

Drug–food interactions

It is well established that food can cause clinically important changes in drug absorption through effects on gastro-intestinal absorption or motility, hence the advice that certain drugs should not be taken with food, for example, iron tablets and antibiotics. Two other common examples already outlined include the interaction between tyramine in some foods and MAOIs, and the interaction between grapefruit juice and the calcium channel blocker felodipine. With improved understanding of drug metabolism mechanisms, there is greater recognition of the effects of some foods on drug metabolism. The interaction between grapefruit juice and felodipine was discovered serendipitously when grapefruit juice was chosen to mask the taste of ethanol in a study of the effect of ethanol on felodipine. Grapefruit juice mainly inhibits intestinal CYP3A4, with only minimal effects on hepatic CYP3A4. This is demonstrated by the fact that intravenous preparations of drugs metabolised by CYP3A4 are not much affected whereas oral preparations of the same drugs are. Some drugs that are not metabolised by CYP3A4 show decreased levels with grapefruit juice, such as fexofenadine. The probable reason for this is that grapefruit juice inhibits some drug transporter proteins and possibly affects organic anion-transporting polypeptides, although inhibition of P-glycoprotein has also been suggested. The active constituent of grapefruit juice is uncertain. Grapefruit contains naringin, which degrades during processing to naringenin, a substance known to inhibit CYP3A4. Although this led to the assumption that whole grapefruit will not interact, but that processed grapefruit juice will, some reports have implicated the whole fruit. Other possible active constituents in the whole fruit include bergamottin and dihydroxybergamottin.

Initial reports of an interaction between cranberry juice and warfarin, prompting regulatory advice that the international normalised ratio (INR) should be closely monitored in patients taking this combination, have not been confirmed by subsequent controlled studies.

Cruciferous vegetables, such as brussels sprouts, cabbage and broccoli, contain substances that are inducers of the CYP450 isoenzyme CYP1A2. Chemicals formed by burning (e.g. barbecuing) meats additionally have these properties. These foods do not appear to cause any clinically important drug interactions in their own right, but their consumption may add another variable to drug interaction studies, so complicating interpretation.

Drug–herb interactions

There has been a marked increase in the availability and use of herbal products in the UK over the past decade, which include Chinese herbal medicines and Ayurvedic medicines. Up to 24% of hospital patients report using herbal remedies (Constable et al., 2007). Such products often contain

pharmacologically active ingredients which can give rise to clinically significant interactions when used inadvertently with other conventional drugs.

Extracts of *Glycyrrhizin glabra* (liquorice) used for treating digestive disorders may cause significant interactions in patients using digoxin or diuretics. It may exacerbate hypokalaemia induced by diuretic drugs and precipitate digoxin toxicity. Herbal products such as Chinese ginseng (*Panax ginseng*), Chan Su (containing bufalin) and Danshen may also contain digoxin-like compounds which can interfere with digoxin assays, leading to falsely elevated levels being detected.

A number of herbal products have anti-platelet and anti-coagulant properties and may increase the risk of bleeding when used with aspirin or warfarin. Herbal extracts containing coumarin-like constituents include Alfalfa (*Medicago sativa*), Angelica (*Angelica archangelica*), Dong Quai (*Angelica polymorpha*, *A. dahurica*, *A. atropurpurea*), chamomile, horse chestnut and red clover (*Trifolium pratense*) which can potentially lead to interactions with warfarin. Herbal products with anti-platelet properties include Borage (*Borago officinalis*), Bromelain (*Ananas comosus*), capsicum, feverfew, garlic, Ginkgo (*Ginkgo biloba*) and turmeric amongst others.

Other examples of drug–herb interactions include enhancement of hypoglycaemic (for example Asian ginseng) and hypotensive (for example hawthorn) effects, and lowering of seizure threshold (for example evening primrose oil and *Shankapushpi*). The most widely discussed drug–herb interactions are those involving St John's wort (*Hypericum* extract) used for depression but these only represent a minority of the potential interactions. It is therefore imperative that patients are specifically asked about their use of herbal medicines as they may not volunteer this information.

Conclusion

Whilst one should acknowledge the impossibility of memorising all potential drug interactions, health care workers need to be alert to the possibility of drug interactions and take appropriate steps to minimise their occurrence. Drug formularies and the Summary of Product Characteristics provide useful information about interactions. Other resources that may also be of use to prescribers include drug safety updates from regulators such as the Medicines and Health care products Regulatory Agency (available at http://www.mhra.gov.uk/index.htm), interaction alerts in prescribing software and the availability of websites which highlight interactions for specific drug classes, for example, HIV drugs (http://www.hiv-druginteractions.org/).

Possible interventions to avoid or minimise the risk of a drug interaction include:

(1) Switching one of the potential interacting drugs.
(2) Allowing an interval of 2–3 h between administration of the interacting drugs.

(3) Altering the dose of one of the interacting drugs, for example, reducing the dose of the drug which is likely to have an enhanced effect as a result of the interaction. In this case, the dose is generally reduced by one-third or half with subsequent monitoring for toxic effects either clinically or by therapeutic drug monitoring. Conversely, if the drug is likely to have reduced effects as a result of the interaction, the patient should be monitored similarly for therapeutic failure and the dose increased if necessary.
(4) Advising patients to seek guidance about their medication if they plan to stop smoking, or start a herbal remedy, as they may need close monitoring during the transition.

Overall, it is important to anticipate when a potential drug interaction might have clinically significant consequences for the patient. In these situations, advice should be given on how to minimise the risk of harm, for example, by recommending an alternative treatment to avoid the combination of risk, by making a dose adjustment or by monitoring the patient closely.

Case studies

Case 4.1

Mrs C is a 62-year-old woman with a history of hypertension, atrial fibrillation and type 2 diabetes. She is a non-smoker and obese. Her current medication comprises flecainide 100 mg twice a day, aspirin 75 mg daily, simvastatin 40 mg and diltiazem 180 mg daily. Mrs C is suffering from a respiratory tract infection and her primary care doctor has prescribed a 5-day course of clarithromycin.

Questions

1. Are there likely to be any clinically significant drug interactions?
2. What advice do you give?

Answers

1. There is potential for interaction between simvastatin and diltiazem and between simvastatin and clarithromycin. Some statins, particularly simvastatin and atorvastatin, are metabolised by cytochrome P450 (CYP3A4) and co-administration of potent inhibitors of this enzyme may particularly increase plasma levels of these statins and so increase the risk of dose-related side effects, including rhabdomyolysis. Clarithromycin is a potent inhibitor of CYP3A4 and diltiazem is a less potent inhibitor.
2. Current advice is that diltiazem and simvastatin may be given together provided the simvastatin dose does not exceed 40 mg daily, so it is reasonable for this therapy to be continued. However, clarithromycin should not be given together with simvastatin. Myopathy and rhabdomyolysis have been reported in patients taking the combination. Mrs C should be advised not to take her simvastatin while she is taking clarithromycin and to start taking it again after she has completed the course of antibiotic.

Case 4.2

A 19-year-old woman is on long-term treatment with minocycline 100 mg daily for acne. She wishes to start using the combined oral contraceptive and her doctor has prescribed a low-strength pill (containing ethinyloestradiol 20 μcg with norethisterone 1 mg). The doctor contacts the pharmacist for advice on whether the tetracycline will interfere with the efficacy of the oral contraceptive.

Question

Is there a clinically significant interaction in this situation?

Answer

Contraceptive failure has been attributed to doxycycline, lymecycline, oxytetracycline, minocycline and tetracycline in about 40 reported cases, seven of which specified long-term antibacterial use. There is controversy about whether or not a drug interaction occurs but if there is one it appears to be very rare. Controlled trials have not shown any effect of tetracycline or doxycycline on contraceptive steroid levels. The postulated mechanism is suppression of intestinal bacteria resulting in a fall in enterohepatic recirculation of ethinyloestradiol. Overall, there is no evidence that this is clinically important.

In the case of long-term use of tetracyclines for acne, a small number of cases of contraceptive failure have been reported. Nevertheless, the only well-designed, case–control study in dermatological practice indicated that the incidence of contraceptive failure due to this interaction could not be distinguished from the general and recognised failure rate of oral contraceptives. The UK Family Planning Association advises that women on long-term antibiotic therapy need only take extra precautions for the first 3 weeks of oral contraceptive use because, after about 2 weeks, the gut flora becomes resistant to the antibiotic. In addition, there is some evidence that ethinyloestradiol may accentuate the facial pigmentation that can be caused by minocycline.

Case 4.3

A 48-year-old man with a history of epilepsy is admitted to hospital with tremor, ataxia, headache, abnormal thinking and increased partial seizure activity. His prescribed medicines are phenytoin 300 mg daily, clonazepam 6 mg daily and fluoxetine 20 mg daily. It transpires that fluoxetine therapy had been initiated 2 weeks previously. The patient's phenytoin level is found to be 35 mg/L; at the last outpatient clinic visit 4 months ago, it was 18 mg/L.

Question

What is the proposed mechanism of interaction between fluoxetine and phenytoin and how should it be managed?

Answer

Fluoxetine is believed to inhibit the metabolism of phenytoin by the cytochrome P450 isoenzyme CYP2C9, potentially leading to increased plasma phenytoin levels. There are a number of published case reports and anecdotal observations of phenytoin toxicity occurring with the combination, but the available evidence is conflicting. A review by the U.S. Food and Drug Administration suggested that a marked increase in plasma phenytoin levels, with accompanying toxicity, can occur within 1–42 days (mean onset time of 2 weeks) after starting fluoxetine. If fluoxetine is added to treatment with phenytoin, the patient should be closely monitored. Ideally the phenytoin plasma levels should be monitored and there may be a need to reduce the phenytoin dosage.

Case 4.4

A 79-year-old man presented to hospital with a 3-day history of increasing confusion and collapse. He had a history of chronic lumbosacral pain, treated with oxycodone 10 mg twice daily and amitriptyline 75 mg daily. Five days before hospital admission he had been prescribed tramadol 100 mg four times daily for worsening sciatica. On admission the patient had a Glasgow Coma Scale of 11 and he was delirious and hallucinating. There were no focal neurological signs. Over the next 2 days he became increasingly unwell, confused and sweaty with pyrexia and muscular rigidity. Biochemical tests showed a metabolic acidosis (base deficit of 10.7) and an elevated creatine kinase level of 380 IU/L. There was no evidence of infection. At this stage a diagnosis of probable serotonin syndrome was made.

Questions

1. What is serotonin syndrome and what drugs are most commonly associated with it?
2. How is serotonin syndrome managed?

Answers

1. Serotonin syndrome is often described as a clinical triad of mental status changes, autonomic hyperactivity and neuromuscular abnormalities. However, not all these features are consistently present in all patients with the disorder. Symptoms arising from a serotonin excess range from diarrhoea and tremor in mild cases to delirium, neuromuscular rigidity, rhabdomyolysis and hyperthermia in life-threatening cases. Disturbance of electrolytes, transaminases and creatine kinase may occur. Clonus is the most important finding in establishing the diagnosis of the serotonin syndrome. The differential diagnosis includes neuroleptic malignant syndrome, sepsis, hepatic encephalopathy, heat stroke, delirium tremens and anticholinergic reactions. Serotonin syndrome may not be recognised in some cases because of its protean manifestations. A wide range of drugs and drug combinations has been associated with the serotonin syndrome, including MAOIs, tricyclic antidepressants, SSRIs, opioids, linezolid and $5HT_1$-agonists. Tramadol is an atypical opioid analgesic with partial μ antagonism and central reuptake inhibition of serotonin (5HT) and noradrenaline. At high doses it may also induce serotonin release. Tramadol is reported as causing serotonin syndrome alone (in a few case reports) and in combination with SSRIs, venlafaxine and atypical antipsychotics.
2. Management of the serotonin syndrome involves removal of the precipitating drugs and supportive care. Many cases typically resolve within 24 h after serotonergic drugs are stopped but symptoms may persist in patients taking medicines with long half-lives or active metabolites. The $5HT_{2A}$-antagonist cyproheptadine and atypical antipsychotic agents with $5HT_{2A}$-antagonist activity, such as olanzapine, have been used to treat serotonin syndrome, although their efficacy has not been conclusively established.

Case 4.5

A 42-year-old woman is on long-term treatment with azathioprine 100 mg daily and bendroflumethiazide 2.5 mg daily. The latter was discontinued after an episode of gout but she had three further episodes over the following year. Her doctor considers prescribing allopurinol as prophylaxis.

Question

Is this likely to cause a clinically significant interaction?

Answer

Azathioprine is metabolised in the liver to mercaptopurine and then converted to an inactive metabolite by the enzyme xanthine oxidase. Allopurinol is an inhibitor of xanthine oxidase and will lead to the accumulation of mercaptopurine which can cause bone marrow suppression and haematological abnormalities such as neutropenia and thrombocytopenia.

The dose of azathioprine should be reduced by at least 50% and close haematological monitoring is required if allopurinol is used concomitantly.

Case 4.6

A 68-year-old woman is on long-term treatment with lansoprazole for gastro-oesophageal reflux disease and warfarin for atrial fibrillation. She is admitted with haematemesis. On direct questioning, she also revealed that she takes various herbal medicines which contain chamomile, horse chestnut, garlic, feverfew, ginseng and St John's wort.

Question

What drug–herb interactions may have contributed to her presentation to hospital?

Answer

Garlic, feverfew and ginseng all inhibit platelet aggregation by inhibiting the production or release of prostaglandins and thromboxanes. In addition, chamomile and horse chestnut contain coumarin-like constituents which can potentiate the anticoagulant effect of warfarin. St John's wort is a potent enzyme inducer and may induce the metabolism of lansoprazole via CYP2C19, thereby reducing the effectiveness of lansoprazole.

Although the effects of herbs individually may be small, their combined effects may lead to serious complications.

5 Adverse drug reactions

J. Krska and A. R. Cox

Key points

- An adverse drug reaction is an unintended noxious response occurring after the normal use of a drug, which is suspected to be associated with the drug.
- Adverse drug reactions can be classified as type A, which are most common and related to the drug's pharmacological effect, or type B, which are rare and unpredictable, although other classes of reaction can be identified.
- Few adverse reactions are identified during pre-marketing studies; therefore, pharmacovigilance systems to detect new adverse drug reactions are essential.
- Spontaneous reporting schemes are a common method of pharmacovigilance which depend primarily on health professionals.
- Patients are encouraged to contribute to post-marketing surveillance schemes in some countries.
- Adverse drug reactions are a significant cause of morbidity and mortality, are responsible for approximately 1 in 20 hospital admissions and are a considerable financial burden on health systems.
- Predisposing factors for adverse drug reactions include age, female gender, ethnicity, genetic factors, co-morbidities and concomitant medication.
- Many adverse drug reactions may be preventable through rational prescribing and careful monitoring of drug therapy.
- Health professionals need to be able to identify and assess adverse drug reactions and play a major role in preventing their occurrence.
- Patients want to receive information about adverse drug reactions; therefore, communicating the risks of using medicines is an important skill for health professionals.

Introduction

All medicines with the ability to produce a desired therapeutic effect also have the potential to cause unwanted adverse effects. Health professionals should have an awareness of the burden that adverse drug reactions (ADRs) place on health services and the public, the identification and avoidance of ADRs and their important role in post-marketing surveillance of medicines to ensure their continued safety.

Risks associated with medicinal substances are documented throughout history; for example, William Withering's 1785 account provides a meticulous description of the adverse effects of digitalis. However, it was the thalidomide disaster that captured public attention and brought about major regulatory changes in drug safety. Thalidomide was first marketed by Chemie Grünenthal in 1957 and distributed in the UK by Distillers Ltd, whose chief medical advisor stated, 'If all the details of this are true, then it is a most remarkable drug. In short, it is impossible to give a toxic dose.' In 1958, thalidomide was recommended for use in pregnant and nursing mothers without supporting evidence. An Australian doctor, Jim McBride, and a German doctor, Widukund Lenz, independently associated thalidomide exposure with serious birth defects and thalidomide was withdrawn in December 1961. Thalidomide left behind between 8000 and 12,000 deformed children and an unknown number of deaths *in utero*.

The 1970s saw another unexpected and serious adverse reaction. The cardioselective beta-adrenergic receptor blocker practolol, launched in June 1970, was initially associated with rashes, some of which were severe. A case series of psoriasis-like rashes linked to dry eyes, including irreversible scarring of the cornea, led other doctors to report eye damage, including corneal ulceration and blindness, to regulators. Cases of sclerosing peritonitis, a bowel condition associated with significant mortality, were also reported. Practolol had remained on the market for 4 years; over 100,000 people had been treated and hundreds were seriously affected.

Some adverse effects can be more difficult to differentiate from background events occurring commonly in the population. The COX-II selective non-steroidal anti-inflammatory drugs (NSAIDs), celecoxib (introduced 1998) and rofecoxib (introduced 1999), were marketed on the basis of reduced gastro-intestinal ADRs in comparison to other non-selective NSAIDs. Apparent excesses of cardiovascular events, which were noted during clinical trials and in elderly patient groups, were ascribed to the supposed cardio-protective effects of comparator drugs. However, in September 2004, a randomised controlled trial of rofecoxib in the prevention of colorectal cancer showed the drug to be associated with a significantly increased risk of cardiovascular events. Celecoxib was also associated with a dose-related increased risk of cardiovascular events in clinical trials. Rofecoxib was voluntarily withdrawn from the market. Further research has provided evidence of thrombotic risk with non-selective NSAIDs, in particular diclofenac. This risk appears to extend to all NSAID users, irrespective of baseline cardiovascular risk.

Not all drug safety issues are related to real effects. In 1998, a widely-publicised paper by Andrew Wakefield and co-authors, later retracted, alleged a link between MMR vaccine and autism, and led to a crisis in parental confidence in the vaccine. This had a detrimental effect on vaccination rates, resulting in frequent outbreaks of measles and mumps, despite epidemiological and virological studies showing no link between MMR vaccine and autism. The MMR vaccine controversy illustrates how media reporting of drug safety information can influence patients' views of medicines and can cause significant harm. Poor presentation of drug safety issues in the media often creates anxiety in patients about medicines which they may be using, regardless of their benefits.

Assessing the safety of drugs

When drugs are newly introduced to the market, their safety profile will be provisional. While efficacy and evidence of safety must be demonstrated for regulatory authorities to permit marketing, it is not possible to discover the complete safety profile of a new drug prior to its launch. Pre-marketing clinical trials involve on average 2500 patients, with perhaps a hundred patients using the drug for longer than a year. Therefore, pre-marketing trials do not have the power to detect important reactions that occur at rates of 1 in 10,000, or fewer, drug exposures. Often, only pharmacologically predictable ADRs with short onset times may be identified in clinical trials, nor can pre-marketing trials detect ADRs which are separated in time from drug exposure. Additionally, patients within trials are often carefully selected, without the multiple disease states or complex drug histories of patients in whom the drug will eventually become used. Furthermore, the patient's perspective is also frequently excluded from clinical trial safety assessments, with ADRs being assessed only by the clinicians who run them (Basch, 2010). For these reasons, rare and potentially serious adverse effects often remain undetected until a wider population is exposed to the drug. The vigilance of health professionals is an essential factor in discovering these new risks, together with regulatory authorities who continuously monitor reports of adverse effects throughout the lifetime of a marketed medicinal product.

As a result of this monitoring, the safety profile of established drugs is often well known, although new risks are occasionally identified. However, an important part of the therapeutic management of medical conditions is the minimisation of these well-known risks through rational prescribing and careful monitoring of drug therapy. Current evidence suggests that this could be improved.

Definitions

Having clear definitions of what constitutes an ADR is important. The World Health Organization (WHO) defines an ADR as 'a response to a drug that is noxious and unintended and occurs at doses normally used in man for the prophylaxis, diagnosis or therapy of disease, or for modification of physiological function' (WHO, 1972). The use of the phrase 'at doses normally used in man' distinguishes the noxious effects of drugs during normal medical use from toxic effects caused by poisoning. Whether an effect is considered noxious depends on both the drug's beneficial effects and the severity of the disease for which it is being used. There is no need to prove a pharmacological mechanism for any noxious response to be termed an ADR.

The terms ADR and adverse drug effect can be used interchangeably; adverse reaction applies to the patient's point of view, while adverse effect applies to the drug. The terms suspected ADR or reportable ADR are commonly used in the context of reporting ADRs to regulatory authorities, for example, through the UK's Yellow Card Scheme, operated by the Medicines and Healthcare Regulatory Authority (MHRA). Although the term 'side effect' and ADR are often used synonymously, the term 'side effect' is distinct from ADR. A side effect is an unintended effect of a drug related to its pharmacological properties and can include unexpected benefits of treatment.

The WHO definition has been criticised for excluding the potential for contamination of a product, ADRs that include an element of error, and ADRs associated with pharmacologically inactive excipients in a product. The use of the term 'drug' also excluded the use of complementary and alternative treatments, such as herbal products. In an attempt to overcome these points, the following definition of an ADR was proposed, 'An appreciably harmful or unpleasant reaction, resulting from an intervention related to the use of a medicinal product, which predicts hazard from future administration and warrants prevention or specific treatment, or alteration of the dosage regime, or withdrawal of the product' (Edwards and Aronson, 2000).

It is important also to avoid confusion with the term adverse drug event (ADE). An ADR in a patient is an adverse outcome that is attributed to a suspected action of a drug, whereas an ADE is an adverse outcome that occurs after the use of a drug, but which may or may not be linked to use of the drug. It therefore follows that all ADRs are ADEs, but that not all ADEs will be ADRs. This distinction is important in the assessment of the drug safety literature, since the term ADE can be used when it is not possible to suggest a causal link between a drug treatment and an adverse outcome. The suspicion of a causal relationship between the drug and the adverse effect is central to the definition of an ADR.

Classification of ADRs

Classification systems for ADRs are useful for educational purposes, for those working within a regulatory environment and for clarifying thinking on the avoidance and management of ADRs.

Rawlins–Thompson classification

The Rawlins–Thompson system of classification divides ADRs into two main groups: Type A and Type B (Rawlins, 1981). Type A reactions are the normal, but quantitatively exaggerated, pharmacological effects of a drug. They include

the primary pharmacological effect of the drug, as well as any secondary pharmacological effects of the drug, for example, ADRs caused by the antimuscarinic activity of tricyclic antidepressants. Type A reactions are most common, accounting for 80% of reactions.

Type B reactions are qualitatively abnormal effects, which appear unrelated to the drug's normal pharmacology, such as hepatoxicity from isoniazid. They are more serious in nature, more likely to cause deaths, and are often not discovered until after a drug has been marketed. The Rawlins–Thompson classification has undergone further elaboration over the years (Table 5.1) to take account of ADRs that do not fit within the existing classifications (Edwards and Aronson, 2000).

The DoTS system

The DoTS classification is based on *Do*se relatedness, *T*iming and patient *S*usceptibility (Aronson and Ferner, 2003). In contrast to the Rawlins–Thompson classification, which is defined only by the properties of the drug and the reaction, the DoTS classification provides a useful template to examine the various factors that both describe a reaction and influence an individual patient's susceptibility.

DoTS first considers the dose of the drug, as many adverse effects are clearly related to the dose of the drug used. For example, increasing the dose of a cardiac glycoside will increase the risk of digitalis toxicity. In DoTS, reactions are divided into toxic effects (effects related to the use of drugs outside of their usual therapeutic dosage), collateral effects (effects occurring within the normal therapeutic use of the drug) and hyper-susceptibility reactions (reactions occurring in sub-therapeutic doses in susceptible patients). Collateral effects include reactions not related to the expected pharmacological effect of the drug or off-target reactions of the expected therapeutic effect in other body systems. It is worth noting that approximately 20% of newly marketed drugs have their dosage recommendations reduced after marketing, often due to drug toxicity.

The time course of a drug's presence at the site of action can influence the likelihood of an ADR occurring. For example, rapid infusion of furosemide is associated with transient hearing loss and tinnitus, and a constant low dose of methotrexate is more toxic than equivalent intermittent bolus doses. DoTS categorises ADRs as either time-independent reactions or time-dependent reactions. Time-independent reactions occur at any time within the treatment period, regardless of the length of course. Time-dependent reactions range from rapid and immediate reactions, to those reactions which can be delayed.

The final aspect of the DoTS classification system is susceptibility, which includes factors such as genetic predisposition, age, sex, altered physiology, disease and exogenous factors such as drug interactions (Table 5.2)

Factors affecting susceptibility to ADRs

Awareness of the factors which increase the risk of ADRs is key to reducing the burden on individual patients by informing prescribing decisions. The risk that drugs pose to patients

Table 5.1 Extended Rawlins–Thompson classification of adverse drug reactions

Type of reaction	Features	Examples
Type A: Augmented pharmacological effect	Common Predictable effect Dose-dependent Low morbidity Low mortality	Bradycardia associated with a beta-adrenergic receptor antagonist
Type B: Bizarre effects not related to pharmacological effect	Uncommon Unpredictable Not dose-dependent High morbidity High mortality	Anaphylaxis associated with a penicillin antibiotic
Type C: Dose-related and time-related	Uncommon Related to the cumulative dose	Hypothalamic pituitary–adrenal axis suppression by corticosteroids
Type D: Time-related	Uncommon Usually dose-related Occurs or becomes apparent some time after use of the drug	Carcinogenesis
Type E: Withdrawal	Uncommon Occurs soon after withdrawal of the drug	Opiate withdrawal syndrome
Type F: Unexpected failure of therapy	Common Dose-related Often cause by drug interactions	Failure of oral contraceptive in presence of enzyme inducer

Table 5.2 DoTS system of ADR classification

Dose relatedness	Time relatedness	Susceptibility
Toxic effects: ADRs that occur at doses higher than the usual therapeutic dose	*Time-independent reactions*: ADRs that occur at any time during treatment.	Raised susceptibility may be present in some individuals, but not others. Alternatively, susceptibility may follow a continuous distribution – increasing susceptibility with impaired renal function.
Collateral effects: ADRs that occur at standard therapeutic doses	*Time-dependent reactions*: *Rapid reactions* occur when a drug is administered too rapidly. *Early reactions* occur early in treatment then abate with continuing treatment (tolerance).	*Factors include*: genetic variation, age, sex, altered physiology, exogenous factors (interactions) and disease.
Hypersusceptability reactions: ADRs that occur at sub-therapeutic doses in susceptible patients	*Intermediate reactions* occur after some delay, but if reaction does not occur after a certain time, little or no risk exists.	
	Late reactions risk of ADR increases with continued-to-repeated exposure, including withdrawal reactions.	
	Delayed reactions occur some time after exposure, even if the drug is withdrawn before the ADR occurs.	

varies dependent on the population exposed and the individual characteristics of patients. Some reactions may be unseen in some populations, outside of susceptible subjects. Other reactions may follow a continuous distribution in the exposed population. Although many susceptibilities may not be known, a number of general factors which affect susceptibility to ADRs and others which affect the propensity of specific drugs to cause ADRs have been elucidated.

Age

Elderly patients may be more prone to ADRs, with age-related decline in both the metabolism and elimination of drugs from the body. They also have multiple co-morbidities and are, therefore, exposed to more prescribed drugs. Chronological age is, therefore, arguably a marker for altered physiological responses to drugs and for the presence of co-morbidities and associated drug use rather than a risk *per se*. As the population ages, the mitigation of preventable ADRs in the elderly will become increasingly important.

Children differ from adults in their response to drugs. Neonatal differences in body composition, metabolism and other physiological parameters can increase the risk of specific adverse reactions. Higher body water content can increase the volume of distribution for water-soluble drugs, reduced albumin and total protein may result in higher concentrations of highly protein bound drugs, while an immature blood–brain barrier can increase sensitivity to drugs such as morphine. Differences in drug metabolism and elimination and end-organ responses can also increase the risk. Chloramphenicol, digoxin, and ototoxic antibiotics such as streptomycin are examples of drugs that have a higher risk of toxicity in the first weeks of life.

Older children and young adults may also be more susceptible to ADRs, a classic example being the increased risk of extrapyramidal effects associated with metoclopramide. The use of aspirin was restricted in those under the age of 12, after an association with Reye's syndrome was found in epidemiological studies. Additionally, children can be exposed to more adverse effects due to the heightened probability of dosing errors and the relative lack of evidence for both safety and efficacy.

Gender

Women may be more susceptible to ADRs. In addition, there are particular adverse reactions that appear to be more common in women than men. For example, impairment of concentration and psychiatric adverse events associated with the anti-malarial mefloquine are more common in females.

Females are more susceptible to drug-induced torsade de pointes, a ventricular arrhythmia linked to ventricular fibrillation and death. Women are also over-represented in reports of torsades de pointes associated with cardiovascular drugs (such as sotalol) and erythromycin. This increased susceptibility in women is thought to be due to their longer QTc interval compared to men.

Co-morbidities and concomitant medicines use

Reductions in hepatic and renal function substantially increase the risk of ADRs. A recent study examining factors that predicted repeat admissions to hospital with ADRs in older patients showed that co-morbidities such as congestive cardiac failure, diabetes, and peripheral vascular, chronic pulmonary, rheumatological, hepatic, renal, and malignant diseases were strong predictors of readmissions for ADRs, while advancing age was not. Reasons for this could be pharmacokinetic and pharmacodynamic changes associated with pulmonary, cardiovascular, renal and hepatic insufficiency, or drug interactions because of multiple drug therapy (Zhang et al., 2009).

Ethnicity

Ethnicity has also been linked to susceptibility to ADRs, due to inherited traits of metabolism. It is known, for example, that the cytochrome P450 genotype, involved in drug metabolism, has varied distribution among people of differing ethnicity. For example, CYP2C9 alleles associated with poor metabolism can affect warfarin metabolism and increase the risk of toxicity. This occurs more frequently in white individuals compared to black individuals.

Examples of ADRs linked to ethnicity include the increased risk of angioedema with the use of ACE inhibitors in black patients (McDowell et al., 2006), the increased propensity of white and black patients to experience central nervous system ADRs associated with mefloquine compared to patients of Chinese or Japanese origin, and differences in the pharmacokinetics of rosuvastatin in Asian patients which may expose them to an increased risk of myopathy. However, susceptibility based on ethnicity could be associated with genetic or cultural factors and ethnicity can be argued to be a poor marker for a patient's genotype.

Pharmacogenetics

Pharmacogenetics is the study of genetic variations that influence an individual's response to drugs, and examines polymorphisms that code for drug transporters, drug-metabolising enzymes and drug receptors. A greater understanding of the genetic basis of variations that affect an individual's response to drug therapy has promised to lead to a new era of personalised medicine. Arguably, pharmacogenetics has yet to deliver on an appreciable scale, the reduction in ADRs that was predicted. However, there are some important examples of severe ADRs that may be avoided with knowledge of a patient's genetic susceptibility.

As already noted, major genetic variation is found in the cytochrome CYP450 group of isoenzymes. This can result in either inadequate responses to drugs, or increased risk of ADRs. Clinically relevant genetic variation has been seen in CYP2D6, CYP2C9, CYP2C19 and CYP3A5. A large effect on the metabolism of drugs can occur with CYP2C9, which accounts for 20% of total hepatic CYP450 content.

The narrow therapeutic index of warfarin, its high interindividual variability in dosing and the serious consequences of toxicity have made it a major target of pharmacogenomic research. Studies of genetic polymorphisms influencing the toxicity of warfarin have focused on CYP2C9, which metabolises warfarin and vitamin K epoxide reductase (VKOR), the target of warfarin anticoagulant activity. Genetic variation in the VKORC1 gene, which encodes VKOR, influences warfarin dosing by a threefold greater extent than CYP2C9 variants. In 2007, the U.S. Food and Drug Administration (FDA) changed the labelling requirement for warfarin, advising that a lower initial dose should be considered in people with certain genetic variations. However, concerns remain because genetic variation only accounts for a proportion of the variability in drug response and clinicians may obtain a false sense of reassurance from genetic testing leading to complacency in monitoring of therapy. In addition, there appears to be little evidence of additional benefit (Laurence, 2009), in terms of preventing major bleeding events, compared to careful monitoring of the INR (see chapter 23)

A success story for pharmacogenetics is the story of the nucleoside analogue reverse transcriptase inhibitor (NRTI) abacavir. Hypersensitivity skin reactions to abacavir are a particular problem in the treatment of human immunodeficiency virus (HIV) infection. Approximately 5–8% of patients taking abacavir develop a severe hypersensitivity reaction, including symptoms such as fever, rash, arthralgia, headache, vomiting and other gastro-intestinal and respiratory disturbances. Early reports that only a subset of patients was affected, a suspected familial predisposition, the short onset time (within 6 weeks of starting therapy), and an apparent lower incidence in African patients led to suspicion of a genetic cause. Subsequent research revealed a strong predictive association with the human leukocyte antigen HLA-B*5701 allele in Caucasian and Hispanic patients. The presence of the allele can be used to stratify the predicted risk of hypersensitivity as high risk (>70%) for carriers of HLA-B*5701 and low risk (<1%) for non-carriers of HLA-B*5701. Evidence from the practical use of HLA-B*5701 screening has shown substantial falls in the incidence of hypersensitivity reactions, as well as a more general improved compliance with the medication (Lucas et al., 2007).

Another example of a success story for pharmacogenetics involves the cutaneous ADRs Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN). Both are serious reactions associated with substantial morbidity and mortality in which up to 40% of patients with TEN may die. SJS and TEN have been associated with numerous drugs, although the incidence of these reactions is extremely rare. Anti-epileptic drugs, such as carbamazepine and phenytoin, are known causes of SJS and TEN. The reactions are more common in South East Asian populations, including those from China, Thailand, Malaysia, Indonesia, the Philippines and Taiwan and, to a lesser extent, India and Japan. The presence of HLA allele, HLA-B*1502, for which genetic testing is available, indicates an increased risk of skin reactions for carbamazepine, phenytoin, oxcarbamazepine and lamotrigine. The FDA has recommended HLA-B*1502 screening before using carbamazepine and phenytoin in South East Asian individuals.

Erythrocyte glucose-6-phophatase dehydrogenase (G6PD) deficiency

G6PD deficiency is present in over 400 million people worldwide. It is a sex-linked inherited enzyme deficiency, leading to susceptibility to haemolytic anaemia. Patients with low levels of G6PD are predisposed to haemolysis with oxidant drugs such as primaquine, sulphonamides and nitrofurantoin. There are many variants of the genotype, leading to varied susceptibilities in individuals.

Porphyrias

The porphyrias are a heterogeneous group of inherited disorders of haem biosynthesis. The disorders are transmitted as autosomal dominants, with the exception of the rare congenital porphyria, which is recessive. The effects of drugs are of most importance in patients with acute porphyrias, in which certain commonly prescribed agents may precipitate life-threatening attacks. Other trigger factors include alcohol and changes in sex hormone balance. In the acute porphyrias, patients develop abdominal and neuropsychiatric disturbances, and they excrete in their urine excessive amounts of the porphyrin precursors 5-aminolaevulinic acid (ALA) and porphobilinogen.

A number of drugs may induce excess porphyrin synthesis. However, it is extremely difficult to predict whether or not a drug may cause problems in patients with porphyria and the only factors shown to be clearly linked with porphyrinogenicity are lipid solubility and membrane fluidisation, that is, the ability to disrupt the phospholipid bilayer of the cell membrane. A number of commonly used drugs induce ALA synthase in the liver, but there is wide variation between porphyric patients in their sensitivity to drugs which may trigger attacks. Thus, whereas a single dose of a drug may be sufficient to trigger an acute attack in one patient, another may require a number of relatively large doses of the same drug to produce any clinically significant effect. Lists of drugs which are known to be unsafe and drugs which are thought to be safe for use in acute porphyria are available in the British National Formulary.

Immunological reactions

The immune system is able to recognise drugs as foreign substances, leading to allergic reactions. Smaller drug molecules (<600 Da) can bind with proteins to trigger an immune response, or larger molecules can trigger an immune response directly. The immune response is not related to the pharmacological action of the drug and prior exposure to the drug is required. Immunological reactions are often distinct recognisable responses.

Allergic reactions range from rashes, serum sickness and angioedema to the life-threatening bronchospasm and hypotension associated with anaphylaxis. Patients with a history of atopic or allergic disorders are at higher risk. Immunological (hypersensitivity) reactions are split into four main types (Table 5.3).

Formulation issues contributing to ADRs

Although ADRs caused by product formulation issues are rare, because of stringent regulatory control, examples have occurred and regulatory authorities remain vigilant for such problems. In 1937, the S.E. Massengill Company in the USA developed a liquid preparation of an early antibiotic sulphanilamide which contained 72% diethylene glycol. Over a 2-week period, 353 patients received the elixir, 30% of whom died, including 34 children. Sadly, episodes of diethylene glycol poisoning have been reported in contemporary times, in countries which include Nigeria, India, Argentina and Haiti. In 2006, cough medicines made using glycerin contaminated with diethylene glycol, sourced from China, were responsible for the suspected deaths of over 300 people in Panama.

Osmosin was a slow-release preparation of indometacin which used a novel osmotic pump to deliver the drug through a laser-drilled hole in an impervious tablet. Osmosin was withdrawn in 1983 after 36 fatal gastro-intestinal haemorrhages, suspected to be caused by the tablet becoming lodged against the mucosa of the gastro-intestinal tract and exposing the mucosa to high localised concentrations of indometacin.

Adverse reactions have also been associated with excipient changes. In Australia and New Zealand, a decision to change

Table 5.3 Classification of immunological (hypersensitivity) reactions

Classification	Mechanism	Symptoms/signs and examples
Type I (immediate)	Drug/IgE complex to mast cells release of histamine and leukotrienes.	Pruritis, urticaria, bronchoconstriction, angioedema, hypotension, shock, for example, penicillin anaphylaxis.
Type II (cytotoxic)	IgG and complement binding to (usually) red blood cell. Cytotoxic T-cells lyse the cell.	Haemolytic anaemia and thrombocytopaenia, for example, associated with cephalosporins, penicillins and rifampicin.
Type III (immune complex)	Drug antigen and IgG or IgM form immune complex, attracting macrophages and complement activation.	Cutaneous vasculitis, serum sickness, for example, associated with chlorpromazine and sulphonamides.
Type IV (delayed type)	Antigen presentation with major histocompatibility complex protein to T-cells and cytokine and inflammatory mediator release.	Usually occur after 7–20 days. Macular rashes and organ failure, including Stevens–Johnson syndrome and toxic epidermal necrolysis, for example, associated with neomycin and sulphonamides.

the formulation of phenytoin to one used in the USA led to previously stable patients developing severe adverse reactions, including coma. In the US formulation calcium sulphate dihydrate was replaced with lactose. Unfortunately, it was subsequently found that the calcium salt slowed absorption of phenytoin, while the lactose in the new formulation increased its absorption.

Although excipients are often referred to as inert substances, serious adverse reactions such as anaphylaxis and angioedema have been reported to these substances. Sweeteners, flavourings, colouring agents/dyes and preservatives have all been associated with adverse reactions (Kumar, 2003).

Epidemiology of ADRs

ADRs are widespread, as shown by both systematic reviews and large-scale studies. A review of 69 studies from many countries in 2002 found that ADRs were responsible for an estimated 2.6% of admissions to hospitals and that between 3.5% and 7.3% of in-patients may suffer an ADR. More recent data, however, shows these to be under-estimates. A prospective study (Pirmohamed et al., 2004) found that 6.5% out of 18,820 admissions to medical units were caused by ADRs, with 2.3% of patients dying as a result. A similar prospective study of 3695 in-patient episodes found that 14.7% of those admitted to medical or surgical wards experienced an ADR during their stay. These were more common in women, older patients and in those admitted to surgical wards (Davies et al., 2009).

In primary care, estimates for the incidence of ADRs are more difficult to obtain. Some studies have relied on patients' reports of ADRs, either to postal questionnaires or telephone surveys. These provide varying estimates in ADR incidence and prevalence, but are hampered by the lack of information about non-responders. Nonetheless, estimates are of the order of 25% in the USA (Ghandi et al., 2003) and 30% in the UK (Jarernsiripornkul et al., 2002). A systematic review in 2007 found an incidence of overall ADEs, including ADRs, of 14.9 per 1000 person-months in primary care settings.

A widely quoted figure is that ADRs are between the fourth and sixth leading cause of death in the USA. This is based on an extrapolation of a meta-analysis of studies carried out in the USA, which showed that the incidence of serious ADRs causing hospital admission or occurring during admissions was 6.7% and resulted in an incidence of fatal ADRs of 0.32% (Lazarou et al., 1998). The study has been criticised for its methodology; however, more recent work from Sweden has identified that ADRs were responsible for 3% of deaths there (Wester et al., 2008), while in England ADRs were shown to occur in 0.4% of all patients admitted to hospital. This latter study showed that mortality was higher in those experiencing an ADR than in those who did not. Furthermore, the median length of stay in patients who experienced an ADR was 20 days compared to 8 days and costs associated with in-patient ADRs were calculated to be £171 million annually for the NHS in England (Davies et al., 2009). Costs to the NHS associated with admissions due to ADRs have been estimated as £466 million annually (Pirmohamed et al., 2004).

Pharmacovigilance and epidemiological methods in ADR detection

As already noted, the inherent weaknesses of pre-marketing studies mean that post-marketing surveillance of medicines is essential to detect previously unnoticed adverse effects of treatment. The science of this process is called pharmacovigilance and has been defined as 'the study of the safety of marketed drugs under the practical conditions of clinical use in large communities'. Pharmacovigilance is concerned with the detection, assessment and prevention of adverse effects or any other possible drug-related problems, with the ultimate goal of achieving rational and safe therapeutic decisions in clinical practice.

Spontaneous reporting

Pharmacovigilance uses multiple methods, but the following will focus on spontaneous reporting systems. Spontaneous reporting systems collect data about suspected ADRs in a central database. Cases are not collected in a systematic manner, but accumulate through reports submitted spontaneously by people who make a connection between a drug and a suspected drug-induced event. In the UK, the spontaneous reporting scheme is the Yellow Card scheme. In some countries reporting is a voluntary activity, in others reporting is a legal requirement. There is no evidence that such a requirement increases reporting rates.

Spontaneous reporting has a number of advantages. It is relatively cheap to administer, can follow a product throughout its life and can also accept reports to over-the-counter medication and herbal treatments. Such schemes are, however, passive surveillance systems, which rely on the ability of health professionals to recognise possible ADRs and to distinguish these from symptoms related to underlying disease. It is important to emphasise that only a suspicion of a causal link between a drug and an adverse event is required, not confirmation of the association. One disadvantage of spontaneous reporting systems is their inability to quantify the risk. Such systems supply a numerator (the number of reports), but estimates of the incidence of reactions cannot be made because the population exposed to the drug cannot be ascertained accurately. Furthermore, only a minority of reactions are reported. Spontaneous reports are, however, an important form of evidence leading to drug withdrawals and are crucial for hypothesis generation.

Signal detection

A signal can be described as a possible causal relationship between an adverse event and a drug, which was previously unknown. One useful analogy for signal detection in a

spontaneous reporting database is to think of a radio signal, which is disguised by the background radio 'noise'. Statistical methods of signal generation can be thought of as methods of tuning in to capture the radio signal from the background noise.

Statistical approaches scan the data accumulated through spontaneous reports for 'drug–adverse event pairs' that are disproportionately present within the database as a whole. Such calculations can be run automatically by modern computer systems, providing the opportunity to scan large databases for potential signals of new ADRs. Only rarely will a signal provide such strong evidence that a restriction on use of the drug or its withdrawal is immediately required.

However, while these mathematical approaches do develop hypotheses and give the illusion of an objective estimate of risk, they are not conclusive in themselves. A signal could be due to causes other than the drug. Confounding factors such as particular groups of patients being 'channelled' into receiving a drug can influence reporting. Similarly, reports may be received and analysed by a varied set of people with differing levels of understanding, competence, training, experience and awareness. There is also a tendency for reporting rates to be higher with newly introduced drugs, while articles in the media, regulatory action and even legal cases can provoke reporting of particular reactions. For that reason, the strength of the signal also depends on the quality of the individual spontaneous reports.

Causality assessment

The assessment of whether a drug is responsible for a suspected ADR is of great importance in both the regulatory environment and within the pharmaceutical industry. Reporters to spontaneous reporting schemes are requested to submit suspected ADRs and such reports contain variable levels of information. For example, since re-challenge with the suspected drug is often ethically unacceptable, very few reports contain such information.

As already noted, while a safety signal can arise from the accumulation of reported cases of the event in a database, causality assessment of individual cases may influence the subsequent decision-making process. However, often causality is difficult to prove in pharmacovigilance and a high degree of suspicion may be all that is necessary for regulatory action.

One of the most common methods of causality assessment in use is unstructured clinical assessment, also known as global introspection. Expert review of clinical information is undertaken and a judgement is made about the likelihood of the reaction being due to drug exposure. The assessment of complex situations, often with missing information, is open to variation between different assessors and studies have shown marked disagreement between experts. The WHO international monitoring centre uses global introspection for case assessment, assigning standardised causality categories to suspected ADRs (Table 5.4).

A number of alternative methods of assessing causality have been developed using standardised decision algorithms in an attempt to increase objectivity and reduce assessor bias.

Table 5.4 WHO causality categories for ADRs

Category	Description
Certain	Pharmacologically definitive, with re-challenge if necessary
Probably/likely	Reasonable temporal relationship, unlikely to be attributed to disease processes or other drugs, with reasonable dechallenge response
Possible	Reasonable temporal relationship, but could be explained by concurrent disease or drugs. No information on withdrawal
Unlikely	Temporal relationship improbable, concurrent disease or drugs provide plausible explanation
Conditional/unclassified	An event which requires more data for assessment
Unassessable/unclassifiable	An event that cannot be judged because of insufficient/contradictory information which cannot be supplemented or verified

One of those most commonly used to assess causality is the Naranjo algorithm. This uses a questionnaire and points are added or taken away based on the responses to each question, such as '*Did the adverse reaction reappear when the drug was re-administered?*' The total score is then used to place the assessed reaction on the following scale: definite, probable, possible or doubtful. Algorithms may be less open to the effects of confounding variables, such as underlying disease states or concomitant drugs, but variation in assessor judgements still occur.

Yellow Card Scheme

The UK's Yellow Card Scheme was established in 1964 following the thalidomide tragedy. The Scheme is operated by the Medicines and Health care Products Regulatory Authority (MHRA). Health care professionals and coroners can submit reports of suspected ADRs using a Yellow Card (found in the British National Formulary) or using an on-line form (http://www.yellowcard.gov.uk). An association between the medicine and the event does not have to be confirmed. A suspicion is sufficient for a report to be submitted. The MHRA request that all serious suspected ADRs are reported by health care professionals concerning established medicines (drugs and vaccines). For newer drugs and vaccines, all suspected ADRs should be reported, even if minor events. Newer medicines under intensive surveillance are identified with an inverted black triangle symbol in product information and standard prescribing texts. Black triangle status is generally maintained for at least 2 years, but the period varies, depending on how much information is obtained about a product's continued

safety. All suspected ADRs occurring in children should be reported even if the medicine has been used off-label.

Information from Yellow Card reports is entered into a database, suspected reactions are categorised using the internationally accepted Medical Dictionary for Regulatory Affairs (MedDRA) and the resultant signals generated by the combined reports are then assessed for causality. Where there is a valid signal which may be an ADR, further work may be required to assess the association further. This could involve requesting further details from reporters, contacting manufacturers, reviewing the literature or conducting pharmacoepidemiological studies. The MHRA estimates that about 40% of the safety signals investigated by the Agency are generated from spontaneous reports.

When new ADRs are identified and an association confirmed, the MHRA may take action in the form of changes to the Summary of Product Characteristics (SmPC) and/or the patient information leaflet (PIL), restricting usage or withdrawing marketing authorisation for the medicine. Withdrawal of marketing authorisation or change in use requires that prescribers and suppliers be informed immediately, but such information is also usually publicised in the media; hence, patients are often aware of these actions and may present with requests for information and advice.

Unfortunately, spontaneous reporting systems, including the Yellow Card Scheme, suffer from severe under-reporting. A systematic review estimated this to be between 82% and 98% (Hazell and Shakir, 2006). There are a variety of reasons for this, including lack of certainty that the medicine caused the symptom, but it is important to emphasise that such certainty is not required. There is also no requirement to provide the patient name or contact details, only those of the actual reporter; hence, confidentiality, also cited as a reason for under-reporting, is no longer an issue. Furthermore, the MHRA have systems in place to check for duplicate reports covering the same incident, thereby eliminating concern about two people submitting reports about the same event in a given patient.

Direct patient reporting

Patients have been permitted to report directly to MHRA since October 2005, with the number of reports increasing steadily since then. Respondents to a survey of UK patient reporters indicated that the facility to report was important and most had an understanding of the purpose of reporting. Many considered it provided an opportunity to influence the content of PILs so that other patients may be better informed. However, there remains a need to further increase awareness of direct patient reporting among both the public and health professionals.

Despite the limited awareness of direct patient reporting, in the main people find it relatively easy to report suspected ADRs (McLernon et al., 2011). The majority of people who reported a suspected ADR identified it as such through issues relating to timing, as outlined in the causality methods used by pharmacovigilance experts, or by accessing information about the medicine from the PIL (Krska et al., 2011). There

are a number of countries world-wide which accept patient reports. It has been suggested that these advantages include faster signal generation, avoiding the filtering effect of interpretation of events by health professionals and not least, maintaining the number of reports at a time when reporting by health professionals may be reducing.

A comparison of the content of patient reports submitted to MHRA in the first 2 years of the scheme indicated they were more likely to describe the impact of the ADR than in reports submitted by health professionals. Comparisons of the ADR reports submitted indicated a wider range of ADRs were reported by patients to more medicines. However, the proportion of reactions judged serious by MHRA was similar between both patients and health professionals. Overall, patient reports make a useful contribution to pharmacovigilance.

Published case reports

The first suspicions of a less common or unpredictable reaction may often be seen in a case report from a practitioner. As seen by the cases of thalidomide and practolol, astute and vigilant clinicians submitting case reports to the medical press has been of importance in drug safety. Case reports have been described as a form of non-systematic voluntary reporting. However, reports are not solicited and their appearance in the medical literature is in the gift of medical editors. Editors may demand a causal link, or a case series, requiring higher standards of investigation than regulatory agencies demand from a spontaneous report. These high standards can prevent case histories from reaching publication and deter many clinicians. Furthermore, the time it takes for a case report about a suspected ADR to be published could be several months, during which time more patients may be exposed to the potential risk.

Cohort studies

Cohort studies are prospective pharmacoepidemiological studies that monitor a large group of patients taking a particular drug over a period of time. Ideally such studies compare the incidence of a particular adverse event in two groups of patients, those taking the drug of interest and, another group, matched for all important characteristics except the use of the drug. These studies can indicate the relative risks associated with the adverse event in people exposed to the drug being studied.

Case–control studies

Case–control studies compare the extent of drug usage in a group of patients who have experienced the adverse event with the extent of usage among a matched control group who are similar in potentially confounding factors, but have not experienced the event. By comparing the prevalence of drug taking between the groups, it may be possible to identify whether significantly more people who experienced the event also took a particular drug. Examples of associations which have been established by case–control studies are Reye's

syndrome and aspirin and the relationship between maternal diethylstilboestrol ingestion and vaginal adenocarcinoma in female offspring. Case–control studies are an effective method of confirming whether or not a drug causes a given reaction once a suspicion has been raised. Being retrospective, they rely on good record-keeping about drug use and are not capable of detecting previously unsuspected adverse reactions.

Roles of health professionals

Ensuring medicines are used safely is fundamental to the role of all health professionals who prescribe, supply, administer, monitor or advise on their use. When selecting a medicine for an individual patient, whether this is to be prescribed or sold, the health professional should take account of all relevant patient factors, which may predispose to an ADR. As outlined above, this includes co-morbidities, concomitant drugs, renal and liver function and genetic predisposition. Importantly, it is invaluable to have information about the patient's ADR history. Studies have repeatedly shown that this is poorly documented, leading to inappropriate re-use of medicines which have previously caused problems. Hence, another important role of all health professionals is the documentation of identified ADRs. The patient may have information about this if documentation is insufficient; therefore, questioning the patient about his/her ability to tolerate specific medicines or extracting a full ADR history should be considered at every opportunity.

Identifying and assessing ADRs in clinical practice

Outside the pharmacovigilance environment of companies and regulatory agencies, the identification of potential ADRs is an essential component of clinical practice. Although assessments in practice may lack the formality of expert or algorithmic assessment, they are likely to take into account similar factors, such as whether the clinical event is commonly drug related, the temporal relationship with drug use, a dose relationship and exclusion of other possible causes. A list of such factors is set out in Box 5.1.

There are many triggers which can lead to the suspicion of an ADR. For example, changes in medicines, dose reduction, prescription of medicines used to treat allergic reactions or those frequently used to counteract the effects of other drugs. Simple questioning of patients could easily be incorporated into many aspects of routine care to increase the chances of detecting potential ADRs.

The process of identifying an ADR then involves making a judgement about whether or not a particular event such as a symptom, condition or abnormal test result could be related to a drug used in the patient experiencing the event. The prior experiences of the patient with other medicines should also be taken into consideration.

Every opportunity should be taken to question patients about their experience, to determine whether they perceive any adverse events which could be due to medicines. While

---

Box 5.1 Factors that may raise or suppress suspicion of a drug-induced event (Shakir, 2004)

The *temporal relationship* between the exposure to the drug and the subsequent event

The *clinical and pathological characteristics of the event* – events which are known to be related to drug use, rather than disease processes

The *pharmacological plausibility* – based on the observer's knowledge of pharmacology

Existing information in published drug information sources – whether or not the event has been noted by others

Concomitant medication – which may be considered the cause of an event

Underlying and concurrent illnesses – may alter the event or be considered the cause of the event

De-challenge – disappearance of symptoms after dose reduction or cessation of therapy

Re-challenge – reappearance of symptoms after dose increases or recommencement of therapy

Patient characteristics and previous medical history – past history of the patient may colour the view of the event

The potential for *drug interactions*

---

routinely asking simple questions is important, it is of equal value to develop a positive attitude towards the patients' perception of suspected ADRs. There is some evidence that health professionals may dismiss patients who report that they have experienced an ADR, but many patients identify such problems appropriately, using factors such as onset, effect of dose change, effect of de-challenge or even re-challenge, as well as the information sources freely accessible to them (Krska et al., 2011). To ascertain whether a symptom reported by a patient can be reasonably suspected of being an ADR requires careful questioning.

As stated above, the MHRA encourage reporting of all serious suspected ADRs to established drugs and all suspected ADRs to new drugs or vaccines. If not reporting themselves, health professionals should consider encouraging others to report. For example, a community pharmacist may have insufficient information to complete a Yellow Card as fully as possible, so may encourage a general practitioner to report. Alternatively, a hospital pharmacist may report on behalf of a consultant clinician. Encouraging others to report also extends to providing information about reporting and educating others, including patients, to report. Community pharmacies and general medical practices should all have a supply of Yellow Cards for patients, but patients may require advice and support in completing these. Pharmacists in particular, because of their role in dispensing prescriptions, may also be involved in educating and supporting others in preventing ADRs and in developing methods to detect ADRs through prescription monitoring.

Preventing ADRs

The majority of ADRs are thought to be preventable; hence, there is potential to dramatically reduce the costs associated with ADRs and possibly also deaths. Assessing preventability is a difficult area, since it involves judgements and many

different methods have been developed for making these judgements. The approach of Hallas et al. (1990) is widely used, providing definitions of avoidability which range from definite (due to a procedure inconsistent with present-day knowledge or good medical practice) to unevaluable (poor data or conflicting evidence). Recent estimates suggest that between 53% and 72% of hospital admissions due to ADEs are preventable, while a meta-analysis (Beijer and de Blaey, 2002) showed that 88% of ADRs causing hospital admission in the elderly were preventable. However, not all ADRs are absolutely preventable and assessments using hindsight are unlikely to replicate clinical decision making at the point of prescribing. Preventability also varies from those with clear solutions, such as the prescribing of a teratogenic drug to a female of child bearing age, to those where the drug increases the risk of an event that occurs within the population.

ADRs can be prevented by checking previous ADR history, minimising the use of drugs known to carry a high risk of ADRs and tailoring drug selection to individuals based on the factors which predispose them to ADRs. Strategies are still required to minimise the burden of ADRs, but many recent initiatives have the potential to do so. For example, electronic decision support, increasing regular review of medicines, improved sharing of information about patients between health care providers and the increasing availability of guidance on drug selection and appropriate use should all increase rational prescribing, which may have an effect on the incidence of ADRs.

Monitoring therapy

Monitoring the effects of drugs either by direct measurement of serum concentration or by measurement of physiological markers is another potential mechanism to reduce the risk of ADRs. For example, it has been estimated that one in four of preventable drug-related hospital admissions are caused by failure to monitor renal function and electrolytes (Howard et al., 2003).

Clozapine, used for the management of treatment resistant schizophrenia and psychosis, is associated with significant risk of agranulocytosis. Mandatory monitoring of white blood cell counts has effectively eliminated the risk of fatal agranulocytosis.

Ideally, advice on monitoring should be clear, provide an evidence-based frequency of monitoring and acceptable values. However, robust evidence for the optimal monitoring frequency is limited, hampering specific guidance on monitoring. Guidelines vary between various expert bodies and drug information sources. An examination of the adequacy of manufacturers' advice on monitoring for haematological ADRs found that advice was too vague to be useful to prescribers (Ferner et al., 2005).

Currently, monitoring is often neglected, although practitioners may take greater care when treating the elderly and those with more co-morbidities (McDowell., 2010). Warfarin remains one of the top 10 drugs involved in drug-induced admissions, despite a clearly defined monitoring requirement.

Explaining risks to patients

Numerous studies have shown that patients want to receive information about side effects, although one study comparing patients' views to those of health professionals found that the latter viewed providing side effect information as of much less importance than patients did in receiving it. One of the main sources of information about ADRs is the PIL, which must be provided every time a medicine is prescribed or supplied. Ultimately, patients then have to make a decision about whether or not to use the medicine. Therefore, they have a right to receive understandable information about the potential for harm that a medicine may cause, to enable them to make an informed decision. While there may still be debate about whether the provision of information on side effects encourages reduced adherence to taking medicines or spurious reporting of adverse effects, it is clear that this information is useful to patients and its availability will increase. Patients do use the PIL when suspected adverse events are experienced, to assist in ascribing the cause of the problem; therefore, as outlined above, side effect information should be understandable and there is now a requirement to test information leaflets with patients prior to granting a marketing authorisation for a medicine.

Patients increasingly access a wide range of information sources about medicines and ADRs themselves; indeed, they are actively encouraged to do so. Hence, they may question judgements about the selection of individual products they have been prescribed or sold. In this situation, the health professional must be able to interpret the information accessed by the patient to ensure it is unbiased and accurate.

The EU recommends using verbal terms to describe the risk of experiencing an ADR, ranging from '*very common*' (for rates of more than 1 in 10) to '*very rare*' (for rates of less than 1 in 10,000). The MHRA advocates combining words with frequencies, for example, '*Common (affects more than 1 in 100 persons)*'. Studies show that patients tend to over-estimate the risk when these are described using words only and that patients differ in their understanding of what the terms mean. Percentages, particularly those below 1%, are also not understood by everybody. This lack of understanding of the risks of experiencing an ADR can potentially reduce willingness to use the medicine.

Another approach is the use of pictures, such as faces, graphs or charts. One example is the 'Paling palette', which is a grid of 1000 stick figures to convey information on the chances of experiencing a particular outcome. A similar method is a 'Cates plot' which is a grid of 100 faces or 1000 faces for rarer events, coloured differently and either smiling or downcast depending on the outcome. An example of a Cates plot is provided in Fig. 5.1. These types of icon grids are mainly used to convey the potential benefits and risks of a particular action, but can also be used to explain the risks of getting a side effect. Cates plots have been used to good effect by the UK's National Prescribing Centre. However, there are people who do not find these easy to understand (Ancker et al., 2006).

Much work has been undertaken on risk communication. It is important to appreciate that, when communicating information

These 96 people will not experience harm, just as if they had not taken drug X

These two people will suffer harm whether or not they take drug X

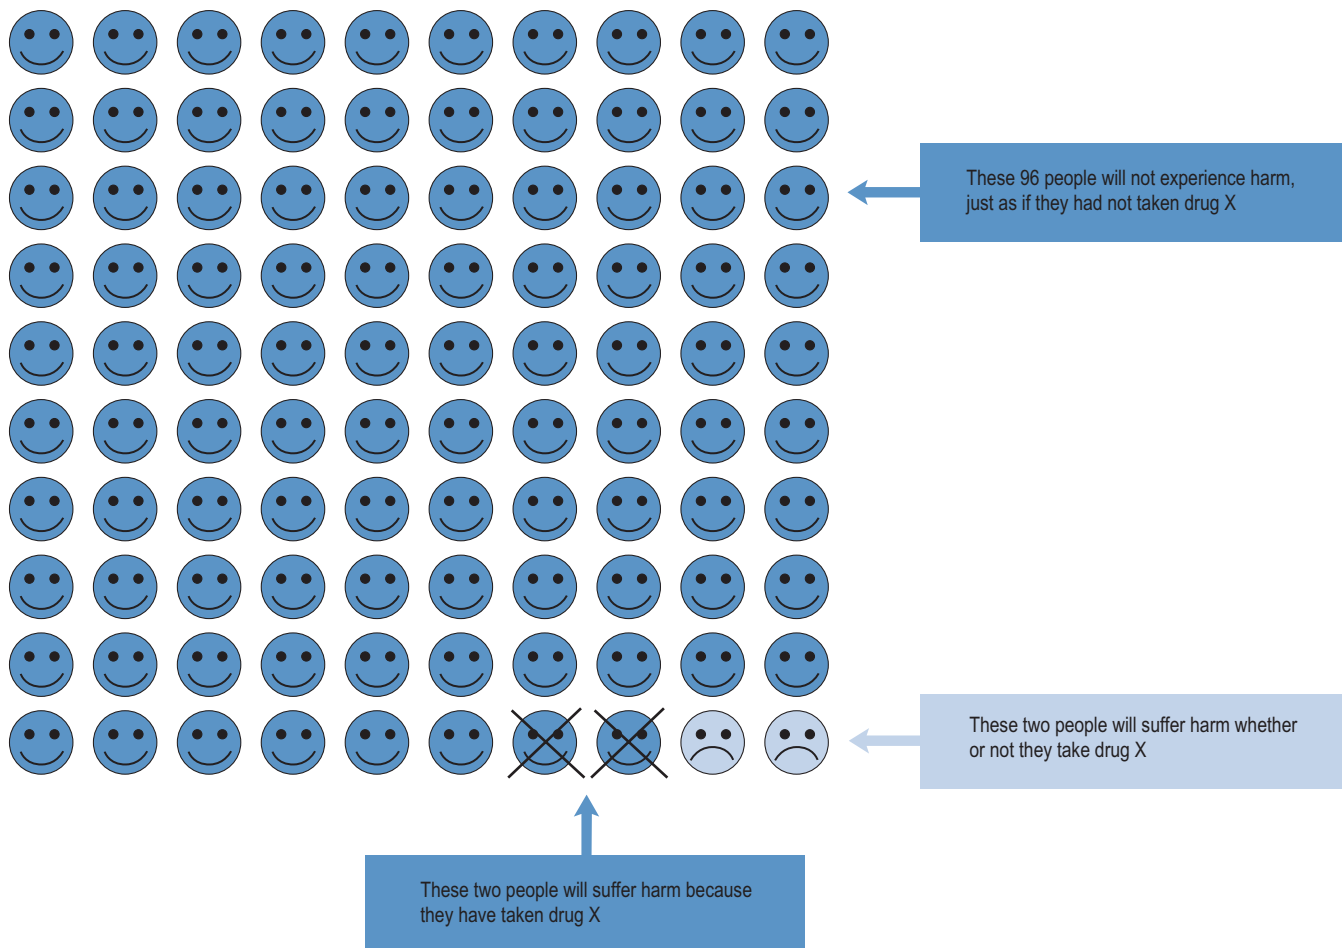
These two people will suffer harm because they have taken drug X


Fig. 5.1   Acute coronary syndrome (ACS) patient decision aid: aspirin plus clopidogrel versus aspirin alone. Copyright National Prescribing Centre, reproduced by permission.

about potential ADRs, how risks are perceived will be affected by the relationship between the health professional and the patient, the patient's prior experience and beliefs, how information is framed and the context in which it is given. Patients may also have views on the acceptability of ADRs, which should be taken into account when selecting a product for an individual. An ADR which is viewed as minor by health professionals may be considered to reduce quality of life by one patient, while another patient may be happy to accept this for the potential benefit the medicine offers. Even when drugs are withdrawn from the market for safety reasons, significant numbers of patients will feel they were willing to accept the harm–benefit of the drug. Communicating the harms and benefits of medicines is, therefore, an important role of health professionals.

Case studies

Case 5.1

Mr KM is a fairly active 69-year-old. He has regularly presented his repeat prescription for atenolol 50 mg daily, aspirin 75 mg daily and simvastatin 40 mg daily to the same community pharmacy for several years. Last month diltiazem SR 60 mg twice daily was added, as he had been getting increasing angina symptoms. He asks for a topical product to treat neck pain, which has developed in the last few days which he puts down to a 'frozen shoulder'.

Questions

1. Could this be an ADR and why did it develop now?
2. Is it appropriate to change to another statin?
3. What actions should the pharmacist take?

....

Answers

1. Neck pain, 'frozen shoulder' and such descriptions are typical of the muscular pain which is induced by statins. The incidence of mild muscle pain with statins is between 2% and 7% in clinical trials. The onset varies from a few weeks to over 2 years after starting treatment, the incidence is dose-related and the severity ranges from mild aches to severe pain, causing reduced mobility. Older people, who may have reduced renal function or liver function, are at greater risk of statin-induced myopathy.

   Diltiazem can inhibit the metabolism of simvastatin due to its actions on cytochrome P450 isoenzyme CYP3A4, thereby increasing the risk of myopathy.

   Statin-induced myopathy ranges from mild myopathies and myalgias, to myositis, to rare cases of potentially life-threatening rhabdomyolysis, in which muscle cell walls are disrupted and the

contents leak into the systemic circulation. Muscle pain in patients taking statins should, therefore, always be taken seriously.

2. The problem is associated with all drugs in the class. Although simvastatin and atorvastatin, the most widely prescribed, are both lipophilic and metabolised by cytochrome P450 3A4 and, therefore, may be most likely to cause muscle pain, there is no reliable comparative data on different statins.

3. Creatinine kinase (CK) levels should have been measured before initiating statin therapy, but regardless of whether or not this was done, a CK level should be measured now, plus liver function tests. Mr KM's primary care doctor should be contacted to inform him about the suspected ADR and the patient encouraged to report the ADR via the Yellow Card Scheme. It may be appropriate to discontinue or reduce the dose of the simvastatin, depending on the result of the CK level and the severity of the symptoms. The problem may not resolve immediately on discontinuation. Grapefruit juice can increase blood levels of simvastatin and high alcohol intake increases the risk of myopathy, so the pharmacist should also warn Mr KL about avoiding these.

Case 5.2

A 39-year-old male taking varenicline for smoking cessation reports that he has been suffering from vivid dreams and has become increasingly aggressive towards his family. Last night he had a major argument with his wife. His wife mentioned he hadn't been the same since he started the varenicline and he would like to know if this was a possible cause.

Questions

1. Is varenicline a possible cause of his vivid dreams and aggression?
2. Is this a reportable adverse drug reaction?

Answers

1. Varenicline has been associated with neuropsychiatric ADRs, including depression, suicidal thoughts, suicidal behaviour and aggression. Vivid dreams and other sleep disorders have also been reported. Prescribers have been warned that such reactions have been reported. Assessing the cause of this reaction is difficult, since smoking cessation itself is associated with exacerbations of underlying psychiatric illness and the risk of symptoms of depression. As varenicline dosing starts 1–2 weeks before stopping smoking, a key question is how long the patient has been taking the drug, and if the symptoms appeared before the smoking cessation date.

2. If a health professional considers that a patient's symptoms are a possible ADR to a newer drug, then they should be reported to regulatory authorities (in the UK, this would be through the MHRA's Yellow Card Scheme). Only a suspicion is necessary to report a reaction, not proven causality. In the case of intensively monitored medicines (identified by an inverted black triangle in the BNF), any reaction, no matter how trivial should be reported. Patients can also report directly to regulatory authorities in some countries, including the UK. Neuropsychiatric reactions such as this are commonly reported by patients.

Case 5.3

A 65-year-old man with heart failure is admitted to hospital with a potassium level of 7.1 mmol/L. Already stabilised on lisinopril 20 mg daily, he had recently been started on spironolactone 25 mg daily. He had a serum creatinine of 160 μmol/L.

Questions

1. What is the mechanism of any possible adverse drug reaction?
2. How should future episodes of hyperkalaemia be avoided?

Answers

1. Spironolactone, an aldosterone receptor antagonist, has a beneficial effect on mortality and hospital admission in patients with heart failure. However, spironolactone can increase potassium serum levels due to its effect on aldosterone. When used in combination with ACE inhibitors, serious hyperkalaemia can occur.

Although clinical trials of spironolactone showed no risk, cases have been reported in the literature and other epidemiological studies have indicated that in real-world clinical situations, the incidence of hyperkalaemia is increased.

2. Care should be taken when prescribing spironolactone outside of trial criteria, particularly with regard to renal function. Other susceptibilities for the development of hyperkalaemia include diabetes and the elderly due to reduced aldosterone production. Changes in other therapy should be monitored, as well as episodes of acute illness. Those with mildly increased serum potassium should have a reduced dose of spironolactone. More intensive monitoring of potassium levels at the commencement of therapy might be useful, although the hyperkalaemia can occur months after initiation.

Case 5.4

A 55-year-old woman attending a warfarin out-patient clinic has a raised INR. On questioning it is discovered that she has recently started taking glucosamine for muscle aches for the last 2 weeks.

Questions

1. What is the likelihood that glucosamine was responsible for the rise in the INR?
2. Should this reaction be reported to regulatory authorities?

Answers

1. Glucosamine is a popular supplement purchased for 'joint health'. It is commonly used by older patients. Spontaneous reports of interactions between warfarin and glucosamine have been submitted to UK, Australian and US regulators. Additional cases have been reported in the literature. While there is no known mechanism and no formal interaction studies, the published cases and spontaneous reports are sufficient evidence to suggest a potential interaction. Given the wide use of glucosamine, the interaction may be rare, although under-reporting is common.

Assessment of this individual case requires further questioning to eliminate other confounding factors such as changes in diet or adherence issues.

2. Interactions with, or adverse reactions to, complementary and alternative remedies can be reported to spontaneous reporting schemes, such as the Yellow Card Scheme. Collation of such reports allows regulators to gather further information on the suspected reaction, and any susceptibilities that may in time provide useful information to other users.

6 Laboratory data

H. A. Wynne and C. Edwards

Key points

- Biochemical and haematological tests provide useful information for the diagnosis, screening, management, prognosis and monitoring of disease and its response to treatment.
- Reference ranges are important guides which generally represent the test values from 95% of the healthy population (mean ± 2 standard deviations).
- A series of values, rather than a single test value, is often required to ensure clinical relevance and eliminate erroneous values due to patient variation and analytical or sampling errors.
- A wide variety of intracellular enzymes may be released into the blood following damage to tissues such as hepatocytes and skeletal muscle. These can be measured in serum to provide useful diagnostic information.
- Commonly requested biochemical test profiles include the so-called 'Us and Es' (urea and electrolytes), liver function tests, troponins and C-reactive protein.
- Commonly requested haematological test profiles include full blood count, differential white cell count, erythrocyte sedimentation rate (ESR), serum folate and vitamin B_{12} and iron status, and clotting screen.
- Drug therapy can cause abnormal test results.
- Drugs can have an important role in preventing or treating abnormalities.

This chapter will consider the common biochemical and haematological tests that are of clinical and diagnostic importance. For convenience, each individual test will be dealt with under a separate heading and a brief review of the physiology and pathophysiology will be given where appropriate to explain the basis of biochemical and haematological disorders.

It is usual for a reference range to be quoted for each individual test (see Tables 6.1 and 6.4). This range is based on data obtained from a sample of the general population which is assumed to be disease-free. Many test values have a normal distribution and the reference values are taken as the mean ± 2 standard deviations (SD). This includes 95% of the population. The 'normal' range must always be used with caution since it takes little account of an individual's age, sex, weight, height, muscle mass or disease state, many of which variables can influence the value obtained. Although reference ranges are valuable guides, they must not be used as sole indicators of health and disease. A series of values rather than a simple test value may be required in order to ensure clinical relevance and to eliminate erroneous values caused, for example, by spoiled specimens or interference from diagnostic or therapeutic procedures. Furthermore, a disturbance of one parameter often cannot be considered in isolation without looking at the pattern of other tests within the group.

Further specific information on the clinical and therapeutic relevance of each test may be obtained by referral to the relevant chapter in this book.

Biochemical data

The homeostasis of various elements, water and acid–base balance are closely linked, both physiologically and clinically. Standard biochemical screening includes several measurements which provide a picture of fluid and electrolyte balance and renal function. These are commonly referred to colloquially as 'Us and Es' (urea and electrolytes) and the major tests are described below.

Sodium and water balance

Sodium and water metabolism are closely interrelated both physiologically and clinically, and play a major role in determining the osmolality of serum.

Water constitutes approximately 60% of body weight in men and 55% in women (women have a greater proportion of fat tissue which contains little water). Approximately two-thirds of body water is found in the intracellular fluid (ICF) and one-third in the extracellular fluid (ECF). Of the ECF 75% is found within interstitial fluid and 25% within serum (Fig. 6.1). Total body water is regulated by the renal action of antidiuretic hormone (ADH), the renin angiotensin–aldosterone system, noradrenaline/norepinephrine and by thirst which is stimulated by rising plasma osmolality.

In general, water permeates freely between the ICF and ECF. Cell walls function as semipermeable membranes, with water movement from one compartment to the other being controlled by osmotic pressure: water moves into the compartment with the higher osmotic concentration. The osmotic content of the two compartments is generally the same, that is, they are isotonic, which ensures normal cell membrane integrity and cellular processes. However, the kidneys are an exception to the rule.

Table 6.1 Biochemical data: typical normal adult reference values measured in serum

Laboratory test	Reference range
Urea and electrolytes	
Sodium	135–145 mmol/L
Potassium	3.4–5.0 mmol/L
Calcium (total)	2.12–2.60 mmol/L
Calcium (ionised)	1.19–1.37 mmol/L
Phosphate	0.80–1.44 mmol/L
Magnesium	0.7–1.00 mmol/L
Creatinine	75–155 µmol/L
Urea	3.1–7.9 mmol/L
Estimated glomerular filtration rate (eGFR)	≥ 90 ml/min/1.73m²
Glucose	
Fasting	3.3–6.0 mmol/L
Non-fasting	<11.1 mmol/L
Glycated haemoglobin	Non-diabetic subjects <43 mmol/mol Inadequate control >58 mmol/mol
Liver function tests	
Albumin	34–50 g/L
Bilirubin (total)	<19 µmol/L
Enzymes	
Alanine transaminase	<45 U/L
Aspartate transaminase	<35 U/L
Alkaline phosphatase	35–120 U/L
γ-Glutamyl transpeptidase	<70 U/L
Ammonia	
Men	15–50 µmol/L
Female	10–40 µmol/L
Amylase	<100 U/L
Cardiac markers	
Troponin I	(99th percentile of upper reference limit) 0.04 µcg/L
Other tests	
C-reactive protein (CRP)	0–5 mg/L
Osmolality	282–295 mOsmol/kg
Uric acid	0.15–0.47 mmol/L
Parathyroid hormone (adult with normal calcium)	10–65 ng/L
25-Hydroxyvitamin D	>75 nmol/L (optimal) >50 nmol/L (sufficient) 30–50 nmol/L (insufficient) 12–30 nmol/L (deficient) <12 nmol/L (severely deficient)

Fig. 6.1 Approximate distribution of water in a 70 kg man.

The amount of water taken in and lost by the body depends on intake, diet, activity and the environment. Over time the intake of water is normally equal to that lost (Table 6.2). The minimum daily intake necessary to maintain this balance is approximately 1100 mL. Of this, 500 mL is required for normal excretion of waste products in urine, whilst the remaining volume is lost via the skin in sweat, via the lungs in expired air, and in faeces. The kidneys regulate water balance, water being filtered, then reabsorbed in variable amounts depending primarily on the level of ADH.

Water depletion

Water depletion will occur if intake is inadequate or loss excessive. Excessive loss of water through the kidney is unusual except in diabetes insipidus or following the overuse of diuretics.

Patients with fever will lose water through the skin and ventilated patients will lose it through the lungs. Diarrhoea causes water depletion. Water loss is usually compensated for if the thirst mechanism is intact or can be responded to, but this may not occur in patients who are unconscious, have swallowing difficulties or are disabled. Severe water depletion may induce cerebral dehydration causing confusion, fits, coma and circulatory failure.

The underlying cause for the water depletion should be identified and treated. Replacement water should be given orally, where possible, or by nasogastric tube, intravenously

The osmolality of the ECF is largely determined by sodium and its associated anions, chloride and bicarbonate. Glucose and urea have a lesser, but nevertheless important, role in determining ECF osmolality. Protein, especially albumin, makes only a small (0.5%) contribution to the osmolality of the ECF but is a major factor in determining water distribution between the two compartments. The contribution of proteins to the osmotic pressure of serum is known as the colloid osmotic pressure or oncotic pressure.

The major contributor to the osmolality of the ICF is potassium.

Table 6.2 Typical daily water balance for a healthy 70 kg adult

	Input (mL)		Output (mL)
Oral fluids	1400	Urine	1500
Food	700	Lung	400
Metabolic oxidation	400	Skin	400
		Faeces	200
Total	2500		2500

or subcutaneously as necessary with 5% dextrose in water or, in patients with associated sodium deficits, isotonic saline. Hypotonic saline is sometimes used, but with great caution, where neurologic effects of hypertonicity predominate. Hypernatraemia should be corrected slowly: not more than half of the water deficit should be corrected in the first 12–24 h.

Water excess

Water excess is usually associated with an impairment of water excretion such as that caused by renal failure or the syndrome of inappropriate secretion of the antidiuretic hormone arginine vasopressin (SIADH). This syndrome has several causes including chest infections and some tumours, particularly small cell carcinoma of the lung. Excess intake is rarely a cause of water excess since the healthy adult kidney can excrete water at a rate of up to 2 mL/min. Patients affected usually present with signs consistent with cerebral overhydration, although if it is of gradual onset, over several days, they may be asymptomatic. Hyponatraemia is usually present.

Water and ECF osmolality

If the body water content changes independent of the amount of solute, osmolality will be altered (the normal range is 282–295 mmol/kg of water). A loss of water from the ECF will increase its osmolality and result in the movement of water from the ICF to ECF. This increase in ECF osmolality will stimulate the hypothalamic thirst centres to promote a desire to drink while also stimulating the release of vasopressin or ADH. ADH increases the permeability of the renal collecting ducts to water and promotes water reabsorption with consequent concentration of urine.

If the osmolality of the ECF falls, there is no desire to drink and no secretion of ADH. Consequently, a dilute urine is produced which helps restore ECF osmolality to normal.

The secretion of ADH is also stimulated by angiotensin II, arterial and venous baroreceptors, volume receptors, stress (including pain), exercise and drugs such as morphine, nicotine, tolbutamide, carbamazepine and vincristine. If blood volume decreases by more than 10%, the hypovolaemia stimulates ADH release and overrides control based on osmolality.

Sodium distribution

The body of an average 70 kg man contains approximately 3000 mmol of sodium. Most of this sodium is freely exchangeable and is extracellular. The normal serum range is 135–145 mmol/L. In contrast, the ICF concentration of sodium is only about 10 mmol/L.

Each day approximately 1000 mmol of sodium is secreted into the gut and 25,000 mmol filtered by the kidney. The bulk of this is recovered by reabsorption from the gut and renal tubules. It should be clear, therefore, that partial failure of homeostatic control can potentially have major consequences.

Sodium and ECF volume

The ECF volume is dependent upon total body sodium since sodium is almost entirely restricted to the ECF, and water intake and loss are regulated to maintain a constant concentration of sodium in the ECF compartment.

Sodium balance is maintained by renal excretion. Normally, 70% of filtered sodium is actively reabsorbed in the proximal tubule, with further reabsorption in the loop of Henle. Less than 5% of the filtered sodium load reaches the distal tubule where aldosterone can stimulate further sodium reabsorption.

Other factors such as natriuretic peptide hormone can also affect sodium reabsorption. This hormone is secreted by the cardiac atria in response to atrial stretch following a rise in atrial pressure associated with, say, volume expansion. It is natriuretic (increases sodium excretion in urine) and, amongst other actions, reduces aldosterone concentration.

Sodium depletion

Inadequate oral intake of sodium is rarely the cause of sodium depletion, although inappropriate parenteral treatment may occasionally be implicated. Sodium depletion commonly occurs with water depletion, resulting in dehydration or volume depletion. The normal response of the body to the hypovolaemia includes an increase in aldosterone secretion (which stimulates renal sodium reabsorption) and an increase in ADH secretion if ECF volume depletion is severe.

The serum sodium level can give an indication of depletion, but it must be borne in mind that the serum sodium may be:

- increased, for example, where there is sodium and water loss but with predominant water loss, as occurs in excessive sweating;
- normal, for example, where there is isotonic sodium and water loss, as occurs from burns or a haemorrhage;
- decreased, for example, sodium loss with water retention as would occur if an isotonic sodium depletion were treated with a hypotonic sodium solution.

Sodium excess

Sodium excess can be due to either increased intake or decreased excretion. Excessive intake is not a common cause, although hypernatraemia can be associated with excessive intravenous saline infusion or unreplaced hypotonic water depletion, due to impaired access to free water or impaired thirst.

Sodium excess is usually due to impaired excretion. It may also be caused by a primary mineralocorticoid excess, for example, Cushing's syndrome or Conn's syndrome. However, it is often due to a secondary hyperaldosteronism associated with, for example, congestive cardiac failure, nephrotic syndrome, hepatic cirrhosis with ascites, or renal artery stenosis. Sodium and water retention causes oedema.

Hypernatraemia

The signs and symptoms of hypernatraemia include muscle weakness and confusion.

Drug-induced hypernatraemia is often the result of a nephrogenic diabetes insipidus-like syndrome whereby the renal tubules are unresponsive to ADH. The affected patient presents with polyuria, polydipsia or dehydration.

- Lithium and phenytoin are the most commonly implicated drugs. The diabetes insipidus-like syndrome with lithium has been reported after only 2 weeks of therapy. The syndrome is usually reversible on discontinuation. Whilst affected, however, many patients are unresponsive to exogenous ADH.
- Demeclocycline can also cause diabetes insipidus and can be used in the management of patients with the syndrome of inappropriate ADH secretion (SIADH).
- Phenytoin generally has a less pronounced effect on urinary volume than lithium or demeclocycline, and does not cause nephrogenic diabetes insipidus. It inhibits ADH secretion at the level of the central nervous system.

Hypernatraemia can be caused by a number of other drugs (Box 6.1) and by a variety of mechanisms; for example, hypernatraemia secondary to sodium retention is known to occur with corticosteroids whilst the administration of sodium-containing drugs parenterally in high doses also has the potential to cause hypernatraemia.

Hyponatraemia

A fall in the serum sodium level can be the result of sodium loss, water retention in excess of sodium usually resulting from defects in free water excretion due to low ECF volume or inappropriate secretion of ADH. Increased water intake may also contribute, or a combination of both factors. A number of drugs have also been implicated as causing hyponatraemia (Box 6.2).

The inappropriate secretion of ADH is the mechanism underlying many drug-induced hyponatraemias. In this syndrome, the drug may augment the action of endogenous ADH (e.g. chlorpropamide), increase the release of ADH (e.g. carbamazepine), or have a direct ADH-like action on the kidney (e.g. oxytocin or, more obviously, desmopressin). Hyponatraemia can also be induced by mechanisms different from those described above. Lithium may cause renal damage and a failure to conserve sodium. Likewise the natriuretic action of diuretics can predispose to hyponatraemia.

Box 6.1   Examples of drugs known to cause hypernatraemia

Adrenocorticotrophic hormone
Anabolic steroids
Androgens
Corticosteroids
Lactulose
Oestrogens
Oral contraceptives
Sodium bicarbonate

Box 6.2   Examples of drugs known to cause hyponatraemia

Amitriptyline and other tricyclic antidepressants
Amphotericin
Angiotensin converting enzyme inhibitors

Cisplatin
Clofibrate
Cyclophosphamide
Diuretics
Heparin
Lithium
Miconazole
NSAIDs
Opiates
Tolbutamide
Vasopressin
Vincristine

Potassium

The total amount of potassium in the body, like sodium, is 3000 mmol. About 10% of the body potassium is bound in red blood cells (RBCs), bone and brain tissue and is not exchangeable. The remaining 90% of total body potassium is free and exchangeable with the vast majority having an intracellular location, being pumped in and out by Na/K-ATPase pumps. This is controlled by mechanisms aimed at ensuring stable intracellular to extracellular ratios, and hence correct muscular and neuronal excitability. Only 2% of the exchangeable total body potassium is in the ECF, the compartment from where the serum concentration is sampled and measured. Consequently, the measurement of serum potassium is not an accurate index of total body potassium, but together with the clinical status of a patient it permits a sound practical assessment of potassium homeostasis.

The serum potassium concentration is controlled mainly by the kidney with the gastro-intestinal tract normally having a minor role. The potassium filtered in the kidney is almost completely reabsorbed in the proximal tubule. Potassium secretion is largely a passive process in response to the need to maintain membrane potential neutrality associated with active reabsorption of sodium in the distal convoluted tubule and collecting duct. The extent of potassium secretion is determined by a number of factors including:

- the amount of sodium available for exchange in the distal convoluted tubule and collecting duct;
- the availability of hydrogen and potassium ions for exchange in the distal convoluted tubule or collecting duct;
- the ability of the distal convoluted tubule or collecting duct to secrete hydrogen ions;
- the concentration of aldosterone;
- tubular fluid flow rate.

As described above, both potassium and hydrogen can neutralise the membrane potential generated by active sodium reabsorption and consequently there is a close relationship between potassium and hydrogen ion homeostasis. In acidosis, hydrogen ions are normally secreted in preference to

potassium and potassium moves out of cells, that is, hyperkalaemia is often associated with acidosis, except in renal tubular acidosis. In alkalosis, fewer hydrogen ions will be present and potassium moves into cells and potassium is excreted, that is, hypokalaemia is often associated with alkalosis.

The normal daily dietary intake of potassium is of the order of 60–200 mmol, which is more than adequate to replace that lost from the body. It is unusual for a deficiency in intake to account for hypokalaemia. A transcellular movement of potassium into cells, loss from the gut or excretion in the urine are the main causes of hypokalaemia.

Hypokalaemia

Transcellular movement into cells. The shift of potassium from the serum compartment of the ECF into cells accounts for the hypokalaemia reported following intravenous or, less frequently, nebulised administration of β-adrenoreceptor agonists such as salbutamol. Parenteral insulin also causes a shift of potassium into cells, and is used for this purpose in the acute management of patients with hyperkalaemia. Catecholamines, for example, adrenaline/epinephrine and theophylline also have this effect.

Loss from the gastro-intestinal tract. Although potassium is secreted in gastric juice, much of this, together with potassium ingested in the diet, is reabsorbed in the small intestine. Stools do contain some potassium, but in a patient with chronic diarrhoea or a fistula, considerable amounts of potassium may be lost and precipitate hypokalaemia. Likewise, the abuse of laxatives increases gastro-intestinal potassium loss and may precipitate hypokalaemia. Analogous to the situation with diarrhoea, the potassium secreted in gastric juice may be lost following persistent vomiting and can also contribute to hypokalaemia.

Loss from the kidneys. Mineralocorticoid excess, whether it be due to primary or secondary hyperaldosteronism or Cushing's syndrome, can increase urinary potassium loss and cause hypokalaemia. Likewise, increased excretion of potassium can result from renal tubular damage. Nephrotoxic antibiotics such as gentamicin have been implicated in this.

Many drugs which can induce hypokalaemia do so by affecting the regulatory role of aldosterone upon potassium–sodium exchange in the distal tubule and collecting duct. Administered corticosteroids mimic aldosterone and can, therefore, increase potassium loss.

The most commonly used groups of drugs that can cause hypokalaemia are thiazide and loop diuretics. Both groups of drugs increase the amount of sodium delivered and available for reabsorption at the distal convoluted tubule and collecting duct. Consequently, this will increase the amount of potassium excreted from the kidneys. Some of the drugs known to cause hypokalaemia are shown in Box 6.3.

Clinical features. The patient with moderate hypokalaemia may be asymptomatic, but the symptoms of more severe hypokalaemia include muscle weakness, hypotonia, paralytic ileus, depression and confusion. Arrhythmias may occur. Typical changes on the electrocardiogram (ECG) are of ST depression, T wave depression/inversion and prolonged

Box 6.3   Examples of drugs known to cause hypokalaemia

Ticarcillin + clavulanic acid

P–R interval. Although hypokalaemia tends to make antiarrhythmic drugs less effective, the action of digoxin, in contrast, is potentiated leading to increased signs of toxicity. Insulin secretion in response to a rising blood glucose concentration requires potassium and this mechanism may be impaired in hypokalaemia. Rarely there may be impaired renal concentrating ability with polyuria and polydipsia.

Hypokalaemia is managed by giving either oral potassium or intravenous suitability dilute potassium solutions, depending on its severity and the clinical state of the patient.

Hyperkalaemia

Hyperkalaemia may arise from excessive intake, decreased elimination or shift of potassium from cells to the ECF. It is rare for excessive oral intake to be the sole cause of hyperkalaemia. The inappropriate use of parenteral infusions containing potassium is probably the most common iatrogenic cause of excessive intake. Hyperkalaemia is a common problem in patients with renal failure due to their inability to excrete a potassium load.

The combined use of potassium-sparing diuretics such as amiloride, triamterene or spironolactone with an angiotensin converting enzyme (ACE) inhibitor, which will lower aldosterone, is a recognised cause of hyperkalaemia, particularly in the elderly. Mineralocorticoid deficiency states such as Addison's disease where there is a deficiency of aldosterone also decrease renal potassium loss and contribute to hyperkalaemia. Those at risk of hyperkalaemia should be warned not to take dietary salt (NaCl) substitutes in the form of KCl.

The majority of body potassium is intracellular. Severe tissue damage, catabolic states or impairment of the energy-dependent sodium pump, caused by hypoxia or diabetic ketoacidosis, may result in apparent hyperkalaemia due to potassium moving out of and sodium moving into cells. If serum potassium rises, insulin release is stimulated which, through increasing activity in Na/K-ATPase pumps, causes potassium to move into cells. Box 6.4 gives examples of some drugs known to cause hyperkalaemia.

Angiotensin converting enzyme inhibitors
Antineoplastic agents (cyclophosphamide, vincristine)
Non-steroidal anti-inflammatory drugs
β-Adrenoreceptor blocking agents
Ciclosporin
Digoxin (in acute overdose)
Diuretics, potassium sparing (amiloride, triamterene, spironolactone)
Heparin
Isoniazid
Lithium
Penicillins (potassium salt)
Potassium supplements
Tetracycline

Haemolysis during sampling or a delay in separating cells from serum will result in potassium escaping from blood cells into serum and causing an artefactual hyperkalaemia.

Clinical features. Hyperkalaemia can be asymptomatic but fatal. An elevated potassium level has many effects on the heart: notably the resting membrane potential is lowered and the action potential shortened. Characteristic changes of the ECG precede ventricular fibrillation and cardiac arrest.

In emergency management of a patient with hyperkalaemia (>6.5 mmol/L ± ECG changes), calcium gluconate (or chloride) at a dose of 10 mL of 10% solution is given intravenously over 5 min. This does not reduce the potassium concentration but antagonises the effect of potassium on cardiac tissue. Immediately thereafter, glucose 50 g with 20 units soluble insulin, for example, by intravenous infusion will lower serum potassium levels within 30 min by increasing the shift of potassium into cells.

If acidosis is present, bicarbonate administration may be considered.

The long-term management of hyperkalaemia may involve the use of oral or rectal polystyrene cation-exchange resins which remove potassium from the body. Chronic hyperkalaemia, in renal failure, is managed by a low potassium diet.

Calcium

The body of an average man contains about 1 kg of calcium and 99% of this is bound within bone. Calcium is present in serum bound mainly to the albumin component of protein (46%), complexed with citrate and phosphate (7%), and as free ions (47%). Only the free ions of calcium are physiologically active. Calcium metabolism is regulated by 1,25-dihydroxycholecalciferol (vitamin D) which, when serum calcium is low, is secreted to promote gastro-intestinal absorption of calcium, and by parathyroid hormone (PTH) which is inhibited by increased serum concentrations of calcium ions. PTH is secreted in response to low calcium concentrations and increases serum calcium by actions on osteoclasts, kidney and gut.

The serum calcium level is often determined by measuring total calcium, that is, that which is free and bound but the measurement of free or ionised calcium offers advantages in some situations.

In alkalosis, hydrogen ions dissociate from albumin, and calcium binding to albumin increases, together with an increase in complex formation. If the concentration of ionised calcium falls sufficiently, clinical symptoms of hypocalcaemia may occur despite the total serum calcium concentration being unchanged. The reverse effect, that is, increased ionised calcium, occurs in acidosis.

Changes in serum albumin also affect the total serum calcium concentration independently of the ionised concentration. A variety of equations are available to estimate the calcium concentration and many laboratories report total and adjusted calcium routinely. A commonly used formula is shown in Fig. 6.2. Caution must be taken when using such a formula in the presence of disturbed blood hydrogen ion concentrations.

Hypercalcaemia

Hypercalcaemia may be caused by a variety of disorders, the most common being primary hyperparathyroidism in which there is autonomous growth of PTH-producing cells and malignancy. Hypercalcaemia of malignancy is seen in multiple myeloma and carcinomas which metastasise in bone. It is also seen in squamous carcinoma of the bronchus, as a result of a peptide with PTH-like activity, produced by the tumour. Hypercalcaemia also occurs in thyrotoxicosis, vitamins A and D intoxication, acute renal failure, renal transplantation and acromegaly. PTH measurement can be pivotal in the establishment of the cause of hypercalcaemia.

Thiazide diuretics, lithium, tamoxifen and calcium supplements used in the management of osteoporosis are examples of some of the drugs which can cause hypercalcaemia.

An artifactual increase in total serum calcium may sometimes be seen as a result of a tourniquet being applied during venous sampling. The resulting venous stasis may cause redistribution of fluid from the vein into the extravascular space, and the temporary haemoconcentration will affect albumin levels.

Management of hypercalcaemia involves correction of any dehydration with normal saline followed by furosemide which inhibits tubular reabsorption of calcium. Bisphosphonates are used to inhibit bone turnover.

For albumin < 40 g/L:
Corrected calcium = [Ca] + 0.02 × (40 – [alb]) mmol/L
For albumin > 45 g/L:
Corrected calcium = [Ca] – 0.02 ([alb] – 45) mmol/L

Fig. 6.2 Formula for correction of total serum calcium concentration for changes in albumin concentration: albumin concentration = [alb] (albumin units = g/L); calcium concentration = [Ca] (total calcium units = mmol/L).

Hypocalcaemia

Hypocalcaemia can be caused by a variety of disorders including severe malnutrition, hypoalbuminaemia, hypoparathyroidism, pancreatitis and those that cause vitamin D deficiency, for example, malabsorption, reduced exposure to sunlight, liver disease and renal disease. In alkalaemia, which may occur when a patient is hyperventilating, there is an increase in protein binding of calcium, which can result in a fall in serum levels of ionised calcium, manifesting itself as paraesthesiae or tetany.

Drugs that have been implicated as causing hypocalcaemia include bisphosphonates which suppress formation and function of osteoclasts, phenytoin, phenobarbital, aminoglycosides, phosphate enemas, calcitonin, cisplatin, mithramycin and furosemide.

Biochemical measurements of serum calcium, phosphate and alkaline phosphatase can be normal in some patients with vitamin D deficiency and osteomalacia. The recent development of non-radioactive automated assays for serum PTH and 25-hydroxy vitamin D (25-OHD) has made measurement of these two hormones possible in many laboratories. There is a lack of consensus regarding a specific level of 25-OHD that is indicative of vitamin D deficiency, but this has usually been established by assessing the point at which serum PTH starts to rise. This, together with methodological and technical issues, prevents direct comparison of values across laboratories. Clinical decision limits for PTH and 25-OHD are laboratory specific and must be interpreted within the clinical context of each patient.

Phosphate

About 85% of body phosphate is in bone, 15% in ICF and only 0.1% in ECF. Its major function is in energy metabolism. Serum levels are regulated by absorption from the diet, which is partly under the control of vitamin D, and PTH which controls its excretion by the kidney and resorption from bone. The recent identification of genes encoding for renal phosphate transporters or associated proteins, and the discovery of a new hormone, fibroblast growth factor 23 and its emerging role in the bone–kidney axis which regulates systemic phosphate, has improved knowledge of homeostasis.

Hypophosphataemia

Clinical features. Severe hypophosphataemia can cause general debility, anorexia, anaemia, muscle weakness and wasting and some bone pain and skeletal wasting. As phosphorus is ubiquitous in various foods, inadequate dietary phosphorus intake requires near starvation. Refeeding of those recovering from energy depletion as a result, for example, of alcoholic bouts or diabetic ketoacidosis, without adequate provision of phophorus, can precipitate hypophosphataemia.

Hyperphosphataemia

Hyperphosphataemia occurs in chronic renal failure. Less common causes are secondary to rhabdomyolysis, tumour lysis or severe haemolysis. Hyperphosphataemia can cause hypocalcaemia. Treatment of hyperphosphataemia requires identification and correction of the underlying cause.

Magnesium

Magnesium is an essential cation, found primarily in bone, muscle and soft tissue. About 1% of the total body content is in the ECF. As an important cofactor for numerous enzymes and ATP, it is critical in energy requiring metabolic processes, protein synthesis, membrane integrity, nervous tissue conduction, neuromuscular excitability, muscle contraction, hormone secretion and in intermediary metabolism. Serum magnesium levels are usually maintained within a tight range (0.7–1.0 mmol/L). Although a serum concentration of less than this usually indicates some level of magnesium depletion, serum levels may be normal in spite of low intracellular magnesium due to magnesium depletion. Hypocalcaemia is a prominent manifestation of moderate to severe magnesium deficiency in humans.

Hypomagnesaemia is frequently seen in critically ill patients. Causes include excessive gastro-intestinal losses, renal losses, surgery, trauma, infection, malnutrition and sepsis. The drugs most likely to induce significant hypomagnesaemia are cisplatin, amphotericin B and ciclosporin, but it is also a potential complication of treatment with amikacin, gentamicin, laxatives, pentamidine, tobramycin, tacrolimus and carboplatin. A hypomagnesaemic effect of furosemide and hydrochlorothiazide is questionable and routine monitoring and treatment are not required. Use of digoxin has been associated with hypomagnesaemia, possibly by enhancing magnesium excretion, which may predispose to digoxin toxicity, for example, dysrhythmias.

Where treatment is indicated, oral supplements are available but because of their slow onset of action and gastro-intestinal intolerance the intravenous route is often preferred and especially in critically ill patients with severe symptomatic hypomagnesaemia.

Hypermagnesaemia is most commonly caused by renal insufficiency and excess iatrogenic magnesium administration.

Creatinine

Serum creatinine concentration is largely determined by its rate of production, rate of renal excretion and volume of distribution. It is frequently used to evaluate renal function.

Creatinine is produced at a fairly constant rate from creatine and creatine phosphate in muscle. Daily production is a function of muscle mass and declines with age from 24 mg/kg/day in a healthy 25-year-old to 9 mg/kg/day in a 95-year-old. Creatinine undergoes complete glomerular filtration with little reabsorption by the renal tubules. Its clearance is, therefore, usually a good indicator of the glomerular filtration rate (GFR). As a general rule, and only at the steady state, if the serum creatinine doubles this equates to a 50% reduction in the GFR and consequently renal function. The serum creatinine level can be transiently elevated following meat ingestion, but less so than urea, or strenuous exercise. Individuals with a high muscle bulk produce more creatinine and, therefore, have a higher serum creatinine level compared to an otherwise identical but less muscular individual.

The value for creatinine clearance is higher than the true GFR due to the active tubular secretion of creatinine. In a patient with a normal GFR, this is of little significance. However, in an individual in whom the GFR is low (<10 mL/min), the tubular secretion may make a significant contribution to creatinine elimination and overestimate the GFR. In this type of patient, the breakdown of creatinine in the gut can also become a significant source of elimination. Some drugs including trimethoprim and cimetidine inhibit creatinine secretion, reducing creatinine clearance and elevating serum creatinine without affecting the GFR.

Measured and estimated GFR

GFR measured as the urinary or plasma clearance of an ideal filtration marker such as inulin is the best overall measure of kidney function but techniques are complex and expensive. Urinary clearance of creatinine allows estimation of GFR, but blood sampling and timed urine collection have practical difficulty and are subject to error.

In the steady state, the serum level of creatinine is related to the reciprocal of the GFR and estimating equations based on this, as well as age, sex, race and body size are in use to facilitate the detection, evaluation and management of chronic kidney disease. The Cockcroft Gault formula is not adjusted for body-surface area whereas the Modification of Diet in Renal Disease (MDRD) study equation is, and is more accurate in older and obese people. Estimates of GFR using these equations fall within the same interval for guiding dose adjustment of renally excreted drugs. Accuracy of estimates of GFR cannot be relied upon in patients with rapidly changing kidney function, those with unusual body habitus or diet, without chronic kidney disease and in patients with estimates of GFR of 60 mL/1.73 m^2 or greater.

Urea

The catabolism of dietary and endogenous amino acids in the body produces large amounts of ammonia. Ammonia is toxic and its concentration is kept very low by conversion in the liver to urea. Urea is eliminated in urine and represents the major route of nitrogen excretion. The urea is filtered from the blood at the renal glomerulus and undergoes significant tubular reabsorption of 40–50%. This tubular reabsorption is pronounced at low rates of urine flow but is reduced in advanced renal failure. Serum urea is a less reliable marker of GFR than creatinine. Urea levels vary widely with diet, rate of protein metabolism, liver production and the GFR. A high protein intake from the diet, tissue breakdown, major haemorrhage in the gut, and consequent absorption of the protein from the blood, and corticosteroid therapy may produce elevated serum urea levels (up to 10 mmol/L). Urea concentrations of more than 10 mmol/L are usually due to renal disease or decreased renal blood flow following shock or dehydration. As with serum creatinine levels, serum urea levels do not begin to increase until the GFR has fallen by 50% or more.

Production is decreased in situations where there is a low protein intake and in some patients with liver disease. Thus, non-renal as well as renal influences should be considered when evaluating changes in serum urea concentrations.

Arterial blood gases

Arterial blood gas analysis provides a rapid and accurate assessment of oxygenation, alveolar ventilation and acid–base status, the three processes which maintain pH homeostasis. The maintenance of arterial CO_2 tension ($PaCO_2$) depends on the quantity of CO_2 produced in the body and its removal through alveolar ventilation. High $PaCO_2$ (>6.1 kPa) indicates alveolar hypoventilation and low $PaCO_2$ (<4.5 kPa) implies alveolar hyperventilation.

The adequate delivery of oxygen to the tissues depends upon the cardiopulmonary system, arterial oxygen tension (PaO_2), oxygen concentration in inspired air and haemoglobin content and its affinity for oxygen. Oxygen saturation is measured by pulse oximetry or by arterial blood gas analysis. Hypoxaemia is defined as a PaO_2 of less than 12 kPa at sea level in an adult patient breathing room air.

Bicarbonate and acid–base

Bicarbonate acts as part of the carbonic acid–bicarbonate buffer system, which is important to maintain acid–base balance and thus the pH of the blood. pH homeostasis is accomplished through the interaction of lungs, kidneys and blood buffers. This interaction is best represented by the Henderson–Hasselbalch equation, an equation by which the pH of a buffer solution, blood plasma being one, can be determined (Fig. 6.3).

Plasma bicarbonate is controlled mainly by kidney and blood buffers. The lungs control the $PaCO_2$.

In metabolic acidosis such as that which occurs in renal failure, diabetic ketoacidosis or salicylate poisoning, bicarbonate levels fall. In metabolic alkalosis, the plasma bicarbonate concentration is high. This can occur, for instance, when there is a loss of hydrogen ions from the stomach, as in severe vomiting, or loss through the kidneys, as in mineralocorticoid excess or severe potassium depletion. In the latter situation, an increase in sodium reabsorption in the kidney results in bicarbonate retention and a loss of hydrogen ions. The blood buffer system of carbonic acid/bicarbonate base can act immediately to prevent excessive change in pH. The respiratory system takes a few minutes but the kidneys up to several days to readjust H^+ ions concentration.

$$pH = pKa + Log_{10} \frac{[HCO_3^-]}{\alpha \, pCO_2}$$

Fig. 6.3 The Henderson–Hasselbalch equation. pH, plasma pH; pK_a, negative log to base 10 of the apparent overall dissociation constant of carbonic acid; [HCO_3^-], plasma bicarbonate concentration; α, solubility of carbon dioxide in blood at 37 °C; pCO_2, partial pressure of carbon dioxide in blood.

Glucose

The serum glucose concentration is largely determined by the balance of glucose moving into, and leaving, the extracellular compartment. In a healthy adult, this movement is capable of maintaining serum levels below 10 mmol/L, regardless of the intake of meals of varying carbohydrate content.

The renal tubules have the capacity to reabsorb glucose from the glomerular filtrate, and little unchanged glucose is normally lost from the body. Glucose in the urine (glycosuria) is normally only present when the concentration in serum exceeds 10 mmol/L, the renal threshold for total reabsorption.

Normal ranges for serum glucose concentrations are often quoted as non-fasting (<11.1 mmol/L) or fasting (3.3–6.0 mmol/L) concentration ranges. Fasting serum glucose levels between 6.1 and 7.0 mmol/L indicate impaired glucose tolerance. When symptoms are typical of diabetes, a fasting level above 7.0 mmol/L or a 2 h post-glucose or random serum glucose level ≥11.1 mmol/L is consistent with a diagnosis of diabetes. Other signs and symptoms, if present, are notably those attributable to an osmotic diuresis, and will suggest clinically the diagnosis of diabetes mellitus.

Glycated haemoglobin

Glucose binds to a part of the haemoglobin molecule to form a small glycated fraction. Normally, about 5% of haemoglobin is glycated, but this amount is dependent on the average blood glucose concentration over the lifespan of the red cells (about 120 days) and where red cell lifespan is reduced this leads to low glycated haemoglobin levels. The major component of the glycated fraction is referred to as HbA_{1C}.

Measurement of HbA_{1C} is well established as an indicator of chronic glycaemic control in patients with diabetes. Several methods exist for its determination, but the International Federation of Clinical Chemistry and Laboratory Medicine has recently approved a reference measurement procedure which is analytically specific. As a consequence, laboratories are moving over to measure the substance fraction of the valyl-I-fructosylated haemoglobin β-chains with the unit millimole per mole, and away from the non-specific HbA_{1C} as measured by various non-standardised laboratory procedures.

Uric acid

The production of uric acid, the end product of purine metabolism, is catalysed by xanthine oxidase, an enzyme linked to oxidative stress, endothelial dysfunction and heart failure. The purines, which are used for nucleic acid synthesis, are produced by the breakdown of nucleic acid from ingested meat or synthesised within the body.

Monosodium urate is the form in which uric acid usually exists at the normal pH of body fluids. The term urate is used to represent any salt of uric acid.

Two main factors contribute to elevated serum uric acid levels: an increased rate of formation and reduced excretion. Uric acid is poorly soluble and an elevation in serum concentration can readily result in deposition, as monosodium urate, in tissues or joints. Deposition usually precipitates an acute attack of gouty arthritis. The aim of treatment is to reduce the concentration of uric acid and prevent further attacks of gout. It has been hypothesised that measurement of urate could serve as a marker of cardiovascular risk because the serum uric acid level is an independent predictor of all causes of mortality in patients at high risk of cardiovascular disease, independent of diuretic use.

Liver function tests (LFTs)

Routine LFTs give information mainly about the activity or concentrations of enzymes and compounds in serum rather than quantifying specific hepatic functions and must be interpreted in the context of the patient's characteristic and the pattern of the abnormalities. Results are useful in confirming or excluding a diagnosis of clinically suspected liver disease, and monitoring its course.

Serum albumin levels and prothrombin time (PT) indicate hepatic protein synthesis; bilirubin is a marker of overall liver function.

Transaminase levels indicate hepatocellular injury and death, while alkaline phosphatase levels estimate the amount of impedance of bile flow.

Albumin

Albumin is quantitatively the most important protein synthesised in the liver, with 10–15 g/day being produced in a healthy man. About 60% is located in the interstitial compartment of the ECF, the remainder in the smaller, but relatively impermeable, serum compartment where it is present at a higher concentration. The concentration in the serum is important in maintaining its volume since it accounts for approximately 80% of serum colloid osmotic pressure. A reduction in serum albumin concentration often results in oedema.

Albumin has an important role in binding, among others, calcium, bilirubin and many drugs. A reduction in serum albumin will increase free levels of agents which are normally bound and adverse effects can result if the 'free' entity is not rapidly cleared from the body.

The serum concentration of albumin depends on its rate of synthesis, volume of distribution and rate of catabolism. Synthesis falls in parallel with increasing severity of liver disease or in malnutrition states where there is an inadequate supply of amino acids to maintain albumin production. Synthesis also decreases in response to inflammatory mediators such as interleukin. A low serum albumin concentration will occur when the volume of distribution of albumin increases, as happens, for example, in cirrhosis with ascites, in fluid retention states such as pregnancy or where a shift of albumin from serum to interstitial fluid causes dilutional hypoalbuminaemia after parenteral infusion of excess protein-free fluid. The movement of albumin from serum into interstitial fluid is often associated with increased capillary permeability in postoperative patients or those with septicaemia.

Other causes of hypoalbuminaemia include catabolic states associated with a variety of illnesses and increased loss of albumin, either in urine from damaged kidneys, as occurs in the nephrotic syndrome, or via the skin following burns or a skin disorder such as psoriasis, or from the intestinal wall in a protein-losing enteropathy. The finding of hypoalbuminaemia and no other alteration in liver tests virtually rules out hepatic origin of this abnormality.

Albumin's serum half-life of approximately 20 days precludes its use as an indicator of acute change in liver function but levels are of prognostic value in chronic disease.

An increase in serum albumin is rare and can be iatrogenic, for example, inappropriate infusion of albumin, or the result of dehydration or shock.

A shift of protein is known to occur physiologically when moving from lying down to the upright position. This can account for an increase in the serum albumin level of up to 10 g/L and can contribute to the variation in serum concentration of highly bound drugs which are therapeutically monitored.

Bilirubin

At the end of their life, RBCs are broken down by the reticuloendothelial system, mainly in the spleen. The haemoglobin molecules, which are subsequently liberated, are split into globin and haem. The globin enters the general protein pool, the iron in haem is reutilised, and the remaining tetrapyrrole ring of haem is degraded to bilirubin. Unconjugated bilirubin, which is water insoluble and fat soluble, is transported to the liver tightly bound to albumin. Unconjugated hyperbilirubinaemia in adults is most commonly the result of haemolysis, or Gilbert's syndrome due to genetic defects in UDP-glucronyltransferase. It is actively taken up by hepatocytes, conjugated with glucuronic acid and excreted into bile. The conjugated bilirubin is water soluble and secreted rapidly into the gut where it is broken down by bacteria into urobilinogen, a colourless compound, which is subsequently oxidised in the colon to urobilin, a brown pigment excreted in faeces. Some of the urobilinogen is absorbed and most is subsequently re-excreted in bile (enterohepatic circulation). A small amount is absorbed into the systemic circulation and excreted in urine, where it too may be oxidised to urobilin. The presence of increased conjugated bilirubin is usually a sign of liver disease.

The liver produces 300 mg of bilirubin each day. However, because the mature liver can metabolise and excrete up to 3 g daily, serum bilirubin concentrations are not a sensitive test of liver function. As a screening test they rarely do other than confirm the presence or absence of jaundice. In chronic liver disease, however, changes in bilirubin concentrations over time do convey prognostic information.

An elevation of serum bilirubin concentration above 50 μmol/L (i.e. approximately 2.5 times the normal upper limit) will reveal itself as jaundice, seen best in the skin and sclerae. Elevated bilirubin levels can be caused by increased production of bilirubin (e.g. haemolysis, ineffective erythropoiesis), impaired transport into hepatocytes (e.g. interference with bilirubin uptake by drugs such as rifampicin or due to hepatitis), decreased excretion (e.g. with drugs such as rifampicin and methyltestosterone, intrahepatic obstruction due to cirrhosis, tumours, etc.) or a combination of the above factors.

The bilirubin in serum is normally unconjugated, bound to protein, not filtered by the glomeruli and does not normally appear in the urine. Bilirubin in the urine (bilirubinuria) is usually the result of an increase in serum concentration of conjugated bilirubin and indicates an underlying pathological disorder.

Enzymes

The enzymes measured in routine LFTs are listed in Table 6.1. Enzyme concentrations in the serum of healthy individuals are normally low. When cells are damaged, increased amounts of enzymes are detected as the intracellular contents are released into the blood.

It is important to remember that the assay of 'serum enzymes' is a measurement of catalytic activity and not actual enzyme concentration and that activity can vary depending on assay conditions. Consequently, the reference range may vary widely between laboratories.

While the measurement of enzymes may be very specific, the enzymes themselves may not be specific to a particular tissue or cell. Many enzymes arise in more than one tissue and an increase in the serum activity of one enzyme can represent damage to any one of the tissues which contain the enzymes. In practice, this problem may be clarified because some tissues contain two or more enzymes in different proportions which are released on damage. For example, alanine and aspartate transaminase both occur in cardiac muscle and liver cells, but their site of origin can often be differentiated, because there is more alanine transaminase in the liver than in the heart. In those situations where it is not possible to look at the relative ratio of enzymes, it is sometimes possible to differentiate the same enzyme from different tissues. Such enzymes have the same catalytic activity but differ in some other measurable property, and are referred to as isoenzymes.

The measured activity of an enzyme will be dependent upon the time it is sampled relative to its time of release from the cell. If a sample is drawn too early after a particular insult to a tissue there may be no detectable increase in enzyme activity. If it is drawn too late, the enzyme may have been cleared from the blood.

Alkaline phosphatase

Alkaline phosphatase is an enzyme which transports metabolites across cell membranes. Alkaline phosphatases are found in the canalicular plasma membrane of hepatocytes, in bone where they reflect bone building or osteoblastic activity, and in the intestinal wall and placenta, kidneys and leucocytes. Each site of origin produces a specific isoenzyme of alkaline phosphatase, which can be electrophoretically separated if concentrations are sufficiently high. Hepatic alkaline phosphatase is present on the surface of bile duct epithelia.

Disorders of the liver which can elevate alkaline phosphatase include intra- or extra-hepatic cholestasis, space-occupying lesions, for example, tumour or abscess, and hepatitis. Drug-induced liver injury, for example, by ACE inhibitors or oestrogens, may present with a cholestatic pattern, that is, a preferential increase in alkaline phosphatase.

Physiological increases in serum alkaline phosphatase activity also occur in pregnancy due to release of the placental isoenzyme and during periods of growth in children and adolescents when the bone isoenzyme is released.

Pathological increases in serum alkaline phosphatase of bone origin may arise in disorders such as osteomalacia and rickets, Paget's disease of bone, bone tumours, renal bone disease, osteomyelitis and healing fractures. Alkaline phosphatase is also raised as part of the acute-phase response, for example, intestinal alkaline phosphatase may be raised in active inflammatory bowel disease. If in doubt, the origin of the enzyme can be indicated by assessment of γ-glutamyl transpeptidase (see next section) or electrophoresis to separate alkaline phosphatase isoenzymes.

Transaminases

The two transaminases of diagnostic use are aspartate transaminase (AST; also known as aspartate aminotransferase) and alanine transaminase (ALT; also known as alanine aminotransferase). These enzymes catalyse the transfer of α-amino groups from aspartate and alanine to the α-keto group of ketoglutaricacid to generate oxalacetic and pyruvic acid. They are found in many body tissues, with the highest concentration in hepatocytes and muscle cells. In the liver, ALT is localised solely in cytoplasm whereas AST is cytosolic and mitrochondrial.

Serum AST levels are increased in a variety of disorders including liver disease, crush injuries, severe tissue hypoxia, myocardial infarction, surgery, trauma, muscle disease and pancreatitis. ALT is elevated to a similar extent in the disorders listed which involve the liver, though to a lesser extent, if at all, in the other disorders. In the context of liver disease, increased transaminase activity indicates deranged integrity of hepatocyte plasma membranes and/or hepatocyte necrosis. They may be raised in all forms of viral and non-viral, acute and chronic liver disease, most markedly in acute viral, drug induced (e.g. paracetamol poisoning), alcohol related and ischaemic liver damage. Non-alcoholic fatty liver disease is now the most common cause of mild alteration of aminotransferase levels in the developed world.

γ-Glutamyl transpeptidase

γ-Glutamyl transpeptidase (Gamma GT; also known as γ-glutamyl transferase) is present in high concentrations in the liver, kidney and pancreas, where it is found within the endoplasmic reticulum of cells. It is a sensitive indicator of hepatobiliary disease but does not differentiate a cholestatic disorder from hepatocellular disease. It can also be elevated in alcoholic liver disease, hepatitis, cirrhosis and non-hepatic disease such as pancreatitis, congestive cardiac failure, chronic obstructive pulmonary disease and renal failure.

Serum levels of γ-glutamyl transpeptidase activity can be raised by enzyme induction by certain drugs such as phenytoin, phenobarbital, rifampicin and oral contraceptives.

Serum γ-glutamyl transpeptidase activity is usually raised in an individual with alcoholic liver disease. However, it can also be raised in heavy drinkers of alcohol who do not have liver damage, due to enzyme induction. Its activity can remain elevated for up to 4 weeks after stopping alcohol intake.

Although it lacks specificity, it has a high sensitivity for liver disease, and is thus useful for identifying the cause of a raised alkaline phosphatase level.

Ammonia

The concentration of free ammonia in the blood is very tightly regulated and is exceeded by two orders of magnitude by its derivative, urea. The normal capacity for urea production far exceeds the rate of free ammonia production by protein catabolism under normal circumstances, such that any increase in free blood ammonia concentration is a reflection of either biochemical or pharmacological impairment of urea cycle function or fairly extensive hepatic damage. Clinical signs of hyperammonaemia occur at concentrations >60 mmol/L and include anorexia, irritability, lethargy, vomiting, somnolence, disorientation, asterixis, cerebral oedema, coma and death; appearance of these findings is generally proportional to free ammonia concentration. Causes of hyperammonaemia include genetic defects in the urea cycle and disorders resulting in significant hepatic dysfunction. Ammonia plays an important role in the increase in brain water which occurs in acute liver failure. Measurement of the blood ammonia concentration in the evaluation of patients with known or suspected hepatic encephalopathy can help in diagnosis and assessing the effect of treatment. Valproic acid can induce hyperammonaemic encephalopathy as one of its adverse neurological effects.

Amylase

The pancreas and salivary glands are the main producers of serum amylase. The serum amylase concentration rises within the first 24 h of an attack of pancreatitis and then declines to normal over the following week. Although a number of abdominal and extra-abdominal conditions including loss of bowel integrity through infarction or perforation, chronic alcoholism, post-operative states and renal failure can result in a high amylase activity, in patients with the clinical picture of severe upper abdominal symptoms the specificity and sensitivity of an amylase level over 1000 IU/L in the diagnosis of pancreatitis is over 90%. There is a lack of prognostic significance of absolute values of amylase as values are directly related to the degree of pancreatic duct obstruction and inversely related to severity of pancreatic disease.

Cardiac markers

Troponins

Cardiac troponin I (cTnI) and cardiac troponin T (cTnT) are regulatory proteins that control the calcium-mediated inter-action between actin and myosin in cardiac muscle. They are the preferred biomarker for myocardial necrosis as they have near absolute myocardial tissue specificity as well as high clinical sensitivity. The major international cardiac societies have introduced an international definition and classification for myocardial infarction which depends on the detection of a rise and/or fall ($\geq$20%) of troponin with at least one value above the 99th percentile of the upper reference limit (URL) plus at least one of the following: (i) symptoms of ischae-mia, or (ii) ECG evidence or imaging evidence of ischae-mia. Sampling of cTn at two time points, usually admission and 12 h from worst pain, is usually needed, although if it is entirely clear that there has been a myocardial infarction, particularly in a late presentation, a second sample may not be needed. They contribute significantly to stratification of individuals with acute coronary syndromes, either alone or in combination with admission ECG or a predischarge exer-cise stress test. The decision as to whether to monitor cTnI or cTnT in a given laboratory is a balance between cost, avail-ability of automated instrumentation and assay performance in which there is not yet standardisation between laborato-ries. Cardiac troponins offer extremely high tissue specific-ity and sensitivity but do not discriminate between ischaemic and non-ischaemic mechanisms of myocardial injury, such as myocarditis, cardiac surgery and sepsis. New, more sensitive assays are being developed, although studies will be required to define the clinical significance of minor releases of cTn and its relation to cardiac tissue viability.

Creatine kinase (CK)

CK is an enzyme which is present in relatively high concen-trations in heart muscle, skeletal muscle and in brain in addi-tion to being present in smooth muscle and other tissues. Levels are markedly increased following shock and circula-tory failure, myocardial infarction and muscular dystrophies. Less marked increases have been reported following muscle injury, surgery, physical exercise, muscle cramp, an epileptic fit, intramuscular injection and hypothyroidism. The most important adverse effects associated with statins are myopa-thy and an increase in hepatic transaminases, both of which occur infrequently. Statin-associated myopathy represents a broad clinical spectrum of disorders, from mild muscle aches to severe pain and restriction in mobility, with grossly ele-vated CK levels. In rhabdomyolysis, a potentially life-threat-ening syndrome resulting from the breakdown of skeletal muscle fibres as a result of ischaemic crush injury, for exam-ple, large quantities of CK are measurable in the blood with the level of CK in the blood predicting the developments of acute renal failure. Medications and toxic substances that increase the risk of rhabdomyolysis are shown in Table 6.3.

Table 6.3 Medications and toxic substances that increase the risk of rhabdomyolysis

Direct myotoxicity	Indirect muscle damage
HMG-CoA reductase inhibitors, especially in combination with fibrate-derived lipid-lowering agents such as niacin (nicotinic acid) Ciclosporin Itraconazole Erythromycin Colchicine Zidovudine Corticosteroids	Alcohol Central nervous system depressants Cocaine Amphetamine Ecstasy (MDMA) LSD Neuromuscular blocking agents

HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LSD, lysergic acid diethylamide; MDMA, methylene dioxymethamphetamine.

CK has two protein subunits, M and B, which combine to form three isoenzymes, BB, MM and MB. BB is found in high concentrations in the brain, thyroid and some smooth muscle tissue. Little of this enzyme is present in the serum, even fol-lowing damage to the brain. The enzyme found in serum of normal subjects is the MM isoenzyme which originates from skeletal muscle.

Cardiac tissue contains more of the MB isoenzyme than skeletal muscle. Following a myocardial infarction there is a characteristic increase in serum CK activity. Although mea-surement of activity of the MB isoenzyme was used in the past to detect myocardial damage, cardiac troponin measure-ment is now the preferred biomarker.

Lactate dehydrogenase (LD)

Lactate dehydrogenase has five isoenzymes (LD1–LD5). Total LD activity is rarely measured because of the lack of tissue specificity. Levels of activity are elevated following damage to the liver, skeletal muscle and kidneys, in both megaloblas-tic and immune haemolytic anaemias, and in intravascular haemolysis such as occurs in thrombotic thrombocytopenic purpura and paroxysmal nocturnal haemoglobinuria. In lymphoma, a high LD activity indicates a poor prognosis. Elevation of LD1 and LD2 occurs after myocardial infarc-tion, renal infarction or megaloblastic anaemia; LD2 and LD3 are elevated in acute leukaemia; LD3 is often elevated in some malignancies; and LD5 is elevated after damage to liver or skeletal muscle.

Tumour markers

Tumour markers are defined as a qualitative or quantita-tive alteration or deviation from normal of a molecule, sub-stance or process that can be detected by some type of assay above and beyond routine clinical and pathological evalua-tion. They may be detected within malignant cells, surround-ing stroma or metastases, or as soluble products in blood,

secretions or excretions. In order to be useful clinically, the precise use of the marker in altering clinical management should have been defined by data based on a reliable assay, and a validated clinical outcome trial.

Whilst only a few markers contribute to the diagnosis of cancer, serial measurements can be useful in assessing the presence of residual disease and response to treatment. A detailed discussion of each marker, which include prostatic-specific antigen, human chorionic gonadotropin, α-fetoprotein, carcinoembryonic antigen, cancer antigen (CA125 and CA19) is outside the scope of this chapter. Updated National Academy of Clinical Biochemistry Laboratory Medicine Practice Guidelines for the use of tumour markers in the clinic were published in 2008 to encourage their optimal use. Use in predicting response to therapy and, therefore, targeting therapy is increasingly used: for breast cancer, oestrogen and progesterone receptors are mandatory for predicting response to hormone therapy, and human epidermal growth factor receptor-2 (HER2) measurement is mandatory for predicting response to trastuzumab.

Prostatic specific antigen (PSA) is a serine protease produced by normal and malignant prostatic epithelium and secreted into seminal fluid. Only minor amounts leak into the circulation from the normal prostate, but the release is increased in prostatic disease. It is not recommended for prostate cancer screening but is useful for the detection of recurrence and response to therapy. Free PSA measurement can improve distinguishing of malignant from benign prostatic disease when total PSA is <10 μcg/L, although results for free PSA differ between commercially available assay methods and require harmonisation.

Immunoglobulins

Immunoglobulins are antibodies which are produced by B lymphocytes. They are detected on elctrophoresis as bands in three regions: α, β and γ, with most occurring in the γ region. Hypergammaglobulinaemia may result from stimulation of B cells and produces an increased staining of bands in the γ region on electrophoresis. This occurs in infections, chronic liver disease and autoimmune disease.

In some diseases such as chronic lymphatic leukaemia, lymphoma and multiple myeloma, a discrete, densely staining band (paraprotein) can be seen in the γ region. In multiple myeloma, abnormal fragments of immunoglobulins are produced (Bence-Jones protein) which clear the glomerulus and are found in the urine.

Haematology data

The haematology profile is an important part of the investigation of many patients and not just those with primary haematological disease.

Typical measurements reported in a haematology screen, with their normal values, are shown in Table 6.4, whilst a list of the common descriptive terms used in haematology is presented in Table 6.5.

Table 6.4 Haematology data: typical normal adult reference values	
Haemoglobin	11.5–16.5 g/dL
Red blood cell (RBC) count	$3.8–4.8 \times 10^{12}$/L
Reticulocyte count	$50–100 \times 10^9$/L
Packed cell volume (PCV)	0.36–0.46 L/L
Mean cell volume (MCV)	83–101 fL
Mean cell haemoglobin (MCH)	27–34 pg
Mean cell haemoglobin concentration (MCHC)	31.5–34.5 g/dL
White cell count (WBC)	$4.0–11.0 \times 10^9$/L
Differential white cell count:	
Neutrophils (30–75%)	$2.0–7.0 \times 10^9$/L
Lymphocytes (5–15%)	$1.5–4.0 \times 10^9$/L
Monocytes (2–10%)	$0.2–0.8 \times 10^9$/L
Basophils (<1%)	$<0.1 \times 10^9$/L
Eosinophils (1–6%)	$0.04–0.4 \times 10^9$/L
Platelets	$150–450 \times 10^9$/L
Erythrocyte sedimentation rate (ESR)	1–35 mm/h
D-dimers	0–230 ng/mL
Ferritin	15–300 μcg/L
Total iron binding capacity (TIBC)	47–70 μmol/L
Serum B_{12}	170–700 ng/L
Red cell folate	160–600 μcg/l
Iron	11–29 μmol/L
Transferrin	1.7–3.4 g/L

RBC count

RBCs are produced in the bone marrow by the process of erythropoiesis. One of the major stimulants of this process is erythropoietin, produced mainly in the kidney. Immature erythroblasts develop into mature erythrocytes which are then released into the circulation:

erythroblasts

↓

normoblasts (nucleated)

↓

reticulocytes (non-nucleated)

↓
erythrocytes

Normally, only reticulocytes and non-nucleated mature erythrocytes are seen in the peripheral blood.

Table 6.5 Descriptive terms in common use in haematology

Anisocytosis	Abnormal variation in cell size (usually refers to RBCs), for example, red cells in iron deficiency anaemia
Agranulocytosis	Lack of granulocytes (principally neutrophils)
Aplastic	Depression of synthesis of all cell types in bone marrow (as in aplastic anaemia)
Basophilia	Increased number of basophils
Hypochromic	MCHC low, red cells appear pale microscopically
Leucocytosis	Increased white cell count
Leucopenia	Reduced white cell count
Macrocytic	Large cells
Microcytic	Small cells
Neutropenia	Reduced neutrophil count
Neutrophilia	Increased neutrophil count
Normochromic	MCHC normal; red cells appear normally pigmented
Pancytopenia	Decreased number of all cell types: it is synonymous with aplastic anaemia
Poikilocytosis	Abnormal variation in cell shape, for example, some red cells appear pear shaped in macrocytic anaemias
Thrombocytopenia	Lack of platelets

The lifespan of a mature red cell is usually about 120 days. If this is shortened, as for instance in haemolysis, the circulating mass of red cells is reduced and with it the supply of oxygen to tissues is decreased. In these circumstances, red cell production is enhanced in healthy bone marrow by an increased output of erythropoietin by the kidneys. Under normal circumstances red cells are destroyed by lodging in the spleen due to decreasing flexibility of the cells. They are removed by the reticuloendothelial system.

A high RBC (erythrocytosis or polycythaemia) indicates increased production by the bone marrow and may occur as a physiological response to hypoxia, as in chronic airways disease, or as a malignant condition of red cells such as in polycythaemia rubra vera.

Reticulocytes

Reticulocytes are the earliest non-nucleated red cells. They owe their name to the fine net-like appearance of their cytoplasm which can be seen, after appropriate staining, under the microscope and contains fine threads of ribonucleic acid (RNA) in a reticular network. Reticulocytes normally represent between 0.5% and 1.0% of the total RBC and do not feature significantly in a normal blood profile. However, increased production (reticulocytosis) can be detected in times of rapid red cell regeneration as occurs in response to haemorrhage or haemolysis. At such times the reticulocyte count may reach 40% of the RBC. The reticulocyte count may be useful in assessing the response of the marrow to iron, folate or vitamin B_{12} therapy. The count peaks at about 7–10 days after starting such therapy and then subsides.

Mean cell volume (MCV)

The MCV is the average volume of a single red cell. It is measured in femtolitres (10^{-15} L). Terms such as 'microcytic' and 'macrocytic' are descriptive of a low and high MCV, respectively. They are useful in the process of identification of various types of anaemias such as caused by iron deficiency (microcytic) or vitamin B_{12} or folic acid deficiency (megaloblastic or macrocytic).

Packed cell volume (PCV)

The PCV or haematocrit is the ratio of the volume occupied by red cells to the total volume of blood. It can be measured by centrifugation of a capillary tube of blood and then expressing the volume of red cells packed in the bottom as a percentage of the total volume. It is reported as a fraction of unity or as a percentage (e.g. 0.45% or 45%). The PCV is calculated nowadays as the product of the MCV and RBC. The PCV often reflects the RBC and will, therefore, be decreased in any sort of anaemia. It will be raised in polycythaemia. It may, however, be altered irrespective of the RBC, when the size of the red cell is abnormal, as in macrocytosis and microcytosis.

Mean cell haemoglobin (MCH)

The MCH is the average weight of haemoglobin contained in a red cell. It is measured in picograms (10^{-12} g) and is calculated from the relationship:

$$MCH = \frac{Haemoglobin}{RBC}$$

The MCH is dependent on the size of the red cells as well as the concentration of haemoglobin in the cells. Thus, it is usually low in iron-deficiency anaemia when there is microcytosis and there is less haemoglobin in each cell, but it may be raised in macrocytic anaemia.

Mean cell haemoglobin concentration (MCHC)

The MCHC is a measure of the average concentration of haemoglobin in 100 mL of red cells. It is usually expressed as grams per litre but may be reported as a percentage. The MCHC will be reported as low in conditions of reduced haemoglobin synthesis, such as in iron-deficiency anaemia. In contrast, in macrocytic anaemias the MCHC may be normal or only

slightly reduced because the large red cells may contain more haemoglobin, thus giving a concentration approximating that of normal cells. The MCHC can be raised in severe prolonged dehydration. If the MCHC is low, the descriptive term 'hypochromic' may be used (e.g. a hypochromic anaemia) whereas the term 'normochromic' describes a normal MCHC.

Haemoglobin

The haemoglobin concentration in men is normally greater than in women, reflecting in part the higher RBC in men. Lower concentrations in women are due, at least in part, to menstrual loss.

Haemoglobin is most commonly measured to detect anaemia. In some relatively rare genetic diseases, the haemoglobinopathies, alterations in the structure of the haemoglobin molecule can be detected by electrophoresis. Abnormal haemoglobins which can be detected in this manner include HbS (sickle haemoglobin in sickle cell disease) and HbA_2 found in β-thalassaemia carriers.

Platelets (thrombocytes)

Platelets are formed in the bone marrow. A marked reduction in platelet number (thrombocytopenia) may reflect either a depressed synthesis in the marrow or destruction of formed platelets.

Platelets are normally present in the circulation for 8–12 days. This is useful information when evaluating a possible drug-induced thrombocytopenia, since recovery should be fairly swift when the offending agent is withdrawn.

A small fall in the platelet count may be seen in pregnancy and following viral infections. Severe thrombocytopenia may result in spontaneous bleeding. A reduced platelet count is also found in disseminated intravascular coagulation, which manifests clinically as severe haemorrhages, particularly in the skin and results in rapid consumption of clotting factors and platelets.

An increased platelet count (thrombocytosis) occurs in malignancy, inflammatory disease and in response to blood loss.

White blood cell (WBC) count

White cells (leucocytes) are of two types: the granulocytes and the agranular cells. They are made up of various types of cells (Fig. 6.4) with different functions and it is logical to consider them separately. A haematology profile often reports a total white cell count and a differential count, the latter separating the composition of white cells into the various types.

Neutrophils

Neutrophils or polymorphonucleocytes (PMNs) are the most abundant type of white cell. They have a phagocytic function, with many enzymes contained in the lysosomal granules. They are formed in the bone marrow from the stem cells which form myoblasts and these develop through a number of
Fig. 6.4   Types of white cells.

stages into the neutrophil with a multiple-segmented nucleus. Neutrophils constitute approximately 40–70% of circulating white cells in normal healthy blood. Their lifespan is 10–20 days. The neutrophil count increases in the presence of infection, tissue damage (e.g. infarction) and inflammation (e.g. rheumatoid arthritis, acute gout). Neutropenia, also described as agranulocytosis in its severest forms, is associated with malignancy and drug toxicity, but may also occur in viral infections such as influenza, infectious mononucleosis and hepatitis.

Basophils

Basophils normally constitute a small proportion of the white cell count. Their function is poorly understood but basophilia occurs in various malignant and premalignant disorders such as leukaemia and myelofibrosis.

Eosinophils

Eosinophils constitute normally less than 6% of white cells. Their function appears to be concerned with inactivation of mediators released from mast cells, and eosinophilia is, therefore, apparent in many allergic conditions such as asthma, hay fever and drug sensitivity reactions as well as some malignant diseases.

Lymphocytes

Lymphocytes are the second most abundant white cells in the circulating blood, but the majority of them are found in the spleen and other lymphatic tissue. They are formed in the bone marrow. An increase in lymphocyte numbers occurs particularly in viral infections such as rubella, mumps, infectious hepatitis and infectious mononucleosis.

Monocytes

Monocytes are macrophages. Their numbers increase in some infections such as typhoid, subacute bacterial endocarditis, infectious mononucleosis and tuberculosis.

Other blood tests

Erythrocyte sedimentation rate (ESR)

The ESR is a measure of the settling rate of red cells in a sample of anticoagulated blood, over a period of 1 h, in a cylindrical tube.

In youth, the normal value is less than 10 mmol/h, but normal values do rise with age. The Westergren method, performed under standardised conditions, is commonly used in haematology laboratories. The ESR is strongly correlated with the ability of red cells to aggregate into orderly stacks or rouleaux. In disease, the most common cause of a high ESR is an increased protein level in the blood, such as the increase in acute-phase proteins seen in inflammatory disease. Proteins are thought to affect the repellent surface charges on red cells and cause them to aggregate into rouleaux and hence the sedimentation rate increases. Although some conditions may cause a low ESR, the test is principally used to monitor inflammatory disease. The ESR may be raised in the active phase of rheumatoid arthritis, inflammatory bowel disease, malignant disease and infection. The ESR is non-specific and, therefore, of little diagnostic value, but serial tests can be helpful in following the progress of disease, and its response to treatment.

C-reactive protein (CRP)

CRP, named for its capacity to precipitate the somatic C-polysaccharide of streptococcus pneumoniae, was the first acute-phase protein to be described. This non-specific acute-phase response occurs in animals in response to tissue damage, infection, inflammation and malignancy. Production of CRP is rapidly and sensitively upregulated, in hepatocytes, under the control of cytokine (IL-6) originating at the site of pathology. It recognises altered self and foreign molecules, as a result of which it activates complement and generates pro-inflammatory cytokines and activation of the adaptive immune system.

Serum concentrations rise by about 6 h, peaking around 48 h. The serum half-life is constant at about 19 h, so serum level is determined by synthesis rate, which therefore reflects the intensity of the pathological process stimulating this, and falls rapidly when this ceases. CRP values are not diagnostic, however, but can only be interpreted in knowledge of all other clinical and pathological results. In most diseases, the circulating value of CRP reflects ongoing inflammation or tissue damage more accurately than do other acute-phase parameters such as serum viscosity or the ESR. Drugs reduce CRP values by affecting the underlying pathology providing the acute-phase stimulus.

Coagulation

Coagulation is the process by which a platelet and fibrin plug is formed to seal a site of injury or rupture in a blood vessel. The current model of a 'coagulation network' differs from the previous popular cascade scheme. It proposes that blood coagulation is localised on the surfaces of activated cells in three overlapping steps: initiation, amplification and propagation. Coagulation is initiated when a tissue factor (TF) bearing cell is exposed to blood flow, following either damage of endothelium such as by perforation of a vessel wall or activation by chemicals, cytokines or the inflammatory process. The formation of a clot then involves a complex interaction between platelets and factor VIII bound to von Willebrand factor which leave the vascular space and adhere to collagen and other matrix components at the site of injury. The coagulation process is amplified when enough thrombin is generated on or near the TF bearing cells to trigger full activation of platelets and coagulation co-factors on the platelet surface. It ends with the generation of sufficient thrombin, to clot fibrinogen. To prevent inappropriate propagation of the thrombus, the process is controlled by naturally occurring anticoagulants and the fibrinolytic system, the final effector of which is plasmin which cleaves fibrin into soluble degradation products. The interaction between TF and factor VII is the most important in the initiation of coagulation and many of the coagulation reactions occur on the surface of cells (particularly platelets). The cellular model of normal haemostasis is shown in Fig. 6.5. Despite the complexity of this model, the basic coagulation tests can still be interpreted in relation to the 'intrinsic', 'extrinsic', and 'final common pathway' components of the traditional and previously held cascade (Fig. 6.6). The extrinsic pathway can be considered to consist of the factor VIIa/TF complex working with the factor Xa/Va complex and the intrinsic pathway to consist of factor XIa working with the complexes of factors VIIIa/IXa and factors Xa/Va. The extrinsic pathway operates on the TF bearing cell to initiate and amplify coagulation with the intrinsic pathway operating on the activated platelet surface to produce the burst of thrombin to form and stabilise the fibrin clot.

Monitoring anticoagulant therapy

The blood tests for the adequacy of the extrinsic pathway, prothombin time (PT) and the intrinsic pathway, activated partial thromboplastin time (aPTT) do not reflect the complexity of haemostasis in vivo, or the risk of bleeding. This requires interpretation of the result in the clinical context of surgical or accidental trauma or medical illness.

One stage PT

Measuring the PT is the most commonly used method for monitoring oral anticoagulation therapy. The PT is responsive to depression of three of the four vitamin K dependent factors (factors II, VII and X). The PT is measured by adding calcium and thromboplastin (a phospholipid-protein extract of tissue that promotes the activation of factor X by factor VIII) to citrated plasma.
Fig. 6.5   Normal haemostasis; the cellular model.

Fibrin monomer
Ca – Calcium
TF – Tissue factor
PK – PreKallikrein
HK – High molecular weight kininogen
PL – Phospholipids from activated platelets
Fig. 6.6   Coagulation network.

International Normalised Ratio (INR)

The results of the test are commonly expressed as a ratio of the PT time of the patient compared with that of the normal control. This is known as the INR, a system used to standardise reporting worldwide.

$$INR = \left\{ \frac{\text{Patient's PT}}{\text{Control PT}} \right\}^{ISI}.$$

The ISI is the international sensitivity index and represents the responsiveness of a given thromboplastin to the reduction of vitamin K dependent clotting factors and is allocated to commercial preparations of thromboplastin to standardise them. More responsive thromboplastins have lower ISI values.

The target value varies according to the indication for the anticoagulant, but for most, including for thrombo-embolic prophylaxis in atrial fibrillation, is 2.5. For some indications including recurrent deep vein thrombosis and pulmonary embolism whilst on warfarin, the target is higher at 3.5.

The most common use of the PT and INR is to monitor oral anticoagulant therapy, but the PT is also useful in assessing liver function because of its dependence on the activity of clotting factors I, II, V, VII and X which are produced in the liver. It may be prolonged also by deficiency in vitamin K, and consumptive coagulopathy. Obstructive jaundice may decrease the absorption of vitamin K and thereby increase PT. PT will respond to parenteral administration of vitamin K, which is ineffective when jaundice is caused by decreased functioning liver mass.

Activated partial thromboplastin time (APTT)

The APTT is the most common method for monitoring unfractionated heparin therapy.

A thromboplastic reagent is added to an activator such as activated silicone or kaolin. If the activator is kaolin, the test may be referred to as the PTTK (partial thromboplastin time kaolin) or the KCCT (kaolin–cephalin clotting time). Cephalin is a brain extract supplying the thromboplastin.

The mixture of thromboplastin and activator is mixed with citrated plasma to which calcium is added, and the time for the mixture to clot is recorded. The desirable APTT for optimal heparin therapy is between 1.5 and 2.5 times the normal control.

Low molecular weight heparins are effective and safe for the prevention and treatment of venous thromboembolism, and because they provide more predictable anticoagulant activity than unfractionated heparin it is usually not necessary to monitor the APTT during treatment. Laboratory monitoring using an anti-factor Xa assay may be of value in certain clinical settings, including patients with renal insufficiency, and use of fractionated heparin for prolonged periods in pregnancy or in newborns and children.

D-dimers

D-dimers are degradation products of fibrin clots, formed by the sequential action of three enzymes, thrombin, factor VIIIa and plasmin which degrades cross-linked fibrin to release fibrin degradation products and expose the D-dimer antigen. D-dimer assays measure an epitope on fibrin degradation products using monoclonal antibodies. As each has its own unique specificity, there is no standard unit of measurement or performance and clinicians need to be aware of that of their institution. Levels of D-dimers in the blood are raised in conditions associated with coagulation and are used to detect venous thromboembolism, although they are influenced by the presence of co-morbid conditions such as cancer, surgery and infectious diseases. D-dimer measurement has been most comprehensively validated in the exclusion of venous thromboembolism in certain patient populations and in the diagnosis and monitoring of coagulation activation in disseminated intravascular coagulation. More recently, assays are being used in the prediction of the risk of VTE recurrence. Diagnosis of DVT or PE should include a clinical probability assessment as well as D-dimer measurements. In patients with a low clinical probability of pulmonary embolism, a negative quantitative D-dimer test result effectively excludes PE. In suspected DVTs, D-dimer measurements combined with a clinical prediction score and compression ultrasonography study have a high predictive value.

Xanthochromia

Xanthochromia is a yellow discolouration of cerebrospinal fluid caused by haemoglobin catabolism. It is thought to arise within several hours of subarachnoid haemorrhage (SAH) and can help to distinguish the elevated red cell count observed after traumatic lumbar puncture from that observed following SAH, particularly if few red cells are present. Spectrophotometry to detect the presence of both oxyhaemoglobin and bilirubin, which both contribute to xanthochromia following SAH, is used, although some hospitals rely on visual inspection.

Iron, transferrin and iron binding

Iron is necessary for the functioning of all mammalian cells, but is particularly important in cells producing haemoglobin and myoglobin. Iron circulating in the serum is bound to transferrin. It leaves the serum pool and enters the bone marrow where it becomes incorporated into haemoglobin in developing red cells. Serum iron levels are extremely labile and fluctuate throughout the day and, therefore, provide little useful information about iron status.

Transferrin, a simple polypeptide chain with two iron binding sites, is the plasma iron binding protein which facilitates its delivery to cells bearing transferrin receptors. Measurement of total iron binding capacity (TIBC), from which the percentage of transferrin saturation with iron may be calculated, gives more information. Saturation of 16% or lower is usually taken to indicate an iron deficiency, as is a raised TIBC of greater than 70 µmol/L.

Ferritin is an iron storage protein found in cell cytosol. It acts as a depot, accepting excess iron and allowing for mobilisation of iron when needed. Serum ferritin measurement is the test of choice in patients suspected of having iron deficiency anaemia.

In normal individuals, the serum ferritin concentration is directly related to the available storage iron in the body. The serum ferritin level falls below the normal range in iron deficiency anaemia, and its measurement can provide a useful monitor for repletion of iron stores after iron therapy. Ferritin is an acute-phase protein and levels may be normal or high in the anaemia of chronic disease, such as occurs in rheumatoid arthritis or chronic renal disease.

Iron balance is regulated by hepcidin, a circulating peptide hormone, which aims to provide iron as needed, whilst avoiding excess iron promoting formation of toxic oxygen radicals.

Iron overload causes high concentrations of serum ferritin, as can liver disease and some forms of cancer. Genetic iron overload results from mutations in molecules which regulate hepcidin production or activity.

Vitamin B$_{12}$ and folate

In the haematology literature, B$_{12}$ refers not only to cyanocobalamin but also to several other cobalamins with identical nutritional properties. Folic acid, which can designate a specific compound, pteroylgutamic acid, is also more commonly used as a general term for the folates. Deficiency of cobalamin can result both in anaemia, usually macrocytic, and neurological disease, including neuropathies, dementia and psychosis. Folate deficiency produces anaemia, macrocytosis, depression, dementia and neural tube defects.

Liver disease tends to increase B$_{12}$ levels, and they may be reduced in folate deficient patients: malabsorption of B$_{12}$ may result from long-term ingestion of antacids such as protonpump inhibitors or H$_2$-receptor antagonists or biguanides (metformin). Serum folate levels tend to increase in B$_{12}$ deficiency, and alcohol can reduce levels. RBC folate is a better measure of folate tissue stores.

Current assays analyse total B$_{12}$ concentration, only a small percentage of which is metabolically active. Varying test sensitivities and specificities result from the lack of a precise 'gold standard' for the diagnosis of cobalamin deficiency. In the future, new assays for the active component which is carried on holotranscobalamin may be of greater relevance if their clinical usefulness can be established.

Case studies

Case 6.1

Mr F is a 70-year-old man who presents with diffuse pains in his arms and legs. He is Asian, from Pakistan, and has been in England for 50 years.
He has the following biochemical test results:

Alkaline phosphatase	436 U/L
Total calcium	2.27 mmol/L
Ionised calcium	1.10 mmol/L
Phosphate	0.97 mmol/L
Vitamin D	6 nmol/L
Parathyroid hormone	434 ng/L
Urea	4.6 mmol/L
Creatinine	63 μmol/L

Questions

1. With respect to Mr F's blood results, what is the diagnosis?
2. How should he be treated?
3. How should he be monitored?

Answers

1. The diagnosis is osteomalacia due to vitamin D deficiency.
2. Vitamin D deficiency is caused by dietary deficiency of vitamin D and deficient endogenous production due to poor sunlight exposure. A deficit in activation can result from liver or kidney disease. People at high or low latitude, especially housebound, and people with dark coloured skin are at particular risk.
   Vitamin D_2 (cholecalciferol) or vitamin D_3 (ergocalciferol) is given orally in doses of 2000–4000 IU (0.05–0.1 mg) daily for 6–12 weeks, followed by daily supplements of 200–400 IU. The dose needed to achieve levels in the sufficient range sometimes requires daily doses over 800 IU. Where osteomalacia is due to intestinal malabsorption, higher doses of vitamin D and large doses of calcium may be required. In some instances, oral vitamin D is ineffective and the parenteral (intramuscular) route is required. In renal impairment, 1α hydroxylated vitamin D is usually prescribed.
3. Serum calcium should be monitored frequently during the first 1–2 months of therapy and less frequently once a stable dose has been established which has ensured return to normal of calcium, alkaline phosphatase and parathyroid hormone levels.

Case 6.2

A 70-year-old man on a hospital medical ward has a fast pulse rate and falling blood pressure. His recent drug history is warfarin as thrombo-embolic prophylaxis for chronic atrial fibrillation and erythromycin for a recent chest infection. He has vomited a moderate quantity of blood.

Haematology results:	Hb 8.8 g/dL
	RBC 4.7 × 10^{12}/L
Platelets	570 × 10^9/L
INR	6.0

MCV, MCH and the rest of the blood profile are normal

Clinical biochemistry:	Urea 11.6 mmol/L

Creatinine is normal and sodium and potassium concentrations are normal.

Questions

1. What is the cause of this patient's low haemoglobin?
2. What is the likely cause of his raised urea level?
3. What might have contributed to his over-anticoagulation as evidenced by his INR?

Answers

1. The cause of his low haemoglobin is a gastro-intestinal bleed. The picture is one of blood loss, manifested by a loss of red cells and haemoglobin. The red cells are of normal size and colour. As haemoglobin is normal immediately after a bleed, this man's bleed must have begun sufficiently long ago for haemodilution, through ingestion of fluid, to have occurred.
2. A raised urea in the presence of a normal creatinine may signify dehydration or gastro-intestinal bleeding. In this case, given the blood picture, the latter is more likely. Blood in the gastro-intestinal tract is a source of protein which will be absorbed into the hepatic portal system and converted to urea in the liver.
3. Erythromycin inhibits the cytochrome P450 system, particularly the CYP3A4 isoenzyme. CYP1A2 and CYP3A4 are the main enzymes for the inactivation of (R)-warfarin. Erythromycin, therefore, potentiates warfarin's action. The patient has been ill and in hospital and, therefore, his recent intake of vitamin K containing foods, for example, green leafy vegetables may well have been lower than is usual for him. Antibiotics can reduce synthesis of vitamin K by gut bacteria but this has little, if any, effect upon anticoagulation, and interactions with warfarin previously attributed to this mechanism have since been attributed to other modes of interaction.

Case 6.3

An 80-year-old patient with a history of Type II diabetes mellitus is admitted to hospital after an episode of vomiting and diarrhoea, followed by increasing confusion and drowsiness. His medication includes bendroflumethiazide and gliclazide. On examination he has a reduced level of consciousness, is dehydrated, and has a low blood pressure.
Biochemistry results show:

Sodium	158 mmol/L
Potassium	4.6 mmol/L
Urea	44 mmol/L
Creatinine	250 μmol/L
Random blood glucose	38 mmol/L

Arterial blood gases on air:

pH	7.39
pCO_2	5.0 kPa
Actual bicarbonate	24 mmol/L
pO_2	12.7 kPa

Questions

1. What is the diagnosis?
2. Why is the sodium raised?
3. What do his blood gases indicate?

Answers

1. The patient has hyperglycaemic hyperosmolar non-ketotic coma, evidenced by his clinical signs, raised blood glucose, sodium, urea and creatinine.

2. This is evidence of water depletion. This patient is dehydrated because of vomiting and diarrhoea, bendroflumethiazide and the osmotic diuresis caused by hyperglycaemia.
3. Normal serum pH and bicarbonate concentration show that he does not have metabolic ketoacidosis, the condition which only occurs in patients with Type I diabetes and which may be precipitated by infection.

Case 6.4

An 83-year-old man presents with a few weeks history of tiredness, unsteadiness and an abnormal sensation in both hands and feet. On examination he is ataxic with poor co-ordination due to absent joint position and vibration sense. Clinical diagnosis is of sensory ataxia due to dorsal column pathology. His drug treatment includes long-term metformin for Type 2 diabetes mellitus and lansoprazole.
Haematology results show:

Haemoglobin	8.9 g/dL
MCV	110 fL
B_{12}	128 ng/L
Red cell folate	300 μcg/L

Questions

1. What is the likely cause of this patient's symptoms and signs?
2. How should his neurological features be investigated?
3. What term describes this type of anaemia?
4. What drug treatment should he receive?

Answers

1. Subacute combined degeneration of the spinal cord and anaemia due to vitamin B_{12} deficiency.
2. Magnetic Resonance Imaging (MRI) of the spine. This is likely to show signal abnormality in the posterior columns of the spinal cord.
3. Macrocytic anaemia.
4. Parenteral administration, usually by intramuscular injection of vitamin B_{12}. In the UK, several loading doses are given followed by maintenance injections (e.g. 1000 μcg every 3 months) for the patient's lifetime. Treatment with pharmacological doses of oral cyanocobalamin is occasionally given, for example, if the patient has needle phobia or is allergic to the IM B_{12} preparation.

7 Parenteral nutrition

S.J. Harwood and A.G. Cosslett

Key points

- Parenteral nutrition is indicated in people who are malnourished or at risk of malnutrition due to a non-functional, inaccessible or perforated gastro-intestinal tract or who have inadequate or unsafe enteral nutritional intake.
- Combinations of oral diet, enteral feeding and parenteral nutrition, either peripherally or centrally, may be appropriate.
- Parenteral nutrition regimens should be tailored to the nutritional needs of the patient and should contain a balance of seven essential components: water, L-amino acids, glucose, lipid with essential fatty acids, vitamins, trace elements and electrolytes.
- Advances in technology alongside expertise in pharmaceutical stability often permit the required nutrients to be administered from a single container. Increasingly, standard formulations are used, including licensed preparations.
- Parenteral nutrition must be compounded under validated aseptic conditions by trained specialists.
- Prescriptions are guided by baseline nutritional assessment, calculation of requirements using a range of algorithms, knowledge of the patient's disease status and ongoing monitoring.
- The incidence of complications with parenteral nutrition is reducing; knowledge of management is improving.

Introduction

Malnutrition

Malnutrition can be described as a deficiency, excess, or imbalance of energy, protein, and other nutrients that causes measurable adverse effects on body tissue, size, shape, composition, function and clinical outcome.

In UK hospitals, most malnutrition appears to be a general undernutrition of all nutrients (protein, energy and micronutrients) rather than marasmus (insufficient energy provision) or kwashiorkor (insufficient protein provision). Alternatively, there may be a specific deficiency, such as thiamine in severe hepatic disease.

Multiple causes may contribute to malnutrition. They may include inadequate or unbalanced food intake, increased demand due to clinical disease status, defects in food digestion or absorption, or a compromise in nutritional metabolic pathways. Onset may be acute or insidious.

Even mild malnutrition can result in problems with normal body form and function with adverse effects on clinical, physical and psychosocial status. Symptoms may include impaired immune response, reduced skeletal muscle strength and fatigue, reduced respiratory muscle strength, impaired thermoregulation, impaired skin barrier and wound healing. In turn, these predispose the patient to a wide range of problems including infection, delayed clinical recovery, increased clinical complications, inactivity, psychological decline and reduced quality of life. As symptoms may be non-specific, the underlying malnutrition may be left undiagnosed. Early nutrition intervention is associated with reduced average length of hospital stay and linked cost savings.

Nutrition screening

Routine screening is recommended by the Malnutrition Advisory Group of the British Association of Parenteral and Enteral Nutrition (BAPEN). This group has worked to promote awareness of the clinical significance of malnutrition and has produced guidelines to monitor and manage malnutrition. A range of screening criteria and tools have been developed and refined to assess nutritional status. Examples include the relatively simple and reproducible body mass index tool with consideration of other key factors (Table 7.1), and the BAPEN 'MUST' tool (Malnutrition Universal Screening Tool; BAPEN, 2003). Body weight should not be used in isolation; significant weight fluctuations may reflect fluid disturbances, and muscle wasting may be due to immobility rather than undernutrition. More complex anthropometry measurements are sometimes indicated to track changes.

Incidence of undernutrition

The incidence of undernutrition in hospitalised patients is not accurately known, although it is estimated as being between 20% and 40%.

Indications for parenteral nutrition (PN)

PN is a nutritionally balanced aseptically prepared or sterile physicochemically stable solution or emulsion for intravenous administration. It is indicated whenever the gastro-intestinal tract is inaccessible, perforated or non-functional or when enteral nutrition is inadequate or unsafe. PN should be considered if the enteral route is not likely to be possible for more

Table 7.1 Body mass index as a screening tool

BMI (kg/m²)	BMI category
<18.5	Underweight
18.5–25	Ideal BMI
25–29.9	Overweight
>30	Obese
Body mass index (BMI) = weight (kg)/height (m)²	

than 5 days. PN may fulfill the total nutritional requirements or may be supplemental to an enteral feed or diet.

The simplest way to correct or prevent undernutrition is through conventional balanced food; however, this is not always possible. Nutritional support may then require oral supplements or enteral tube feeding. Assuming the gut is functioning normally, the patient will be able to digest and absorb their required nutrients. These include water, protein, carbohydrate, fat, vitamins, minerals and electrolytes; however, if the gut is not accessible or functioning adequately to meet the patient's needs, or gut rest is indicated, then PN may be used. While the enteral route is the first choice, this may still fail to provide sufficient nutrient intake in a number of patients. Complications and limitations of enteral nutrition need to be recognised.

A decision pathway can be followed to guide initial and ongoing nutritional support. While many are published, a locally tailored and regularly updated pathway is favoured. A useful starting point may be found at Fig. 7.1.

Close monitoring should ensure the patient's needs are met; a combination of nutrition routes is sometimes the best course. Where possible, patients receiving PN should also receive enteral intake, even minor gut stimulation has been linked with a reduction in the incidence of bacterial translocation through maintaining gut integrity and preventing overgrowth and cholestatic complications. PN should not be stopped abruptly but should be gradually reduced in line with the increasing enteral diet.

Nutrition support teams

A report published by the Kings Fund Report (1992) highlighted the issue of malnutrition both in the hospital and home setting. The findings led to the development of the British Association of Enteral and Parenteral Nutrition (BAPEN) and nutrition support teams throughout the UK. These multidisciplinary nutrition support teams comprise a doctor, nurse, pharmacist and dietitian. They function in a variety of ways, depending on the patient populations and resources. In general, they adopt either a consultative or an authoritative role in nutrition management. Many studies have shown their positive contribution to the total nutritional care of the patient through efficient and appropriate selection and monitoring of feed and route.

Components of a PN regimen

In addition to water, six main groups of nutrients need to be incorporated in a PN regimen (Table 7.2). The aim is to provide appropriate sources and amounts of all the equivalent building blocks in a single daily admixture.

Water volume

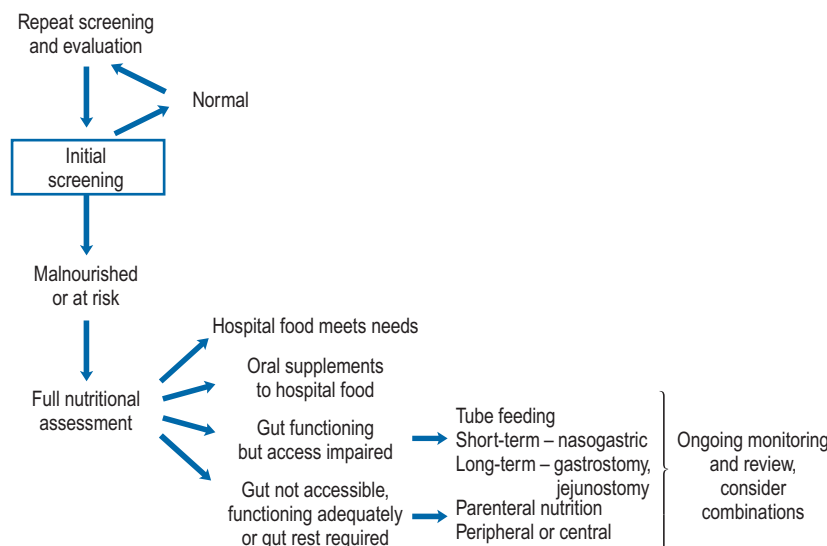
Water is the principal component of the body and accounts for approximately 60% and 55% of total body weight in men and women, respectively. Usually, homeostasis maintains appropriate fluid levels and electrolyte balance, and thirst drives the


Fig. 7.1 Decision pathway to guide initial and ongoing nutritional support.

Table 7.2 Oral and equivalent parenteral nutrition source

Oral diet	Parenteral nutrition source
Water	Water
Protein	L-amino acids mixture
Carbohydrate	Glucose
Fat with essential fatty acids	Lipid emulsions with essential fatty acids
Vitamins	Vitamins
Minerals	Trace elements
Electrolytes	Electrolytes

healthy person to drink; however, some patients are not able physically to respond by drinking and so this homeostasis is ineffective. There is risk of over- or underhydration if the range of factors affecting fluid and electrolyte balance is not fully understood and monitored. In general, an adult patient will require 20–40 ml/kg/day fluid; however, Table 7.3 describes other factors that should be considered in tailoring input to needs.

Amino acids

Twenty L-amino acids are required for protein synthesis and metabolism, and the majority of these can be synthesised endogenously. Eight are called 'essential' amino acids because they cannot be synthesised (isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan and valine). A further group of 'conditionally essential' amino acids (arginine, choline, glutamine, taurine and S-adenosyl-L-methionine) are defined as the patient's needs exceed synthesis in clinically stressed conditions. Also, due to the immature metabolic pathways of neonates, infants and children, some other amino acids are essential in the young patient, and these include histidine, proline, cysteine, tyrosine and taurine. Immature neonatal metabolism does not fully metabolise glycine, methionine, phenylalanine and threonine and so requirements are reduced.

To balance the patient's amino acid requirements and the chemical characteristics of the amino acids (solubility, stability and compatibility), a range of commercially available licensed solutions has been formulated containing a range of amino acid profiles (Table 7.4). Aminoplasmal®, Aminoven, Synthamin® and Vamin® are designed for adult patients. The amino acid profiles of Primene® and Vaminolact® are specifically tailored to neonates, infants and children (reflecting the amino acid profile of maternal cord blood and breast milk, respectively).

L-glutamine was initially excluded from formulations due to its low solubility and relatively poor stability in the aqueous environment; however, it is recognised that there is a clinical need for this amino acid in catabolic stress, and it is now available as an additive (Dipeptiven®) and as an amino acid solution containing a dipeptide form of glutamine (Glamin®) in which the peptide bond cleaves in the blood, releasing free L-glutamine. Research is also considering the rationale and merits of supplementing arginine, glutathione and ornithine α-ketoglutarate.

Table 7.3 Factors affecting fluid requirements

Consider increasing fluid input	Consider reducing fluid input
Signs/symptoms of dehydration	Signs/symptoms of fluid overload
Fever: increased insensible losses from lungs in hyperventilation and from skin in sweating. Allow 10–15% extra water per 10°C above normal	High humidity: reduced rate of evaporation
Acute anabolic state: increased water required for increased cell generation	Blood transfusion: volume input
High environmental temperature or low humidity: increased rate of evaporation	Cardiac failure: may limit tolerated blood volume
	Drug therapy: assess volume and electrolyte content of infused drug
Abnormal GI loss (vomiting, wounds, ostomies, diarrhoea): consider both volume loss and electrolyte content	
Burns or open wound(s): increased water evaporation	
	Renal failure: fluid may accumulate so reduce input accordingly or provide artificial renal support
Blood loss: assess volume lost and whether replaced by transfusion, colloid, crystalloid	

Table 7.4 Examples of amino acid and consequential nitrogen content of licensed amino acid solutions available in the UK

Name	Nitrogen content (g/L)	Electrolytes present
Aminoplasmal® 5% E	8	Potassium, magnesium, sodium and dihydrogen phosphate
Aminoplasmal® 10%	16	
Aminoven® 25	25.7	
Glamin®	22.4	
Hyperamine® 30	30	Sodium
Primene® 10%	15	
Synthamin® 9	9.1	Potassium, magnesium, sodium and acid phosphate
Synthamin® 9 EF	9.1	
Synthamin® 14	14	Potassium, magnesium, sodium and acid phosphate
Synthamin® 14 EF	14	
Synthamin® 17	17	Potassium, magnesium, sodium and acid phosphate
Synthamin® 17 EF	17	
Vamin® 9 Glucose	9.4	Potassium, magnesium, sodium and calcium
Vamin® 14	13.5	Potassium, magnesium, sodium and calcium
Vamin® 14EF	13.5	
Vamin® 18EF	18	
Vaminolact®	9.3	

For adults, PN solutions are generally prescribed in terms of the amount of nitrogen they provide, rounding to the nearest gram; for example, 9, 11, 14 or 18 g nitrogen regimens may be prescribed. Assuming adequate energy is supplied, most adult patients achieve nitrogen balance with approximately 0.2 g nitrogen/kg/day, although care should be taken with overweight patients.

A 24-h urine collection can be used as an indicator of nitrogen loss, assuming all urine is collected and urea or volume output is not compromised by renal failure; however, a true nitrogen output determination requires measurement of nitrogen output from all body fluids, including urine, sweat, faeces, skin and wounds. Nitrogen balance studies can indicate the metabolic state of the patient (positive balance in net protein synthesis, negative balance in protein catabolism).

Urinary urea constitutes approximately 80% of the urinary nitrogen. The universally accepted conversion factor for nitrogen to protein is 1 g nitrogen per 6.25 g of protein.

Amino acid solutions are hypertonic to blood and should not be administered alone into the peripheral circulation.

Energy

Many factors affect the energy requirement of individual patients and these include age, activity and illness (both severity and stage). Predictive formulae can be applied to estimate the energy requirement, for example, the Harris Benedict equation or the more commonly used Schofield equation, which is shown below in Table 7.5.

Alternatively, calorimetry techniques can be used; however, no single method is ideal or suits all scenarios. Often it is found that two methods result in different recommendations. The majority of adults can be appropriately maintained on 25–35 non-protein kcal/kg/day. There is debate over whether to include amino acids as a source of calories since it is simplistic to assume they are either all spared for protein synthesis or fed into the metabolic pathways (Krebs cycle) and contribute to the release of energy-rich molecules. In general, we refer to 'non-protein energy' and sufficient lipid and glucose energy is supplied to spare the amino acids. As a rough guide, the non-protein energy-to-nitrogen ratio is approximately 150:1, although an ideal ratio for all patients has not been absolutely defined. A lower ratio is considered for critically ill patients, while higher ratios are considered for less catabolic patients.

Dual energy

In general, energy should be sourced from a balanced combination of lipid and glucose; this is termed 'dual energy' and is more physiological than an exclusive glucose source. Typically, the fat-to-glucose ratio remains close to the 60:40–40:60 ranges.

Dual energy can minimise the risk of giving too much lipid or glucose since complications increase if the metabolic capacity of either is exceeded. A higher incidence of acute adverse

Table 7.5 Schofield equation

Age (years)	Male	Female
15–18	BMR = 17.6 × weight (kg) + 656	BMR = 13.3 × weight (kg) + 690
18–30	BMR = 15.0 × weight (kg) + 690	BMR = 14.8 × weight (kg) + 485
30–60	BMR = 11.4 × weight (kg) + 870	BMR = 8.1 × weight (kg) + 842
>60	BMR = 11.7 × weight (kg) + 585	BMR = 9.0 × weight (kg) + 656

BMR, basal metabolic rate.

effects is noted with faster infusion rates and higher total daily doses, especially in patients with existing metabolic stress. It is, therefore, essential that the administered dose complements the energy requirements and the infusion rate does not exceed the metabolic capacity.

While effectively maintaining nitrogen balance, lipid inclusion is seen to confer a number of advantages (Box 7.1). Some patients, notably long-term home patients, do not tolerate daily lipid infusions and need to be managed on an individual basis. Depending on the enteral intake and nutritional needs, lipids are prescribed for a proportion of the days. A trial with the newer generation lipid emulsions may be appropriate.

Glucose

Glucose is the recommended source of carbohydrate (1 g anhydrous glucose provides 4 kcal). Table 7.6 indicates the energy provision and tonicity for a range of concentrations. Glucose 5% is regarded as isotonic with blood. The higher concentrations cause phlebitis if administered directly to peripheral veins and should, therefore, be given by a central vein or in combination with compatible solutions to reduce the tonicity.

The glucose infusion rate should generally be between 2 and 4 mg/kg/min. An infusion of 2 mg/kg/min (equating to approximately 200 g (800 kcal) per day for a 70 kg adult) represents the basal glucose requirement, whereas 4 mg/kg/day is regarded as the physiological optimal rate. Higher levels are

tolerated by some patients especially those at home on PN, but monitoring of blood glucose is required at least initially. Care needs to be taken as glucose oxidation occurs, but there is an increased conversion to glycogen and fat. If excess glucose is infused and the glycogen storage capacity exceeded, the circulating glucose level rises, *de novo* lipogenesis occurs (production of fat from glucose) and there is an increased incidence of metabolic complications.

Lipid emulsions

Lipid emulsions are used as a source of energy and for the provision of the essential fatty acids, linoleic and alpha-linolenic acid. Supplying 10 kcal energy per gram of lipid, they are energy rich and can be infused directly into the peripheral veins since they are relatively isotonic with blood.

Typically, patients receive up to 2.5 g lipid/kg/day. For practical compounding reasons, and assuming clinical acceptance, this tends to be rounded to 100 g or 50 g. Details of lipid emulsions available within the UK can be found in Table 7.7.

Lipid emulsions are oil-in-water formulations. Figure 7.2 shows the structure of triglycerides (three fatty acids on a glycerol backbone) and a lipid globule, stabilised at the interface by phospholipids. Ionisation of the polar phosphate group of the phospholipid results in a net negative charge of the lipid globule and an electromechanically stable formulation. The lipid globule size distribution is similar to that of the naturally occurring chylomicrons (80–500 nm), as indicated in Fig. 7.3.

The first-generation lipid emulsions have been in use since the 1970s and utilise soybean oil as the source of long chain fatty acids. More recent research on lipid metabolic pathways and clinical outcomes has indicated that the fatty acid profile of soybean oil alone is not ideal. For example, it is now recognised that these lipid emulsions contain

---

Box 7.1 Examples of the advantages of dual energy systems over glucose-only energy systems

Minimise risk of hyperglycaemia and related complications
Prevent and reverse fatty liver (steatosis)
Reduce carbon dioxide production and respiratory distress
Meet higher calorie requirements of septic and trauma patients when glucose oxidation reduced and lipid oxidation increased
Reduce metabolic stress
Support immune function
Improve lean body mass and reduce water retention
Permit peripheral administration, through reduced tonicity
Facilitate fluid restriction, as lipid is a concentrated source of energy
Are a source of essential fatty acids, preventing and correcting deficiency

---

Table 7.6 Energy provision and tonicity of glucose solutions

Concentration (w/v)	Energy content (kcal/L)	Osmolarity (mOsmol/L)
5%	200	278
10%	400	555
20%	800	1110
50%	2000	2775
70%	2800	3885

Table 7.7 Examples of licensed lipid emulsions available in the UK

Lipid emulsion type	Details of products with kJ per litre
Soybean oil	Intralipid® 10% (4600), 20% (8400), 30% (12600)
Purified olive oil/soybean oil	ClinOleic® 20% (8360)

excess essential polyunsaturated fatty acids, resulting in a qualitative and quantitative compromise to the eicosanoid metabolites that have important roles in cell structure, haemodynamics, platelet function, inflammatory response and immune response.

The molecular structure of the fatty acids has an important impact on the patient's oxidative stress. Two strategies have been applied to overcome this: a reduction in the polyunsaturated fatty acid content through an improved balance of fatty acids or the inclusion of medium chain fatty acids. This has resulted in the development of lipid emulsions that include olive oil (rich in monounsaturated oleic acid and antioxidant α-tocopherol with an appropriate level of essential polyunsaturated fatty acids), fish oil (rich in omega 3 fatty acids) and medium chain triglycerides or structured triglycerides (reduced long chain fatty acid content). Clinical application of these newer lipid emulsions depends upon good clinical studies within the relevant patient population. Such studies should evaluate the efficacy of energy provision and clinical tolerance and report improvements in the eicosanoid-dependent functions or oxidative stress.

Both egg and soybean phospholipids include a phosphate moiety. There is a debate as to whether this is bioavailable.

Therefore, some manufacturers include the phosphate content in their stability calculations, while others do not.

The 20% lipid emulsions are favoured, especially in paediatrics, as they contain less phospholipid than the 10% emulsions in relation to triglyceride provision. If there is incomplete clearance of the infused phospholipids, lipoprotein X, an abnormal phospholipid-rich low-density lipoprotein, is generated and a raised blood cholesterol observed. The incidence of raised lipoprotein X levels is greater with the 10% emulsions as they present proportionally more phospholipid.

Lipid clearance monitoring is particularly important in patients who are at risk of impaired clearance, including those who are hyperlipidaemic, diabetic, septic, have impaired renal or hepatic function or are critically ill (Crook, 2000).

Micronutrients

Micronutrients have a key role in intermediary metabolism, as both co-factors and co-enzymes. For example, zinc is required by over 200 enzyme systems and affects many diverse body functions including acid–base balance, immune function and nucleic acid synthesis. It is evident, therefore, that the availability of micronutrients can affect enzyme activity and total metabolism. When disease increases the metabolism of the major substrates, the requirement for micronutrients is increased. Some of the micronutrients also play an essential role in the free radical scavenging system. These include the following:

- copper, zinc and manganese, in the form of superoxide dismutase, dispose of superoxide radicals
- selenium, in the form of glutathione peroxidase, removes hydroperoxyl compounds
- vitamin C is a strong reducing agent
- vitamins A, E and ß-carotene react directly with free radicals

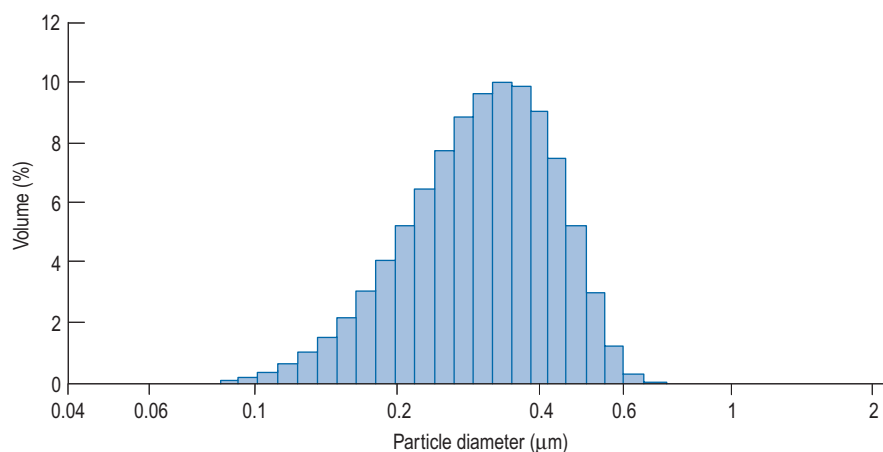
By the time a patient starts PN, they may have already developed a deficiency of one or more essential nutrients. By the time a specific clinical deficiency is observed, for example,


Fig. 7.3 Lipid globule size distribution curve of Ivelip® 20%.

depigmentation of hair in copper deficiency or skin lesions in zinc deficiency, the patient will already have tried to compensate to maintain levels, compromised intracellular enzyme activity and antioxidant systems and expressed non-specific symptoms such as fatigue and impaired immune response. A summary of factors that affect micronutrient needs is presented in Box 7.2.

Measuring blood levels of vitamins and trace elements in acutely ill patients is of limited value. It is recommended that these are measured every 1–6 months depending on levels, and in patients at home on PN (NICE, 2006). Deficiency states are clinically significant but, with non-specific symptoms, they are often difficult to diagnose.

Micronutrient experts prefer to prevent a deficit developing and compromising the clinical state, rather than perform regular monitoring of blood results.

Micronutrients should be included daily from the start of the PN. The requirements are increased during critical illness and in chronically depleted patients. Patients with major burns and trauma or with artificial renal support can quickly become depleted. Their supplementation may influence the outcome of the disease. Even if the patient has reasonable levels and reserves initially, they can quickly become depleted if they are not supported by daily administration. Additional oral or enteral supplements may be considered if there is some intestinal absorption. However, copper deficiency can increase iron absorption and zinc intake can decrease copper absorption.

The micronutrients naturally fall into two groups: the trace elements and vitamins. Micronutrients should be added to all PN infusions under appropriate, controlled, environmental conditions prior to administration (NICE, 2006).

Trace elements

Trace elements are generally maintained at a relatively constant tissue concentration and are present to a level of less than 1 mg/kg body weight. They are essential; deficiency results in structural and physiological disorders which, if identified early enough, can be resolved by re-administration. Ten essential trace elements are known: iron, copper, zinc, fluorine, manganese, iodine, cobalt (or as hydroxycobolamin), selenium, molybdenum and chromium. Adult reference ranges for daily requirements of trace metals can be found in Table 7.8. Currently two preparations are commercially available for adults (Decan®, Additrace®) together with a single paediatric preparation (Peditrace®).

Various recommended baseline doses have been published but no single licensed preparation provides all trace elements at the dose required. Concern over neurotoxicity with accumulated manganese, especially in liver failure, led to a reduction in the advised daily dose and recommendations for plasma monitoring. Recognising the benefits of zinc and selenium on the free radical scavenging system, some specialists advise an increase in the administered dose. Some patients, notably those with burns, renal replacement therapy and/or multiple trauma, as well as long-term patients, may require extra trace elements (Fleming, 1989).

Vitamins

There are two groups of vitamins: the water-soluble vitamins and the fat-soluble vitamins. Fat-soluble vitamins are stored in the body fat, whereas excess water-soluble vitamins are renally cleared; therefore, if there is inadequate provision, deficiency states for the water-soluble vitamins reveal themselves first. The adult reference range for daily requirements of vitamins can be found in Table 7.9. Commercially available preparations are Solivito® N (water soluble), Vitlipid® N Adult/Infant (fat soluble), Cernevit® (water and fat soluble).

In an attempt to reduce the risk of osteoporosis, especially in home PN patients, there have been recent changes to recommended biochemical vitamin D levels (Holick, 2007). Patients on long-term PN should have vitamin D levels measured

Table 7.8 Adult daily reference range for trace elements					
Sex	Age	Iron (µmol/day)	Zinc (µmol/day)	Copper (µmol/day)	Selenium (µmol/day)
Male	19–50+	160	145	19	0.9
Female	19–50	260	110	19	0.8
Female	50+	160	110	19	0.8

Table 7.9   Adult daily reference ranges for vitamins (adapted from Department of Health, 1991)

Sex	Age	Thiamin (mg/day)	Riboflavin (mg/day)	Niacin (mg/day)	Vit B6 (mg/day)	Vit B12 (µcg/day)	Folate (µcg/day)	Vit C (mg/day)	Vit A (µcg/day)	Vit D (µcg/day)
Male	19–50	1.0	1.3	17	1.4	1.5	200	40	700	–
Male	50+	0.9	1.3	16	1.4	1.5	200	40	700	–[a]
Female	19–50	0.8	1.1	13	1.2	1.5	200	40	600	–
Female	50+	0.8	1.1	12	1.2	1.5	200	40	600	–[a]

[a] After age 65, the recommended normal daily intake is 10µcg/day for male and females.

every 6 months. If low, this should be supplemented in order to help protect against osteoporosis which is a well recognised complication of home PN.

Electrolytes

Electrolytes are included to meet the patient's needs. Typical daily parenteral requirements are

- sodium (1–1.5 mmol/kg)
- potassium (1–1.5 mmol/kg)
- calcium (0.1–0.15 mmol/kg)
- magnesium (0.1–0.2 mmol/kg)
- phosphate (0.5–0.7 mmol/kg).

Depending upon the stability of the patient's clinical state, they are kept relatively constant or adjusted on a near daily basis, reflecting changes in blood biochemistry. Tables, for example, British National Formulary can be used to guide electrolyte replacement if there is excessive gastro-intestinal waste or high losses through burns. Hypophosphataemia should be corrected before starting parenteral or enteral nutrition to avoid the refeeding syndrome. Varying amounts of electrolytes are lost from the different gastro-intestinal secretions. Table 7.10 gives an indication of the content of various gastro-intestinal secretions. This should be taken into account when formulating PN for a patient who may have such losses.

Administration of PN

Routes of administration

PN can be administered peripherally or centrally.

Peripheral route

Administration of PN via a peripheral venous catheter should be considered for patients who are likely to need short-term feeding (less than 14 days) and who have no other need for central venous access. Peripheral lines are less costly than central lines and they may be inserted at the bedside providing the patient has good venous access. Ultrasound machines may be used to aid placement. There is no need for a chest X-ray to confirm placement as the line does not reach the central circulation. Mid-lines should be considered which are usually about 20 cm long.

Care should be taken when formulating PN to be administered via a peripheral catheter with regard to the tonicity of the solution.

Some indications and contraindications to the use of the peripheral route are summarised in Box 7.3.

Peripheral administration is sometimes complicated or delayed by phlebitis, where an insult to the endothelial vessel wall causes inflammation, redness, pain and possible extravasation. Hot and cold compresses have been used to treat this. A 5 mg glyceryl trinitrate patch placed where the line tip is estimated to be may cause some local vasodilation which is believed to prevent thrombophlebitis (Khawaja and Williams, 1991). Peripheral tolerance can be influenced by a range of factors (Box 7.4).

Many consider that the tonicity of the infused solution or emulsion is a key factor defining peripheral infusion tolerance. The total number of osmotically active particles in the intracellular and extracellular fluids is essentially the same, approximately 290–310 mOsmol/L. When a lipid emulsion is included, infusions of approximately three times this osmolarity are generally well tolerated via the peripheral route and there are reports of success with higher levels. However, other factors should also be considered. Patient factors, such as vein

---

Box 7.3   Indications and contraindications to the use of peripheral parenteral nutrition

Indications
- Duration of feed likely to be short term
- Supplemental feeding
- Compromised access to central circulation, for example, local trauma, surgery or thrombosis
- No immediate facilities or trained staff to insert central catheter
- High risk of fungal or bacterial sepsis, for example, patients with purulent tracheostomy secretions, immune deficiency state, history of repeated sepsis
- Contraindication to central venous catheterisation

Contraindications
- Inadequate or inaccessible peripheral veins
- Large volumes of administration
- High calorie/nitrogen requirements alongside fluid restrictions (admixture osmolarity too high)

- Aseptic insertion and line care
- Selection of large vessel with good blood flow and direct path, for example, cephalic vein
- Fine-bore catheter (22G) for minimal trauma on insertion and disturbance of blood flow
- Fine polyurethane catheter
- Secure catheter to minimise physical trauma
- Glyceryl trinitrate patch distal to insertion site, over tip to vasodilate vein
- Flushing of lines not in use
- Low-tonicity infusions
- Inclusion of lipid emulsion; venoprotective and isotonic with blood

fragility and blood flow, may mean that some infusion episodes are better tolerated than others. The osmolarity of a PN formulation can be estimated by applying the following equation:

$$= \frac{\sum[\text{osmolarity}_n(\text{mOsmol}/\text{L}) \times \text{volume}_n(\text{L})]}{\text{Total volume(L)}},$$

where n indicates the component.

By considering the macronutrients included in the regimen, that is, the amino acids, glucose and lipid, an estimation of the osmolarity can be made. The value will be increased by electrolyte or micronutrient additions; however, since the peripheral tolerance is affected by so many factors, including tonicity, and because the limit is only an estimate, the effect of these additions is relatively low unless high levels of monovalent ions are included.

Central route

The central venous route is indicated when longer-term feeding is anticipated, high tonicity or large volume formulations are required, or the peripheral route is inaccessible. The rapid and turbulent blood flow in the central circulation and the constant movement of the heart ensure rapid mixing and reduce the risk of osmotically induced injury to the endothelium.

A range of single-, double-, triple- and quadruple-lumen central lines are available and one lumen must be dedicated for the intravenous nutrition. These lines require skilful insertion, usually into the jugular or subclavian vein, and confirmation of their position by X-ray. This relatively invasive and costly procedure is performed by trained medical staff. Tunnelling of the line to an appropriate exit site facilitates line care and may reduce the incidence of significant line sepsis. The femoral route is not favoured due to a higher incidence of sepsis. If cared for well, a tunnelled central line placed in a patient receiving home PN may last for many years.

Peripherally Inserted Central Catheters (PICCs)

PICCs are typically inserted into a peripheral vein, usually the cephalic or basilic in the upper arm, with the exit tip in the superior vena cava just above the right atrium. As the name suggests, they are used for the central administration of infusions. Single- and double-lumen versions are available; some also have a one-way valve to prevent backflow. Insertion is less invasive than for conventional central lines and can be undertaken by trained nurse practitioners at the bedside. A chest X-ray is necessary to confirm placement.

Infusion control

Pumps

PN must always be administered under the control of an infusion pump. Acute overload of fluid, nutrition and electrolytes can have morbid consequences.

Infusion pumps should be used with an appropriate infusion or giving set which is compatible with both the infusion pump and the PN admixture. For home patients, small, simple battery-powered ambulatory pumps are favoured.

Temperature

PN should be at room temperature when it is infused. It must, therefore, be removed from the refrigerator in which it is stored approximately 2h before connection. No external heat should be applied, although intermittent inversion of the bag may help.

If a cold admixture is infused, the patient may experience infusion discomfort, and the acute release of gas from where it was dissolved in the admixture may cause the pump to alarm 'air in line'.

Compounded formulations

Historically, PN was administered from a series of separate bottles, where health care staff had to accurately and safely manage a combination of giving sets, infusion rates and total infusion times. Most patients now receive their complete nutrition from a single daily bag of a pharmaceutically stable PN formulation.

Various terms are used to describe the PN formulation, depending on whether lipid is included. If it contains lipid, it is called a 3-in-1, ternary or all-in-one admixture, if no lipid is present, the terms 2-in-1, binary or aqueous admixture are used. Various methods now exist for compounding PN, these range from high-tech, computer run compounding machines through to basic principle techniques such as gravity filling.

Standardised formulations

Depending on the type (size and specialty) of the hospital, a range of standard formulations are maintained and supported with prescribing guidelines. These may be compounded from scratch, compounded from 'base-bags' locally or by a licensed unit, or purchased as licensed ready-to-use presentations.

The range is specifically selected to meet the needs of the patients managed by the hospital and will typically include a

low-tonicity regimen suitable for peripheral administration, a higher calorie and nitrogen regimen for central administration to catabolic patients and a high-tonicity regimen for fluid-restricted patients. Baseline electrolytes will generally be included, although the flexibility for reduced levels is usually offered.

Licensed ready-to-use products

A range of licensed ready-to-use preparations are available and should have micronutrients added prior to infusing. For convenience, baseline electrolyte levels are included in many formulations and meet the needs of most patients and additional electrolytes may be added up to the limits set by the manufacturer. Electrolyte-free options are also available. Some are licensed for use in paediatrics and/or for peripheral use. Manufacturers advise on stability and shelf-life for electrolyte and micronutrient additions. The range of ready-to-use products includes:

- triple chamber bags (OliClinomel®, Kabiven®, StructoKabiven® and Nutriflex® Lipid ranges): chambers separately pre-filled with lipid, amino acid and glucose and terminally sterilised, these are activated by applying external pressure so weak seal peels open, mixing the contents to form a 3-in-1 formulation.
- dual chamber bags (Clinimix® and Nutriflex® ranges): chambers separately pre-filled with amino acid and glucose and terminally sterilised, these are activated to form a 2-in-1 formulation. They provide the flexibility to allow staff to omit or add a compatible lipid.

The range of commercially available PN formulations is continually expanding. For hospital pharmacies who do not have compounding facilities, this offers an opportunity to ensure the correct formulation is given to meet individual patients needs. PN formulations are now available with micronutrients added and with extended shelf-lives when stored in a refrigerator.

Cyclic infusions

Cyclic PN is when the daily requirements are administered over a short period. A classic example is the stable home patient who administers their feed overnight, freeing themselves from the constraints of an infusion during the day. This enables them to have more physical freedom and improves their quality of life. Some patients, however, prefer to administer their PN during the day time. This is made possible by use of a small ambulatory pump and a back pack in which they may carry their PN.

Since cyclic feeding more closely simulates the human feeding pattern and is a closer match to normal hormonal and metabolic cycles, it also offers a range of metabolic and clinical advantages. Steatosis, fatty infiltration of the liver, is less common and may be corrected by employing cyclic feeding because the feed-free period facilitates lipolysis and fat mobilisation. Peripheral tolerance may be improved as the endothelia recover between infusion periods.

Initially, the patient should receive the PN infusion slowly over the full 24 h, as tolerated, the rate of infusion can be increased slowly to decrease the infusion time. This should be done over a series of days. During this period, the patient must be monitored closely for any signs of fluid, electrolyte or acid-base imbalance and hyper/hypoglycaemia. For example, on stopping the infusion, rebound hypoglycaemia may occur.

Pharmaceutical issues

Having identified the balance of nutrients required for a patient in a single day, it is necessary to formulate a physically and chemically stable aseptically prepared admixture. PN admixtures contain over 50 chemical entities and, as such, are extremely complex and have many chemical interactions taking place which could lead to instability in the final formulation. Professional advice or appropriate reference material should

Table 7.10 Electrolyte content of gastro-intestinal secretions

Intestinal tract locality	Volume (ml)	Sodium (mmol/L)	Potassium (mmol/L)	Chloride (mmol/L)	Bicarbonate (mmol/L)
Saliva	1500	10	25	10	30
Gastric juice (fasting)	1500	60	15	90	15
Pancreatic fistula	700	140	5	75	120
Biliary fistula	500	145	5	100	40
Jejunostomy	2000–3000	110	5	100	30
Ileostomy	500	115	8	45	30
Proximal colostomy	300	80	20	45	30
Diarrhoea	500–1500	120	25	90	45

be sought and used before compounding and administering of PN takes place. Manufacturers and third party experts can advise on stability issues.

Physical stability

Physical instability takes a number of forms including precipitation of crystalline material and breakdown of the lipid emulsion.

Precipitation

Precipitation carries two key risks. First, the potential to infuse solid particles to the narrow pulmonary capillaries may result in fatal emboli. Second, the prescribed nutrients may not be infused to the patient. Clinically dangerous precipitates may not always be visible to the naked eye, especially if lipid emulsion is present. They may also develop over time, and an apparently 'safe' admixture may develop fatal precipitates when in use.

Precipitation of solid is epitomised by the formation of calcium phosphate; this is of special concern in neonatal admixtures where the requirements to prevent hypophosphataemic rickets and severe osteopenia may exceed the safe concentrations. Such concentrations are rarely seen in adult regimens. It is known that calcium and phosphate can form a number of different salt forms each with different solubility profiles, for example, $Ca(H_2PO_4)_2$ which is highly soluble in comparison to $CaHPO_4$ and $Ca_3(PO_4)_2$. $Ca_3(PO_4)_2$ precipitation occurs relatively immediate and has a white, fluffy amorphous appearance; however, $CaHPO_4.2H_2O$ precipitation is time mediated and has a more crystalline appearance.

Factors affecting calcium phosphate precipitation are shown in Table 7.11. Practical measures can be taken to minimise the risks; these include accurate calculation of the proposed formulation, comparison against professionally defined comprehensive matrices and thorough mixing. Solubility curves and algorithms should be used with extreme caution, even if they are quoted for a specific amino acid source, this is because they do not consider all the factors and do not consistently identify risk. Assuming the sodium content can be tolerated, use of an organic phosphate salt form may be beneficial due to the higher solubility of the sodium glycerophosphate salt form.

Trace elements have also been associated with clinically significant precipitation; these include iron phosphate and copper sulphide (hydrogen sulphide from the minor degradation of cysteine/cystine). These very fine precipitate forms are less likely to cause occlusion of catheters or lung capillaries, but have been associated with significant clinical delivery losses when they are taken up by inline filtration devices.

Lipid destabilisation

The oil-in-water lipid emulsions are sensitive to destabilisation by a range of factors including the presence of positively charged ions, pH changes and changes in environmental

Table 7.11   Factors affecting calcium phosphate precipitation

Factor	Mechanism and effect
pH	Low pH supports solubility, whereas a higher pH supports precipitation. Depending on the amount and buffering capacity of the amino acids, this can be affected by different concentrations and sources of glucose solution and acetate salt forms.
Temperature	Higher temperatures associated with greater precipitation, increased availability of free calcium to interact and a shift to the more insoluble salt forms.
Amino acids	Buffer pH changes. Complex with calcium so less available to react with phosphate. Both the source of amino acid and the relative content are important.
Magnesium	Complex with phosphate forming soluble salts rather than less soluble calcium salts.
Calcium salt form	Calcium chloride dissociates more readily than calcium gluconate, releasing it to react with the phosphate.
Phosphate salt form	Monobasic salts, for example, dipotassium phosphate, dissociate more readily than dibasic salts, for example, potassium acid phosphate, releasing phosphate to react with the calcium. Organic salts, such as sodium glycerophosphate and glucose-1-phosphate, are more stable.
Mixing order	Optimum stability achieved by only permitting calcium and phosphate to come together in a large volume admixture. Agitate between additions to avoid pockets of concentration.

temperature. The lipid globules may come together and coalesce to form larger globules and release free oil; this could occlude the lung microvasculature and cause respiratory and circulatory compromise and lead to death.

Positively charged ions destabilise the admixture by drawing the negatively charged lipid globules together, overwhelming the electromechanical repulsion of the charged phospholipids and increasing their tendency to join or coalesce. Divalent and trivalent ions have a more significant effect; therefore, there are tightly defined limits for the amount of Ca^{2+}, Mg^{2+} and Fe^{3+} that can be added to a 3-in-1 admixture. Although the limits for the other polyvalent ions (such as zinc and selenium) are also controlled, because they are given in micromolar or nanomolar quantities, they are less of a problem. Low concentrations of amino acids and extremes of glucose

concentration (high and low) also reduce the stability of the emulsion and increase the tendency for creaming and cracking of the lipid emulsion.

The naked eye can identify large-scale destabilisation, as shown in Table 7.12; however, the limitations of this method need to be recognised; clinically significant destabilisation might not be visible to the naked eye. In practice, stability laboratories use specialised technical equipment to determine defined criteria so as to establish the physical stability of a formulation. These tests include assessing changes in lipid globule size distribution with optical microscopes, and variety of particle size analysis instruments against the defined limits of pharmaceutical acceptance. A wide safety margin is applied.

Chemical stability

Chemical stability takes many forms, notably chemical degradation of the vitamins and amino acids.

Vitamin stability

Many vitamins readily undergo chemical degradation, and vitamin stability often defines the shelf-life of a given formulation.

Vitamin C (ascorbic acid), the least stable component, is generally regarded as the marker for vitamin degradation. Vitamin C oxidation is accelerated by heat, oxygen and certain trace elements, including copper. Other examples include vitamin A photolysis and vitamin E photo-oxidation. Measures that minimise oxygen presence, such as minimal aeration during compounding, evacuation of air at the end of compounding and use of multi-laminated oxygen barrier bags, and light protection of admixture containers and delivery sets are recommended.

Amino acid stability

The amino acid profile should be maintained for the shelf-life of the formulation and manufacturers perform assays to confirm this prior to issuing stability reports.

Maillard reaction

The Maillard reaction is a complex pathway of chemical reactions that starts with a condensation of the carbonyl group of the glucose and the amino group of the amino acid. At present, relatively little is known about the clinical effects of these Maillard reaction products; however, it is prudent to minimise their presence by protecting from light and avoiding high temperatures.

Microbial contamination

PN is a highly nutritious medium whose hypertonicity will partially limit microbial growth potential. Growth in the presence of lipid emulsion is greater. Pharmaceutical developments have enabled terminal sterilisation of many of the components, including the multi-chamber bag presentations; however, additional manipulations should only be performed using validated aseptic techniques in appropriate pharmaceutically clean environments by suitably trained staff. Nurses, patients and carers must be trained to apply aseptic methods when connecting and disconnecting infusions, for this reason, many centres have documented line care and PN protocols.

Shelf-life and temperature control

The manufacturer may be able to provide physical and chemical stability data to support a formulation for a shelf-life of up to 90 days at 2–8°C followed by 24 h at room temperature for infusion; this assumes that a strict aseptic technique is used during compounding. Units holding a manufacturing license covering aseptic compounding of PN are potentially able to assign this full shelf-life (if stability data is available), whilst unlicensed units are limited to a maximum shelf-life of 7 days.

PN must be stored and transported within the defined temperature limits and should not be exposed to temperature cycling (e.g. the formulations must not freeze); for this reason, a validated cold-chain must be employed especially when delivering formulations to home care patients. Pharmaceutical-grade fridges should be used and monitored

Table 7.12 Lipid instability		
	Description	Visual observation
Stable, normal emulsion	Lipid globules equally dispersed. Suitable for administration	Normal emulsion
Light creaming	Lipid globules rising to the top of the bag. Slight layering visible. Readily redisperses on inverting the bag. Suitable for administration	Light creaming
Heavy creaming, flocculation	Lipid globules coming together but not joining. Rising to the top of the bag. More obvious layering visible. Readily redisperses on inverting the bag. Acceptable for administration	Heavy creaming
Coalescence	Lipid globules come together, coalesce to form larger globules and rise to the surface. Larger globules join, releasing free oil. Irreversible destabilisation of the lipid emulsion. Not suitable for administration	Cracked. Oil layer viewed close up

to ensure appropriate air cycling and temperature maintenance. The temperature during the infusion period should be known with neonatal units and their patient incubators classically maintained at higher temperatures; therefore, formulations used for this environment must have been stability-validated at these temperatures.

Drug stability

The addition of drugs to PN admixtures, or Y-site co-administration, is actively discouraged unless the compatibility has been formally confirmed. Wherever possible, the PN should be administered through a dedicated line. Multilumen catheters can be used to infuse PN separately from other infusion(s); however, extreme competition for intravenous access may prompt consideration of drug and PN combinations. Many factors need to be considered: the physical and chemical stability of the PN, the physical and chemical stability of the drug, the bioavailability of the drug (especially when a lipid emulsion is present) and the effect of stopping and starting Y-site infusions on the actual administration rates. It is not possible to reliably extrapolate data from a specific PN composition, between brands of solutions and salt forms or between brands or doses of drugs. A range of studies has been performed and published; however, these should be used with caution.

In practice, drugs should only be infused with PN when all other possibilities have been exhausted. These may include gaining further intravenous access and changing the drug(s) to clinically acceptable non-intravenous alternatives. The relative risks of stopping and starting the PN infusion and repeatedly breaking the infusion circuit should be fully considered before sharing a line for separate infusions of PN and drug. In most cases, the risks outweigh the benefits; however, if this option is adopted, the line must be flushed before and after with an appropriate volume of solution known to be stable with both the PN and the drug. Strict aseptic technique should be adopted to minimise the risk of contaminating the line and infusions.

Filtration

All intravenous fluids pass through the delicate lung microvasculature with its capillary diameter of 8–12 μm. The presence of particulate matter has been demonstrated to cause direct embolisation, direct damage to the endothelia, formation of granulomata and formation of foreign body giant cells, and to have a thrombogenic effect. In addition, the presence of microbial and fungal matter can cause a serious infection or inflammatory response.

Precautions taken to minimise the particulate load of the compounded admixture must include:

- use of filter needles or straws (5 μm) during compounding to catch larger particles such as cored rubber from bottles and glass shards from ampoules
- air particle levels kept within defined limits in aseptic rooms by the use of air filters and non-shedding clothing and wipes

- use of quality raw materials with minimal particulate presence, including empty bags and leads
- confirmation of physical and chemical stability of the formulation prior to aseptic compounding applying approved mixing order (stability for the required shelf-life time and conditions)

Guidelines have been published that endorse the use of filters, especially for patients requiring intensive or prolonged parenteral therapy, including home patients, the immuno-compromised, neonates and children (Bethune et al., 2001). The filter should be placed as close to the patient as possible and validated for the PN to be used. For 2-in-1 formulations, 0.2 μm filters may be used, for 3-in-1 formulations, validated 1.2 μm filters may be used.

Light protection

It is widely recognised that exposure to light, notably phototherapy light and intense sunlight, may increase the degradation rate of certain constituents such as vitamins A and E. It is recommended that all regimens should be protected from light both during storage and during infusion, since

- the presence of a lipid emulsion does not totally protect against vitamin photodegradation
- the Maillard reaction is influenced by light exposure
- ongoing research suggests lipid peroxidation is accelerated by a range of factors, including exposure to certain wavelengths of light
- validated bag and delivery set covers should only be used

Nutritional assessment and monitoring

Initial assessment

Once screening has identified that a patient is in need of nutritional intervention, a more detailed assessment is performed; this will include an evaluation of nutritional requirements, the expected course of the underlying disease, consideration of the enteral route and, where appropriate, identification of access routes for PN. This will be supported by a clinical assessment that will include:

- clinical history
- dietary history
- physical examination
- anthropometry including muscle function tests
- biochemical, haematological and immunological review.

Monitoring

PN monitoring has a number of objectives. It should

- evaluate ongoing nutritional requirements, including fluid and electrolytes
- determine the effectiveness of the nutritional intervention

- facilitate early recognition of complications
- identify any deficiency, overload or toxicity to individual nutrients
- determine discrepancies between prescribed, delivered and received dose.

Regular monitoring contributes to the success of the PN and a monitoring protocol should be in place for each individual patient. Baseline data should be recorded so deviations can be recognised and interpreted. In the early stages, while the patient is in the acute stage of their illness and the nutritional requirements are being established, the frequency of monitoring will be greatest. Some tests may be defined by the underlying disease state, rather than by the presence of PN *per se*. As the patient's status stabilises, the frequency of monitoring will reduce, although the range of parameters monitored is likely to increase. Examples of parameters monitored include the following:

- *Clinical symptoms or presentation:* may be specific, for example, thrombophlebitis, or non-specific, for example, confusion.
- *Temperature, blood pressure and pulse:* vigilance for the risk of sepsis.
- *Fluid balance and weight:* acute weight changes reflect fluid gain or loss and prompt review of the volume of the PN. Slow, progressive changes are more likely to reflect nutritional status.
- *Nitrogen balance:* an assessment of urine urea and insensible loss and their relation to nitrogen input. It is difficult to obtain accurate figures.
- *Visceral proteins*: albumin levels may indicate malnutrition but its long half-life limits sensitivity to detect acute changes in nutritional status. Other markers with a shorter half-life may be more useful, for example, transferrin.
- *Haematology:* platelet counts and clotting studies for thrombocytopenia.
- *C-reactive protein:* monitor the inflammatory process.
- *Blood glucose:* hyperglycaemia is a relatively frequent complication. Management includes either a reduction in the infused dose or lengthening of the infusion period. If these measures fail, insulin may be used. Hyperglycaemia may also indicate sepsis. Rebound hypoglycaemia can occur when an infusion is stopped. If this is a problem, the infusion should be tapered off during the last hour or two of the infusion. Some infusion pumps are programmed to do this automatically.
- *Lipid tolerance:* turbidity, cholesterol and triglyceride profiles required.
- *Electrolyte profile:* indicates appropriate provision or complicating clinical disorder. In the first few days, low potassium, magnesium and/or phosphate with or without clinical symptoms may reflect the refeeding syndrome (see below).
- *Liver function tests:* an abnormal liver profile may be observed and it is often difficult to identify a single cause. PN and other factors such as sepsis, drug therapy and underlying disease may all interplay. In adults,

PN-induced abnormalities tend to be mild, reversible and self-limiting. In the early stages, fatty liver (steatosis) is seen. In longer-term patients, a cholestatic picture tends to present. Varying the type of lipid used and removing lipid from some formulations may be of benefit.

- *Anthropometry:* assesses longer-term status.
- *Acid–base profile:* indicative of respiratory or metabolic compromise and may require review of PN formulation.
- *Vitamin and trace element screen:* a range of single compounds or markers to consider tolerance and identify deficiencies, although of limited value as some tests are non-specific and inaccurate.
- *Catheter entry site:* vigilance for phlebitis, erythema, extravasation, infection, misplacement.

Complications

Complications of PN fall into two main categories: catheter-related and metabolic (Box 7.5). Overall, the incidence of such complications has reduced because of increased knowledge and skills together with more successful management (Maroulis and Kalfarentzos, 2000).

Line sepsis

This is a serious and potentially life-threatening condition. Monitoring protocols should ensure that signs of infection are identified early and a local decision pathway should be in place to guide efficient diagnosis and management. Management will depend upon the type of line and the source of infection. Alternative sources of sepsis should be considered. Initially, the PN is usually stopped.

Box 7.5   Examples of complications during parenteral nutrition

Catheter-related
- Thrombophlebitis (peripheral)
- Catheter-related infection, local or systemic
- Venous thrombosis
- Line occlusion (lipid, thrombus, particulate, mechanical)
- Pneumothorax, catheter malposition, vessel laceration, embolism, hydrothorax, dysrhythmias, incorrect placement (central)

Metabolic
- Hyperglycaemia or hypoglycaemia
- Electrolyte imbalance
- Lipid intolerance
- Refeeding syndrome
- Dehydration or fluid overload
- Specific nutritional deficiency or overload
- Liver disease or biliary disease
- Gastro-intestinal atrophy
- Metabolic bone dysfunction (in long term)
- Thrombocytopenia
- Adverse events with parenteral nutrition components
- Essential fatty acid deficiency

Line occlusion

Line occlusion may be caused by a number of factors, including:

- fibrin sheath forming around the line, or a thrombosis blocking the tip
- internal blockage of lipid, blood clot or salt and drug precipitates
- line kinking
- particulate blockage of a protective line filter.

Management will depend on the cause of the occlusion; in general, the aim is to save the line and resume feeding with minimum risk for the patient. The use of locks and flushes with alteplase (for fibrin and thrombosis), ethanol (for lipid deposits) and dilute hydrochloric acid (for salt and drug precipitates) may be considered. In some cases, the lines may need to be replaced.

These complications can be minimised by having a dedicated line for PN, flushing the line well with sodium chloride 0.9% before and after use and a regular slow flush of ethanol 20% may be used to prevent lipid deposition.

Refeeding syndrome

Patients should be assessed as to their risk of developing refeeding syndrome (see Table 7.13). Refeeding syndrome can be defined as 'the potentially fatal shifts in fluids and electrolytes that may occur in malnourished patients receiving nutrition'. Undernourished patients are catabolic and their major sources of energy are fat and muscle. As the PN infusion (which contains glucose) starts, this catabolic state is pushed to anabolic which in turn causes a surge of insulin. As the insulin levels increase, there is an intracellular shift of magnesium, potassium and phosphate, and acute hypomanganesaemia, hypokalaemia and hypophosphataemia result. This can cause cardiac and neurological dysfunction and may be fatal. PN should be gradually increased over a period of 2–7 days depending on the patient's body mass index and risk of developing refeeding syndrome. Oral thiamine and vitamin B compound strong or full dose intravenous vitamin B preparation may be administered before PN is started and for the first few days of infusion.

Table 7.13   Risk factors for developing refeeding syndrome (NICE, 2006)

One or more of the following:	Two or more of the following:
BMI <16 kg/m^2	BMI <18.5 kg/m^2
Unintentional weight loss greater than 15% within the last 3–6 months	Unintentional weight loss greater than 10% within the last 3–6 months
Little or no nutritional intake for more than 10 days	Little or no nutritional intake for more than 5 days
Low levels of potassium, phosphate or magnesium prior to feeding	A history of alcohol abuse or drugs including insulin, chemotherapy, antacids or diuretics

Specific disease states

Liver

Although abnormal liver function tests associated with short-term PN are usually benign and transient, liver dysfunction in long-term PN patients is one of the most prevalent and severe complications. Its underlying pathophysiology, however, largely remains to be elucidated. The content of PN should be examined and care should be taken not to overfeed with glucose and/or lipid. Supplementation with taurine in the formulation has been reported to ameliorate PN associated cholestasis through promoted bile flow. Various lipid preparations are now available, including preparations containing fish oils which have been reported to be beneficial in reversing liver disease (De Meijer et al., 2009). Lipid emulsions containing a mix of medium and long chain triglycerides are also available and have an improved liver tolerability. Due to the complexity of liver function, the range of potential disorders and its role in metabolism, the use of PN in liver disease is not without problems. Consensus guidelines for the use of PN in liver disease have been published (Plauth et al., 2009). Nutritional intervention may be essential for recovery, although care must be exercised with amino acid input and the risk of encephalopathy, calorie input and metabolic capacity, and the reduced clearance of trace elements such as copper and manganese (Maroulis and Kalfarentzos, 2000). Low-sodium, low-volume feeds are indicated if there is ascites. Cyclic feeding appears useful, especially in steatosis.

Renal failure

Fluid and electrolyte balance demand close attention, and guidelines for nutrition in adult renal failure are available (Cano et al., 2009). A low volume and poor quality urine output may necessitate a concentrated PN formulation with a reduction in electrolyte content, particularly a reduction in potassium and phosphate. In the polyuric phase or the nephrotic syndrome, a higher volume formulation may be required. If there is fluid retention, ideal body weight should be used for calculating requirements rather than the actual body weight.

The metabolic stress of acute renal failure and the malnutrition of chronic renal failure may initially demand relatively high nutritional requirements; however, nitrogen restriction may be necessary to control uraemia in the absence of dialysis or filtration and to avoid uraemia-related impaired glucose tolerance, because of peripheral insulin resistance, and lipid clearance.

Micronutrient requirements may also change in renal disease. For example, renal clearance of zinc, selenium, fluoride and chromium is reduced and there is less renal 1α-hydroxylation of vitamin D.

Intradialytic PN (IDPN) may be administered at the same time as dialysis; however, this is not without complications. High blood sugars and fluid overload can be a problem and there is uncertainty as to how much of the PN is

retained by the body and how much is removed by dialysis. Administration requires local guidelines and monitoring to be in place (Foulks, 1999; Lazarus, 1999).

Pancreatitis

Acute pancreatitis is a metabolic stress that requires high-level nutritional support and pancreatic rest to recover. Guidelines for nutrition in acute pancreatitis are available (Gianotti et al., 2009). While enteral nutrition stimulates the pancreas, PN does not appear to. Hyperglycaemia may occur and require exogenous insulin.

Sepsis and injury

Significant fluctuations in macronutrient metabolism are seen during sepsis and injury. There are two metabolic phases: the 'ebb' phase of 24–48 h and the following 'flow' phase. The initial hyperglycaemia, reflecting a reduced utilisation of glucose, is followed by a longer catabolic state with increased utilisation of lipid and amino acids. The effect of the different lipid emulsions on immune function is the subject of much research. It is important not to overfeed and also to consider the reduced glucose tolerance during the critical days. This is due to increased insulin resistance and incomplete glucose oxidation. Exogenous insulin may be required.

Respiratory

While underfeeding and malnutrition can compromise respiratory effort and muscle function, overfeeding can equally compromise respiratory function due to increased carbon dioxide and lipid effects on the circulation. While chronic respiratory disease may be linked with a long-standing malnutrition, the patient with acute disease will generally be hypermetabolic.

Cardiac failure

Cardiac failure and multiple drug therapy may limit the volume of PN that can be infused. Concentrated formulations are used and, as a consequence of the high tonicity, administered via the central route. Close electrolyte monitoring and adjustment is required. Cardiac drugs may affect electrolyte clearance. Although central lines may already be in use for other drugs or cardiac monitoring, it is essential to maintain a dedicated lumen or line for the feed.

Diabetes mellitus

Diabetic patients can generally be maintained with standard dual-energy regimens. It is important to use insulin to manage blood glucose rather than reduce the nutritional provision of the feed. Close glucose monitoring will guide exogenous insulin administration. This should be given as a separate infusion (sliding scale) or, if the patient is stable, in bolus doses. Insulin should not be included within the PN formulation due to stability problems and variable adsorption to the equipment. Y-site infusion with the PN should be avoided as changes in insulin rates will be delayed and changes in feed rates will result in significant fluctuations in insulin administration. Extra potassium and phosphate may be required due to the impact of the glucose and insulin. Long-term PN patients may need differing insulin regimes depending on the glucose load (aqueous/lipid) in the formulation. Although using oral antihypoglycaemic agents with PN may be considered, care should be taken as to the potentially erratic absorption and so varying blood glucose levels.

Cancer and palliative care

Nutritional support in cancer and palliative care is guided by the potential risks and benefits of the intervention, alongside the wishes of the patient and their carers. Further research is required to evaluate the effects of PN on length and quality of life.

Standard PN may be useful during prolonged periods of gastro-intestinal toxicity, as in bone marrow transplant patients. The use of PN is not thought to stimulate tumour growth (Nitenberg and Raynard, 2000).

Short bowel syndrome

The small intestine is defined as 'short' if it is less than 100 cm. Treatment options depend upon which part of the gut has been removed and the functional state of the remaining organ. The surface area for absorption of nutrition and reabsorption of fluid and electrolytes is significantly compromised. Fluid and electrolyte balance needs to be managed closely due to the high-volume losses. High-volume PN formulations with raised electrolyte content (notably sodium and magnesium) may be required. Vitamin and trace element provision is very important.

Long-term PN

Home care is well established in the UK, with some patients successfully supported for over 20 years. Total or supplemental PN may be appropriate. Trace elements, notably selenium, should be managed closely as requirements may be increased.

Most patients are extremely well informed about their underlying disease and their PN; many also benefit from support group PINNT (Patients on Intravenous and Nasogastric Nutrition Therapy) and LITRE (Looking into the Requirements for Equipment), a standing committee of BAPEN which looks at equipment issues.

There are an increasing number of patients at home on PN. Scotland and Wales now have designated networks to care for these patients. Many patients are trained to connect and disconnect their PN and to care for their central lines. Patients are encouraged to lead as active and normal life as possible. Foreign travel is now possible for patients on home PN, as are most other normal daily activities and sports (Staun et al., 2009).

Paediatric PN

Nutritional requirements

Early nutritional intervention is required in paediatric patients due to their low reserve, especially in neonates. Where possible, premature neonates should commence feeding from day 1. In addition to requirements for the maintenance of body tissue, function and repair, it is also important to support growth and development, especially in the infant and adolescent.

Typical guidelines for average daily requirements of fluid, energy and nitrogen are shown in Table 7.14. The dual-energy approach is favoured in paediatrics. Approximately 30% of the non-protein calories are provided as lipid using a 20% emulsion. Most centres gradually increase the lipid provision from day 1 from 1 g/kg/day to 2 g/kg/day and then 3 g/kg/day, monitoring lipid clearance through the serum triglyceride level. This ensures the essential fatty acid requirements of premature neonates are met.

Formulation and stability issues

Many centres use standard PN formulations including the specific paediatric amino acid solutions (Primene® or Vaminolact®). Prescriptions and formulations are tailored to reflect clinical status, biochemistry and nutritional requirements.

Micronutrients are included daily. Paediatric licensed preparations are available and are included on a ml/kg basis up to a maximum total volume (Peditrace®, Solivito® N and Vitlipid® N Infant). Electrolytes are also monitored and included in all formulations on a mmol/kg basis. Acid–base balance should be considered. Potassium and sodium acetate salt forms are used in balance with the chloride salt forms in neonatal formulae to avoid excessive chloride

Table 7.14 Suggested paediatric daily PN requirements (adapted from Koletzko et al., 2005)

		Day 1	Day 2	Day 3	Day 4	Na⁺	K⁺	Ca²⁺	Mg²⁺
		\>1 month but <10 kg				mmol/kg/day			
Fluid requirement	100 ml/kg								
						3	2.5	0.6	0.1
Nitrogen	g/kg	0.15	0.2	0.3	0.4				
Glucose	g/kg	10	12	14	16				
Lipid	g/kg	1	2	2	3				
Phosphate[a]	mmol/kg/day	0.5	0.58	0.58	0.6				
		10–15 kg							
Fluid requirement	1000 ml + 50 ml/kg for each kg above 10 kg								
						3	2.5	0.2	0.07
Nitrogen	g/kg	0.15	0.2	0.3	0.3				
Glucose	g/kg	6	8	10	12				
Lipid	g/kg	1.5	2	2.5	2.5				
Phosphate[a]	mmol/kg/day	0.23	0.27	0.3	0.3				
		16–20 kg							
Fluid requirement	1000 ml + 50 ml/kg for each kg above 10 kg								
						3	2	0.2	0.07
Nitrogen	g/kg	0.15	0.2	0.3	0.3				
Glucose	g/kg	4	6	8	10				
Lipid	g/kg	1.5	2	2	2				
Phosphate[a]	mmol/kg/day	0.22	0.26	0.26	0.26				

Table 7.14 Suggested paediatric daily PN requirements (adapted from Koletzko et al., 2005)—Cont'd

21–30 kg								
Fluid requirement	1500 ml + 20 ml/kg for each kg above 20 kg							
					3	2	0.2	0.07
Nitrogen	g/kg	0.2	0.3	0.3				
Glucose	g/kg	4	6	8				
Lipid	g/kg	1	2	2				
Phosphate[a]	mmol/kg/day	0.18	0.26	0.26				
>30 kg								
Fluid requirement	1500 ml + 20 ml/kg for each kg above 20 kg							
					3	2	0.2	0.07

Glucose	g/kg	3	5					
Lipid	g/kg	1	2					
Phosphate[a]	mmol/kg/day	0.18	0.25					

[a]includes phosphate from lipid emulsion and Vitlipid® preparations.

input contributing to acidosis (acetate is metabolised to bicarbonate, an alkali). In the initial stages, neonates tend to hypernatraemia due to relatively poor renal clearance; this should be reflected in the standard formulae used.

Due to the balance of nutritional requirements, a relatively high glucose requirement with high calcium and phosphate provision, the neonatal and paediatric prescription may be supplied by a separate 2-in-1 bag of amino acids, glucose, trace elements and electrolytes and a lipid syringe with vitamins. These are generally given concurrently, joining at a Y-site. Older children can sometimes be managed with 3-in-1 formulations. A single infusion is particularly useful in the home care environment. Some ready-to-use formulations are licensed for use in paediatrics and include the Kabiven® and OliClinomel® range.

Improved stability profiles with the new lipid emulsions, and increasing stability data, may support 3-in-1 formulations that meet the nutritional requirements of younger children.

Concerns over the contamination of calcium gluconate with aluminium and the association between aluminium contamination of neonatal PN and impaired neurological development have favoured the use of calcium chloride over gluconate; however, chloride load should be considered if the former is used. If calcium gluconate is to be used it must be from plastic containers.

Heparin

Historically, low concentrations of heparin were included in 2-in-1 formulations in an attempt to improve fat clearance through enhanced triglyceride hydrolysis, prevent the formation of fibrin around the infusion line, reduce thrombo-sis and reduce thrombophlebitis during peripheral infusion; however, this is no longer recommended. It is recognised that when the 2-in-1 formulation comes into contact with the lipid phase, calcium-heparin bridges form between these lipid globules, destabilising the formulation. Also, there is limited evidence of clinical benefit of the heparin inclusion.

Route of administration

Peripheral administration is less common in neonates and children due to the risk of thrombophlebitis; however, it is useful when low-concentration, short-term PN is required and there is good peripheral access. The maximum glucose concentration for peripheral administration in paediatrics is generally regarded to be 12%. However, considering all the other factors that can affect the tonicity of a regimen and peripheral tolerance, it is clear that this is a relatively simplistic perspective. Many centres favour a limit of 10% with close clinical observation.

Central administration is via a PICC, a long-term tunnelled central line, a jugular or subclavian line. Femoral lines are a less preferred option owing to their location and, therefore, high risk of becoming infected.

Case study

Case 7.1

Mrs B, aged 47, was admitted for investigation of chronic diarrhoea and 6 kg weight loss over the past 3 months.
See Table 7.15.

Table 7.15   Clinical details for Case 7.1

Day	Clinical observation/event	PN changes
1	Admitted to gastroenterology ward from clinic for investigation of chronic diarrhoea and weight loss. Current weight 49 kg, height 1.65 m. Usual weight 55 kg, 1.65 m. Estimated current energy requirement 1500 kcal.	
2	Contrast study revealed intestinal fistula between small bowel and transverse colon. Diarrhoea approx. 1.5 L/day.	
3	Case discussed with surgeons. For PN for 2–3 weeks prior to surgery to improve nutritional status. Patient made 'nil by mouth'. Central line inserted for PN use only.	PN prescribed (considering both fluid and electrolytes from other therapies, and potassium loss from diarrhoea of approx. 30–70 mmol/L): Volume 2 L, nitrogen 9 g, carbohydrate 400 kcal, lipid 550 kcal, Na^+ 230 mmol, K^+ 80 mmol, Ca^{2+} 5 mmol, Mg^{2+} 11 mmol, phosphate 35 mmol and micronutrients added (daily).
4	Biochemistry results: Na^+ 129 mmol/L (135–145 mmol/L), K^+ 3.2 mmol/L (3.4–5.0 mmol/L), urea 6.9 mmol/L (3.1–7.9 mmol/L), Cr 86 μmol/L (75–1550 μmol/L), corr Ca^{2+} 2.3 mmol/L (2.12–2.60 mmol/L), Mg^{2+} 0.75 mmol/L (0.7–1.0 mmol/L), phosphate 0.85 mmol/L (0.80–1.44 mmol/L). Temperature/pulse/respiration normal, diarrhoea losses reduced to 800 mL/day.	Regimen unchanged.
5	Biochemistry results: Na^+ 132 mmol/L, K^+ 3.1 mmol/L, urea 4.3 mmol/L, Cr 85 μmol/L, corr Ca^{2+} 2.2 mmol/L, Mg^{2+} 0.50 mmol/L, phosphate 0.60 mmol/L	PN regimen unchanged. Additional 20 mmol Mg^{2+} prescribed in 500 mL of saline infused over 6 h.
6	Biochemistry results: Na^+ 138 mmol/L, K^+ 3.5 mmol/L, urea 3.0 mmol/L, Cr 86 μmol/L, corr Ca 2.2 mmol/L, Mg^{2+} 0.78 mmol/L, phosphate 0.9 mmol/L. Diarrhoea reduced to 500 mL/day.	PN regimen changed to: Volume 2 L, nitrogen 11 g, carbohydrate 800 kcal, lipid 800 kcal, Na^+ 100 mmol, K^+ 80 mmol, Ca^{2+} 5 mmol, Mg^{2+} 15 mmol, phosphate 40 mmol.
7	Biochemistry results: Na^+ 139 mmol/L, K^+ 4.1 mmol/L, urea 2.8 mmol/L, Cr 78 μmol/L, Mg^{2+} 0.95 mmol/L, phosphate 1.3 mmol/L.	K^+ reduced to 60 mmol, Mg^{2+} reduced to 10 mmol, phosphate reduced to 30 mmol.

Questions

1. Calculate Mrs B's current body mass index (BMI)
2. Why were the calories provided in the initial bags less than Mrs B's requirements?
3. Why should potassium, magnesium and phosphate levels be monitored closely and explain a possible reason for the slight drop in these biochemical values on day 5?
4. Explain why the amounts of sodium and potassium were chosen in the initial formulation.
5. What additional vitamin should have been prescribed prior to PN starting?
6. Why was no extra magnesium given in the PN on day 5?
7. How much nutrition can be provided to promote weight gain and how could this be provided?

Answers

1. 18 kg/m^2.
2. Mrs B's significant weight loss, low BMI and likely malabsorption place her at risk of refeeding syndrome. An initial maximum rate of 10–20 kcal/kg is recommended. In practice, this is often achieved by administering half the patient's nutritional requirements over 24 h; however, the provision of adequate quantities of magnesium, potassium and phosphate can be problematic. It is also essential that sufficient micronutrients are provided, especially thiamine, to ensure effective metabolism of the macronutrients provided.
3. Potassium, magnesium and phosphate are all driven intracellularly during the refeeding response.
4. In 1500 mL of diarrhoea, Mrs B will lose approximately 180 mmol sodium and 38 mmol potassium; this should be added

to her basic requirements of 50 mmol sodium and 50 mmol potassium.

5. Oral thiamine or full dose intravenous vitamin B should have been prescribed to minimise the risk of refeeding syndrome.

6. Extra magnesium could not be added to the regimen on day 5 due to the stability limits for the regimen prescribed. The lipid content of the regimen places tight limits on the divalent ion content. This can be overcome by using lipid-free regimens, but this must be considered in the context of the patient's long-term nutritional plan.

7. Mrs B's predicted basic metabolic rate is only 1250 kcal. Allowing for activity, energy expenditure can be expected to increase to 1500 kcal. The provision of additional calories to promote weight gain is only appropriate if the patient is in an anabolic state and able to utilise the additional energy and nitrogen effectively to gain functional tissue. Excessive calorie intake in the face of ongoing catabolism is most likely to increase metabolic stress and increase the risk of complications such as abnormal LFTs. An additional 400–1000 kcal/day is considered sufficient to promote weight gain. The increased calories can be provided within a 3-in-1 regimen but care should be taken not to exceed the predicted glucose oxidation rate or lipid intake of 1.5 g/kg/day.

8 Pharmacoeconomics

J. Cooke

Key points

- Expenditure on medicines is increasing at a greater rate than other health care costs.
- Increasingly governments are employing health economics to help prioritise between different medicines and other health technologies.
- In health economics, consequences of a treatment can be expressed in monetary terms (cost–benefit), natural units of effectiveness (cost-effectiveness) and in terms of patient preference or utility (cost–utility).
- Head-to-head studies offer the best way of determining overall effectiveness and cost-effectiveness.
- Sensitivity analysis can be used to address areas of uncertainty.
- Medication non-adherence, medication errors and unwanted drug effects place a considerable burden on societal health care costs.
- Decision analysis techniques offer a powerful tool for comparing alternative treatment options.

The demand for and the cost of health care are growing in all countries. Many governments are focusing their activities on promoting the effective and economic use of resources allocated to health care. The increased use of evidence-based programmes not only concentrates on optimizing health outcomes but also utilises health economic evaluations.

While there have been marked gains in life expectancy in those countries which make up the Organization for Economic Co-operation and Development (OECD), health costs have also risen in all of them. The USA spent 16% of its national income (gross domestic product, GDP) on health in 2007, a value considerably greater than many other OECD countries (Fig. 8.1).

Medicines form a small but significant proportion of total health care costs; this has been increasing consistently as new medicines are marketed. For example, the overall NHS expenditure on medicines in England in 2008 was £11.6 billion. Primary care expenditure was £8.1 million and hospital use accounted for 28.7% of the total cost at £3.3 million, up from 25.8% in 2007. The cost of medicines has increased by 3.4% overall and by 15.2% in hospitals.

Most OECD countries have seen growth in spending on medicines outstrip growth in total health spending over this period. In the USA and Australia, pharmaceutical spending has increased at more than double the rate of growth in total health spending (OECD, 2009).

There are a number of reasons why prescribing costs are increasing:

- Demographic changes have resulted in an ageing population which is living longer and has greater needs for therapeutic interventions. This patient group is more susceptible to unwanted effects of medicines which in turn consume more resources.
- More patients have complex clinical problems and co-morbidities that have higher dependency on medicines.
- Health screening programmes and improved diagnostic techniques are uncovering previously non-identified diseases, which subsequently require treatment.
- The marketing of new medicines that offer more effective and less toxic alternatives to existing agents. Invariably these are more expensive, especially biotechnology medicines, such as monoclonal antibodies which can cost in excess of £30,000 per patient per year.
- The use of existing agents becoming more widespread as additional indications for their use are found.
- Increasing numbers of standards in guidelines of care are being set by national bodies such as the National Institute for Health and Clinical Excellence (NICE).
- Public and patients have a higher expectation of their rights to access high-cost health care.
- Higher acquisition costs are also due to inflation and currency fluctuations.

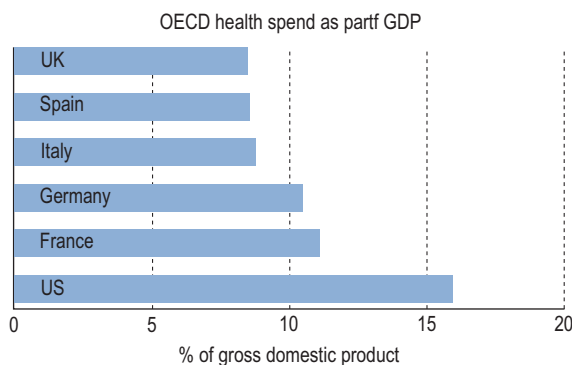
In the UK, health reforms over the past decade have addressed the quality of care through promotion of quality and safety standards. The formation of NICE in 1998


Fig. 8.1 Comparison of health spend as a percentage of gross domestic product in different countries in 2007 (OECD, 2009).

'to improve standards of patient care and to reduce inequities in access to innovative treatment' has formalised this process. NICE undertakes appraisals of medicines and other treatments (health technologies) and addresses the clinical and cost-effectiveness of therapies and compares outcomes with alternative use of NHS funds. The increased use of evidence-based programmes not only concentrates on optimizing health outcomes but also utilises health economic evaluations. Formalised health technology assessments provide an in-depth and evidence-based approach to this process.

Terms used in health economics

Pharmacoeconomics can be defined as the measurement of both the costs and consequences of therapeutic decision making. Pharmacoeconomics provides a guide for decision makers on resource allocation but does not offer a basis on which decisions should be made. Pharmacoeconomics can assist in the planning process and help assign priorities where, for example, medicines with a worse outcome may be available at a lower cost and medicines with better outcome and higher cost can be compared.

When economic evaluations are conducted it is important to categorise various costs. Costs can be direct to the organisation, that is physicians' salaries, the acquisition costs of medicines, consumables associated with drug administration, staff time in preparation and administration of medicines, laboratory charges for monitoring effectiveness and adverse drug reactions. Indirect costs include lost productivity from a disease which can manifest itself as a cost to the economy or taxation system as well as economic costs to the patient and the patient's family. All aspects of the use of medicines may be allocated costs, both direct, such as acquisition and administration costs, and indirect, such as the cost of a given patient's time off work because of illness, in terms of lost output and social security payments. The consequences of drug therapy include benefits for both the individual patient and society at large and may be quantified in terms of health outcome and quality of life, in addition to the purely economic impact.

It is worthwhile here to describe a number of definitions that further qualify costs in a health care setting. The concept of *opportunity cost* is at the centre of economics and identifies the value of opportunities which have been lost by utilizing resources in a particular service or health technology. This can be valued as the benefits that have been forsaken by investing the resources in the best alternative fashion. Opportunity cost recognises that there are limited resources available for utilising every treatment, and therefore the rationing of health care is implicit in such a system.

Average costs are the simplest way of valuing the consumption of health care resources. Quite simply, they represent the total costs (i.e. all the costs incurred in the delivery of a service) of a health care system divided by the units of production. For example, a hospital might treat 75,000 patients a year (defined as finished consultant episodes, FCEs) and have a total annual revenue cost of £150 million. The average cost per FCE is, therefore, £2000.

Fixed costs are those which are independent of the number of units of production and include heating, lighting and fixed staffing costs. *Variable costs*, on the other hand, are dependent on the numbers of units of productivity. The cost of the consumption of medicines is a good example of variable costs.

The inevitable increases in the medicines budget in a particular institute which is treating more patients, or treating those with a more complex pathology, have often been erroneously interpreted by financial managers as a failure to effectively manage the budget. To better describe the costs associated with a health care intervention, economists employ the term '*marginal costs*' to describe the costs of producing an extra unit of a particular service. The term '*incremental cost*' is employed to define the difference between the costs of alternative interventions.

Choice of comparator

Sometimes a claim is made that a treatment is cost effective. But cost effective against what? As in any good clinical trial, a treatment has to be compared against a reasonable comparator. The choice of comparator is crucial to this process. A comparator that is no longer in common use or in a dose that is not optimal will result in the evaluated treatment being seen as more effective than it actually is. Sadly many evaluations of medicines fall into this trap as sponsors seldom wish to undertake head-to-head studies against competitors. Again, the reader has to be careful when interpreting economic evaluations from settings which are different from those in local practice. A common error can be made when viewing international studies that have different health care costs and ways of treating patients and translating them directly into 'one's own practice'.

In addition, hospital charges, including those for hotel services such as heating and lighting overheads, meals and accommodation, which may constitute a major cost, should be considered. These are frequently included in an average cost per patient day.

Types of health economic evaluations

Cost–benefit analysis (CBA)

In CBA, consequences are measured in terms of the total cost associated with a programme where both costs and consequences are measured in monetary terms. While this type of analysis is preferred by economists, its use in health care is problematical as it is frequently difficult to ascribe monetary values to clinical outcomes such as pain relief, avoidance of stroke or improvements in quality of life.

Methods are available for determining cost–benefit for individual groups of patients that centre around a concept known as *contingent valuation*. Specific techniques include *willingness to pay*, where patients are asked to state how much they would be prepared to pay to avoid a particular event or symptom, for example pain or nausea following day-care surgery. Willingness to pay can be fraught with difficulties of interpretation in countries with socialised health care systems which are

invariably funded out of general taxation. *Willingness to accept* is a similar concept but is based on the minimum amount an individual person or population would receive in order to be prepared to lose or reduce a service.

CBA can be usefully employed at a macro level for strategic decisions on health care programmes. For example, a countrywide immunisation programme can be fully costed in terms of resource utilisation consumed in running the programme. This can then be valued against the reduced mortality and morbidity that occur as a result of the programme.

CBA can be useful in examining the value of services, for example centralised intravenous additive services where a comparison between a pharmacy-based intravenous additive service and ward-based preparation by doctors and nurses may demonstrate the value of the centralised pharmacy service, or a clinical pharmacokinetics service where the staffing and equipment costs can be offset against the benefits of reduced morbidity and mortality.

Cost-effectiveness analysis (CEA)

CEA can be described as an examination of the costs of two or more programmes which have the same clinical outcome as measured in physical units, for example lives saved or reduced morbidity. Treatments with dissimilar outcomes can also be analysed by this technique. Where two or more interventions have been shown to be or are assumed to be similar, then if all other factors are equal, for example convenience, side effects, availability, etc., selection can be made on the basis of cost. This type of analysis is called cost-minimisation analysis (CMA). CMA is frequently employed in formulary decision making where often the available evidence for a new product appears to be no better than for existing products. This is invariably what happens in practice as clinical trials on new medicines are statistically powered for equivalence as a requirement for licensing submission.

As previously described, CEA examines the costs associated with achieving a defined health outcome. While these outcomes can be relief of symptoms such as nausea and vomiting avoided, pain relieved, etc., CEA frequently employs years of life gained as a measure of the success of a particular programme. This can then offer a method of incrementally comparing the costs associated with two or more interventions. For example, consider a hypothetical case of the comparison of two drug treatments for the management of malignant disease.

Treatment 1 represents a 1-year course of treatment for a particular malignant disease. Assume that this is the current standard form of treatment and that the average total direct costs associated with this programme are £A per year. This will include the costs of the medicines, antiemetics, inpatient stay, radiology and pathology. Treatment 2 is a new drug treatment for the malignancy which as a result of comparative controlled clinical trials has demonstrated an improvement in the average life expectancy for this group of patients from 3.5 years for treatment 1 to 4.5 years for treatment 2. The average annual total costs for treatment 2 are £B. A comparative table can now be constructed.

Strategy	Treatment costs	Effectiveness
Treatment 1	£A	3.5 years
Treatment 2	£B	4.5 years

Incremental cost-effectiveness ratio:

$$= £B - £A / (4.5 - 3.5) \text{ per life year gained.}$$

Cost–utility analysis (CUA)

An alternative measurement for the consequences of a health care intervention is the concept of utility. Utility provides a method for estimating patient preference for a particular intervention in terms of the patient's state of well-being. Utility is described by an index which ranges between 0 (representing death) and 1 (perfect health). The product of utility and life years gained provides the term quality-adjusted life-year (QALY).

There are a number of methods for the calculation of utilities.

- The *Rosser–Kind matrix* relies on preferences from population samples from certain disease groups.
- The *visual analogue scale* method seeks to obtain patient preferences for their perceived disease state by scoring themselves on a line scaled between 0 and 1 as above.
- The *standard gamble* method requires individuals to choose between living the rest of their lives in their current state of health or making a gamble of an intervention which will restore them to perfect health. Failure of the gamble will result in instant death. The probabilities of the gamble are varied until there is indifference between the two events.
- The *time trade-off* method requires individuals to decide how many of their remaining years of life expectancy they would be prepared to exchange for complete health.

Using the previous model, if treatment 1 provides on average an increase of 3.5 years life expectancy but that this is valued at a utility of 0.9, then the health gain for this intervention is $0.9 \times 3.5 = 3.15$ QALYs. Similarly, if the increase in life expectancy with treatment 2 only has a utility of 0.8 (perhaps because it produces more nausea) then the health gain for this option becomes $0.8 \times 4.5 = 3.6$ QALYS. An incremental CUA can be undertaken as follows:

Strategy	Treatment costs	Effectiveness	Utility
Treatment 1	£A	3.5 years	0.9
Treatment 2	£B	4.5 years	0.8

Incremental cost–utility ratio:

$$= (£B - £A) / [(4.5 \times 0.8) - (3.5 \times 0.9)] \text{ per QALY gained.}$$

The calculation of QALYs provides a method which enables decision makers to compare different health interventions and assign priorities for decisions on resource allocation. However, the use of QALY league tables has provided much debate amongst stakeholders of health care as to their value and use.

According to NICE, there is no empirical basis for assigning a particular value (or values) to the cut-off between cost-effectiveness and cost-ineffectiveness. The general view is that those interventions with an incremental cost-effectiveness

ratio of less than £20,000 per QALY should be supported and that there should be increasingly strong reasons for accepting as cost-effective interventions with an incremental cost-effectiveness ratio of over £30,000 per QALY.

Costs and consequences

Discounting

Discounting is an economic term which is based mainly on a time preference that assumes individuals prefer to forego a part of the benefits of a programme if they can have those benefits now rather than fully in an uncertain future. The value of this preference is expressed by the discount rate. There is intense debate amongst health economists regarding the value for this annual discount level and whether both costs and consequences should be subjected to discounting. If a programme does not exceed 1 year then discounting is felt to be unnecessary.

Decision analysis

Decision analysis offers a method of pictorial representation of treatment decisions. If the results from clinical trials are available, probabilities can be placed within the arms of a decision tree and outcomes can be assessed in either monetary or quality units. An example of this can be found in the assessment of glycoprotein IIb/IIIa inhibitors in acute coronary syndrome (National Institute for Health and Clinical Excellence, 2002). The evidence of clinical and economic outcomes compares percutaneous coronary intervention and coronary artery bypass grafting. To populate a decision tree, it is necessary to obtain information from the literature on the probabilities for the clinical benefits and risks of each procedure (Table 8.1). The costs of the various procedures, consumables and bed stay are then calculated (Table 8.2). From these a decision tree can be constructed that determines the cost-effectiveness of one intervention over another (Fig. 8.2).

Table 8.1 Baseline probabilities used in the short-term model of percutaneous coronary intervention (PCI) versus coronary artery bypass graph (CABG; National Institute for Health and Clinical Excellence, 2002)

Node	Description	Probability	Parameters of the beta distribution	
			α	β
A	Acute PCI	0.05	53	980
B	Repeat revasc.	0.048	8	157
C	Repeat revasc. PCI	1.00	–	–
D	Death (revasc. PCI)	0.00	0.01	7.99
E	MI (revasc. PCI)	0.13	1	7
F	Death (revasc. CABG)	0.00	–	–
G	MI (revasc. CABG)	0.00	–	–
H	Death (no repeat revasc.)	0.03	5	152
I	MI (no repeat revasc.)	0.03	5	147
J	CABG	0.05	47	933
K	Death (CABG)	0.11	5	42
L	MI (CABG)	0.07	3	39
M	6-month revasc.	0.05	48	885
N	6-month revasc. PCI	0.48	23	25
O	Death (6-month revasc. PCI)	0.09	2	21
P	MI (6-month revasc. PCI)	0.10	2	19
Q	Death (6-month revasc. CABG)	0.00	0.01	24.99
R	MI (6-month revasc. CABG)	0.16	4	21

Table 8.1 Baseline probabilities used in the short-term model of percutaneous coronary intervention (PCI) versus coronary artery bypass graph (CABG; National Institute for Health and Clinical Excellence, 2002)—cont'd

Node	Description	Probability	Parameters of the beta distribution	
			α	β
S	Death (no revasc.)	0.08	68	817
T	MI (no revasc.)	0.05	40	777
	Baseline risk of gastro-intestinal bleeding:			
	(i) Undergoing PCI in acute period	0.00	0.01	52.99
	(ii) Undergoing CABG in acute period	0.02	1	46
	(iii) No initial revasc.	0.01	12	921

CABG, coronary artery bypass graft; MI, myocardial infarction; PCI, percutaneous coronary intervention; revasc., revascularisation intervention; MI, myocardial infarction.

Table 8.2 Unit costs used in the analysis of percutaneous coronary intervention (PCI) versus coronary artery bypass graph (CABG; National Institute for Health and Clinical Excellence, 2002)

Unit cost	Unit	Base-case value
PCI	Procedure	£1410.04
CABG	Procedure	£4902.22
Repeat PCI	Per diem	£2976
Angiogram	Procedure	£748.25
Cardiac ward	Day	£157.47
Non-cardiac ward	Day	£244.00
CCU	Day	£459.04
Outpatient	Visit	£59.70
Cardiac day case	Visit	£108.58
Non-cardiac day case	Visit	£182.00
Guidewire	Item	£61.75
Stent	Item	£599.01
Guiding catheter	Item	£37.05
Blood	Unit	£85.00
Full blood count	Item	£4.00
Endoscopy	Item	£246.00
Tirofiban	12.5 mg vial	£146.11 (+VAT)
Eptifibatide	20 mg vial	£15.54 (+VAT)
Eptifibatide	75 mg vial	£48.84 (+VAT)

Table 8.2 Unit costs used in the analysis of percutaneous coronary intervention (PCI) versus coronary artery bypass graph (CABG; National Institute for Health and Clinical Excellence, 2002)—cont'd

Unit cost	Unit	Base-case value
Abciximab	10 mg vial	£280.00 (+VAT)
Omeprazole	28 tab pack 10 mg	£18.91
Clopidogrel	28 tab pack 75 mg	£35.31

CABG, coronary artery bypass graft; CCU, coronary care unit; PCI, percutaneous coronary intervention.

If there is uncertainty about the robustness of the values of the variables within the tree, they can be varied within defined ranges to see if the overall direction of the tree changes. This is referred to as *sensitivity analysis* and is one of the most powerful tools available in an economic evaluation.

Economic evaluation of medicines

A number of countries have introduced explicit guidelines for the conduct of economic evaluations of medicines. Others require economic evaluations before allowing a medicine onto an approved list or formulary. Guidelines have been published which aim to provide researchers and peer reviewers with background guidance on how to conduct an economic evaluation and how to check its quality (Drummond et al., 2005), whilst others (National Institute for Health and Clinical Excellence, 2009a,b) have set out how they incorporate health economics in the evaluation of medicines.

Risk management of unwanted drug effects

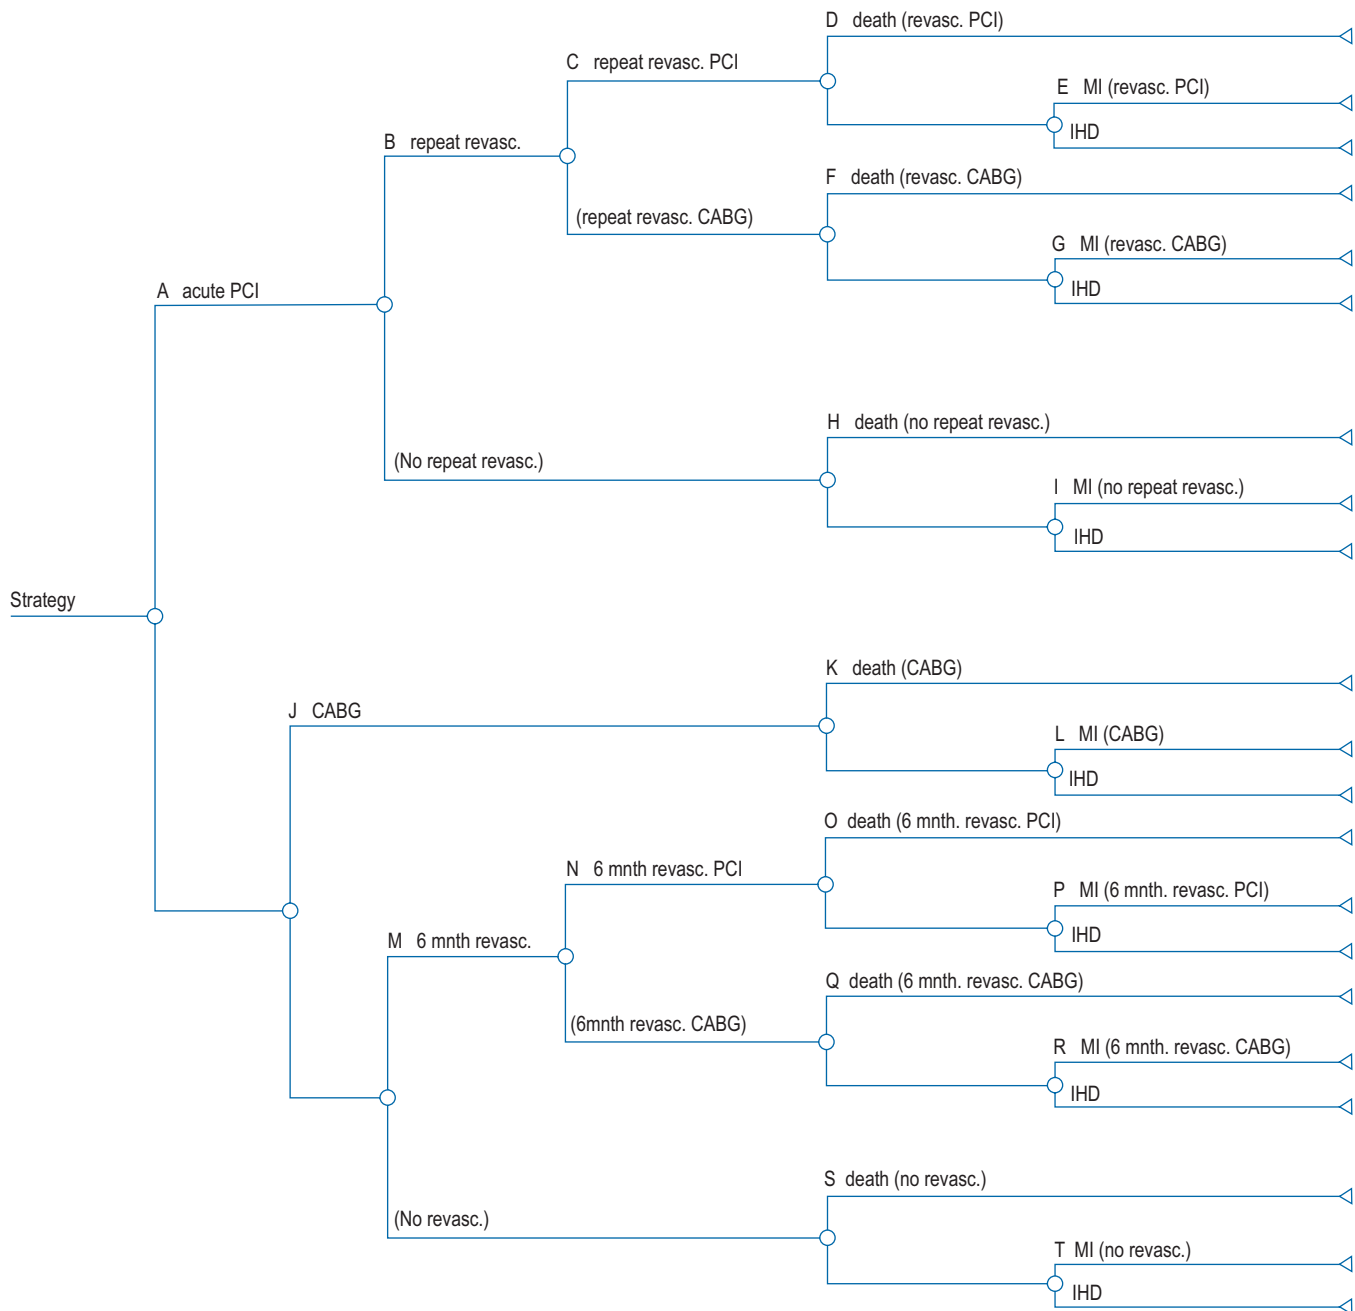
Avoiding the adverse effects of medicines has become a desirable goal of therapeutic decision makers as well as those who promote quality assurance and risk management. Not only can there be


Fig. 8.2 Clinical decision tree for choices of percutaneous coronary intervention (PCI) versus coronary artery bypass graph (CABG; National Institute for Health and Clinical Excellence, 2002). MI, myocardial infarction; IHD, ischaemic heart disease; revasc., revascularisation intervention.

significant sequelae in terms of increased morbidity associated with adverse drug effects but the economic consequences can be considerable. For example, gentamicin is often regarded as a relatively inexpensive antibiotic but in the USA each case of nephrotoxicity has been reported to cost several thousands of pounds in terms of additional resources consumed even without any assessment of the reduction in a patient's quality of life. The increasingly litigious nature of society has resulted in economic valuation of perceived negligence, for example, with irreversible vestibular toxicity associated with prolonged unmonitored aminoglycoside therapy. As a result, many health care systems have targeted a significant reduction in the number of serious errors in the use of prescribed medicines.

Medication non-adherence

The costs of non-adherence with medicines are considerable. In the USA, it has been calculated that 11% of all admissions to hospital are directly associated with some form of non-adherence. This equates to two million hospital admissions a year in the USA resulting from medication non-adherence at a total cost of over £5 billion. In addition, lost work productivity through non-adherence has been estimated to cost in excess of a further £3 billion per year. The scale of the problem in the UK is probably similar.

In the UK, between a half and one-third of all medicines prescribed for long-term conditions are not taken as recommended

(Horne et al., 2005) and the estimated drug cost of unused or unwanted medicines in the NHS in England is around £100 million a year (Department of Health, 2008) annually. National guidance on medicines adherence has been issued (National Institute for Health and Clinical Excellence, 2009a,b).

Incentives and disincentives

There are good examples of both incentives and disincentives being used in the NHS to save money. In England, the contract for hospitals penalises those organisations that fail to achieve their targets for reducing *Clostridium difficile* infections. Good antimicrobial stewardship is essential for addressing this as each case of *Clostridium difficile* infection can cost at least £4000. Reduction in prescribing of both fluoroquinolones and second and third generation cephalosporins is associated with a reduction in *Clostridium difficile* infection (Department of Health and Health Protection Agency, 2008). It follows from this that reducing the use of these agents can reduce acquisition costs of the medicines.

Examples of incentives to reduce expenditure can be seen within the NHS commissioning processes in England. A typical example involves a scheme where commissioners must make 1.5% of contract value (or equivalent non-contract activity value) available for each provider's quality and innovation scheme and these include prescribing targets (Department of Health, 2010).

Conclusion

A fundamental element of the use of pharmacoeconomics in practice is the viewpoint from which the analysis is conducted. Ideally this should be from a societal perspective but frequently it is from a government or Department of Health

---

Box 8.1   Ten examples of the application of pharmacoeconomics in practice

- The value of one treatment over another in terms of the cost for each unit of health gained
- Avoidance of costs associated with the failure to use an appropriate medicine, for example antimicrobial surgical prophylaxis
- Avoidance of the costs of the side effects or adverse effects of a medicine
- Financial planning and horizon scanning for new medicines
- Prioritisation of health care resources
- Health gain, quality of life issues and patient preferences
- Duration of care and balance between inpatient, day care and outpatient care
- Changes in legislative controls, for example reclassification of medicines from prescription only to pharmacy status
- Costs of concordance and non-concordance
- Economics of health service delivery

---

viewpoint. Purchasers of health care may also have a different perspective from provider units, and the viewpoint of clinicians may differ from that of the patient. The pharmaceutical industry will probably have another viewpoint that will be focused on their particular products. As a consequence, with all economic evaluations the perspective from which they have been analysed should be clear.

The effect of having budgets that are rigorously defended in every section of the health service, as occurs with the medicines budget, is to deny the application of economic decision making in the most efficient way for the population served. It is clear that pharmacoeconomics has an important part to play in the practice of therapeutics (Box 8.1) and needs to be an integral part of all planned therapeutic developments.

SECTION **2**

LIFE STAGES

9 Neonates

M. P. Ward Platt

The earliest in pregnancy at which newborn babies can sometimes survive is around 23 weeks' gestation, when survival is about 10% for liveborn babies. Conventionally, any baby born at less than 32 weeks is regarded as being at relatively high risk of death or disability. About 7.5% of all births are technically 'premature' (<37 weeks) but only 1.4% of births take place before 32 weeks of gestation. Likewise, 7% of all babies are low birth weight (LBW), for example, <2500 g, and 1.4% are very low birth weight (VLBW). However, it is the gestation at birth rather than the birth weight which is of more practical and prognostic value. The definitions of selected terms used for babies are given in Table 9.1.

Because mothers with high-risk pregnancies will often be transferred for delivery to a hospital capable of providing neonatal intensive care, the proportion of preterm and LBW babies cared for in such units is greater than in smaller maternity units in peripheral hospitals. In the population as a whole, between 1% and 2% of all babies will receive intensive care, and the most common reason for this among preterm babies is the need for respiratory support of some kind. Over three-quarters of babies born at 25 weeks' gestation now survive to discharge home.

Babies of less than 32 weeks' gestation invariably need some degree of special or intensive care, and generally go home when they are feeding adequately, somewhere between 35 and 40 weeks of postmenstrual age. So although in epidemiological terms the neonatal period is up to the first 28 postnatal days, babies may be 'neonatal' inpatients for as long as 3 or 4 months; during this time their weight may triple and their physiology and metabolism will change dramatically.

Drug disposition

Absorption

An important and unique source of drug absorption, available until birth, is the placenta. Maternal drugs pass to the fetus and back again during pregnancy, but from delivery, any drugs present in the neonatal circulation can no longer be eliminated by that route and must be dealt with by the baby's own systems. Important examples of maternal drugs which may adversely affect the newborn baby include opiates given for pain relief during labour, β-blockers given for pregnancy-induced hypertension and benzodiazepines for eclamptic seizures. In addition, a mother may be given a drug with the intention of treating not her but her fetus. An example of this is the use of corticosteroids to promote fetal lung maturation when preterm delivery is planned or expected. In this situation, betamethasone is normally the drug of choice as prednisolone is metabolised in the placenta and does not reach the fetus.

Enteral drug absorption is erratic in any newborn baby and unavailable in the ill baby because the stomach does not always empty effectively. Therefore, most drugs are given intravenously to ensure maximum bioavailability. Some drugs, such as paraldehyde and diazepam (for neonatal seizures) and paracetamol (for simple analgesia), can be given rectally. The trachea may be used as the preferred route of administration when surfactant administration is required or where adrenaline (epinephrine) is given for resuscitation. The buccal route may be used to administer glucose gel in the treatment of hypoglycaemia. In the very preterm baby of 28 weeks' gestation or less, the skin is extremely thin and a poor barrier to water loss; consequently it is also permeable to substances in contact with it. This is harmful to the baby if there is prolonged skin contact with alcohol, as in chlorhexidine in 70% methylated spirit, which causes severe chemical burn and has resulted in systemic methyl alcohol poisoning. The intramuscular route is normally avoided in premature babies because of their small muscle bulk, although the notable exceptions to this are the administration of vitamin K and naloxone.

Distribution

Drugs are distributed within a baby's body as a function of their lipid and aqueous solubility, as at any other time of life. The main difference in the neonate is that the size of the body water pool under renal control is related not to the baby's

Table 9.1 Definitions of terms

Normal length of human pregnancy (term)	37 up to 42 completed weeks of gestation
Preterm	<37 weeks of gestation at birth
Post-term	42 completed weeks onwards
Neonatal period	Up to the 28th postnatal day
Low birth weight (LBW)	<2500 g
Very low birth weight (VLBW)	<1500 g
Extremely low birth weight (ELBW)	<1000 g

surface area but to body weight. Furthermore, the absolute glomerular filtration rate increases logarithmically with post-conceptional age irrespective of the length of a baby's gestation. This has implications for predicting the behaviour of water-soluble drugs such as gentamicin. The amount of adipose tissue can vary substantially between different babies. Any baby born more than 10 weeks early, and babies of any gestation who have suffered intrauterine growth restriction, may have little body fat. Conversely, the infant of a diabetic mother may have a particularly large fat layer and this affects the retention of predominantly lipid-soluble drugs. Protein binding in the plasma is influenced by the amount of albumin available and this in turn is related to gestation, with albumin values found 12 weeks prior to term being only two-thirds of adult concentrations.

Metabolism

The metabolic fate of drugs in the newborn is not qualitatively different to that in the older child, for example, hydroxylation, oxidation and conjugation to sulphate or glucuronide. It is the efficiency with which these processes are carried out that distinguishes the baby from the older person. In addition to the immaturity of the metabolic pathways for drug disposal, drug metabolism is also affected by the physiological hyperbilirubinaemia of the newborn. The bilirubin can compete both for enzyme-binding sites and for glucuronate, and may thus affect drug metabolism for as long as unconjugated hyperbilirubinaemia persists.

Elimination

The relative immaturity of hepatic and renal function results in correspondingly slow elimination of most drugs from the neonate. This is not necessarily a problem, so long as due account is taken of the slow elimination and dose intervals are modified accordingly. It may even be a useful property, as with phenobarbital, which when given as a loading dose (usually 20 mg/kg) will remain in circulation for days in useful therapeutic quantities, often avoiding the need for further

doses. On the other hand, drugs such as gentamicin and vancomycin, which have a relatively narrow therapeutic index, must be given far less frequently than in children or adults and serum drug levels must be assayed to avoid toxicity.

There has been little study of pharmacodynamics in the term or preterm neonate. Most clinicians work on the assumption that the kinetics of drug behaviour are so different in this group of patients that the pharmacodynamic properties must follow the same pattern. In practice, the most important pharmacodynamic effect is probably that of the behaviour of opiates derived from the mother in labour. Pethidine and diamorphine are the opiates most likely to cause significant respiratory depression in the neonate. Such respiratory depression can be treated with naloxone, and a special neonatal preparation (20 μcg/mL) is available. However, after birth the opiates and their metabolites have a long serum half-life in the baby whereas the naloxone is rapidly eliminated. The initial dramatic effect of naloxone can give a false sense of security, as the baby may become narcosed after a few hours following transfer to the postnatal ward. To try to prevent this late-onset narcosis, adult naloxone (400 μcg/mL) may be given intramuscularly to ensure it remains active over several hours. Even when the respiratory effects have disappeared, opiates may have prolonged behavioural effects on both mother and baby.

Major clinical disorders

Respiratory distress syndrome (RDS)

Among preterm babies the most commonly encountered disorder is RDS (also sometimes called hyaline membrane disease from its appearance on lung histology, or surfactant deficiency lung disease in recognition of the aetiology). The root cause of this disease is the lack of sufficient pulmonary surfactant at the time of birth. The condition is rare in babies born at or near term and becomes increasingly likely the more preterm a birth takes place. It is now quite unusual to see classical RDS because it is prevented both by the use of antenatal betamethasone in the mother and the postnatal administration of surfactant to babies at highest risk (see below).

Clinically, RDS is manifested by obvious difficulty with breathing, with nasal flaring, rib recession, tachypnoea and a requirement for oxygen therapy. The natural history is that RDS becomes worse over the first 2 days, reaches a plateau and then gradually improves. The use of antenatal steroid therapy to the mother, and surfactant therapy for the infant, has not only transformed the clinical course of this condition but also greatly reduced mortality.

A relatively big baby born around 32–34 weeks of gestation with mild RDS may need no more treatment than extra oxygen. In contrast, smaller, more premature or more severely affected babies need some degree of mechanical assistance: either continuous positive airway pressure by nasal prongs or full artificial ventilation through an endotracheal tube. A few babies require high inspired concentrations of oxygen (up to 100%) for several days. Fortunately, pulmonary oxygen

toxicity is not as much a problem to the neonate as it is to the adult, though it may have a causal role in the development of bronchopulmonary dysplasia. The major concern is the damage that prolonged arterial hyperoxia can do to the retina, resulting in retinopathy of prematurity. The goal is to give enough inspired oxygen to keep the arterial partial pressure within a range of about 6–12 kPa.

Mechanical ventilation is not a comfortable experience, for adults or children, but it has taken a long time to appreciate that this may also be true for premature babies. Paralysing agents such as pancuronium are sometimes given to ventilated neonates but these only prevent the baby from moving and are not sedative. Pancuronium is widely used, partly because it wears off slowly so that the baby is not suddenly destabilised. Shorter acting agents such as atracurium are often used for temporary paralysis for intubation. Whether or not the baby is paralysed, morphine is commonly given either as intermittent doses or as an infusion, to provide narcosis and analgesia to reduce the distress of neonatal intensive care.

Antenatal steroids given to the mother reduce the incidence, severity and mortality of RDS caused by surfactant deficiency. Unfortunately, it is not possible to identify and treat all mothers whose babies could benefit. Babies of less than 32 weeks' gestation gain most benefit because they are at greatest risk of death and disability from RDS. Optimum treatment is four oral doses of 6 mg betamethasone, each given 12-hourly, or two doses of 12 mg intramuscularly 24 h apart.

Similarly, the introduction of exogenous surfactant, derived from the pig or calf, has revolutionised the management of RDS. Natural surfactants derived from animals are currently more effective than artificial synthetic ones. The first dose should be given as soon as possible after birth since the earlier it is given, the greater the benefit (Soll, 1999).

There are several other important ways of treating babies in respiratory failure. Inhaled nitric oxide dilates pulmonary arterioles and lowers the excessive pulmonary blood pressure which often complicates respiratory failure. Persistent pulmonary hypertension may also complicate early onset septicaemia and meconium aspiration syndrome; in term and near-term babies, nitric oxide is both more effective than the previous drug therapies and much less likely to lead to systemic hypotension. However, it does not reduce mortality or major complications when used in babies with birth weights less than 1500 g (Van Meurs et al., 2005).

For some babies of at least 34 weeks of gestation and at least 2 kg birth weight, extracorporeal membrane oxygenation (ECMO), in which a baby is in effect put on partial heart–lung bypass for a few days, may be life-saving when ventilation and nitric oxide fails (ECMO Collaborative Trial Group., 1996).

Patent ductus arteriosus (PDA)

PDA can be a problem in the recovery phase of RDS, and usually shows itself as a secondary increase in respiratory distress and/or ventilatory requirement, an increasing oxygen requirement, wide pulse pressure and a characteristic heart murmur. Physiologically, as pressure in the pulmonary artery falls, an open duct allows blood from the aorta to flow into the pulmonary artery, which engorges the lungs and reduces their compliance, while putting strain on the heart. Echocardiography is used to confirm the clinical suspicion. About one-third of all babies with birth weights less than 1000 g will develop signs of PDA, for example, the characteristic heart murmur, but treatment is only needed when the baby is haemodynamically compromised. When treatment is needed the options are either medical treatment (with indometacin or ibuprofen) or surgical ligation.

Indometacin is usually given intravenously in the UK, because when given enterally its absorption is unpredictable and it may need to be given before the baby has started enteral feeds. The alternative is intravenous ibuprofen. Potential serious side effects of both drugs include renal impairment, gastric haemorrhage and gut perforation. Surgery is considered when one or more courses of medical treatment fail to close the PDA or if drugs are contraindicated for any reason. There are no good randomised controlled trials to guide clinicians on the best approach to managing PDA.

Bronchopulmonary dysplasia (BPD)

BPD, also sometimes generically known as chronic lung disease of prematurity, most frequently occurs in very immature babies who have undergone prolonged respiratory support. The factors predisposing to BPD are the degree of prematurity, the severity of RDS, infection, the occurrence of PDA, oxygen toxicity and probably intrinsic genetic factors. BPD can be defined as oxygen dependency lasting more than 28 days from birth, but this definition is not very useful in that many babies born at less than 28 weeks of gestation require oxygen for 28 days or more, but few still need it after 8 weeks. A more useful functional and epidemiological definition of established BPD is oxygen dependency at 36 weeks of postmenstrual age, in a baby born before 32 weeks.

Established BPD not severe enough to need continuing mechanical ventilation is either treated with nasal continuous positive airway pressure with or without oxygen supplementation, or if less severe again is treated with oxygen through nasal cannulae. Enough oxygen must be used to maintain an oxygen saturation high enough to control pulmonary artery pressure, while avoiding chronic low-grade hyperoxia which could contribute to retinopathy of prematurity. Optimum oxygen saturations in these babies have not been rigorously defined but the outcome of several large trials is awaited.

A chronic inflammatory process is part of the pathology of BPD, and for this reason much attention has been given to the role of corticosteroids in treating it. Steroid use generally results in a rapid fall in oxygen requirements, but does not improve mortality. Indeed, there is evidence that when dexamethasone is used within the first 1 or 2 weeks there may even be an increased rate of cerebral palsy, so one of the principal indications for steroid use is when a baby remains ventilator dependent at the age of 4 weeks or more. A wide variety of treatment regimens has been tested in trials and there is no standard approach; both the initial dose (usually between 50 and 250 μcg/kg) and the rate of reduction of dose are generally individualised to the baby. Side effects such as

hypertension and glucose intolerance are common, although mostly reversible, but the effects on growth can be more serious if steroids are given for a long time.

BPD leads to increases in both pulmonary artery pressures and lung water content. The consequent strain on the heart can lead to heart failure, with excessive weight gain, increasing oxygen requirements and clinical signs such as oedema and a cardiac 'gallop' rhythm. The first-line treatment for heart failure, as in any age group, is with diuretics. Thiazides improve pulmonary mechanics as well as treating heart failure (Brion et al., 2002). Sometimes furosemide is used but its side effects are significant urinary loss of potassium and calcium, and renal calcification. An alternative is to combine a thiazide with spironolactone which causes less calcium and potassium loss. By reducing lung water content, diuretics can also improve lung compliance and reduce the work of breathing. However, BPD is not routinely treated with diuretics, since many babies do well without them. Systemic hypertension sometimes occurs among babies with BPD and may need treatment with antihypertensive drugs such as nifedipine.

For some babies with severe BPD, in whom echocardiography demonstrates pulmonary arterial pressures close to, or greater than, systemic pressure, many neonatologists try sildenafil, as there has been considerable experience using this drug off-label to prevent pulmonary hypertensive crises in babies after cardiac surgery. However, sildenafil has very variable pharmacokinetics in babies, so the dose is difficult to define, and the commonly recommended upper limit of 2 mg/kg four times a day may not be sufficient for some babies (Ahsman et al., 2010).

Significantly preterm babies still in oxygen at 36 weeks' postmenstrual age are almost certain to need oxygen at home after discharge, and home oxygen programmes for ex-premature babies with BPD are now widespread. Most babies manage to wean off supplementary oxygen in a few months but a very few may need it for up to 2 years.

Infection

Important pathogens in the first 2 or 3 days after birth are group B β-haemolytic streptococci and a variety of Gram-negative organisms, especially *Escherichia coli*. Coagulase-negative staphylococci and *Staphylococcus aureus* are more important subsequently. In general, it is wise to use narrow-spectrum agents and short courses of antibiotics whenever possible, and to discontinue blind treatment quickly, for example, after 48 h if confirmatory evidence of bacterial infection, such as blood culture, is negative. The most serious neonatal infections are listed in Table 9.2.

Superficial candida infection is common in all babies, but systemic candida infection is a particular risk in very preterm babies receiving prolonged courses of broad-spectrum antibiotics, with central venous access, and receiving intravenous feeding. Increasingly, units are adopting policies of prophylaxis with either enteral nystatin or systemic fluconazole in the highest risk preterm babies.

It is usual to start antibiotics prophylactically whenever preterm labour is unexplained, where there has been prolonged

Table 9.2 Serious neonatal infections and pathogens

Septicaemia	*Staphylococcus epidermidis*, group B streptococci, *Escherichia coli*
Systemic candidiasis	*Candida* spp.
Necrotizing enterocolitis	No single causal pathogen
Osteomyelitis	*Staphylococcus aureus*
Meningitis	Group B streptococci, *E. coli*

rupture of the fetal membranes prior to delivery, and when a baby is ventilated from birth. A standard combination for such early treatment is penicillin G and an aminoglycoside, to cover group B streptococci and Gram-negative pathogens. Treatment can be stopped after 48 h if cultures prove negative. Blind treatment starting when a baby is more than 48 h old has to take account of the expected local pathogens, but will always include cover for *S. aureus*. Cephalosporins such as cefotaxime and ceftazidime have been heavily promoted for use in the blind treatment of neonatal infection on the grounds of their lower toxicity when compared to aminoglycosides, their wide therapeutic index and the absence of any need to monitor serum concentrations. Their main disadvantage is the breadth of their spectrum which may result in fungal overgrowth or the spread of resistance, although they compare favourably with ampicillin in this regard. Since courses of blind treatment are often only for 48 h, and the antibiotics can be stopped when cultures are negative, there is often no need to measure levels in babies receiving aminoglycosides, thereby negating much of the apparent advantage of cephalosporins. Moreover, there is now good evidence for giving gentamicin 24 hourly rather than more frequently, as it has similar efficacy and less potential for toxicity.

Methicillin-resistant *S. aureus* (MRSA) has emerged as a real problem in hospitals in recent years, but there is little evidence that neonatal units are a particularly hazardous environment.

The most important active viral infection in neonates is cytomegalovirus (CMV), and the most important one from which to protect babies in the UK is vertically transmitted human immuno-deficiency virus (HIV). For CMV, which is now thought to be a major factor in non-hereditary sensori-neural hearing loss, treatment is with intravenous ganciclovir and oral valganciclovir.

For HIV, the goal of management is to prevent 'vertical' transmission from mother to baby. The main strategy to combat this is to use aggressive maternal treatment throughout pregnancy to suppress the maternal viral load. Current practice is to give the baby zidovudine, as a single agent, for 4 weeks when the maternal viral load is low, or triple therapy if the load is high.

Necrotizing enterocolitis (NEC)

NEC is an important complication of neonatal intensive care, and can arise in any baby. However, it most commonly occurs in premature babies and those already ill. It is especially

associated with being small for gestational age, birth asphyxia and the presence of a PDA. Since many sick babies have multiple problems, it has been difficult to disentangle causal associations from spurious links to conditions that occur anyway in ill infants, such as the need for blood transfusion. There is general agreement that the pathophysiology is related to damage of the gut mucosa, which may occur because of hypotension or hypoxia, coupled with the presence of certain organisms in the gastro-intestinal tract that invade the gut wall to give rise to the clinical condition. It almost never arises in a baby who has never been fed, whilst early 'minimal' feeding, and initiating feeding with human breast milk, appears to be protective. Probably the most important protection that can be given exogenously is enteral probiotics (AlFaleh & Bassler, 2008).

A baby who becomes ill with NEC is often septicaemic and may present acutely with a major collapse, respiratory failure and shock, or more slowly with abdominal distension, intolerance of feeds with discoloured gastric aspirates and blood in the stool. The medical treatment is respiratory and circulatory support if necessary, antibiotics, and switching to intravenous feeding for a period of time, usually 7–10 days. One of the most difficult surgical judgements is deciding if and when to operate to remove necrotic areas of gut or deal with a perforation.

The antibiotic strategy for NEC is to cover Gram-positive, Gram-negative and anaerobic bacteria. Metronidazole is used to cover anaerobes in the UK but clindamycin is preferred in some other countries. As with other drugs, metronidazole behaves very differently in neonates compared with older children and adults, having an elimination half-life of over 20 h in term babies. The elimination half-life is up to 109 h in preterm babies, partly due to poor hepatic hydroxylation in infants born before 35 weeks' gestation. There is probably a case to be made for monitoring serum levels of this drug, but in practice this is seldom done.

Haemorrhagic disease of the newborn

Haemorrhagic disease of the newborn, better described as vitamin K-dependent bleeding, is very rare but it may cause death or disability if it presents with an intracranial bleed. Except in the case of malabsorption, it affects only breast-fed babies because they get very little vitamin K in maternal milk, and their gut bacteria do not synthesise it. Formula fed infants get sufficient vitamin K in their diet.

There are several possible strategies for giving vitamin K with a view to preventing haemorrhagic disease. An intramuscular injection of phytomenadione 1 mg (0.5 mL) can be given either to every newborn baby or selectively to babies who have certain risk factors such as instrumental delivery, preterm birth, etc. Vitamin K can be given orally, so long as an adequate number of doses is given, and this has been shown to be effective in preventing disease (Wariyar et al., 2000). Intramuscular injections are an invasive and unpleasant intervention for the baby since muscle bulk is small in the newborn, and particularly the preterm, and other structures such as the sciatic nerve can be damaged even if the intention is to give the injection into the lateral thigh. Intramuscular injections can be reserved for those babies with doubtful oral absorption, for example, all those admitted for special care, or at high risk because of enzyme-inducing maternal drugs such as anticonvulsants.

Apnoea

Apnoea is the absence of breathing. Babies (and adults) normally have respiratory pauses, but preterm babies in particular are prone to prolonged pauses in respiration of over 20 s which can be associated with significant falls in arterial oxygenation. Apnoea usually has both central and obstructive components, is often accompanied by bradycardia, and requires treatment to prevent life-threatening episodes of arterial desaturation.

Episodes of apnoea and bradycardia can be treated in three ways: intubating and mechanically ventilating the baby, giving nasal continuous positive airway pressure (nCPAP) or giving respiratory stimulants such as caffeine or doxapram. The main goal of medical treatment is to reduce the number and severity of the episodes without having to resort to artificial ventilation. Caffeine both reduces apnoea in the short term, and improves long-term outcome (Schmidt et al., 2006). Doxapram is occasionally given as an adjunct to both caffeine and nCPAP, to avoid resorting to mechanical ventilation. Most clinicians stop giving respiratory stimulants when the baby is around 34 weeks of postmenstrual age, by which time most babies will have achieved an adequate degree of cardiorespiratory stability and no longer need even the most basic forms of monitoring device.

Seizures

Seizures may arise as part of an encephalopathy, when they are accompanied by altered consciousness, or as isolated events when the baby is neurologically normal between seizure episodes. Investigations are directed to finding an underlying cause but in about half of all term babies having fits without an encephalopathy, no underlying cause can be found.

Just as with children and adults, treatment may be needed to control an acute seizure which does not terminate quickly, or given long term to prevent the occurrence of fits. In the neonate, the first-choice anticonvulsant for the acute treatment of seizures is phenobarbital because it is effective, seldom causes respiratory depression, and is active for many hours or days because of its long elimination half-life. Diazepam is sometimes used intravenously or rectally but it upsets temperature control, causes unpredictable respiratory depression, and is very sedating compared to phenobarbital. Paraldehyde is occasionally used because it is easy to give rectally, is relatively non-sedating and short acting. It is excreted by exhalation and the smell can make the working environment quite unpleasant for staff. Phenytoin is often used when fits remain uncontrolled after two loading doses of phenobarbital (total 40 mg/kg) but is not usually given long term because of its narrow therapeutic index. When seizures are intractable, options include clonazepam, midazolam or lidocaine; the

last two are given as infusions. There is little experience with intravenous sodium valproate in the neonate. Longer term treatment is commonly with phenobarbital but after the first few postnatal months, carbamazepine or sodium valproate is more suitable.

Hypoxic–ischaemic encephalopathy (HIE), which usually results either from intrapartum asphyxia or from an antepartum insult such as placental abruption, is an important cause of seizures. Convulsions are a marker of a more severe insult; they usually occur within 24 h of birth and may last for several days, after which they spontaneously resolve. The less severely affected babies quickly return to neurological normality. No drug has been shown to improve outcome when given after the insult has occurred, but cooling a baby to between 33 and 34 °C for 72 h has been shown to improve the degree of neurodisability among survivors and has rapidly become standard therapy (Edwards et al., 2010).

The therapeutic dilemma lies in the degree of aggression with which convulsions should be treated, since no conventional anticonvulsant is very effective in reducing electrocerebral seizure activity, even when the clinical manifestations of seizures are abolished, and as stated before, convulsions tend naturally to cease after a few days. However, seizures which compromise respiratory function need to be treated to prevent serious falls in arterial oxygen tension and possible secondary neurological damage. Also, babies with frequent or continuous seizure activity are difficult to nurse and cause great distress to their parents. Therefore, in practice it is usual to try to suppress the clinical manifestation of seizure activity, and phenobarbital remains the most commonly used first-line treatment. Where a decision is taken to keep a baby on anticonvulsant medication, therapeutic drug monitoring can provide helpful information and may need to be repeated from time to time during follow-up.

Principles and Goals of Therapy

The ultimate aim of neonatal care at all levels is to maximise disability-free survival and identify treatable conditions which would otherwise compromise growth or development. It follows that potential problems should be anticipated and the complexities of intensive care should be avoided if at all possible.

Many of the drugs used in neonatal care are not licensed for such use, or are used off-label. There is a high potential for errors because of the small doses used, which sometimes calls for unusual levels of dilution when drawing up drugs. Constant vigilance, electronic prescribing and the use of specialised neonatal formularies are all important in preventing harm.

Rapid growth

Once the need for intensive care has passed, the growth of a premature baby can be very rapid indeed if the child is being fed with a high-calorie formula modified for use with preterm infants. Indeed, most babies born at 27 weeks, and weighing around 1 kg, can be expected to double their birth weight by the time they are 8 weeks old. Since the dose of all medications is calculated on the basis of body weight, constant review of dose is necessary to maintain efficacy, particularly for drugs that may be given for several weeks such as respiratory stimulants, diuretics and anticonvulsants. Conversely, all that is necessary to gradually wean a baby from a medication is to hold the dose constant so that the baby gradually 'grows out' of the drug. This practice is frequently used with diuretic medication in BPD, the need for which becomes less as the baby's somatic growth reduces the proportion of damaged lung in favour of healthy tissue.

Therapeutic drug monitoring

The assay of serum concentrations of various drugs has a place in neonatal medicine, particularly where the therapeutic index of a drug is narrow. It is routine to assay levels of antibiotics such as aminoglycosides and vancomycin, of which the trough measurement is of most value since it is accumulation of the drug which must be avoided. More rarely, it may be necessary to assay minimal inhibitory or bactericidal concentrations of antibiotics in blood or cerebrospinal fluid if serious infections are being treated, but constraints on sampling limit the frequency with which this may be undertaken.

Where phenobarbital or other anticonvulsants are given long term, intermittent measurement of serum levels can be a useful guide to increasing the dose. All these drugs have a long half-life, so it is most important that drug concentrations are not measured too early, or too frequently, to prevent inappropriate changes in dose being made before a steady state is reached.

Avoiding harm

Intramuscular injections are considered potentially harmful because of the small muscle bulk of babies. However, it is not always easy to establish venous access and occasionally it may be necessary to use the intramuscular route instead. For vaccines the intramuscular route is unavoidable.

For sick preterm infants ventilated for respiratory failure, handling of any kind is a destabilising influence, so the minimal necessary intervention should be the rule. Merely opening the doors of an incubator can destabilise a fragile baby. It is, therefore, a good practice to minimise the frequency of drug administration and to try to coordinate the doses of different medications.

Time-scale of clinical changes

In babies, the time-scale for starting drug treatments is very short because the clinical condition of any baby can change with great rapidity. For example, where a surfactant is required it should be given as soon as possible after birth to premature babies who are intubated and ventilated. Similarly, infection can be rapidly progressive, so starting antibiotics is a priority when the index of suspicion is high or where congenital bacterial infection is likely. The same applies for antiretroviral drugs when a baby is born to a mother positive for HIV, especially if the maternal viral load is high.

For the sick preterm infant, this model applies to a wide range of interventions. It is seldom possible to wait a few hours for a given drug, and this has obvious implications for the level of support required by a neonatal service.

Early urgent immunisation with hepatitis B vaccine and the administration of anti-hepatitis B immunoglobulin are very important in preventing vertical transmission of hepatits B when the mother is e-antigen positive. Of less urgency, but considerable importance, is making sure that premature babies who are still on the neonatal unit 8 weeks after birth get their routine immunisations, since these should be given according to chronological age irrespective of prematurity.

Patient and parent care

It is all too easy to take a mechanistic approach to neonatal medicine, on the grounds that premature infants cannot communicate their needs. Such an approach to therapy is inappropriate. Even when receiving intensive care, any infant who is not either paralysed or very heavily sedated does in fact respond with a wealth of cues and non-verbal communication in relation to their needs. Monitors, therefore, do not replace clinical skills, but provide supplementary information and advance warning of problems. Even the most premature babies show individual characteristics, which emphasises that individualised care is as important in this age group as in any other. In particular, neonatal pain and distress have effects on nociception and behaviour well into the childhood years.

Involvement of parents in every aspect of care is a necessary goal in neonatal clinical practice, and care is increasingly regarded as a partnership between professionals and parents rather than the province of professionals alone. Routine administration of oral medication is thus an act in which parents may be expected to participate, and for those whose baby has to be discharged home still requiring continuous oxygen, the parent will rapidly obtain complete control, with support from the hospital and the primary health care team. The growing number of babies who survive very premature birth but whose respiratory state requires continued support after discharge presents an increasing therapeutic challenge for the future.

Case studies

Case 9.1

Ms A went into labour as a result of an antepartum haemorrhage at 28 weeks of gestation. There was no time to give her steroids when she arrived at the maternity unit and her son, J, was born by vaginal delivery in good condition. However, he required intubation and ventilation at the age of 10 min to sustain his breathing; surfactant was immediately given down the endotracheal tube. He was not weighed at the time but was given intramuscular vitamin K and then taken to the special care unit. On arrival in the unit, baby J was weighed (1270 g) and placed in an incubator for warmth. He was connected to a ventilator. Blood was taken for culture and basic haematology, and he was prescribed antibiotics. A radiograph confirmed the diagnosis of respiratory distress syndrome.

Questions

1. Which antibiotic(s) would be appropriate initially for baby J?
   Over the next 2 days, baby J required modest ventilation and remained on antibiotics. A second dose of surfactant was given 12 h after the first. Parenteral feeding was commenced on day 2 as per unit policy, and on day 3 very slow continuous milk feeding into his stomach was started. Blood cultures were negative at 48 h and the antibiotics were stopped. On day 4 he was extubated into 30% oxygen.
   On day 5, baby J looked unwell with a rising oxygen requirement, increased work of breathing and poor peripheral perfusion. Examination revealed little else except that his liver was enlarged and a little firm, his pulses rather full and easy to feel and there was a moderate systolic heart murmur. One possibility was infection.
2. Which antibiotics would be appropriate for baby J on day 5?
   Another possibility was a patent arterial duct leading to heart failure.
3. How could his heart failure and patent ductus arteriosus be treated?
   After appropriate treatment he looked progressively better and when the blood culture was negative after 2 days, the antibiotics were stopped. By the age of 2 weeks, baby J was on full milk feeds and the duct had closed. He was in air. However, he began to have increasingly frequent episodes of spontaneous bradycardia, sometimes following apnoeic spells in excess of 20 s duration. Examination between episodes showed a healthy, stable baby. Investigations such as haematocrit, serum sodium and an infection screen were normal.
4. At 2 weeks, which drug of choice could be used to treat his apnoea and bradycardia? What would be the expected duration of treatment with this drug?

Answers

1. Blind antibiotic cover is usually started until negative blood cultures are received. Penicillin and gentamicin would provide good cover for streptococci and Gram-negative organisms, which are the most likely potential pathogens at this stage. A suitable dose would be 30 mg/kg of penicillin every 12 h and 2.5 mg/kg of gentamicin every 12 h. Alternatively, a third-generation cephalosporin such as cefotaxime could be used for initial blind treatment. If cultures were negative at 48 h, antibiotics could be stopped provided that there were no clinical indications to continue.
2. At day 5, antibiotic treatment should take account of the likely pathogens such as *S. aureus* and others causing nosocomial infections. A suitable choice for the former would be flucloxacillin, if there was no concern about MRSA, or vancomycin if there was. The vancomycin starting dose would be 15 mg/kg every 12 h. The addition of another agent with good Gram-negative activity such as gentamicin or a third-generation cephalosporin would provide good cover.
3. Intravenous indometacin or ibuprofen would be suitable for the treatment of patent ductus arteriosus. Furosemide (1 mg/kg as a single dose) is the drug of choice for acute heart failure.
4. Caffeine is now the drug of choice. A suitable dose of caffeine for baby J would be a loading dose of 20 mg/kg with maintenance dose of 5 mg/kg/day, increasing to 10 mg/kg/day if necessary. The frequency of episodes of apnoea and bradycardia should decline immediately. The treatment is likely to continue until he is about 34 weeks of postmenstrual age, when his control of breathing should be mature enough to maintain good respiratory function.

Case 9.2

Baby B was born at 25 weeks' gestation and was ventilated for 5 days before being extubated onto continuous positive airways pressure. On extubation she was initially in air, but now at the age of 4 weeks she is mostly in about 30% oxygen, fully fed on milk, and growing well. Her chest X-ray shows the pattern typical of chronic lung disease. One morning she is noticed to be in 45% oxygen, she has had a large weight gain and she looks quite oedematous all over.

Questions

1. What do these symptoms suggest?
   After careful evaluation, baby B is given an oral dose of furosemide 1 mg/kg, following which the oedema goes down, her weight falls and her oxygen requirement returns to 30%.
2. What are the disadvantages of giving regular furosemide in this situation?
   A thiazide diuretic and spironolactone are prescribed. Four days later, routine biochemistry tests show a sodium of 125 mmol/L.
3. What is the choice the attending team has to make?

Answers

1. The symptoms suggest heart failure. Medical examination would probably have revealed an enlarged liver, and the heart might have had a 'gallop' rhythm as well. In babies, the symptoms and signs commonly suggest both left and right ventricular failure.
2. Regular treatment with furosemide causes hypercalcuria, as well as excessive loss of sodium and potassium. Chronic hypercalcuria can lead to nephrocalcinosis. For this reason, a combination of thiazides and spironolactone is commonly used.
3. The sodium is low (but the normal range in preterm babies is 130–140 mmol/L, lower than in children and adults). That it is low is probably an effect of the diuretics. The choice lies between carrying on with the diuretics and supplementing the sodium intake, or stopping the diuretics and observing the baby for any recurrence of heart failure.

10 Paediatrics

C. Barker, A. J. Nunn and S. Turner

Key points

- Children are not small adults.
- Patient details such as age, weight and surface area need to be accurate to ensure appropriate dosing.
- Weight and surface area may change in a relatively short time period and necessitate dose adjustment
- Pharmacokinetic changes in childhood are important and have a significant influence on drug handling and need to be considered when choosing an appropriate dosing regimen for a child.
- The ability of the child to use different dosage forms changes with age, so a range should be available, for example, oral liquid, dispersible tablets, capsules.
- The availability of a medicinal product does not mean it is appropriate for use in children.
- The use of an unlicensed medicine in children is not illegal, although it must be ensured that the choice of drug and dose is appropriate.

Paediatrics is the branch of medicine dealing with the development, diseases and disorders of children. Infancy and childhood is a period of rapid growth and development. The various organs, body systems and enzymes that handle drugs develop at different rates; hence, drug dosage, formulation, response to drugs and adverse reactions vary throughout childhood. Compared with adult medicine, drug use in children is not extensively researched and the range of licensed drugs in appropriate dosage forms is limited.

For many purposes it has been common to subdivide childhood into the following periods:

- neonate: the first 4 weeks of life
- infant: from 4 weeks to 1 year
- child: from 1 year to 12 years

For the purpose of drug dosing, children over 12 years of age are often classified as adults. This is inappropriate because many 12 year olds have not been through puberty and have not reached adult height and weight. The International Committee on Harmonization (2001) has suggested that childhood be divided into the following age ranges for the purposes of clinical trials and licensing of medicines:

- preterm newborn infant
- term newborn infants (0–27 days)
- infants and toddlers (28 days to 23 months)

- children (2–11 years)
- adolescents (12–16/18 years)

These age ranges are intended to reflect biological changes: the newborn (birth to 4 weeks) covers the climacteric changes after birth, 4 weeks to 2 years the early growth spurt, 2–11 years the gradual growth phase and 12–18 years puberty and the adolescent growth spurt to final adult height. Manufacturers of medicines and regulatory authorities are working towards standardising the age groups quoted in each product's Summary of Product Characteristics.

Demography

The 2001 census revealed that dependent children still make up a substantial number of people, at 11.7 million, but figures published by the Office for National Statistics in 2009 indicate that over the last 25 years the percentage of the population aged 16 years and under has decreased from 21% to 19%. This trend is predicted to continue and by 2033 the percentage of the population under 16 years old is predicted to be 18%. The UK census in 2011 will be the next opportunity to confirm this trend.

Children make substantial use of hospital-based services. It has been estimated that of the 14 million attendances at hospital emergency departments reported each year in England, 2.9 million were for children. At the same time there were 4.5 million outpatient attendances and 700,000 in-patient admissions. The 10 most common admission diagnoses in a specialist children's hospital over an 18-month period are shown in Table 10.1.

Congenital anomalies

Congenital anomalies remain an important cause of infant and child mortality in England and Wales, and account for an increasing proportion of infant deaths. The National Congenital Anomaly System (NCAS), established in 1964 in the wake of the thalidomide tragedy, has monitored congenital anomalies nationally in England and Wales. Registers such as NCAS are important in planning service delivery and alerting specialists to conditions where research is required. However, it relies on voluntary notifications and collaborates with local registers to improve the quality and quantity of data (see Useful Paediatric Websites at end of chapter).

Table 10.1 Top 10 diagnoses on admission to a specialist children's hospital

Ranking	Diagnosis
1	Respiratory tract infections
2	Chronic diseases of tonsils and adenoids
3	Asthma
4	Abdominal and pelvic pain
5	Viral infection (unspecified site)
6	Non-suppurative otitis media
7	Inguinal hernia
8	Unspecified head injury
9	Gastroenteritis/colitis
10	Undescended testicle

Data for 2008 are available but there is ongoing discussion about the future direction of the recording service, given the wide variability in reporting between areas with and without regional congenital anomaly registers. In 2007, a new classification of congenital anomalies was introduced to include tighter rules for deciding which congenital anomalies should be included in the Office for National Statistics report making year on year comparisons more difficult.

In 2008, there were 175 central nervous system (CNS) anomalies, for example, hydrocephalus, 282 cleft lip/palate, 932 heart and circulatory, 258 hypospadias and 225 Down's syndrome reported to NCAS.

Neural tube defects (spina bifida) are one example of devastating congenital malformations that have been influenced by public health intervention programmes. The results of a long-term study (MRC Vitamin Study Research Group, 1991) showed that folate supplementation prevented 72% of neural tube defects when given to women at high risk of having a child with a neural tube defect. Hence, folate supplementation is now part of the routine advice given in antenatal clinics.

Cancer

Cancer is very rare in childhood; around 1700 new cases are diagnosed in children less than 15 years old in the UK each year. About one-third of all childhood cancers are leukaemias and of these, about 80% are of the acute lymphoblastic type (ALL). Although rare, childhood cancer is the most common cause of death from illness in children aged between 1 and 15 years of age.

As a consequence of the technical advances in treatment and the centralisation of services in specialist centres, a much greater number of childhood cancer sufferers are surviving to adulthood.

Asthma, eczema and hay fever

Asthma, eczema and hay fever (allergic rhinitis) are among the most common chronic diseases of childhood and most of the affected children are managed in primary care. During the 1970s and 1980s there was considerable expansion of epidemiological research into these disorders, prompted mainly by concern about the increase in hospital admissions for childhood asthma despite the availability of effective anti-asthma medication. These studies failed to identify any demographic, perinatal or environmental factor which could explain more than a small proportion of the large changes in prevalence of asthma, hay fever or eczema. Incidence rates of acute asthma in children under 5 years old were reported to be 1.5 per 1000 per week in 1991; the rates for children aged 5–14 years old were 0.9 per 1000 per week. Between 1993 and 2000 the incidence rates for both groups declined, but asthma continues to be an important childhood illness placing a burden on the health service.

Infections

Despite a dramatic decline in the incidence of childhood infectious diseases during the twentieth century, they remain an important cause of ill health in childhood. Major advances in the prevention of infections have been achieved through the national childhood vaccination programme.

The importance of maintaining high vaccine uptake has been demonstrated by the resurgence of vaccine-preventable diseases where children have not been vaccinated. Adverse publicity surrounding the MMR (measles, mumps and rubella) vaccine, involving a possible association with Crohn's disease and autism, resulted in a loss of public confidence in the vaccine and a decrease in MMR coverage. This occurred in spite of rigorous scientific investigation and evidence refuting the claims. The annual coverage for MMR for 2-year olds declined from 92% in 1992 to 87% in 2000 and data for 2004 show that it dropped to 81.5%. Although this decline is far less than that seen for pertussis in the 1970s, if MMR coverage remains at this level or declines further, resurgences of MMR in primary schoolchildren will become more common. NHS information centre data revealed 85% of children in England had received the MMR vaccine in 2007/8. However, to achieve herd immunity, 95% of children need to be immunised; unless this figure is improved a measles epidemic still remains a possibility.

An important gastro-intestinal infection that appears to be increasing is infection with verotoxin-producing *Escherichia coli* (VTEC). This is important because it is the main cause of haemolytic uraemic syndrome, a severe condition which can lead to acute renal failure in children. VTEC is an example of an emerging infection. Before the 1980s it was unknown and during the 1990s reports of infection with VTEC in children in the UK tripled from 172 in 1991 to 531 in 1999. In 2009 the rates of VTEC 0157 decreased as age increased, with significantly higher rates in the 0–4 year age group (8 per 100,000) than in 5–9 year olds (4 per 100,000) and a further decrease (2 per 100,000) in the 10–19 year age group. It is a

public health priority to improve VTEC 0157 surveillance and improve diagnostic testing.

Respiratory syncytial virus (RSV) is the most important cause of lower respiratory tract infection in infants and young children in the UK, in whom it causes bronchiolitis, tracheo-bronchitis and pneumonia. It is responsible for seasonal outbreaks of respiratory tract infection most commonly between October and April. The main burden of disease is borne by children under 2 years and there are around 7000–10000 confirmed laboratory reports of RSV in children in England and Wales each year. During the winter months, RSV is the single greatest cause of admission to hospital in children.

Mental health disorders

Mental health disorders are another emerging concern in the child health arena. In 2004, 1 in 10 children and young people aged 5–16 years old had a clinically diagnosed mental health disorder. These included 4% with an emotional disorder such as depression or anxiety, 6% with a conduct disorder, 2% with a hyperkinetic disorder and 1% with less common disorders, for example, autism, tics.

Groups at particular high risk of psychiatric disorder include children in the care system, young people who are homeless and young offenders. Longitudinal evidence has confirmed that many child psychiatric disorders persist well into adult life. Biological, psychological and social factors all seem likely to contribute to the risk of psychiatric disorders, and may act in combination.

Drugs, smoking and alcohol

The harm that drugs, smoking and drinking can do to the health of children and young people is recognised and a number of targets have been set in an attempt to reduce prevalence. Recent figures on smoking, alcohol and drug use among young people have been provided by the NHS Information Centre in their 2008 report.

In 2008, 6% of schoolchildren smoked regularly (at least once a week). Girls are more likely to smoke than boys and the prevalence increases with age. Around 14% of 15-year olds smoke regularly compared to 0.5% of 11-year olds. However, the prevalence of smoking amongst children has halved since its peak in the mid-1990s (13% in 1996), suggesting a decline in prevalence to below government targets. In 2007, the minimum age for buying tobacco was increased from 16 years old to 18 years old.

More than half of pupils (52%) aged 11–15 years have drunk alcohol in their lifetime. In 2008, a national survey identified that the mean amount of alcohol consumed by pupils who had drunk in the last week was 14.6 units. Boys drink more than girls and older pupils drink more than younger pupils. In one large survey, 17% of pupils aged 11–15 years old admitted to being drunk in the last 4 weeks.

The prevalence of drug use has declined since 2001. In 2008, 22% of pupils said that they had ever used drugs with 33% reporting that they had ever been offered drugs. Pupils were most likely to have taken cannabis (9%). Five percent of pupils had sniffed glue or other volatile substances in the last year and 2.9% had sniffed poppers. Overall, 3.6% of pupils had taken class A drugs in the last year.

Nutrition and exercise

Health during childhood can impact upon well-being in later life. Good nutrition and physical exercise are vital both for growth and development and for preventing health complications in later life. In addition, dietary patterns in childhood and adolescence have an influence on dietary preferences and eating patterns in adulthood.

In 2000, an international definition of overweight and obesity in childhood and adolescence was proposed to help calculate internationally comparable prevalence rates of overweight and obesity in children and adolescents. The definition interprets overweight and obesity in terms of reference points for body mass index (BMI, in kg/m^2) by age and sex, and is linked to the widely used adult overweight cut-off point of 25 and adult obesity cut-off point of 30.

In 2004, it was estimated that 14% of boys and 17% of girls aged 2–15 years of age were obese. Probable reasons for a rise in overweight and obesity in children are changes in diets and an inactive lifestyle. There is evidence that obesity at an early age tends to continue to adulthood.

Being overweight is linked to the development of type 2 diabetes, high blood pressure, heart disease, stroke, certain cancers and other types of illnesses. Therefore, healthy eating is not only important in relation to weight but also contributes to reducing the risk of heart disease, stroke and some cancers in later life. It is recommended that a well-balanced diet providing all the nutrients required should include at least five portions of fruit and vegetables a day. It is now practice in many areas for infant children (aged 4–7 years) each day to be provided with a piece of free fruit during school break time.

The normal child

Growth and development are important indicators of a child's general well-being and paediatric practitioners should be aware of the normal development milestones in childhood. In the UK, development surveillance and screening of babies and children is well established through child health clinics.

Weight is one of the most widely used and obvious indicators of growth, and progress is assessed by recording weights on a percentile chart (Fig. 10.1). A weight curve for a child which deviates from the usual pattern requires further investigation. Separate recording charts are used for boys and girls and since percentile charts are usually based on observations of the white British population, adjustments may be necessary for some ethnic groups. The World Health Organization (WHO) has challenged the widely used growth charts, based on growth rates of infants fed on formula milk. In 2006, it published new growth standards based on a study of more than 8000 breast-fed babies from six countries around the world. The optimum size is now that of a breast-fed baby. Recently, new growth charts have been introduced for children
Fig. 10.1 Example of a centile chart (Child Growth Foundation).

from birth to 4 years of age. These combine the UK and WHO data. Copies can be accessed at http://www.rcpch.ac.uk/Research/UK-WHO-Growth-Charts.

Height (or length in children less than 2 years of age) is another important tool in developmental assessment. In a similar way to weight, height or length should follow a percentile line. If this is not the case or if growth stops completely, then further investigation is required. The normal rate of growth is taken to be 5 cm or more per year and any alteration in this growth velocity should be investigated.

For infants up to 2 years of age, head circumference is also a useful parameter to monitor. In addition to the above, assessments of hearing, vision, motor development and speech are undertaken at the child health clinics. A summary of age-related development is shown in Fig. 10.2.

Child health clinics play a vital role in the national childhood immunisation programme, which commences at 2 months of age. Immunisation is a major success story for preventive medicine, preventing diseases that have the potential to cause serious damage to a child's health, or even death. An example of the impact that immunisation can have on the profile of infectious diseases is demonstrated by the meningitis C immunisation campaign, which began in November 1999. The UK was the first country to introduce the meningitis C conjugate (MenC) vaccine and uptake levels have been close to 90%. The programme was targeted at under-20 year olds and has been a huge success, with a 90% reduction in cases in that age group. Authorities were hoping to mirror the success of the meningitis C campaign with the introduction of the seven valent pneumococcal vaccine into the routine UK childhood immunisation schedule in April 2006. Post-licensing surveillance has shown a large reduction in both invasive and non-invasive disease incidence due to vaccine serotypes in vaccinated individuals. However, during the same period, the UK has seen an increase in invasive disease due to the non-vaccine serotypes, caused for a large part by the six serotypes not covered by the seven valent vaccine, but present in a new 13 valent vaccine. In April 2010, the 13 valent pneumoccocal vaccine replaced the seven valent vaccine in the standard immunisation schedule. Human papilloma virus vaccine has also recently been introduced to the immunisation programme in the UK for females aged 12–13 years of age, to reduce the risk of cervical cancer.

Advice on the current immunisation schedule can be found in the current edition of the British National Formulary for Children.

Drug disposition

Pharmacokinetic factors

An understanding of the variability in drug disposition is essential if children are to receive rational and appropriate drug therapy (Anderson and Holford, 2008, 2009). For convenience, the factors that affect drug disposition will be dealt with separately. However, when treating a patient all the factors have a dynamic relationship and none should be considered in isolation.

Absorption

Oral absorption. The absorption process of oral preparations may be influenced by factors such as gastric and intestinal transit time, gastric and intestinal pH and gastrointestinal contents. Posture, disease state and therapeutic interventions such as nasogastric aspiration or drug therapy can also affect the absorption process. It is not until the second year of life that gastric acid output increases and is comparable on a per kilogram basis with that observed in adults. In addition, gastric emptying time only approaches adult values at about 6 months of age.

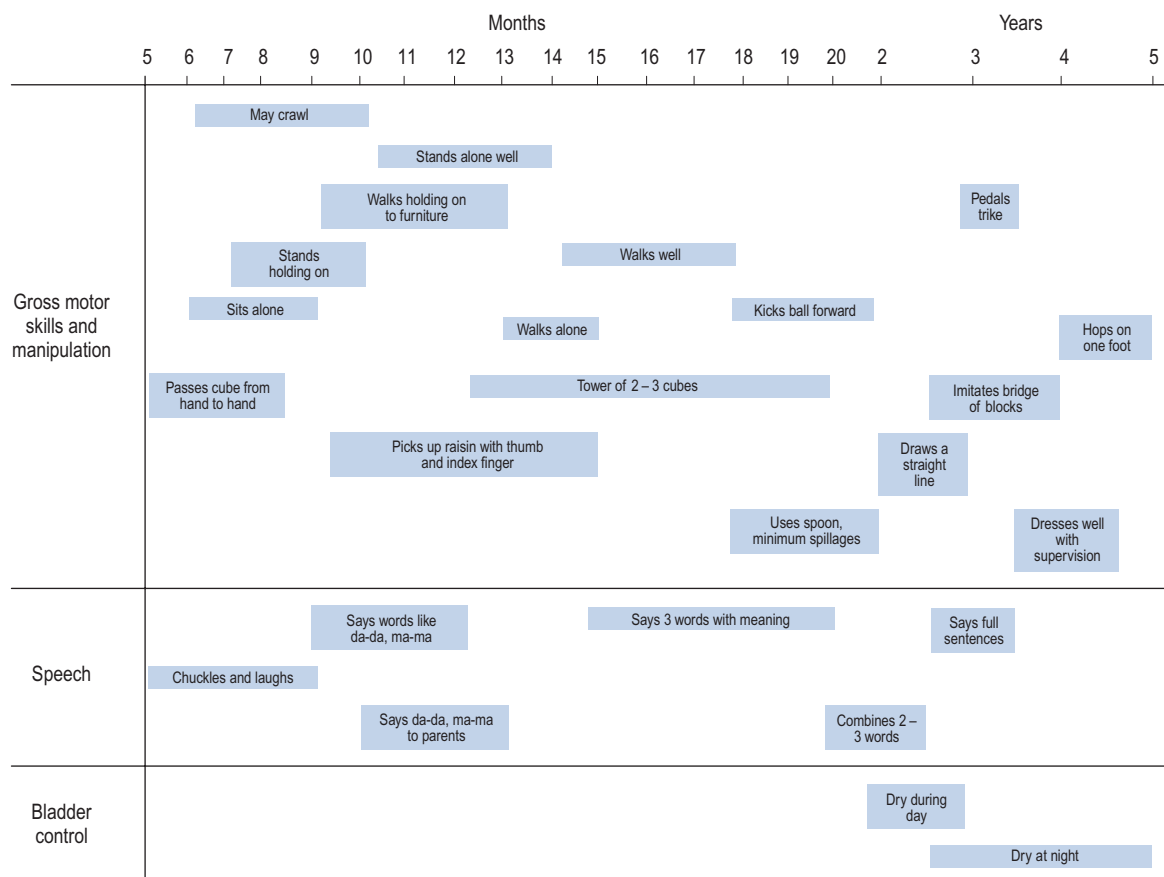
The bioavailability of sulphonamides, digoxin and phenobarbital has been studied in infants and children of a wide age distribution. Despite the different physicochemical properties of the drugs, a similar bioavailability pattern was observed in each case. The rate of absorption was correlated with age, being much slower in neonates than in older infants and children. However, few studies have specifically reported on the absorption process in older infants or children. The available data suggest that in older infants and children orally administered drugs will be absorbed at a rate and extent similar to those in healthy adults. Changes in the absorption rate would appear to be of minor importance when compared to the age-related differences of drug distribution and excretion.


Fig. 10.2 A summary of the various stages of development.

Intramuscular absorption. Absorption in infants and children after intramuscular (i.m.) injection is noticeably faster than in the neonatal period, since muscle blood flow is increased. On a practical note, intramuscular administration is very painful and should, where possible, be avoided. The route should not be used for the convenience of staff if alternative routes of administration are available.

Intraosseous absorption. This is a useful route of administration in patients in whom intravenous access cannot be obtained. It is especially useful in paediatric cardiorespiratory arrests where rapid access is required. A specially designed needle is usually inserted into the flat tibial shaft until the marrow space is reached. This route is considered equivalent to the intravenous route for rate of drug absorption, and most drugs can be given by this route.

Topical absorption. Advances in transdermal drug delivery systems have led to an increased use of this route of administration. For example, patch formulations of hyoscine hydrobromide have been found to be very useful to dry up secretions in children with excess drooling; likewise fentanyl patches can be useful in pain management. Percutaneous absorption, which is inversely related to the thickness of the stratum corneum and directly related to skin hydration, is generally much greater in the newborn and young infant than in the adult. This can lead to adverse drug reactions (ADRs). For example, the topical application of a preparation containing prilocaine and lidocaine (EMLA) should not be used in preterm infants because of concerns about significant absorption of prilocaine in this age group, which may lead to methaemoglobinaemia. The development of needle-free subcutaneous jet injection systems appears to bring many benefits as a method of drug administration. They have been shown to give comparable levels to standard subcutaneous injections and overcome the problems of needle phobia, with less pain on administration. This system has been used with growth hormone, insulin, sedation prior to procedures and vaccination in children.

Another route of topical absorption is ophthalmically. Significant amounts of drugs may be absorbed from ophthalmic preparations through ophthalmic or nasolacrimal duct absorption; for example, administration of phenylephrine eye drops can lead to hypertensive episodes in children.

Rectal absorption. The rectal route of administration is generally less favoured in the UK than in other European countries. It can be useful in patients who are vomiting or in infants or children reluctant or unable to take oral medication. The mechanism of rectal absorption is probably similar to that of the upper part of the gastro-intestinal tract, despite differences in pH, surface area and fluid content. Although some products are erratically absorbed from the rectum, the rapid onset of action can be invaluable; for example, rectal diazepam solution produces a rapid cessation of seizures in epilepsy and can be easily administered by parents in an emergency.

Buccal absorption. The buccal cavity is a potentially useful route of administration in patients who cannot tolerate

medications via the oral route; for example, postoperative patients or those with severe nausea. Highly lipophilic drugs can rapidly cross the buccal mucosa. Fentanyl is available as a lozenge formulation (Actiq®). This has been used to relax children before painful procedures and as a treatment for breakthrough pain in palliative care patients, although it remains unlicensed for use in children. Midazolam has also been administered via this route for the acute treatment of seizures and is favoured over rectal diazepam for this purpose.

There are a number of 'melt' and 'wafer' formulations available, for example, piroxicam and ondansetron. These preparations have the advantage of palatability; however, they are not absorbed via the buccal muscosa but require swallowing and enteral absorption of the active constituent. Desmopressin for buccal absorption has been introduced as an alternative to the tablet formulation 120μcg is given buccally compared to 200μcg orally.

Intranasal absorption. The intranasal route is another useful route of administration. Medicines can be administered intranasally for their local action, for example, sympathomimetics, or for their systemic effects, for example, desmopressin in the treatment of diabetes insipidus. Midazolam has been widely used intranasally in children for the treatment of anxiety prior to procedures and also for the treatment of childhood seizures. Highly lipophilic analgesics such as fentanyl are used via this route for the treatment of acute pain, particularly in situations where intravenous access is difficult, for example, reduction of fractures in the emergency department. Diamorphine may be administered by nasal instillation and is preferred to intramuscular or oral morphine.

Significant systemic absorption of medicines given intranasally for their local effect can also occur; for example, corticosteroids used in the treatment of allergic rhinitis have led to cushingoid symptoms and growth suppression.

Inhalation absorption. Direct delivery of drug therapies to the lungs has been the mainstay of treatment for asthma for many years. However, systemic absorption of corticosteroids used in the treatment of asthma may produce adrenal suppression.

The administration of insulin by inhalation for the treatment of both type 1 and type 2 diabetes mellitus in adults was anticipated to be of benefit in children. The first licensed product (for adults) was launched in 2006 but was withdrawn in 2007 due to disappointing worldwide sales. No similar product has replaced it.

Distribution

A number of factors that determine drug distribution within the body are subject to change with age. These include vascular perfusion, body composition, tissue-binding characteristics and the extent of plasma protein binding.

As a percentage of total body weight, the total body water and extracellular fluid volume decrease with age (Table 10.2). Thus, for water-soluble drugs such as aminoglycosides, larger doses on a milligram per kilogram of body weight basis are required in the neonate than in the older child to achieve similar plasma concentrations.

Table 10.2 Extracellular fluid volume and total body water as a percentage of body weight at different life stages

Age	Total body water (%)	Extracellular fluid (%)
Preterm neonate	85	50
Term neonate	75	45
3 months	75	30
1 year	60	25
Adult	60	20

Protein binding. Despite normal blood pH, free fatty acid and bilirubin levels in infants, binding to plasma proteins is reduced as a result of low concentrations of both globulins and albumin. It has been suggested that binding values comparable with those seen in adults are reached within the third year of life for acidic drugs, whereas for basic drugs adult values are not reached until between 7 and 12 years of life. The clinical significance of this reduction in infants and older children is minimal. The influence of disease states, such as renal impairment, on plasma protein binding is more important.

Drug metabolism

At birth the majority of the enzyme systems responsible for drug metabolism are either absent or present in considerably reduced amounts compared with adult values, and evidence indicates that the various systems do not mature at the same time. This reduced capacity for metabolic degradation at birth is followed by a dramatic increase in the metabolic rate in the older infant and young child. In the 1–9 year age group in particular, metabolic clearance of drugs is shown to be greater than in adults, as exemplified by theophylline, phenytoin and carbamazepine. Thus, to achieve plasma concentrations similar to those observed in adults, children in this age group may require a higher dosage than adults on a milligram per kilogram basis (Table 10.3).

Metabolic pathways that play only a minor role in adults may play a more significant role in children and compensate for any deficiencies in the normal adult metabolic pathway. For example, glucuronidation accounts for up to 70% of the metabolic pathway of paracetamol in adulthood; however,

Table 10.3 Theophylline dosage in children older than 1 year

Age	Dosage (mg/kg/day)
1–9 years	24
9–12 years	20
12–16 years	18
Adult	13

Table 10.4 Renal clearance of gentamicin

	Plasma half-life
Small premature infants weighing less than 1.5 kg	11.5 h
Small premature infants weighing 1.5–2 kg	8 h
Term infants and large premature infants less than 1 week of age	5.5 h
Infants 1 week to 6 months	3–3.5 h
Infants more than 6 months to adulthood	2–3 h

in the early newborn period glucuronidation is deficient, accounting for less than 20% of paracetamol metabolism. This is compensated for by a more pronounced sulphate conjugation and this leads to an apparently normal half-life in newborns. Paracetamol appears to be less toxic in children than in adults and this may be in part explained by the compensatory routes of metabolism.

Renal excretion

The anatomical and functional immaturity of the kidneys at birth limits renal excretory capacity. Below 3–6 months of age the glomerular filtration rate is lower than that of adults, but may be partially compensated for by a relatively greater reduction in tubular reabsorption. Tubular function matures later than the filtration process. Generally, the complete maturation of glomerular and tubular function is reached only towards 6–8 months of age. After 8 months the renal excretion of drugs is comparable with that observed in older children and adults. Changes in renal clearance of gentamicin provide a good example of the maturation of renal function (Table 10.4).

Other factors

In addition to age-related changes in drug disposition, nutritional status and disease states can influence drug handling. High plasma clearance of antibiotics such as penicillins and aminoglycosides has been demonstrated in children with cystic fibrosis; increased elimination of furosemide has been reported in children with nephrotic syndrome, while prolonged elimination of furosemide has been reported in infants with congestive cardiac failure. Altered protein binding has been demonstrated in hepatic disease, nephrotic syndrome, malnutrition and cardiac failure.

Drug therapy in children

Dosage

Doses of medicines in children should be obtained from a paediatric dosage handbook and should not be extrapolated from the adult dose. There are a number of such texts available

internationally. The information within them may be based on evidence from clinical studies in children or reflect the clinical experience of the contributors. In the UK, the BNF-C (see Further reading section) is a national formulary which includes prescribing guidelines and drug monographs. It contains information on licensed, unlicensed and off-label use of medicines. When consulting any dosage reference resource, care should be taken to identify the dosage convention being used. Most formularies use a single dose convention and indicate the number of times the dose should be repeated in a 24-h period. Other formularies indicate the total daily dose and the number of doses this is divided into. Some formularies combine both conventions. Confusing the total daily dose with the single dose to be repeated may have catastrophic consequences and the single dose convention has become the preferred convention.

While age, weight and height are the easiest parameters to measure, the changing requirement for drug dosage during childhood corresponds most closely with changes in body surface area (BSA). Nomograms which allow the surface area to be easily derived are available. There are practical problems in using the surface area method for prescribing; accurate height and weight may be difficult to obtain in a sick child, and manufacturers rarely provide dosage information on a surface area basis. The surface area formula for children has been used to produce the percentage method, giving the percentage of adult dose required at various ages and weights, although use should be reserved for exceptional circumstances (Table 10.5).

In selecting a method of dosage calculation, the therapeutic index of the drug should be considered. For agents with

Table 10.5 Percentage of adult dose required at various ages and body weights

	Mean weight for age (lb)	Mean weight for age (kg)	Percent of adult dose
Newborn (full term)	7.7	3.5	12.5
2 months	10	4.5	15
4 months	14	6.5	20
1 year	22	10	25
3 years	33	15	33.3
7 years	50	23	50
10 years	66	30	60
12 years	86	39	75
14 years	110	50	80
16 years	128	58	90
Adult	150	68	100

a narrow therapeutic index, such as cytotoxic agents, where recommendations are quoted per square metre, dosing must be based on the calculated surface area. However, there may be exceptions, for example, in children less than 1 year of age who have a proportionally larger surface area than other age groups. In children less than 1 year, dosages of chemotherapeutic agents are often based on weight rather than surface area to prevent overestimation of the dose in this age group.

For drugs with a wide therapeutic index, such as penicillin, single doses may be quoted for a wide age range. Between these two extremes, doses are quoted in milligrams per kilogram and this is the most widely used method of calculation. Whichever method is used, the resulting dosage should be rounded sensibly to facilitate dose measurement and administration and subsequently modified according to response or adverse effects.

It is important to note that none of the available methods of dosage calculation account for the change in dosage interval that may be required because of age-related changes in drug clearance. Where possible, the use of therapeutic drug monitoring to confirm the appropriateness of a dose is recommended.

Choice of preparation

The choice of preparation and its formulation will be influenced by the intended route of administration, the age of the child, availability of preparations, other concomitant therapy and, possibly, underlying disease states. The problems of administering medicines to children were reviewed by the European Medicines Evaluation Agency (EMEA, 2005).

Buccal route

Drugs may be absorbed rapidly from the buccal cavity (the cheek pouch) or they may dissolve when administered and be swallowed and absorbed from the stomach. 'Melt®' technology, for example, desmopressin, piroxicam, ondansetron, in which the drug and flavourings are freeze-dried into a rapidly dissolving pellet, can be very useful. The 'melt' dissolves instantly into a very small volume which is difficult for the child to reject. Gels, sprays and liquids can also be administered into the buccal cavity, using drugs such as midazolam to treat seizures.

Oral route

The oral route is usually the most convenient but in an unco-operative child it can be the least reliable. Safe and effective drug therapy requires accurate administration, yet the 5-mL spoon is a difficult means of administering liquid medicines. Use of an oral syringe can provide controlled administration, ensure accurate measurement of the calculated dose and avoids the need for dilution of preparations with syrup. Use of oral syringes (which will not fit an intravenous Luer connector) are mandatory in UK practice. Concentrated formulations may be administered as oral drops in a very small volume. Although convenient, there could be significant dosage errors if drops are not delivered accurately.

In general, liquid preparations are more suitable for children under 7 years of age; there is a wide variability in the age at which children can swallow tablets and capsules but some quite young children can cope with solid dose formulations, especially mini-tablets. Some commercially available products contain excipients such as alcohol, propylene glycol and dyes that may cause adverse effects or be inappropriate for use in children with particular disease states. The osmolality and tonicity of preparations may be important; necrotizing enterocolitis (a disorder seen in the neonatal period) has been associated with many different factors including high-osmolality infant feeding formulae and pharmaceutical preparations, although a causal relationship has not been established. Oral liquids with high-osmolality or extremes of pH may irritate the stomach and should be diluted for administration. Sugar-free preparations may be necessary in the diabetic child or be desirable in other children for the prevention of dental caries. It is, however, important to be aware of the potential problems associated with substitutes for sucrose. The artificial sweetening agent aspartame, used in some preparations, should be used with caution in children with phenylketonuria because of its phenylalanine content. Other substitutes such as sorbitol and glycerol may not contribute to dental caries but produce diarrhoea if large doses are given. In these instances, a specially formulated preparation containing a higher amount of the active drug in small volume may be preferable.

Injection solutions can sometimes be administered orally, although their concentration and pH must be considered together with the presence of unsuitable excipients. Powders or small capsules may be prepared and used as an alternative. However, lactose is a common diluent in powders and caution must be exercised in children with lactose intolerance as a result of an inborn error of metabolism, or temporarily following gastro-intestinal diseases or gut surgery.

Parents are often discouraged from adding the dose of medicine to an infant's feed. Quite apart from potential interactions which may arise with milk feeds, if the entire feed is not taken a proportion of the dose will be lost. It is also important to advise parents when it is not appropriate to crush solid dosage forms (e.g. sustained-release preparations). However, it should be recognised that addition of a medicine to a food or liquid may be the only way of rendering an unpalatable medicine acceptable. Whenever possible, evidence that this is pharmaceutically acceptable should be sought.

Manufacturers are increasingly recognising the difficulties associated with administration of medicines to children and are responding with novel formulations.

Mini tablets of just a few millimetres diameter may be useful to ease administration and allow flexibility of dosage. They may be presented in capsules or counted from bulk and can be individually coated for positioned or sustained release. Increased surface area may present larger quantities of excipients to the child and requires careful control.

If an age-appropriate formulation is not available, for example, for a medicine used off-label, a liquid oral preparation

may be prepared extemporaneously, often by crushing the 'adult' tablets and suspending the powder in commercial or locally produced suspending agents. Alternatively the 'adult' dosage form may be manipulated, for example, by splitting tablets. Due consideration must be given to safety, accuracy and stability, when modifying dosage forms.

Nasogastric and gastrostomy administration

Medicines may be administered into the stomach via a nasogastric tube in the unconscious child or when swallowing is difficult. A gastrostomy tube may be placed into the stomach transcutaneously if the problem is long term, for example, in some children with cerebral palsy. Enteral nutrition may also be administered through such tubes. Drugs such as phenytoin may adsorb to the plastic of the tubes and interact with enteral feeds, requiring special administration techniques to ensure bioavailability. Suitability of drugs for nasogastric or gastrostomy tube administration should always be checked.

Intranasal route

Several drugs, such as desmopressin, diamorphine, fentanyl and midazolam, have been shown to be absorbed from the nasal mucosa. This route may avoid the need for injections but administration may be difficult in the uncooperative child and drugs administered may irritate the mucosa or be painful.

Rectal route

Although the rectal route can be useful, it is limited by the range of products available and the dosage inflexibility associated with rectal preparations. Some oral liquid preparations such as chloral hydrate and carbamazepine can be administered rectally. The route is useful in the unconscious child in the operating theatre or intensive care unit and it is not uncommon to administer perioperative analgesics such as diclofenac and paracetamol and the antiemetic ondansetron using suppository formulations. Parents and teachers may express concerns about using this route, fearing accusations of child abuse, but it is an important route of administration for diazepam or paraldehyde in the fitting child. Increasingly, buccal administration of midazolam may be preferred.

When oral and rectal routes are inappropriate, the parenteral route may be necessary.

Parenteral route

The problems associated with the administration of intramuscular injections in infants and children have been described earlier in this chapter. The route has a limited role in paediatric drug therapy and should not be used routinely. The intravenous route of administration is more widely used, but it is still associated with a number of potential problems that are outlined below.

Intravenous access. The practical difficulties of accessing small veins in the paediatric patient do not require explanation. However, these difficulties can often explain the sites of access that are chosen. Scalp veins, commonly used in newborn infants, are often very prominent in this age group, allowing easy access. It is also more difficult for the infant to dislodge a cannula from this site than from a site on the arm or foot. Likewise the umbilical artery offers a useful route for monitoring the patient but can also be used for drug administration in some circumstances. Vasoconstrictive drugs, such as adrenaline (epinephrine), dopamine and isoprenaline, should not be given by this route.

Fluid overload. In infants and children, the direct administration of intravenous fluids from the main infusion container is associated with the risk of inadvertent fluid overload. This problem can be avoided by the use of a paediatric administration set and/or a volumetric infusion device to control the flow rate. A paediatric administration set incorporates a graduated volumetric chamber with a maximum capacity of 150 mL. Although this system is intended primarily as a safety device, the volume within the burette chamber can be readily adjusted, allowing its use for intermittent drug administration and avoiding the need for the 'piggyback system' commonly used in adult intravenous administration.

Dilution of parenteral preparations for infusion may also cause inadvertent fluid overload in children. In fluid-restricted or very young infants, it is possible that the volume of diluted drug can exceed the daily fluid requirement. In order to appreciate this problem, the paediatric practitioner should become familiar with the fluid volumes that children can tolerate. As a guide these volumes can be calculated using the following formula: 100 mL/kg for the first 10 kg, plus 50 mL/kg for the next 10 kg, plus 20 mL/kg thereafter. Worked examples are given in Table 10.6. It is important to remember that these volumes do not account for losses such as those caused by dehydration, diarrhoea or artificial ventilation. While the use of more concentrated infusion solutions may overcome the problem of fluid overload, stability data on concentrated solutions are often lacking. It may, therefore, be necessary to manipulate other therapy to accommodate the treatment or even to consider alternative treatment options. Fluid overload may also result from excessive volumes of flushing solutions and is described later. Guidance on selecting appropriate intravenous fluids for administration to children to avoid fluid induced hyponatraemia are available (National Patient Safety Agency, 2007).

Lack of suitable paediatric formulations. A large number of parenteral products are only available in adult dose sizes.

Table 10.6 Calculation of standard daily fluid requirements in paediatric patients

15 kg patient	35 kg patient
100 mL/kg × 10 kg = 1000 mL	100 mL/kg × 10 kg = 1000 mL
Plus 50 mL/kg × 5 kg = 250 mL	Plus 50 mL/kg × 10 kg = 500 mL
Total = 1250 mL/day	Plus 20 mL/kg × 15 kg = 300 mL
	Total = 1800 mL/day

The concentrations of these products can make it difficult to measure the small doses required in paediatrics. Dilution to achieve measurable concentrations, miscalculations and misinterpretation of decimal points may lead to errors. 'Ten times' errors are common particularly when drawing the dose from a single ampoule or vial that contains sufficient for an adult patient.

Displacement volume. Reconstitution of powder injections in accordance with manufacturers' directions usually makes no allowance for the displacement volume of the powder itself. Hence, the final volume may be greater than expected and the concentration will, therefore, be less than expected. This can result in the paediatric patient receiving an underdose, which becomes even more significant in younger patients receiving smaller doses or more concentrated preparations. Paediatric units usually make available modified reconstitution directions which take account of displacement volumes.

Rates of infusion. The slow infusion rates often necessary in paediatrics may influence drug therapy. The greater the distance between the administration port and the distal end of the delivery system, and the slower the flow rate, the longer the time required for the drug to be delivered to the patient. In very young infants and children, it may take several hours for the drug to reach the patient, depending on the point of injection. This is an important consideration if dosage adjustments are being made in response to plasma level monitoring. Bolus injections should always be given as close to the patient as possible.

Dead space. Following administration via an injection port, a residual amount of drug solution can remain trapped at the port. If dose volumes are small the trapped fluid may represent a considerable proportion of the intended dose. Similarly, the volume of solution required to prime the intravenous lines or the in-line filters (i.e. the dead space) can be a significant proportion of the intended dose. This problem can be minimised by ensuring that drugs are flushed at an appropriate rate into the main infusion line after administration via an injection port or through a filter, and by priming the lines initially with a compatible solution. The small volumes required to prime filters and tubing specifically designed for infants and children can be used to minimise the dead space. Modern filter materials can produce less adsorption of drugs so that more of the drug is delivered to the patient.

It is important to remember that flushing volumes can add a significant amount to the daily fluid and sodium intake, and it may be important to record the volume of flushing solutions used in patients susceptible to fluid overload.

Excipients. Analogous to oral preparations, excipients may be present in parenteral formulations and can be associated with adverse effects. Benzyl alcohol, polysorbates and propylene glycol are commonly used agents which may induce a range of adverse effects in children including metabolic acidosis, altered plasma osmolality, central nervous system depression, respiratory depression, cardiac arrhythmias and seizures. Knowledge of the products that contain these ingredients may influence drug selection.

Many hospitals have established centralised intravenous additive services (CIVAS) that prepare single intravenous doses under aseptic conditions, thus avoiding the need for preparation at ward level. Such services have not only significantly decreased the risks associated with intravenous therapy, particularly in the paediatric population, but can also produce considerable cost savings.

Pulmonary route

The use of aerosol inhalers for the prevention and treatment of asthma presents particular problems for children because of the coordination required. The availability of breath-activated devices and spacer devices and large-volume holding chambers has greatly improved the situation. Guidance has been published on the use of inhaler devices in children less than 5 years of age (National Institute for Health and Clinical Excellence, 2000) and older children (National Institute for Health and Clinical Excellence, 2002) and updated in 2008 (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2008). Recent experience has shown that different types of large-volume holding chambers alter drug delivery and absorption and should not be considered as interchangeable.

It must be remembered that drugs can be absorbed into the systemic circulation after pulmonary administration or may be absorbed by the enteral route when excess drug is swallowed. High-dose corticosteroid inhalation may suppress the adrenal cortical axis and growth by this mechanism.

Dose regimen selection

A summary of the factors to be considered when selecting a drug dosage regimen or route of administration for a paediatric patient is shown in Table 10.7.

Counselling, adherence and concordance

Parents or carers are often responsible for the administration of medicines to their children and, therefore, the concordance and adherence of both parties must be considered. Literature about non-adherence and concordance in children is limited, but the problem is considered to be widespread and similar to that reported in adults.

Non-adherence may be caused by several factors such as patient resistance to taking the medicine, complicated dosage regimens, misunderstanding of instructions and apparent ineffectiveness or side effects of treatment. In older children and adolescents who may be responsible for their own medication, different factors may be responsible for non-adherence; for example, they may be unwilling to use their medication because of peer pressure.

Several general principles should be considered in an attempt to improve adherence. Adherence is usually better when fewer medicines are prescribed. Attention should be given to the formulation, taste, appearance and ease of

Table 10.7 Factors to be considered when selecting a drug dosage regimen or route of administration for a paediatric patient

Factor	Comment
1. Age/weight/surface area	Is the weight appropriate for the stated age? If it is not, confirm the difference. Can the discrepancy be explained by the patient's underlying disease, for example, patients with neurological disorders such as cerebral palsy may be significantly underweight for their age? Is there a need to calculate dosage based on surface area, for example, cytotoxic therapy? Remember heights and weights may change significantly in children in a very short space of time. It is essential to recheck the surface area at each treatment cycle using recent heights and weights
2. Assess the appropriate dose	The age/weight of the child may have a significant influence on the pharmacokinetic profile of the drug and the manner in which it is handled. In addition, the underlying disease state may influence the dosage or dosage interval
3. Assess the most appropriate interval	In addition to the influence of disease states and organ maturity on dosage interval, the significance of the child's waking day is often overlooked. A child's waking day is generally much shorter than that of an adult and may be as little as 12 h. Instructions given to parents particularly should take account of this, for example, the instruction 'three times a day' will bear no resemblance to 'every 8 hours' in a child's normal waking day. If a preparation must be administered at regular intervals, then the need to wake the child should be discussed with the parents or preferably an alternative formulation, such as a sustained-release preparation, should be considered
4. Assess the route of administration in the light of the disease state and the preparations and formulations available	Some preparations may require manipulation to ensure their suitability for administration by a specific route. Even preparations which appear to be available in a particular form may contain undesirable excipients that require alternatives to be found, for example, patients with the inherited metabolic disorder phenylketonuria should avoid oral preparations containing the artificial sweetener aspartame because of its phenylalanine content
5. Consider the expected response and monitoring parameters	Is the normal pharmacokinetic profile altered in children? Are there any age-specific or long-term adverse effects, such as on growth, that should be monitored?
6. Interactions	Drug interactions remain as important in reviewing paediatric prescriptions as they are in adult practice. However, drug–food interactions may be more significant; particularly drug–milk interactions in babies having 5–6 milk feeds per day
7. Legal considerations	Is the drug licensed? If an unlicensed drug is to be used, the pharmacist should have sufficient information to support its use

administration of treatment. The regimen should be simple and tailored to the child's waking day. If possible the child should be involved in choosing a suitable preparation when choice is available.

Many health professionals often counsel the parents/carer only, rather than involving the child in the counselling process. Where possible, treatment goals should be set in collaboration with the child. Studies have shown that parents consider the 8–10 year age group the most appropriate at which to start including the child in the counselling process. As well as verbal instruction, parents often want written information. However, current patient information leaflets (PILs) must reflect the Summary of Product Characteristics (SmPC) and so are often inappropriate. If a drug is used in an 'off-label' manner, statements such as 'not recommended for use in children' may cause confusion and distress. Care needs to be taken, therefore, to ensure that the information provided, whether written or spoken, is appropriate for both the parent and the child.

Information provided with medicines is often complex and may not always be relevant to children. The Royal College of

Paediatrics and Child Health in conjunction with other bodies have launched a range of information leaflets on medicines for parents and carers. The leaflets cover off-label use of specific drugs and aim to provide appropriate and accurate and easily understandable information on dosage and side effects to those administering medicines to children. The leaflets can be downloaded from the website: www. medicinesforchildren.org.uk

Medicines in schools

Children who are acutely ill will be treated with medicines at home or in hospital, although during their recovery phase it may be possible to return to school. Children with chronic illness such as asthma or epilepsy, and children recovering from acute illnesses, may require medicines to be administered whilst at school. In addition, there are some medical emergencies which may occur at school or on school trips that require prompt drug administration before the arrival of the emergency services. These emergencies include anaphylaxis

(associated with food allergy or insect stings), severe asthma attacks and seizures.

Policies and guidance

There is considerable controversy over the administration of medicines in schools. There is no legal or contractual duty on school staff to administer medicine or supervise a pupil taking it. This is a voluntary role. Some support staff may have specific duties to provide medical assistance as part of their contract. Policies and procedures are required to ensure that prescribed medicines are labelled, stored and administered safely and appropriately, and that teachers and care assistants are adequately trained and understand their responsibilities.

Advice has been provided for schools and their employers on how to manage medicines in schools (Department for Education and Skills, 2005). The roles and responsibilities of employers, parents and carers, governing bodies, head teachers, teachers and other staff and of local health services are all explained. The advice considers staffing issues such as employment of staff, insurance and training. Other issues covered include drawing up a health care plan for a pupil, confidentiality, record keeping, the storage, access and disposal of medicines, home-to-school transport, and on-site and off-site activities. It also provides general information on four common conditions that may require management at school: asthma, diabetes, epilepsy and anaphylaxis.

Responsibility for common medicines

Responsible pupils should be allowed to administer their own medication. Asthmatics should carry their 'reliever' inhaler (e.g. salbutamol or terbutaline), a spare should be available in school, and easy access before and during sports assured. There should be no need to have 'preventer' inhalers at school since two or three times daily administration schedules are appropriate and can avoid school hours. Medicines with a two or three times daily administration schedule should be supplied wherever possible so that dosing during school hours is avoided. Sustained-release preparations or drugs with intrinsically long half-lives may be more expensive but avoid the difficulties of administration at school. Sustained-release methylphenidate and atomoxetine, both used in the management of attention deficit hyperactivity disorder or ADHD, are examples. When administration at school is unavoidable, the school time doses can be provided in a separate, labelled container.

Special schools

Some children with severe, chronic illness will go to special rather than mainstream schools where their condition can receive attention from teachers and carers who have undergone appropriate training. Some special schools will be residential. Pupils may also attend another institution for respite care. Particular attention to communication of changes to drug treatment between parents, primary care doctors, hospital doctors and school staff is required if medication errors are to be avoided.

Monitoring parameters

Paediatric vital signs (Table 10.8) and haematological and biochemical parameters (Table 10.9) change throughout childhood and differ from those in adults. The figures presented in the tables are given as examples and may vary from hospital to hospital.

Table 10.8 Paediatric vital signs

	Age		
	<1 year	2–5 years	5–12 years
Heart rate (beats/min)	120–140	100–120	80–100
Blood pressure (systolic) (mmHg)	70–90	80–90	90–110
Respiratory rate (breaths/min)	25–45	25–30	16–25

Table 10.9 Biochemical and haematology reference ranges

	Neonate	Child	Adult
Albumin (g/L)	24–48	30–50	35–55
Bilirubin (µmol/L)	<200	<15	<17
Calcium (mmol/L)	1.8–2.8	2.15–2.7	2.20–2.55
Chloride (mmol/L)	95–110	95–110	95–105
Creatinine (µmol/L)	28–60	30–80	50–120
Haemoglobin (g/dL)	18–19	11–14	13.5–18.0 (males) 12–16 (females)
Haematocrit	0.55–0.65	0.36–0.42	0.4–0.45 (males) 0.36–0.44 (females)
Magnesium (mmol/L)	0.6–1.0	0.6–1.0	0.7–1.0
Phosphate (mmol/L)	1.3–3.0	1.0–1.8	0.85–1.4
Potassium (mmol/L)	4.0–7.0	3.5–5.5	3.5–5.0
Sodium (mmol/L)	130–145	132–145	135–145
Urea (mmol/L)	1.0–5.0	2.5–6.5	3.0–6.5
White cell count (×10^9/L)	6–15	5–14	3.5–11

Assessment of renal function

There are a number of methods of measuring renal function in children. These include the use of ^{51}Cr-EDTA, ^{99m}Tc-DTPA and using serum and urine creatinine concentrations over a timed period. However, despite some limitations, serum creatinine and estimated creatinine clearance are the most frequently used and most practical methods for day-to-day assessment of renal function.

In adults, several formulae and nomograms are available for calculating and estimating renal function. However, these cannot be extrapolated to the paediatric population; the Cockcroft and Gault equation and the estimated GFR (eGFR) equation are validated only for patients aged 18 years and over.

A number of validated models are available for use in children. These equations use combinations of serum creatinine, height, weight, BSA, age and sex to provide a simple estimate of creatinine clearance. A number of these equations have been further modified to better predict creatinine clearance; however, the advantage of simplicity is thereby lost. Several examples with their validated age ranges are shown below:

- Traub and Johnson (age 1–18 years)

$$\frac{\text{Creatinine clearance}}{(\text{mL/min}/1.73\,\text{m}^2)} = \frac{42 \times \text{height (cm)}}{\text{Serum creatinine (mmol/L)}}$$

- Counahan-Barratt (age 2 months to 14 years)

$$\frac{\text{Creatinine clearance}}{(\text{mL/min}/1.73\,\text{m}^2)} = \frac{38 \times \text{height (cm)}}{\text{Serum creatinine (mmol/L)}}$$

- Schwartz

$$\frac{\text{Creatinine clearance}}{(\text{mL/min}/1.73\,\text{m}^2)} = \frac{k \times \text{height (cm)}}{\text{Serum creatinine (mmol/L)}}$$

where k varies dependent on the age of the patient:

    low birth weight infants = 30
    normal infants 0–18 months = 40
    girls 2–16 years = 49
    boys 2–13 years = 49
    boys 13–16 years = 60

Whichever equation is chosen, it should be borne in mind that there are limitations to their use; for example, they should not be used in rapidly changing renal function, anorexic or obese patients, and they should not be taken as an accurate measure but as a guide to glomerular filtration rate.

Adverse drug reactions

The incidence of ADRs in children outside the neonatal period is thought to be less than at all other ages; however, the nature and severity of the ADRs that children experience may differ from those experienced by adults.

Studies have shown an incidence of ADRs in paediatric patients of between 0.2% and 22% of patients. The wide range reflects the limited number of formal prospective and retrospective studies examining the incidence and characteristics of ADRs in the paediatric age group and the variations in study setting, patient group and definition of ADR used. Data can also be skewed by vaccination campaigns since adverse effects are common and reporting encouraged. One consistent finding is that the greater the number of medications the child is exposed to, the greater the risk of ADRs.

ADRs in infants and older children typically occur at lower doses than in adults, and symptoms may be atypical. Examples include:

- enamel hypoplasia and permanent discolouration of the teeth with tetracyclines
- growth suppression with long-term corticosteroids in prepubertal children
- paradoxical hyperactivity in children treated with phenobarbital
- hepatotoxicity associated with the use of sodium valproate. There are three major risk factors:
  - age under 3 years
  - child receiving other anticonvulsants
  - developmental delay
- increased risk of Reye's syndrome with the use of salicylates in children with mild viral infection. Reye's syndrome is a life-threatening illness associated with drowsiness, coma, hypoglycaemia, seizures and liver failure. The mechanism of this toxicity remains unknown but aspirin should generally be avoided in children under 16 years of age.

Many ADRs occur less frequently in the paediatric population, for example, gastro-intestinal bleeds with NSAIDs, hepatotoxicity with flucloxacillin and severe skin reactions with trimethoprim/sulfamethoxazole.

The reporting of ADRs is particularly important because the current system of drug development and authorisation not only deprives children of useful drugs because of the lack of clinical trials in children but may also exclude them from epidemiological studies of ADRs to prescribed drugs. The Commission on Human Medicines strongly encourages the reporting of all suspected ADRs in children, including those relating to unlicensed or off-label use of medicines, even if the intensive monitoring symbol (an inverted black triangle) has been removed. This reporting scheme has been extended in recent years to allow pharmacists, nurses and patients/carers to report suspected ADRs.

Medication errors

In contrast to ADRs, medication errors occur as a result of human mistakes or system flaws. Medication errors are now recognised as an important cause of adverse drug events in paediatric practice and should always be considered as a possible causative factor in any unexplained situation. They can produce a variety of problems ranging from minor discomfort to death. In the USA, it is estimated that

100–150 deaths occur annually in children in hospitals due to medication errors. The actual reported incidence of errors varies considerably between studies, ranging from 0.15% to 17% of admissions. However, different reporting systems and criteria for errors make direct comparisons between studies difficult.

The incidence of medication errors and the risk of serious errors occurring in children are significantly greater than in adults. The causes are many and include:

- Heterogeneous nature of the paediatric population and the corresponding lack of standard dosage.
- Calculation errors by the prescriber, pharmacist, nurse or caregiver.
- Lack of available dosage forms and concentrations appropriate for administration to children, necessitating additional calculations and manipulations of commercially available products or preparation of extemporaneous formulations from raw materials.
- Lack of familiarity with paediatric dosing guidelines.
- Confusion between adult and paediatric preparations.
- Limited published information.
- Need for precise dose measurement and appropriate drug delivery systems; absence leads to administration errors and use of inappropriate measuring devices.
- Ten-fold dosing errors are particularly important and potentially catastrophic; but reports still appear regularly in the published literature.

The reporting and prevention of medication errors is important. The causes of medication errors are usually multifactorial and it is essential that when investigating medication errors, particular focus should be placed on system changes.

Licensing medicines for children

Medicines licensing process

All medicines marketed in the UK must have been granted a product licence (PL) under the terms of the Medicines Act 1968, or a marketing authorisation (MA) following more recent European legislation on the authorisation of medicines. The aim of licensing is to ensure that medicines have been assessed for safety, quality and efficacy. In the UK, evidence submitted by a pharmaceutical company is assessed by the Medicines and Healthcare products Regulatory Agency (MHRA) with independent advice from the Commission on Human Medicines (CHM) and its paediatric medicines expert group.

The licensed indications for a drug are published in the SmPC. Many medicines granted a product license or MA for adult use have not been scrutinised by the licensing authorities for use in children. This is reflected by contraindications or cautionary wording in the SmPC. There has been a lack of commercial incentive to develop medicines for the relatively small paediatric market and perceived difficulties in carrying out clinical trials in this group. It is not illegal to use medicines for indications or ages not specified in the data sheet but to ensure safe and effective treatment, health professionals should have adequate supporting information about the intended use before proceeding. Failure to ensure that the use of a medicine is reasonable could result in a suit for negligence if the patient comes to harm.

Unlicensed and 'off-label' medicines

It has been reported that up to 35% of drugs used in a children's hospital and 10% of drugs used in general practice may be used outside the terms of the approved, licensed indications (McIntyre et al., 2000, Turner et al., 1998). The term 'off-label' is often used to describe this. Because many of these medicines will have been produced in 'adult' dose forms, such as tablets, it is often necessary to prepare extemporaneously a suitable liquid preparation for the child. This may be made from the licensed dose form, for example, by crushing tablets and adding suitable excipients, or from chemical ingredients. An appropriate formula with a validated expiry period and ingredients to approved standards should be used. Care must be taken to ensure accurate preparation, particularly when using formulae or ingredients which are unfamiliar.

On some occasions the drug to be used has no product license or MA, perhaps because it is only just undergoing clinical trials in adults, has been imported from another country, has been prepared under a 'specials' manufacturing licence or is being used for a rare condition for which it has not previously been employed. As with 'off-label' use, there must always be information to support the quality, efficacy and safety of the medicine as well as information on the intended use. There is always a risk in using such a medicine, which must be balanced against the seriousness of the child's illness and discussed with the parents if practicable.

Many authorities require that the patient should always be informed if the medicine prescribed is unlicensed or 'off-label' and even that written informed consent be obtained before treatment begins. In many situations, in paediatrics, this would be impractical but if parents are not informed the PIL included with many medicines may cause confusion since it may state that it is 'not for use in children'. Patient or parent information specific to the situation should be prepared and provided.

Recent legislation on medicines for children

The worldwide legislation on medicines for children is changing. This is in recognition of the limited research and small number of licensed medicines brought about by a lack of incentive for commercial development. Both Europe and the USA have orphan drugs regulations designed to offer incentives for the development of medicines for rare diseases. Although not exclusively for paediatric conditions, the regulations have assisted the development of important drugs such as antiretrovirals (HIV/AIDS), alendronate (osteogenesis imperfecta), α-galactosidase (Fabry's disease), sodium phenylbutyrate (hyperammonaemia) and ibuprofen injection (closure of patent ductus arteriosus).

The USA has had regulations designed to promote the development of paediatric preparations for more than 10 years (Best Pharmaceuticals for Children Act 2002 and Pediatric Research Equity Act 2003). However, these regulations have resulted in

few significant developments in medicines for children in other countries. In the European Union, the 'European Parliament and Council Regulation (EC) on medicinal products for paediatric use' became law in January 2007. Thereafter, pharmaceutical companies wishing to market medicines for adults must agree to a Paediatric Investigation Plan with the EMEA. In return for such development, the company will receive an additional 6 months market exclusivity for its product. There are also expected to be incentives for developing paediatric formulations and indications for off-patent medicines.

Several European governments have funded paediatric clinical trials networks to stimulate research and help undertake studies resulting from the paediatric medicines regulations. In the UK, the Medicines for Children Research Network (MCRN) is part of the UK National Institute for Health Research and has six local research networks in England with equivalent provision in the other UK countries. Research and development of paediatric formulations is part of the MCRN programme.

The WHO has a 'Make medicines child size' programme to stimulate the development of age-appropriate formulations of medicines for children, particularly for those which appear in the List of Essential Medicines for Children. In June 2010, the first ever WHO model formulary for children was released to provide information on how to use over 240 essential medicines for treating illness and disease in children from 0 to 12 years of age. A number of individual countries have developed their own formularies over the years, but until now there was no single comprehensive guide for all countries (available at: http://www.who.int/childmedicines/en/).

Service frameworks

National service frameworks (NSFs) are long-term strategies for improving specific areas of care. Two paediatric service frameworks have been published; one for paediatric intensive care (Department of Health, 2002) and another for children, young people and maternity services (Department of Health, 2004) and continue to influence practice.

The service framework for paediatric intensive care defines the nature of paediatric intensive care, the elements of a high-quality paediatric intensive care service and a policy framework for the future organisation of services. Standards for district general hospitals, lead centres, major acute general hospitals and specialist hospitals are set out and cover medical and nurse staffing, facilities, and clinical effectiveness and management. Other aspects considered include retrieval services, education and training needs, and the implications for audit and research.

The framework for children, young people and maternity services sets standards for children's health and social services, and the interface of those services with education. It establishes clear standards for promoting the health and well-being of children and young people and for providing high-quality services which meet their needs.

The recommendations that relate to the use of medicines for children and young people include:

- All children and young people should receive medicines that are safe and effective, in formulations that can be easily administered and are appropriate to their age, having minimum impact on their education and lifestyle.
- Medicines should be prescribed, dispensed and administered by professionals who are well trained, informed and competent to work with children to improve health outcomes and minimise harm and any side effects of medicines.
- Children and young people and their parents or carers should be well informed and supported to make choices about their medicines and competent in the administration of medicines.

Markers of good practice are defined as:

- The use of medicines in children is based on the best available evidence of clinical use and cost-effectiveness and safety, ideally derived from clinical trials but also including, where appropriate, medicines that are not licensed for their age group or for their particular health problem ('off-label') or those that do not have a licence at all ('unlicensed') in order to achieve the best possible health outcomes and minimise harm and side effects.
- In all settings and whatever the circumstances, children and young people have equitable access to clinically safe and cost-effective medicines in age-appropriate formulations.
- Appropriate information and decision support are available for professionals who prescribe, dispense and administer medicines for children and young people.
- Children, young people and their parents/carers receive consistent, up-to-date, comprehensive, timely information on the safe and effective use of medicines.
- In all settings, professionals enable parents, young people and, where appropriate, children to be active partners in the decisions about the medicines prescribed for them.
- Primary and secondary care providers should ensure that the use of medicines in children is incorporated in their clinical governance and audit arrangements.
- The contribution of pharmacists to the effective and safe use of medicines in children is maximised.

Case studies

Case 10.1

Name: PT
Age: 7 years old
Sex: Male
Weight: 16 kg

Presenting condition:	**Presented in the emergency department with a 2-day history of worsening groin and hip pain. Could not bear weight. Patient was febrile with a temperature of 39.2°C, vomiting and dehydrated. There was no history of injury.**
Previous medical history:	**Nil of note**
Allergies:	**No known drug allergies**
Drug history:	**Nil of note**

Differential diagnosis:	Septic arthritis, osteomyelitis
Tests:	Urea and electrolytes
	Full blood count
	CRP, ESR
	Blood culture and sensitivities
	X-ray (hips and abdomen)
	Bone scan
Results:	Bone scan revealed right pubic osteomyelitis
	CRP = 56 mg/L (normal range 0–10 mg/L)
	ESR = 34 mm/h (normal range 1–10 mm/h)
	Blood culture revealed *Staphylococcus aureus* sensitive to flucloxacillin
Prescribed:	Flucloxacillin i.v. 800 mg four times a day for 2 weeks. To be followed by oral flucloxacillin 800 mg four times a day for 4 weeks
Progress:	Temperature settled and ESR/CRP decreased following initiation of antibiotic therapy

On the third day of treatment the patient developed a raised red rash which was suspected of being an allergic reaction to flucloxacillin. Treatment was changed to i.v. clindamycin 160 mg three times a day (10 mg/kg/dose) for 2 weeks followed by oral clindamycin 160 mg three times a day for a further 4 weeks.

....

Question

Comment on the drug therapy and any monitoring required.

....

Answer

There are a number of points to consider in this patient.
- Body weight appears low for age; therefore, need to check if the weight is correct (expected weight for a 7-year old to be approx. 23 kg). If incorrect, doses of medication will need to be recalculated.
- Recommended i.v. dose of flucloxacillin of 50 mg/kg/dose is correct. However, usual maximum oral dose of flucloxacillin is 25 mg/kg/dose. This is because of the increased risk of gastric side effects with high oral doses of flucloxacillin.
- There is a need to consider compliance with oral flucloxacillin therapy due to poor palatability of the suspension formulation (if the child would not take capsules) and the frequent dosing regimen.
- Whilst the risk of flucloxacillin-induced hepatotoxicity is low in children, there is a need to consider measuring baseline and repeat liver function tests because of the prolonged course (more than 2 weeks) of flucloxacillin therapy.
- Clindamycin has good oral bioavailability, so i.v. therapy may be unnecessary.
- The recommended dose of clindamycin by i.v. infusion is up to 10 mg/kg dose 6 hourly in severe infection. The infusion should be diluted to 6 mg/mL with sodium chloride 0.9% or dextrose 5% (or a combination) and administered over 30–60 min at a maximum rate of 20 mg/kg/h. Consider 160 mg in 27 mL sodium chloride 0.9% over 30 min.
- The recommended standard oral dose of clindamycin is 3–6 mg/kg/dose four times a day. This may contribute to problems with adherence to long-term therapy. A three times daily dosing regimen is to be preferred, particularly as this child may return to school, and four times daily dosing would require a dose to be administered at school which may be problematic.
- Consideration should be given to how to administer clindamycin. Clindamycin palmitate suspension, which was palatable, is no longer available as a licensed preparation in the UK. Whilst

extemporaneous formulations are available that use clindamycin hydrochloride capsules, the palatability of the resultant suspension is a major concern, particularly given the prolonged course of therapy. A 75 mg/5 mL suspension, licensed in Belgium, can be imported. From a safety and efficacy perspective it is preferable to use such a product, which has been through a regulatory process similar to that of the UK, than to compound an extemporaneous preparation, which has not undergone appropriate pharmaceutical/pharmacokinetic evaluation.
- Consideration could be given to decreasing the dose of clindamycin to 150 mg three times a day to accommodate capsules, although the child may have difficulty taking these.
- The most serious adverse effect of clindamycin is antibiotic-associated colitis. Therefore, it is important to monitor for diarrhoea. If this arises treatment should be discontinued.

Case 10.2

Name: CS
Age: 18 months old
Sex: Female
Weight: 10 kg

Presenting condition:	Severe right-sided abdominal pain
	Vomiting and loss of appetite
	Increased temperature 38.2°C
Previous medical history:	Nil of note
Allergies:	No known allergies
Drug history:	Nil of note
Tests:	Ultrasound
Provisional diagnosis:	Appendicitis

CS went to theatre where an appendicectomy was performed. The appendix was noted to be perforated.

Prescribed:	Morphine 50 mg in 50 mL to run at 1–4 mL/h (10–40 μcg/kg/h)
	Paracetamol 200 mg four times a day as required orally or per rectum
	Diclofenac 12.5 mg twice a day as required per rectum.
	or
	Ibuprofen 100 mg four times a day as required orally when tolerating milk
	Five days of i.v. antibiotic therapy with:
	Gentamicin 70 mg daily
	Ampicillin 250 mg four times a day
	Metronidazole 75 mg three times a day

....

Question

Comment on the patient's drug therapy.

....

Answer

- The morphine dose is incorrect. If the infusion is prepared as directed, 1 mL/h will actually provide 100 μcg/kg/h. This is a 10-fold overdose which is a medication error frequently seen in children.
- There is a need to consider how to administer the appropriate rectal dose of paracetamol to this child. Often post appendicectomy patients will need to be nil by mouth for several days. Rectal bioavailability is lower than oral bioavailability and there may be a need to consider giving a larger rather than smaller paracetamol dose, that is, possibly 250 mg/rectum 8 hourly rather than 125 mg 6 hourly, for up to 48 h, but not exceeding 90 mg/kg/day.
- Suggest that paracetamol and NSAID are administered regularly in addition to the morphine for at least the first few days post-surgery. Multimodal analgesic therapy is recommended.

- There will be a need to monitor CS for side effects. Nausea, vomiting and pruritus all occur frequently with morphine but can be treated/prevented.
- Young children are particularly susceptible to developing myoclonic jerks with morphine. These are often worrying for parents but resolve on withdrawal of the morphine.
- NSAIDs are well tolerated by children and the risk of adverse events is much lower in children than the adult population. However, it is important to ensure adequate hydration status postoperatively, particularly when using NSAIDs. Acute renal failure has been reported in children who have been treated with NSAIDs and not adequately hydrated.
- The choice of antibiotics for CS is appropriate. High-dose (7 mg/kg) once-daily aminoglycoside (gentamicin/tobramycin) therapy is now routinely used in children. It is administered by short infusion over 20 min. Plasma drug levels should be monitored to achieve a 18–24 h trough level of <1 mg/L. Monitor urea and electrolytes and serum creatinine. Ampicillin can be given as a bolus injection over 3–5 min. Metronidazole should be given as a short infusion over 20 min.

Key points

- The elderly form about 18% of the population and receive about one-third of health service prescriptions in the UK.
- Ageing results in physiological changes that affect the absorption, metabolism, distribution and elimination of drugs.
- Alzheimer's disease and vascular dementia are the most important diseases of cognitive dysfunction in the elderly. Donepezil, rivastigmine and galantamine are inhibitors of acetylcholinesterase and improve cognitive function in Alzheimer's disease.
- The elderly patient with Parkinson's disease is more susceptible to the adverse effects of levodopa such as postural hypotension, ventricular dysrhythmias and psychiatric effects.
- Aspirin, dipyridamole and clopidogrel reduce the reoccurrence of non-fatal strokes in the elderly.
- Treatment of elevated systolic and diastolic blood pressure in the elderly with a low dose thiazide diuretic, β-blocker, calcium antagonist or angiotensin-converting enzyme (ACE) inhibitor have all been shown to be beneficial.
- Urinary incontinence can be classified as stress incontinence, overflow incontinence or due to detrusor instability. Stress incontinence is not amenable to drug therapy. The most common drugs used in detrusor instability are oxybutynin and tolterodine.
- Non-steroidal anti-inflammatory drugs (NSAIDs) are more likely to cause gastroduodenal ulceration and bleeding in the elderly.

The elderly have multiple and often chronic diseases. It is not surprising, therefore, that they are the major consumers of drugs. Elderly people receive about one-third of National Health Service (NHS) prescriptions in the UK. In most developed countries, the elderly now account for 25–40% of drug expenditure.

A survey of drug usage in 778 elderly people in the UK showed that 70% had been on prescribed medication and 40% had taken one or more prescribed drugs within the previous 24 h; 32% were taking cardiovascular drugs, and the other therapeutic categories used in decreasing order of frequency were for disorders of the central nervous system (24%), musculoskeletal system (10%), gastro-intestinal system (8%) and respiratory system (7%). The most commonly used drugs were diuretics; analgesics; hypnotics, sedatives and anxiolytics; antirheumatic drugs; and β-blockers.

Institutionalised patients tend to be on larger numbers of drugs compared with patients in the community. One study has shown that patients in long-term care facilities are likely to be receiving, on average, eight drugs. Psychotropic drugs are used widely in nursing or residential homes.

For optimal drug therapy in the elderly, a knowledge of age-related physiological and pathological changes that might affect handling of and response to drugs is essential. This chapter discusses the age-related pharmacokinetic and pharmacodynamic changes which might affect drug therapy and the general principles of drug use in the elderly.

There has been a steady increase in the number of elderly people, defined as those over 65 years of age, since the beginning of the twentieth century. They formed only 4.8% of the population in 1901, increasing to 15.2% in 1981 and about 18% in 2001. In 2008, there were 4.8 million people over the age of 75 years in the UK. Their number is projected to increase to 5.8 million by 2018 and to 8.7 million by 2033 – a rise of 81% over 25 years. In addition, the number of people over 85 years of age is also projected to increase from 1.3 million in 2008 to 3.3 million in 2033. The number of centenarians is projected to increase from 11,000 in 2008 to 80,000 in 2033 (Office for National Statistics, 2010). The significant increase in the number of very elderly people will have important social, financial and health care planning implications.

Pharmacokinetics

Ageing results in many physiological changes that could theoretically affect absorption, first-pass metabolism, protein binding, distribution and elimination of drugs. Age-related changes in the gastro-intestinal tract, liver and kidneys are

- reduced gastric acid secretion
- decreased gastro-intestinal motility
- reduced total surface area of absorption
- reduced splanchnic blood flow
- reduced liver size
- reduced liver blood flow
- reduced glomerular filtration
- reduced renal tubular filtration.

Absorption

There is a delay in gastric emptying, reduction in gastric acid output and splanchnic blood flow with ageing. These changes do not significantly affect the absorption of the majority of drugs. Although the absorption of some drugs such as digoxin may be slower, the overall absorption is similar to that in the young.

First-pass metabolism

After absorption, drugs are transported via the portal circulation to the liver, where many lipid-soluble agents are metabolised extensively (more than 90–95%). This results in a marked reduction in systemic bioavailability. Obviously, even minor reductions in first-pass metabolism can result in a significant increase in the bioavailability of such drugs.

Impaired first-pass metabolism has been demonstrated in the elderly for several drugs, including clomethiazole, labetalol, nifedipine, nitrates, propranolol and verapamil. The clinical effects of some of these, such as the hypotensive effect of nifedipine, may be significantly enhanced in the elderly. In frail hospitalised elderly patients, that is, those with chronic debilitating disease, the reduction in pre-systemic elimination is even more marked.

Distribution

The age-related physiological changes which may affect drug distribution are

- reduced lean body mass
- reduced total body water
- increased total body fat
- lower serum albumin level
- α_1-acid glycoprotein level unchanged or slightly raised.

Increased body fat in the elderly results in an increased volume of distribution for fat-soluble compounds such as clomethiazole, diazepam, desmethyl-diazepam and thiopental. On the other hand, reduction in body water results in a decrease in the distribution volume of water-soluble drugs such as cimetidine, digoxin and ethanol.

Acidic drugs tend to bind to plasma albumin, while basic drugs bind to α_1-acid glycoprotein. Plasma albumin levels decrease with age and therefore the free fraction of acidic drugs such as cimetidine, furosemide and warfarin will increase. Plasma α_1-acid glycoprotein levels may remain unchanged or may rise slightly with ageing, and this may result in minimal reductions in free fractions of basic drugs such as lidocaine. Disease-related changes in the level of this glycoprotein are probably more important than age *per se*.

The age-related changes in distribution and protein binding are probably of significance only in the acute administration of drugs because, at steady state, the plasma concentration of a drug is determined primarily by free drug clearance by the liver and kidneys rather than by distribution volume or protein binding.

Renal clearance

Although there is a considerable interindividual variability in renal function in the elderly, in general the glomerular filtration rate declines, as do the effective renal plasma flow and renal tubular function. Because of the marked variability in renal function in the elderly, the dosages of predominantly renally excreted drugs should be individualised. Reduction in dosages of drugs with a low therapeutic index, such as digoxin and aminoglycosides, may be necessary. Dosage adjustments may not be necessary for drugs with a wide therapeutic index, for example, penicillins.

Hepatic clearance

Hepatic clearance (Cl_H) of a drug is dependent on hepatic blood flow (Q) and the steady state extraction ratio (E), as can be seen in the following formula:

$$Cl_H = Q \times \frac{C_a - C_v}{C_a} = Q \times E$$

where C_a and C_v are arterial and venous concentrations of the drug, respectively. It is obvious from the above formula that when E approaches unity, Cl_H will be proportional to and limited by Q. Drugs which are cleared by this mechanism have a rapid rate of metabolism, and the rate of extraction by the liver is very high. The rate-limiting step, as mentioned earlier, is hepatic blood flow, and therefore drugs cleared by this mechanism are called 'flow limited'. On the other hand, when E is small, Cl_H will vary according to the hepatic uptake and enzyme activity, and will be relatively independent of hepatic blood flow. The drugs which are cleared by this mechanism are termed 'capacity limited'.

Hepatic extraction is dependent upon liver size, liver blood flow, uptake into hepatocytes, and the affinity and activity of hepatic enzymes. Liver size falls with ageing and there is a decrease in hepatic mass of 20% and 40% between the third and tenth decade. Hepatic blood flow falls equally with declining liver size. Although it is recognised that the microsomal monooxygenase enzyme systems are significantly reduced in ageing male rodents, evidence suggests that this is not the case in ageing humans. Conjugation reactions have been reported to be unaffected in the elderly by some investigators, but a small decline with increasing age has been described by others.

Impaired clearance of many hepatically eliminated drugs has been demonstrated in the elderly. Morphological changes rather than impaired enzymatic activity appear to be the main cause of impaired elimination of these drugs. In frail debilitated elderly patients, however, the activities of drug-metabolising enzymes such as plasma esterases and hepatic glucuronyltransferases may well be impaired.

Pharmacodynamics

Molecular and cellular changes that occur with ageing may alter the response to drugs in the elderly. There is, however, limited information about these alterations because

of the technical difficulties and ethical problems involved in measuring them. It is not surprising, therefore, that there is relatively little information about the effect of age on pharmacodynamics.

Changes in pharmacodynamics in the elderly may be considered under two headings:

- those due to a reduction in homeostatic reserve and
- those that are secondary to changes in specific receptor and target sites.

Reduced homeostatic reserve

Orthostatic circulatory responses

In normal elderly subjects, there is blunting of the reflex tachycardia that occurs in young subjects on standing or in response to vasodilatation. Structural changes in the vascular tree that occur with ageing are believed to contribute to this observation, although the exact mechanism is unclear. Antihypertensive drugs, drugs with α receptor blocking effects (e.g. tricyclic antidepressants, phenothiazines and some butyrophenones), drugs which decrease sympathetic outflow from the central nervous system (e.g. barbiturates, benzodiazepines, antihistamines and morphine) and antiparkinsonian drugs (e.g. levodopa and bromocriptine) are, therefore, more likely to produce hypotension in the elderly.

Postural control

Postural stability is normally achieved by static reflexes, which involve sustained contraction of the musculature, and phasic reflexes, which are dynamic, short term and involve transient corrective movements. With ageing, the frequency and amplitude of corrective movements increase and an age-related reduction in dopamine (D_2) receptors in the striatum has been suggested as the probable cause. Drugs which increase postural sway, for example hypnotics and tranquillisers, have been shown to be associated with the occurrence of falls in the elderly.

Thermoregulation

There is an increased prevalence of impaired thermoregulatory mechanisms in the elderly, although it is not universal. Accidental hypothermia can occur in the elderly with drugs that produce sedation, impaired subjective awareness of temperature, decreased mobility and muscular activity, and vasodilatation. Commonly implicated drugs include phenothiazines, benzodiazepines, tricyclic antidepressants, opioids and alcohol, either on its own or with other drugs.

Cognitive function

Ageing is associated with marked structural and neurochemical changes in the central nervous system. Cholinergic transmission is linked with normal cognitive function, and in the elderly the activity of choline acetyltransferase, a marker enzyme for acetylcholine, is reduced in some areas of the cortex and limbic system. Several drugs cause confusion in the elderly. Anticholinergics, hypnotics, H_2 antagonists and β-blockers are common examples.

Visceral muscle function

Constipation is a common problem in the elderly as there is a decline in gastro-intestinal motility with ageing. Anticholinergic drugs, opiates, tricyclic antidepressants and antihistamines are more likely to cause constipation or ileus in the elderly. Anticholinergic drugs may cause urinary retention in elderly men, especially those who have prostatic hypertrophy. Bladder instability is common in the elderly, and urethral dysfunction more prevalent in elderly women. Loop diuretics may cause incontinence in such patients.

Age-related changes in specific receptors and target sites

Many drugs exert their effect via specific receptors. Response to such drugs may be altered by the number (density) of receptors, the affinity of the receptor, postreceptor events within cells resulting in impaired enzyme activation and signal amplification, or altered response of the target tissue itself. Ageing is associated with some of these changes.

α-Adrenoceptors

α_2-Adrenoceptor responsiveness appears to be reduced with ageing while α_1-adrenoceptor responsiveness appears to be unaffected.

β-Adrenoceptors

β-Adrenoceptor function declines with age. It is recognised that the chronotropic response to isoprenaline infusion is less marked in the elderly. Propranolol therapy in the elderly produces less β-adrenoceptor blocking effect than in the young. In isolated lymphocytes, studies of cyclic adenosine monophosphate (AMP) production have shown that on β-adrenoceptor stimulation the dose–response curve is shifted to the right, and the maximal response is blunted.

An age-related reduction in β-adrenoceptor density has been shown in animal adipocytes, erythrocytes and brain, and also in human lymphocytes in one study, although this has not been confirmed by other investigators. As maximal response occurs on stimulation of only 0.2% of β-adrenoceptors, a reduction in the number by itself is unlikely to account for age-related changes. Some studies have shown a reduction in high-affinity binding sites with ageing, in the absence of change in total receptor numbers, and others have suggested that there may be impairment of postreceptor transduction mechanisms with ageing that may account for reduced β-adrenoceptor function.

Cholinergic system

The effect of ageing on cholinergic mechanisms is less well known. Atropine produces less tachycardia in elderly humans than in the young. It has been shown in ageing rats that the hippocampal pyramidal cell sensitivity to acetylcholine is reduced. The clinical significance of this observation is unclear.

Benzodiazepines

The elderly are more sensitive to benzodiazepines than the young, and the mechanism of this increased sensitivity is not known. No difference in the affinity or number of benzodiazepine-binding sites has been observed in animal studies. Habituation to benzodiazepines occurs to the same extent in the elderly as in the young.

Warfarin

The elderly are more sensitive to warfarin. This phenomenon may be due to age-related changes in pharmacodynamic factors. The exact mechanism is unknown.

Digoxin

The elderly appear to be more sensitive to the adverse effects of digoxin, but not to the cardiac effects.

Common clinical disorders

This section deals in detail only with the most important diseases affecting older people. Other conditions are mentioned primarily to highlight areas where the elderly differ from the young or where modifications of drug therapy are necessary.

Dementia

Dementia is characterised by a gradual deterioration of intellectual capacity. Alzheimer's disease (AD), vascular dementia (VaD), dementia with Lewy bodies and frontotemporal dementia are the most important diseases of cognitive dysfunction in the elderly. AD has a gradual onset, and it progresses slowly. Forgetfulness is the major initial symptom. The patient has difficulty in dressing and other activities of daily living. He or she tends to get lost in his or her own environment. Eventually, the social graces are lost. VaD is the second most important cause of dementia. It usually occurs in patients in their 60s and 70s, and is more common in those with a previous history of hypertension or stroke. It is commonly associated with mood changes and emotional lability. Physical examination may reveal focal neurological deficits. A number of drugs and other conditions cause confusion in the elderly, and their effects may be mistaken for dementia. These are listed in Box 11.1.

In patients with AD, damage to the cholinergic neurones connecting subcortical nuclei to the cerebral cortex has been

Box 11.1   Drugs causing confusion in the elderly

Steroids
Tricyclic antidepressants

consistently observed. Postsynaptic muscarinic cholinergic receptors are usually not affected, but ascending noradrenergic and serotonergic pathways are damaged, especially in younger patients. Based on those abnormalities, several drugs have been investigated for the treatment of AD. Lecithin, which increases acetylcholine concentrations in the brain, 4-aminopyridine, piracetam, oxitacetam and pramiracetam, all of which stimulate acetylcholine release, have been tried, but have produced no, or unimpressive, improvements in cognitive function. Anticholinesterases block the breakdown of acetylcholine and enhance cholinergic transmission. Donepezil, galantamine and rivastigmine are recommended for treatment of patients with AD of moderate severity only (those with a Mini Mental State Examination (MMSE) score of between 10 and 20 points; NICE, 2009). Donepezil is a piperidine-based acetylcholinesterase inhibitor. It has been shown to improve cognitive function in patients with mild to moderately severe AD. However, it does not improve day-to-day functioning, quality-of-life measures or rating scores of overall dementia. Rivastigmine is a non-competitive cholinesterase inhibitor. It has been shown to slow the rate of decline in cognitive and global functioning in AD. Galantamine, a reversible and competitive inhibitor of acetylcholinesterase, has also been shown to improve cognitive function significantly and is well tolerated. Adverse effects of cholinesterase inhibitors include nausea, vomiting, diarrhoea, weight loss, agitation, confusion, insomnia, abnormal dreams, muscle cramps, bradycardia, syncope and fatigue. Treatment with these drugs should only be continued in people with dementia who show an improvement or no deterioration in their minimental score, together with evidence of global (functional and behavioural) improvement after first few months of treatment. The treatment effect should then be reviewed critically every 6 months, before a decision to continue drug therapy is made.

Memantine, an N-methyl-D-aspartate (NMDA) antagonist, has also been used for the treatment of moderate to severe AD. It acts mainly on subtypes of glutamate receptors related to memory (i.e. NMDA), resulting in improvements in cognition. It has also been shown to have some beneficial effects on behaviour and its use is recommended in patients with moderate to severe AD as part of well-designed clinical studies (NICE, 2009).

Deposition of amyloid (in particular the peptide β/A4) derived from the Alzheimer amyloid precursor protein (APP) is an important pathological feature of the familial form of

AD that accounts for about 20% of patients. Point mutation of the gene coding for APP (located in the long arm of chromosome 21) is thought to be associated with familial AD. Future treatment strategies, therefore, might involve development of drugs which inhibit amyloidogenesis.

In some studies, donepezil and galantamine have been shown to improve cognition, behaviour and activities of daily living in patients with VaD, and in those with AD and coexistent cerebrovascular disease. Memantine has been reported to stabilise progression of VaD compared with placebo. However, acetylcholinesterase inhibitors and memantine should not be prescribed for the treatment of cognitive decline in patients with VaD, except as part of properly constructed clinical studies (National Collaborating Centre for Mental Health, 2007). Aspirin therapy has also been reported to slow the progression of VaD. The incidence of VaD is likely to decrease with other stroke prevention strategies such as smoking cessation, anticoagulation for atrial fibrillation, control of hypertension and hyperlipidemia.

Parkinsonism

Parkinsonism is a relatively common disease of the elderly with a prevalence between 50 and 150 per 100,000. It is characterised by resting tremors, muscular rigidity and bradykinesia (slowness of initiating and carrying out voluntary movements). The patient has a mask-like face, monotonous voice and walks with a stoop and a slow shuffling gait.

The elderly are more susceptible than younger patients to some of the adverse effects of antiparkinsonian drugs. Age-related decline in orthostatic circulatory responses, means that postural hypotension is more likely to occur in elderly patients with levodopa therapy. The elderly are more likely to have severe cardiac disease, and levodopa preparations should be used with caution in such patients because of the risk of serious ventricular dysrhythmias. Psychiatric adverse effects such as confusion, depression, hallucinations and paranoia occur with dopamine agonists and levodopa preparations. These adverse effects may persist for several months after discontinuation of the offending drug and may result in misdiagnosis (e.g. of AD) in the elderly. Bromocriptine and other ergot derivatives should be avoided in elderly patients with severe peripheral arterial disease as they may cause peripheral ischaemia. 'Drug holidays', which involve discontinuation of drugs, for example, for 2 days per week, may reduce the incidence of adverse effects of antiparkinsonian drugs, but their role is questionable.

Stroke

Stroke is the third most common cause of death and the most common cause of adult disability in the UK. About 110,000 people in England and Wales have their first stroke each year and about 30,000 people go on to have further strokes (National Collaborating Centre for Chronic Conditions, 2008). The incidence of stroke increases by 100-fold from the fourth to the ninth decade. About 85% of strokes are ischaemic and 15% are due to haemorrhages.

Treatment of acute stroke

Thrombolytic agents. The National Institute of Neurological Disorders and Stroke (1995) in the United States showed that, compared with placebo, thrombolysis with tissue plasminogen activator (rt-PA) within 3 h of onset of ischaemic stroke improved clinical outcome at 3 months despite increased incidence (6%) of symptomatic intracranial bleeding. Several studies have since confirmed the efficacy of intravenous rt-PA, administered within 3 h and up to 4.5 h, in acute ischaemic stroke. The odds ratio for improved outcome at 3 months, however, decreases from 2.5, if treatment is given between 0 and 90 min, to 1.3 between 181 and 270 min. A pooled analysis of the major randomised placebo-controlled trials of rt-PA (alteplase) for acute stroke showed large parenchymal haemorrhage in 5.2% of 1850 patients assigned to alteplase and 1.0% of 1820 controls, with no clear relation to onset of stroke to time of treatment (OTT). Adjusted odds of mortality increased with OTT (from 0.78 for 0–90 min to 1.22 for 181–270 min; Lees et al., 2010). Most of the clinical trials with rt-PA have excluded patients over 80 years of age. However, analysis of data from studies which have included patients over the age of 80 years, indicates that thrombolysis is effective in this age group but may be associated with a higher risk of bleeding. The currently ongoing International Stroke Trial 3 is specifically investigating the safety and efficacy of rt-PA in patients aged 80 years or more.

Antiplatelet therapy. Aspirin in doses of 150–300 mg commenced within 48 h of onset of ischaemic stroke has been shown to reduce the relative risk of death or dependency by 2.7% up to 6 months after the event in two large studies (Chen et al., 2000).

Anticoagulation. Use of intravenous unfractionated heparin and low molecular weight heparin have not been shown to be beneficial and are associated with increased risk of intracranial haemorrhage.

Neuroprotective agents. A large number of neuroprotective agents have been used for treatment of acute ischaemic stroke but none have been shown to have long-term beneficial effects.

Secondary prevention

Aspirin in doses of 75–1500 mg/day reduces the risk of stroke recurrence by about 23% as compared with placebo. This is likely to be due to its antiplatelet effect. Clopidogrel has been shown to reduce the relative risk for stroke recurrence by 8% compared with aspirin. When compared with aspirin alone, the combination of aspirin (75 mg daily) plus extended-release dipyridamole (200 mg twice daily) has been reported to reduce the relative risk by 20–23%. Aspirin plus extended-release dipyridamole has not been shown to be superior to clopidogrel alone in preventing recurrent stroke (Sacco et al., 2008). Clopidogrel plus aspirin (75 mg each daily) compared with aspirin alone is associated with an absolute increase in the risk for life-threatening bleeding by 1.3%, and therefore this combination is not recommended for secondary stroke prevention (Diener et al., 2004).

In patients with atrial fibrillation who have had a previous stroke or transient ischaemic attack, anticoagulation with warfarin (INR 1.5–2.7) has been shown to be significantly better than aspirin for secondary prevention (Hart et al., 2007). Anticoagulation has not been shown to be effective for secondary prevention in patients with sinus rhythm. Dabigatran, an oral direct thrombin inhibitor, at a dose of 110 mg twice daily is associated with similar rates of stroke and systemic embolism but lower rates of major haemorrhage. At a dose of 150 mg twice daily, it is associated with lower rates of stroke and systemic embolism but similar rates of major haemorrhage compared with warfarin (Connolly et al., 2009). Unlike warfarin, this drug does not require routine monitoring of anticoagulation. Two orally administered Factor Xa inhibitors, apixaban and rivaroxaban, are currently under investigation for stroke prevention in atrial fibrillation.

Adequate control of hypertension, diabetes, hyperlipidaemia, stopping smoking and reducing alcohol consumption are also important in secondary stroke prevention.

Primary prevention

A number of randomised controlled trials have shown that anticoagulation with warfarin compared with placebo reduces the risk of stroke in patients with atrial fibrillation (Hart et al., 2007). Control of risk factors such as hypertension, hyperlipidaemia, diabetes, and smoking is likely to play an important role in primary prevention.

Osteoporosis

Osteoporosis is a progressive disease characterised by low bone mass and micro-architectural deterioration of bone tissue resulting in increased bone fragility and susceptibility to fracture. It is an important cause of morbidity in postmenopausal women. The most important complication of osteoporosis is fracture of the hip. Fractures of wrist, vertebrae and humerus also occur. Increasing age is associated with higher risk of fractures, which occur mostly in those aged over 75 years. In the UK, over 200,000 fractures occur each year, costing the NHS £1.8 billion per year, of which 87% is spent on hip fractures (Poole and Compston, 2006).

Prevention

As complications of osteoporosis have enormous economic implications, preventive measures are extremely important. Regular exercise has been shown to halve the risk of hip fractures. Stopping smoking before the menopause reduces the risk of hip fractures by 25%.

Treatment

Vitamin D and calcium. Vitamin D deficiency is common in elderly people. Treatment for 12–18 months with 800 IU of vitamin D plus 1.2 g of calcium given daily has been shown to reduce hip and non-vertebral fractures in elderly women (mean age 84 years) living in sheltered accommodation. It is not known whether vitamin D supplementation alone reduces hip fractures. Calcium supplementation on its own does not reduce fracture incidence and is no longer recommended for treatment of osteoporosis.

Calcitriol and alfacalcidol. Calcitriol (1,25-dihydroxyvitamin D), the active metabolite of vitamin D, and alfacalcidol, a synthetic analogue of calcitriol, reduce bone loss and have been shown to reduce vertebral fractures, but not consistently. Serum calcium should be monitored regularly in patients receiving these drugs.

Bisphosphonates. Bisphosphonates, synthetic analogues of pyrophosphate, bind strongly to the bone surface and inhibit bone resorption. Currently, three oral bisphosphonates are available for the treatment of osteoporosis: alendronate, etidronate and risedronate. Alendronate can be given either daily (10 mg) or weekly (70 mg) with equal efficacy. It is effective in reducing vertebral, wrist and hip fractures by about 50%. Etidronate is given cyclically with calcium supplements to reduce the risk of bone mineralisation defects. It reduces the risk of vertebral fractures by 50% in postmenopausal women. There is no evidence to support its effectiveness in preventing hip fractures. Risedronate reduces vertebral fractures by 41% and non-vertebral fractures by 39%. It has been shown to significantly reduce the risk of hip fractures in postmenopausal women. Alendronate and risedronate are currently used as first-line drugs in older women with osteoporosis.

Intravenous ibandronate, given at a dose of 3 mg once every 3 months, can be used for treatment of postmenopausal osteoporosis. It can also be given orally at a dose of 150 mg once monthly.

All bisphosphonates cause gastro-intestinal side effects. Alendronate and risedronate are associated with severe oesophageal reactions including oesophageal stricture. Patients should not take these tablets at bed-time and should be advised to stay upright for at least 30 min after taking them. They should avoid food for at least 2 h before and after taking etidronate. Alendronate and risedronate should be taken 30 min before the first food or drink of the day. Bisphosphonates should be avoided in patients with renal impairment.

Strontium ranelate, which both increases bone formation and reduces bone resorption, reduces vertebral and non-vertebral (including hip) fractures in postmenopausal women with osteoporosis. It is well tolerated. It can be used in those who are unable to tolerate alendronate or risedronate. It should be avoided in patients with severe renal disease (creatinine clearance below 30 mL/min). It can be used with caution in patients at increased risk of venous thromboembolism and those with phenylketonuria.

Hormone replacement therapy (HRT). Oestrogens increase bone formation and reduce bone resorption. They also increase calcium absorption and decrease renal calcium loss. HRT, if started soon after the menopause, is effective in preventing vertebral fractures but has to be continued lifelong if protection against fractures is to be maintained. It is associated with increased risk of endometrial cancer, breast cancer and venous thromboembolism. One study has shown

that HRT may increase the risk of deaths due to myocardial disease in elderly women with pre-existing ischaemic heart disease. It should be avoided in older patients.

Raloxifene. Raloxifene, an oral selective oestrogen receptor modulator (SERM) that has oestrogenic actions on bone and anti-oestrogenic actions on the uterus and breast. It reduces the risk of vertebral fractures, but not those at other sites. Adverse effects include hot flushes, leg cramps, and risk of venous thromboembolism. It also protects against breast cancer. Its use is restricted, as a second-line drug, to younger postmenopausal women with vertebral osteoporosis.

Parathyroid hormone peptides. Teriparatide is the recombinant portion of human parathyroid hormone, amino acid sequence 1–34, of the complete molecule (which has 84 amino acids). It reduces vertebral and non-vertebral fractures in postmenopausal women. It does not reduce hip fractures. It is given subcutaneously at a dose of 20 μcg daily. The recombinant (full 1–84 amino acid sequence) parathyroid hormone peptide (Preotact®) can also be used at a dose of 100 μcg daily. It has similar efficacy as teriparatide. Both these drugs are expensive and teriparatide is associated with an increased risk of osteosarcoma in animal studies.

Calcitonin. Calcitonin inhibits osteoclasts and decreases the rate of bone resorption, reduces bone blood flow and may have central analgesic actions. It is effective in all age groups in preventing vertebral bone loss. It is costly and has to be given parenterally or intranasally. It should not be given for more than 3–6 months at a time to avoid its inhibitory effects on bone resorption and formation, which usually disappear after 2–4 weeks. Antibodies do develop against calcitonin, but they do not affect its efficacy. Calcitonin is useful in treating acute pain associated with osteoporotic vertebral fractures.

Arthritis

Osteoarthrosis, gout, pseudogout, rheumatoid arthritis and septic arthritis are the important joint diseases in the elderly. Treatment of these conditions is similar to that in the young. If possible, NSAIDs should be avoided in patients with osteoarthrosis. Total hip and knee replacements should be considered in patients with severe arthritis affecting these joints.

Hypertension

Hypertension is an important risk factor for cardiovascular and cerebrovascular disease in the elderly. The incidence of myocardial infarction is 2.5 times higher, and that of cerebrovascular accidents twice as high in elderly hypertensive patients compared with non-hypertensive subjects. Elevated systolic blood pressure is the single most important risk factor for cardiovascular disease and more predictive of stroke than diastolic blood pressure.

Blood pressure lowering has been shown to be beneficial in those patients below and above the age of 65 years with no substantial variation in reduction in major vascular events with different drug classes (Blood Pressure Lowering Treatment Trialists' Collaboration, 2008). There is evidence that treatment of both systolic and diastolic blood pressure in the elderly is beneficial. One large study has shown reductions in cardiovascular events, and mortality associated with cerebrovascular accidents in treated elderly patients with hypertension (Amery et al., 1986). The treatment did not reduce the total mortality significantly. Another study (SHEP, 1991), which used low-dose chlortalidone to treat isolated systolic hypertension (systolic blood pressure 160 mmHg or more with diastolic blood pressure less than 95 mmHg), showed a 36% reduction in the incidence of stroke, with a 5-year benefit of 30 events per 1000 patients. It also showed a reduction in the incidence of major cardiovascular events with a 5-year absolute benefit of 55 events per 1000 patients. In addition, this study reported that antihypertensive therapy was beneficial even in patients over the age of 80 years. There is increasing evidence that antihypertensive therapy in patients over 80 years of age is beneficial. Subgroup meta-analysis of seven randomised controlled trials, which included 1670 patients over 80 years, showed that antihypertensive therapy for about 3.5 years reduces the risk of heart failure by 39%, strokes by 34% and major cardiovascular events by 22% (Gueyffier, 1999). In one placebo-controlled study which included 3845 patients who were 80 years of age or older and had a sustained systolic blood pressure of 160 mmHg or more, treatment with the diuretic indapamide (sustained release, 1.5 mg) plus perindopril (2 or 4 mg) to achieve the target blood pressure of 150/80 mmHg resulted in a 30% reduction in the rate of fatal or non-fatal stroke, a 39% reduction in the rate of death from stroke, a 21% reduction in the rate of death from any cause, a 23% reduction in the rate of death from cardiovascular causes and a 64% reduction in the rate of heart failure (Beckett et al., 2008).

Treatment of hypertension

Non-pharmacological. In patients with asymptomatic mild hypertension, non-pharmacological treatment is the method of choice. Weight reduction to within 15% of desirable weight, restriction of salt intake to 4–6 g/day, regular aerobic exercise such as walking, restriction of ethanol consumption and stopping smoking are the recommended modes of therapy.

Pharmacological

Thiazide diuretics. Thiazides lower peripheral resistance and do not significantly affect cardiac output or renal blood flow. They are effective, cheap, well tolerated and have also been shown to reduce the risk of hip fracture in elderly women by 30%. They can be used in combination with other antihypertensive drugs. Adverse effects include mild elevation of creatinine, glucose, uric acid and serum cholesterol levels as well as hypokalaemia. They should be used in low doses, as higher doses only increase the incidence of adverse effects without increasing their efficacy.

β-Adrenoceptor blockers. Although theoretically the β-blockers are expected to be less effective in the elderly, they have been shown to be as effective as diuretics in clinical

studies. Water-soluble β-blockers such as atenolol may cause fewer adverse effects in the elderly.

Calcium antagonists. Calcium antagonists act as vasodilators. Verapamil and, to some extent, diltiazem decrease cardiac output. These drugs do not have a significant effect on lipids or the central nervous system. They may be more effective in the elderly, particularly in the treatment of isolated systolic hypertension. Adverse effects include headache, oedema and postural hypotension. Verapamil may cause conduction disturbances and decrease cardiac output. The use of short-acting dihydropyridine calcium antagonists, for example nifedipine, is controversial. Some studies indicate adverse outcomes with these agents, particularly in those patients with angina or myocardial infarction.

ACE inhibitors and angiotensin receptor blockers (ARBs): ACE inhibitors and ARBs used for treatment of hypertension are discussed elsewhere (see chapter 19). These drugs should be used with care in the elderly, who are more likely to have underlying atherosclerotic renovascular disease that could result in renal failure. Excessive hypotension is also more likely to occur in the elderly.

Myocardial infarction

The diagnosis of myocardial infarction in the elderly may be difficult in some patients because of an atypical presentation (Bayer et al., 1986). In the majority of patients, chest pain and dyspnoea are the common presenting symptoms. Confusion may be a presenting factor in up to 20% of patients over 85 years of age. The diagnosis is made on the basis of history, serial electrocardiograms and cardiac enzyme estimations.

The principles of management of myocardial infarction in the elderly are similar to those in the young. Thrombolytic therapy has been shown to be safe and effective in elderly patients.

Cardiac failure

In addition to the typical features of cardiac failure, that is, exertional dyspnoea, oedema, orthopnoea and paroxysmal nocturnal dyspnoea (PND), elderly patients may present with atypical symptoms. These include confusion due to poor cerebral circulation, vomiting and abdominal pain due to gastro-intestinal and hepatic congestion, or insomnia due to PND. Dyspnoea may not be a predominant symptom in an elderly patient with arthritis and immobility. Treatment of cardiac failure depends on the underlying cause and is similar to that in the young. Diuretics, ACE inhibitors, β-blockers and digoxin are the important drugs used in the treatment of cardiac failure in the elderly.

Leg ulcers

Leg ulcers are common in the elderly. They are mainly of two types: venous or ischaemic. Other causes of leg ulcers are blood diseases, trauma, malignancy and infections (Cornwall et al., 1986), but these are less common in the elderly. Venous ulcers occur in patients with varicose veins who have valvular incompetence in deep veins due to venous hypertension. They are usually located near the medial malleolus and are associated with varicose eczema and oedema. These ulcers are painless unless there is gross oedema or infection. Ischaemic ulcers, on the other hand, are due to poor peripheral circulation, and occur on the toes, heels, foot and lateral aspect of the leg. They are painful and are associated with signs of lower limb ischaemia, such as absent pulse or cold lower limb. There may be a history of smoking, diabetes or hypertension.

Venous ulcers respond well to treatment, and over 75% heal within 3 months. Elevation of the lower limbs, exercise, compression bandage, local antiseptic creams when there is evidence of infection, with or without steroid cream, are usually effective. There is no evidence of benefit from the use of oral zinc sulphate in patients with chronic leg ulcers. Dressings impregnated with silver have not been shown to be better than simple low-adherent dressings for the healing of venous leg ulcers. Use of 5% Eutectic Mixture of Local Anaesthetics (EMLA): lidocaine–prilocaine cream results in statistically significant reduction in debridement pain scores but it appears to have no impact on wound healing. Ibuprofen dressings have not been shown to offer pain relief (Briggs et al., 2010). Antiseptics should not be used when there is granulation tissue. Topical streptokinase may be useful to remove the slough on ulcers. Gell colloid occlusive dressings may also be useful in treating chronic ulcers. Skin grafting may be necessary for large ulcers. Ischaemic ulcers do not respond well to medical treatment, and the patients should be assessed by vascular surgeons.

Urinary incontinence

Urinary incontinence in the elderly may be of three main types:

Stress incontinence: due to urethral sphincter incompetence. It occurs almost exclusively in women and is associated with weakening of pelvic musculature. Involuntary loss of small amounts of urine occurs on performing activities which increase intra-abdominal pressure, for example, coughing, sneezing, bending, lifting, etc. It does not cause significant nocturnal symptoms.

Overlow incontinence: constant involuntary loss of urine in small amounts. Prostatic hypertrophy is a common cause and is often associated with symptoms of poor stream and incomplete emptying. Increased frequency of micturition at night is often a feature. Use of anticholinergic drugs and diabetic autonomic neuropathy are other causes.

Detrusor instability: causes urge incontinence where a strong desire to pass urine is followed by involuntary loss of large amounts of urine either during the day or night. It is often associated with neurological lesions or urinary outflow obstruction, for example, prostatic hypertrophy, but in many cases the cause is unknown.

Stress incontinence is not amenable to drug therapy. In patients with prostatic hypertrophy α_1-blockers such as prazosin, indoramin, alfuzosin, terazosin, and tamsulosin

have all been shown to increase peak urine flow rate and improve symptoms in about 60% of patients. They reduce outflow obstruction by blocking α_1-receptors and thereby relaxing prostate smooth muscle. Postural hypotension is an important adverse effect and occurs in between 2% and 5% of patients.

5α-Reductase converts testerone to dihydrotesterone (DHT) which plays an important role in the growth of prostate. The 5α-reductase inhibitor finasteride reduces the prostate volume by 20% and improves peak urine flow rate. The clinical effects, however, might not become apparent until after 3–6 months of treatment. Main adverse effects are reductions in libido and erectile dysfunction in 3–5% of patients.

Several antimuscarinic drugs including darifenacin, oral and transdermal oxybutynin, modified-release propiverine, solifenacin, and modified-release tolterodine have been licensed for overactive bladder syndrome. All these drugs are similar in efficacy and cause antimuscarinic side effects such as dry mouth, blurred vision and constipation. Immediate-release oxybutynin is the least expensive drug and is more likely to cause adverse effects. Transdermal and modified release preparations are better tolerated, but are more expensive (Anon, 2007).

Constipation

The age-related decline in gastro-intestinal motility and treatment with drugs which decrease gastro-intestinal motility predispose the elderly to constipation. Decreased mobility, wasting of pelvic muscles and a low intake of solids and liquids are other contributory factors. Faecal impaction may occur with severe constipation, which in turn may cause subacute intestinal obstruction, abdominal pain, spurious diarrhoea and faecal incontinence. Adequate intake of dietary fibre, regular bowel habit and use of bulking agents such as bran or ispaghula husk may help to prevent constipation. When constipation is associated with a loaded rectum, a stimulant laxative such as senna or bisacodyl may be given. Frail, ill elderly patients with a full rectum may have atonic bowels that will not respond to bulking agents or softening agents, and in such cases a stimulant is more effective. A stool-softening agent such as docusate sodium is effective when stools are hard and dry. For severe faecal impaction a phosphate enema may be needed. Long-term use of stimulant laxatives may lead to abuse and atonic bowel musculature.

Gastro-intestinal ulceration and bleeding

Gastro-intestinal bleeding associated with peptic ulcer is less well tolerated by the elderly. The clinical presentation may sometimes be atypical with, for example, patients presenting with confusion. *Helicobacter pylori* infection is common and its treatment is similar to that in younger patients. NSAIDs are more likely to cause gastroduodenal ulceration and bleeding in the elderly (Griffin et al., 1988).

Principles and goals of drug therapy in the elderly

A thorough knowledge of the pharmacokinetic and pharmacodynamic factors discussed is essential for optimal drug therapy in the elderly. In addition, some general principles based on common sense, if followed, may result in even better use of drugs in the elderly.

Avoid unnecessary drug therapy

Before commencing drug therapy it is important to ask the following questions:

- Is it really necessary?
- Is there an alternative method of treatment?

In patients with mild hypertension, non-drug therapies which are of proven efficacy should be considered in the first instance. Similarly, unnecessary use of hypnotics should be avoided. Simple measures such as emptying the bladder before going to bed to avoid having to get up, avoidance of stimulant drugs in the evenings or night, or moving the patient to a dark, quiet room may be all that is needed.

Effect of treatment on quality of life

The aim of treatment in elderly patients is not just to prolong life but also to improve the quality of life. To achieve this, the correct choice of treatment is essential. In a 70-year-old lady with severe osteoarthrosis of the hip, for example, total hip replacement is the treatment of choice rather than prescribing NSAIDs with all their attendant adverse effects.

Treat the cause rather than the symptom

Symptomatic treatment without specific diagnosis is not only bad practice but can also be potentially dangerous. A patient presenting with 'indigestion' may in fact be suffering from angina, and therefore treatment with proton pump inhibitors or antacids is clearly inappropriate. When a patient presents with a symptom every attempt should be made to establish the cause of the symptom and specific treatment, if available, should then be given.

Drug history

A drug history should be obtained in all elderly patients. This will ensure the patient is not prescribed a drug or drugs to which they may be allergic, or the same drug or group of drugs to which they have previously not responded. It will help to avoid potentially serious drug interactions.

Concomitant medical illness

Concurrent medical disorders must always be taken into account. Cardiac failure, renal impairment and hepatic dysfunction are particularly common in the elderly, and may increase the risk of adverse effects of drugs.

Choosing the drug

Once it is decided that a patient requires drug therapy, it is important to choose the drug likely to be the most efficacious and least likely to produce adverse effects. It is also necessary to take into consideration coexisting medical conditions. For example, it is inappropriate to commence diuretic therapy to treat mild hypertension in an elderly male with prostatic hypertrophy.

Dose titration

In general, elderly patients require relatively smaller doses of all drugs compared with young adults. It is recognised that the majority of adverse drug reactions in the elderly are dose related and potentially preventable. It is, therefore, rational to start with the smallest possible dose of a given drug in the least number of doses and then gradually increase both, if necessary. Dose titration should obviously take into consideration age-related pharmacokinetic and pharmacodynamic alterations that may affect the response to the chosen drug.

Choosing the right dosage form

Most elderly patients find it easy to swallow syrups or suspensions or effervescent tablets rather than large tablets or capsules.

Packaging and labelling

Many elderly patients with arthritis find it difficult to open child-resistant containers and blister packs. Medicines should be dispensed in easy-to-open containers that are clearly labelled using large print.

Good record keeping

Information about a patient's current and previous drug therapy, alcohol consumption, smoking and driving habits may help in choosing appropriate drug therapy and when the treatment needs to be altered. It will help to reduce costly duplications and will also identify and help to avoid dangerous drug interactions.

Regular supervision and review of treatment

A UK survey showed that 59% of prescriptions to the elderly had been given for more than 2 years, 32% for more than 5 years and 16% for more than 10 years. Of all prescriptions given to the elderly, 88% were repeat prescriptions; 40% had not been discussed with the doctor for at least 6 months, especially prescriptions for hypnotics and anxiolytics. It also showed that 31% of prescriptions were considered pharmacologically questionable, and 4% showed duplication of drugs. It is obvious that there is a need for regular and critical review of all prescriptions, especially when long-term therapy is required.

Adverse drug reactions (ADRs)

It is recognised that ADRs occur more frequently in the elderly. A multicentre study in the UK in 1980 showed that ADRs were the only cause of admission in 2.8% of 1998 admissions to 42 units of geriatric medicine. It also showed that ADRs were contributory to a further 7.7% of admissions. On the basis of this study it can be estimated that up to 15,000 geriatric admissions per annum in the UK are at least partly due to an ADR. Obviously, this has enormous economic implications.

The elderly are more susceptible to ADRs for a number of reasons. They are usually on multiple drugs, which in itself can account for the increased incidence of ADRs. It is, however, recognised that ADRs tend to be more severe in the elderly, and gastro-intestinal and haematological ADRs are more common than would be expected from prescribing figures alone. Age-related pharmacokinetic and pharmacodynamic alterations and impaired homeostatic mechanisms are the other factors which predispose the elderly to ADRs, by making them more sensitive to the pharmacological effects of the drugs. Not surprisingly, up to 80% of ADRs in the elderly are dose-dependent and therefore predictable.

Adherence

Although it is commonly believed that the elderly are poor compliers with their drug therapy, there is no clear evidence to support this. Studies in Northern Ireland and continental Europe have shown that the elderly are as adherent with their drug therapy as the young, provided that they do not have confounding disease. Cognitive impairment, which is common in old age, multiple drug therapy and complicated drug regimens may impair adherence in the elderly. Poor adherence may result in treatment failure. The degree of adherence required varies depending on the disease being treated. For treatment of a simple urinary tract infection, a single dose of an antibiotic may be all that is required, and therefore compliance is not important. On the other hand, adherence of 90% or more is required for successful treatment of epilepsy or difficult hypertension. Various methods have been used to improve adherence. These include prescription diaries, special packaging, training by pharmacists and counselling.

Conclusion

The number of elderly patients, especially those aged over 75 years, is steadily increasing, and they are accounting for an ever-increasing proportion of health care expenditure in the West. Understanding age-related changes in pharmacodynamic factors, avoiding polypharmacy and regular and critical review of all drug treatment will help in the rationalisation of drug prescribing, reduction in drug-related morbidity and also the cost of drug therapy for this important subgroup of patients.

Case studies

Case 11.1

An 80-year-old woman presented to an out-patient clinic with a history of severe giddiness and a few episodes of blackouts. She was being treated for angina and hypertension. She had been on bendroflumethiazide 2.5 mg once daily, and slow-release isosorbide mononitrate 60 mg once daily for a few years. Her general practitioner had recently commenced nifedipine SR 20 mg twice daily for poorly controlled hypertension. On examination her blood pressure was 120/70 mmHg while supine and 90/60 mmHg on standing up.

Question

What is the underlying problem in this patient, and could it be caused by any of the medications that the patient is taking?

Answer

This patient obviously has significant postural hypotension. All her drugs have the potential to produce postural hypotension, and when used together they may produce symptomatic postural hypotension.

It is important to recognise that some drugs such as nifedipine and nitrates have impaired first-pass metabolism in the elderly and that their clinical effects are enhanced. In addition, orthostatic circulatory responses are also impaired in the elderly. The need for antihypertensive drugs should be carefully assessed in all elderly patients, and, if therapy is indicated, the smallest dose of drug should be commenced and increased gradually. Patients should also be told to avoid sudden changes of posture.

Case 11.2

An 85-year-old man was admitted to hospital with anorexia, nausea and vomiting. He was known to have atrial fibrillation, congestive cardiac failure and chronic renal impairment. He was on digoxin 250 μcg once daily and furosemide 80 mg twice daily.

His serum biochemistry revealed the following (normal range in parentheses):

Potassium	4.5 mmol/L	(3.5–5)
Urea	40 mmol/L	(3.0–6.5)
Creatinine	600 μmol/L	(50–120)
Digoxin	3.5 μcg/L	(1–2)

Question

What are the likely causes of medical problems in this patient and how should the drug therapy be altered?

Answer

The patient's biochemical results confirm the presence of renal impairment and digoxin toxicity. The renal impairment could be related to the relatively high dose of furosemide which needs to be reduced. As digoxin is predominantly excreted through the kidneys, the dose should be reduced in severe renal impairment. In such

situations, digitoxin, which is predominantly metabolised in the liver, can be used instead of digoxin.

Case 11.3

An 80-year-old woman with a previous history of hypothyroidism presented with a history of abdominal pain and vomiting. She had not moved her bowels for the previous 7 days. Two weeks earlier her general practitioner had prescribed a combination of paracetamol and codeine to control pain in her osteoarthritic hips.

Question

What are the likely underlying causes of this patient's bowel dysfunction?

Answer

This patient developed severe constipation after taking a codeine-containing analgesic. Ageing is associated with decreased gastro-intestinal motility. Hypothyroidism, which is common in the elderly, is also associated with reduced gastro-intestinal motility. Whenever possible, drugs that are known to reduce gastro-intestinal motility should be avoided in the elderly.

Case 11.4

A 75-year-old lady who suffered from osteoarthritis of hip and knee joints presented with a history of passing black stools. Her drug therapy included diclofenac 50 mg three times daily and paracetamol 1 g as required.

Question

What is the likely cause of this patient's symptoms?

Answer

The likely cause is upper gastro-intestinal bleeding due to diclofenac, which is an NSAID. Elderly people are more prone to develop ulceration in stomach and duodenum with NSAIDs compared with young patients.

Case 11.5

A 70-year-old man was found by his general practitioner to have hypertension and was commenced on lisinopril 5 mg once a day. He had a previous history of peripheral vascular disease for which he had required angioplasty. Two weeks after commencing antihypertensive treatment, he presented with lack of appetite, nausea and decreased urine output.

Question

What do you think has happened and is the most likely underlying problem?

Answer

The patient is probably developing renal failure. With a previous history of peripheral vascular disease, he is likely to have bilateral renal artery stenosis. ACE inhibitors can cause renal failure in the presence of bilateral renal stenosis by reducing blood supply to the kidneys.

SECTION 3

THERAPEUTICS

12 Peptic ulcer disease

M. Kinnear

Key points

- The two main types of peptic ulcer disease are those associated with *Helicobacter pylori* and those associated with non-steroidal anti-inflammatory drugs (NSAIDs) and aspirin.
- Ulcer-like dyspepsia does not correlate with diagnosis of peptic ulcer.
- Uninvestigated dyspepsia without alarm symptoms may be treated empirically without an endoscopic diagnosis.
- An *H. pylori* test and treat strategy means it is unknown if the patient has an ulcer.
- Triple therapy with a proton pump inhibitor (PPI), clarithromycin and amoxicillin twice daily for 7 days is currently the recommended first-line *H. pylori* eradication regimen.
- Patient adherence influences the success of *H. pylori* eradication therapy.
- *H. pylori* eradication therapy does not have a role in the management of gastro-oesophageal reflux disease (GORD). Its benefit in the management of functional dyspepsia is small.
- Associated risks of *Clostridium difficile* infection, pneumonia and osteoporosis have led to judicious use of PPIs.
- Patients who need to continue NSAID therapy are the only patients with peptic ulcer disease in whom continued ulcer-healing therapy is necessary after the ulcer has healed and *H. pylori* has been eradicated.
- Upper gastro-intestinal symptoms in NSAID users do not correlate well with presence or absence of peptic ulcers.
- The risk of ulcers associated with NSAID use is common to all non-specific NSAIDs and is dose dependent. The risk is maintained during treatment and decreases once treatment is stopped.
- Risk factors for NSAID-induced gastro-intestinal complications include previous history of peptic ulcer or gastro-intestinal bleeding, age >65, concomitant use of aspirin, anticoagulants or corticosteroids.
- Adding a PPI to non-specific NSAIDs provides a similar reduction in risk of gastro-intestinal toxicity to that offered by cyclo-oxygenase-2 (COX-2) inhibitors alone.
- Enteric coating or taking them with food does not reduce the risk of upper gastro-intestinal bleeding associated with NSAIDs and low-dose aspirin.
- Adding a PPI to aspirin is associated with lower risk of recurrent gastro-intestinal bleeding than clopidogrel alone.
- Concomitant PPI therapy may decrease clopidogrel activity through competitive hepatic metabolism; the combination is not recommended unless dual antiplatelet therapy is indicated.
- *H. pylori* eradication has a greater effect on decreasing recurrent peptic ulcer bleeding rate than PPIs alone in patients who continue low-dose aspirin; an additive effect is seen if both strategies are used.
- Cardiovascular risks must be weighed against gastro-intestinal risks in deciding whether or not to discontinue aspirin and for how long in patients who present with gastro-intestinal bleeding.
- Approximately one-third of deaths from gastro-intestinal bleeding are due to NSAIDs, and up to one-third of NSAID/ aspirin deaths are attributed to low-dose aspirin.
- High dose intravenous PPI therapy is indicated to prevent re-bleeding in patients at high risk (active bleeding or non-bleeding visible vessel) following endoscopic haemostatic treatment for bleeding peptic ulcer. It is not recommended in those at low risk or pre-endoscopy.
- *H. pylori* eradication reduces re-bleeding rate in patients with gastro-intestinal bleeding but eradication treatment can be delayed until normal oral intake is resumed.
- Adding a PPI to a COX-2 inhibitor (in those not at cardiovascular risk) decreases the re-bleeding rate in those patients at high risk of re-bleeding in comparison to COX-2 inhibitors alone. No comparison has been made with non-selective NSAID in combination with PPI.

The term 'peptic ulcer' describes a condition in which there is a discontinuity in the entire thickness of the gastric or duodenal mucosa that persists as a result of acid and pepsin in the gastric juice (Fig. 12.1). Oesophageal ulceration due to acid reflux is generally classified under GORD. This definition excludes carcinoma and lymphoma, which may also cause gastric ulceration, and also excludes other rare causes of gastric and duodenal ulceration such as Crohn's disease, viral infections and amyloidosis. About 10% of the population in developed countries is likely to be affected at some time by peptic ulcer, with the prevalence for active ulcer disease being about 1% at any particular point in time.

Peptic ulcer disease often presents to clinicians as dyspepsia. However, not all patients with dyspepsia have peptic ulcer disease. Dyspepsia is defined as persistent or recurrent pain or discomfort centred in the upper abdomen. The most common causes of dyspepsia are non-ulcer or functional dyspepsia, GORD and peptic ulcer. Other causes include gastric cancer, pancreatic or biliary disease. Peptic ulcer accounts for 10–15% of dyspepsia, and oesophagitis for about 20%. However, 60–70% of patients have no obvious abnormality and have functional dyspepsia or endoscopy-negative GORD. Dyspepsia is a common symptom and affects about 40% of
Fig. 12.1 Duodenal ulcer seen at endoscopy. Note also a visible blood vessel that is a stigma of recent haemorrhage.

Fig. 12.2 *Helicobacter pylori*. The Gram-negative spiral bacterium *H. pylori*, formerly known as *Campylobacter pylori*, was isolated serendipitously from patients with gastritis by Barry Marshall and Robin Warren in 1982. Seven years later, it was conceded that *H. pylori* is responsible for most cases of gastric and duodenal ulcer.

people annually. It is the reason for 5–10% of consultations with primary care physicians, and up to 70% of referrals to gastro-intestinal units are patients with dyspepsia. However, the widely adopted test and treat recommendation for uninvestigated dyspepsia has reduced endoscopy referrals.

Epidemiology

The incidence of duodenal ulcer is now declining, which follows the decline in *H. pylori* infection. However, hospital admission rates for gastro-intestinal bleeding associated with gastric and duodenal ulcers are rising, especially in older patients. This is probably a consequence of increased prescriptions for low-dose aspirin, NSAIDs, antiplatelets, anticoagulants and selective serotonin reuptake inhibitors (SSRI). Over the previous decade there has been an increase in idiopathic peptic ulcer disease in patients who test negative for *H. pylori* and who do not take NSAIDs or aspirin. In some countries, up to one-quarter of peptic ulcers are idiopathic and there is a decrease in prevalence of *H. pylori* infection. Idiopathic ulcers should be investigated to attempt to identify the underlying cause following careful reassessment of *H. pylori* status and medication history.

Infection by *H. pylori*, a spiral bacterium of the stomach, remains an important epidemiological factor in causing peptic ulcer (Fig. 12.2). Most *H. pylori* infections are acquired by oral–oral and oral–faecal transmission. The most important risk factors for *H. pylori* infection are low social class, overcrowding and home environment during childhood, for example, bed sharing. Transmission may occur within a family, a fact demonstrated by the finding that family members, especially spouses, may have the same strain of *H. pylori*. *H. pylori* seropositivity increases with age as colonisation persists for the lifetime of the host. Subjects who become infected with *H. pylori* when young are more likely to develop chronic or atrophic gastritis with reduced acid secretion that may protect them from developing duodenal ulcer. However, it may promote development of gastric ulcer as well as gastric cancer.
Duodenal ulcer seems to develop in those who are infected with *H. pylori* at the end of childhood or later. Historically, developing countries have a higher ratio of duodenal ulcer to gastric ulcer but as rates of *H. pylori* infection decline with improvements in hygiene and rates of gastric ulcer increase with the use of ulcerogenic drugs, this ratio of duodenal to gastric ulcer is declining. The prevalence of *H. pylori* still tends to be higher in the Asian adult population in whom a lower parietal cell mass has been found. These factors together with slower metabolism may explain the greater efficacy of PPIs in Asian populations. There may be other genetic, environmental or cultural factors influencing peptic ulcer disease.

Pathogenesis

There are two common forms of peptic ulcer disease: those associated with the organism *H. pylori* and those associated with the use of aspirin and NSAIDs. Less common is ulcer disease associated with massive hypersecretion of acid which occurs in the rare gastrinoma (Zollinger–Ellison) syndrome.

Helicobacter pylori

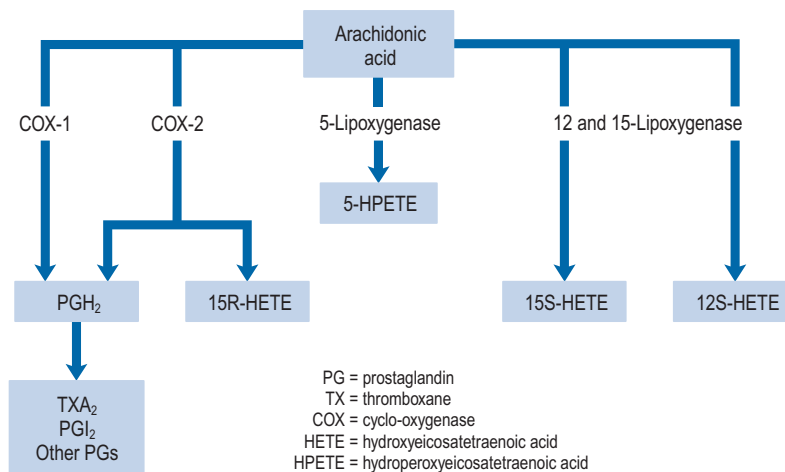
This organism is a Gram-negative microaerophilic bacterium found primarily in the gastric antrum of the human stomach (see Fig. 12.2). Ninety-five percent or more of duodenal ulcers and 80–85% of gastric ulcers are associated with *H. pylori*. The bacterium is located in the antrum and the acid-secreting microenvironment of the corpus of the stomach is less hospitable to the bacterium. In the developed world, reinfection rates are low, about 0.3–1.0% per year, whereas in the developing world reinfection rates are higher, approximately 20–30%. Ulcerogenic strains of *H. pylori*, ulcer-prone hosts, age of infection and interaction with other ulcerogenic factors such as NSAIDs determine peptic ulcer development


Fig. 12.3 Arachidonic acid pathway.

following *H. pylori* infection. The contribution of *H. pylori* infection to the risk of ulcers in NSAID users is not clear but there appears to be an additive effect. The risk of peptic ulcer in long-term NSAID users is greater in those who test positive for *H. pylori* and eradication of *H. pylori* in these patients prior to commencing NSAID treatment has been shown to reduce the risk of *H. pylori* NSAID-associated peptic ulcer.

Although the majority of species in the *H. pylori* genus have been associated with pathology, some are more virulent than others which probably explains why, in combination with host-related factors, only 5–10% of those infected go on to develop peptic ulcer disease.

The underlying pathophysiology associated with *H. pylori* infection involves the production of cytotoxin-associated gene A (*CagA*) proteins and vacuolating cytotoxins, such as vac A, which activate the inflammatory cascade. *CagA* status and one genotype of the vac A gene are also predictors of ulcerogenic capacity of a strain. In addition, a number of enzymes produced by *H. pylori* may be involved in causing tissue damage and include urease, haemolysins, neuraminidase and fucosidase.

Gastrin is the main hormone involved in stimulating gastric acid secretion, and gastrin homeostasis is also altered in *H. pylori* infection. The hyperacidity in duodenal ulcer may result from *H. pylori*-induced hypergastrinaemia. The elevation of gastrin may be a consequence of bacterially mediated decrease of antral D cells that secrete somatostatin, thus losing the inhibitory modulation of somatostatin on gastrin, or direct stimulation of gastrin cells by cytokines liberated during the inflammatory process. Long-standing hypergastrinaemia leads to an increased parietal cell mass. High acid content in the proximal duodenum leads to metaplastic gastric-type mucosa, which provides a niche for *H. pylori* infection followed by inflammation and ulcer formation.

Non-steroidal anti-inflammatory drugs

Three patterns of mucosal damage are caused by NSAIDs. These include superficial erosions and haemorrhages, silent ulcers detected at endoscopy and ulcers causing clinical symptoms and complications. Weak acid NSAIDs, such as acetylsalicylic acid, are concentrated from the acidic gastric juice into mucosal cells, and may produce acute superficial erosions via inhibition of COX and by mediating the adherence of leucocytes to mucosal endothelial cells. Enteric coating may prevent this superficial damage but does not demonstrate any clinical benefit in terms of reduction of gastro-intestinal bleeding or ulceration (Bhatt et al., 2008). The major systemic action of NSAIDs that contributes to the formation of ulcers is the reduction of mucosal prostaglandin production. All NSAIDs share the ability to inhibit COX (Fig. 12.3). The presence of NSAID-induced ulcers does not correlate with abdominal pain and NSAIDs themselves often mask ulcer pain. Approximately 20% of patients taking NSAIDs experience symptoms of dyspepsia but symptoms correlate poorly with the presence of mucosal damage. Ulcers and ulcer complications occur in approximately 4% of NSAID users every year. Patients taking NSAIDs have a four-fold increase in risk of ulcer complications compared with non-users. The risk of ulcer bleeding in low-dose aspirin users is two- to three-fold and there may be differences in risk factors. For example, the risk with aspirin is less influenced by age than the risk associated with NSAIDs (McQuaid and Laine, 2006) and *H. pylori* may have greater influence on the risk of bleeding with low-dose aspirin than with NSAIDs (Lanza et al., 2009).

Each year, in the UK population over the age of 60 years, there are ~3500 hospitalisations and over 400 deaths associated with NSAIDs. The risk of ulcer complications (Box 12.1) is progressive depending upon the number of risk factors present (Lanza et al., 2009). The most important risk factors

---

Box 12.1 Risk factors for NSAID ulcers

Age greater than 65 years
Previous peptic ulceration/bleeding
High dose of NSAID or more than one NSAID (including aspirin)
Short-term history of NSAID use (<1 month)
Concomitant corticosteroid or anticoagulant use
Cardiovascular disease

are a history of ulcer complications and advancing age, particularly over 75 years. Ulcers have been found to be more common in patients who have taken NSAIDs for less than 3 months, with the highest risk observed during the first month of treatment. The risk increases with higher doses of NSAID but mucosal damage occurs with even very low doses of NSAIDs, particularly aspirin. Corticosteroids alone are an insignificant ulcer risk, but potentiate the ulcer risk when added to NSAIDs, particularly in daily doses of at least 10 mg prednisolone (Lanza et al., 2009).

Low-dose aspirin (75 mg/day) alone increases the risk of ulcer bleeding and this effect may be due to the antiplatelet action, independent of other risk factors. Concomitant use of aspirin with NSAIDs further increases the risk. There is no evidence that anticoagulants increase the risk of NSAID ulcers but they are associated with an increase in the risk of haemorrhage. The presence of cardiovascular disease is also considered as an independent risk factor.

Selective cyclo-oxygenase-2 inhibitors

The gastro-intestinal side effects of conventional NSAIDs are mediated through the inhibition of COX-1 (see Fig. 12.3). COX-1 stimulates synthesis of homeostatic prostaglandins while COX-2 is predominantly induced in response to inflammation. Selective COX-2 inhibitors tend not to reduce the mucosal production of protective prostaglandins to the same extent as NSAIDs. COX-2 inhibitors are, therefore, considered to be safer than non-selective NSAIDs in patients at high risk of developing gastro-intestinal mucosal damage. Although studies have confirmed the reduction of endoscopic and symptomatic ulcers (Hooper et al., 2004), an increase in cardiovascular risk, including heart attack and stroke, has resulted in the withdrawal of some COX-2 inhibitors from the market. Additional contraindications are now in place for those COX-2 inhibitors that remain on the market. Amongst the new contraindications is the recommendation that they should not be taken by patients with established heart or cerebrovascular disease, or taken in combination with low-dose aspirin as this negates any beneficial gastro-intestinal protective effects. The need for and choice of anti-inflammatory agent should therefore take into account gastro-intestinal, cardiovascular and other risks such as potential cardio-renal effects. For all agents, the lowest effective dose should be used for the shortest duration.

Candidates for COX-2 inhibitors are patients at high risk of NSAID-related gastro-intestinal events but who do not require low-dose aspirin therapy. The lowering of risk of gastro-intestinal events is similar for COX-2 inhibitors and non-selective NSAIDs combined with a gastroprotective agent.

Nitric oxide-releasing NSAIDs

Nitric oxide (NO)-releasing NSAIDs are being investigated to see if the gastric mucosa protection associated with nitric oxide prevents ulceration when prostaglandins are inhibited by NSAIDs (Fiorucci et al., 2007). Nitric oxide is coupled to the NSAID via an ester, resulting in prolonged release of nitric oxide. Nitric oxide itself has anti-inflammatory effects adding to the potency of the NSAID. Animal studies suggest NO-releasing agents, such as naproxcinod, have minimum cardiovascular and gastro-intestinal toxicity.

Clinical manifestations

Upper abdominal pain occurring 1–3 h after meals and relieved by food or antacids is the classic symptom of peptic ulcer disease. The relationship to meals is more marked in duodenal ulcer than in gastric ulcer. However, the symptoms of peptic ulcer disease lack specificity; they do not distinguish between duodenal ulcer, gastric ulcer or functional dyspepsia. Anorexia, weight loss, nausea and vomiting, heartburn and eructation can all occur with peptic ulcer disease. Patients with predominant symptoms of heartburn are likely to have GORD. Complications of peptic ulcer disease may occur with or without previous dyspeptic symptoms. These are haemorrhage, chronic iron-deficiency anaemia, pyloric stenosis and perforation. In the elderly, the presentation is more likely to be silent and gastro-intestinal bleeding may be the first clinical sign of disease. Peptic ulcer bleeding is the most frequent and severe complication of peptic ulcer disease. Physical examination may be negative or reveal epigastric tenderness. Peptic ulcers in the past tended to relapse and remit, and 70–80% of ulcers relapse within 1–2 years after being healed by antisecretory therapy. This tendency to relapse is dramatically reduced by eradication of *H. pylori*.

Patient assessment

Presenting symptoms of dyspepsia require careful assessment to judge the risk of serious disease or to provide appropriate symptomatic treatment. Symptom subgroups such as ulcer, reflux and dysmotility type may be useful in identifying the predominant symptom subgroup to which a patient belongs. Many patients have symptoms which fit more than one subgroup (Box 12.2). Many patients seek reassurance, lifestyle advice and symptomatic treatment with a single consultation, others have chronic symptoms. In some cases, medications may be the cause of dyspepsia and should be reviewed (Box 12.3).

Patients at any age who present with alarm features (Box 12.4) should be referred for endoscopic investigation. These groups of patients are at a higher risk of underlying serious disease such as cancer, ulcers or severe oesophagitis. Referral is also recommended for patients over the age of 55 if symptoms are unexplained or persistent despite initial management (NICE, 2004; SIGN, 2003). Malignant disease is rare in young people and in those without alarm features.

Patients with predominant reflux-like symptoms are likely to respond to acid-suppressing therapy and one month's treatment of standard dose of PPI should be given in patients whose symptoms persist despite antacid and lifestyle adjustment. Eradication of *H. pylori* is not beneficial in GORD.

Box 12.2 Dyspepsia symptom subgroups

Reflux-like dyspepsia
Heartburn plus dyspepsia
Acid regurgitation plus dyspepsia
Ulcer-like dyspepsia
Localised epigastric pain
Pain when hungry
Pain relieved by food
Pain relieved by antacids or acid-reducing drugs
Pain that wakens the patient from sleep
Pain with remission and relapses
Dysmotility-like dyspepsia
Upper abdominal discomfort (pain not dominant)
Early satiety
Postprandial fullness
Nausea
Retching or vomiting
Bloating in the upper abdomen (no visible distension)
Upper abdominal discomfort often aggravated by food
Unspecified dyspepsia

Box 12.3 Drugs causing dyspepsia

Antibiotics
Bisphosphonates
Calcium channel blockers
Corticosteroids
Drugs with antimuscarinic effects, for example, tricyclic antidepressants
Iron
Nitrates
NSAIDs including aspirin
Potassium chloride
Theophylline

Box 12.4 Alarm features

Dysphagia
Pain on swallowing
Unintentional weight loss
Gastro-intestinal bleeding or anaemia
Persistent vomiting
On NSAIDs or warfarin

In those patients who do not have reflux-like dyspepsia, testing for the presence of *H. pylori* is recommended. Eradication treatment should be prescribed for those who test positive and empirical acid suppression for those who test negative. The small proportion of patients with symptoms due to ulcers should be cured. Overall, in functional dyspepsia, symptom control is poor but a small and significant benefit of eradication treatment has been shown. Acid suppression is only of benefit in a small proportion of patients with functional dyspepsia. There is no evidence to support other pharmacological therapies and non-pharmacological strategies may have a future role in functional dyspepsia. Patients should be reassured that the condition is common and not serious. National

guidelines (NICE, 2004) provide algorithms to guide practitioners through the management of patients presenting with dyspepsia (Fig. 12.4A and B).

Investigations

Endoscopy

Endoscopy is generally the investigation of choice for diagnosing peptic ulcer, and the procedure is sensitive, specific and safe. However, it is also invasive and expensive. Routine endoscopy in patients presenting with dyspepsia without alarm features (see Box 12.4) is not necessary. Endoscopic investigation should be undertaken in patients with alarm features and in those patients over 55 years who present with unexplained or persistent symptoms of dyspepsia. Biopsies may be taken to exclude malignancy and uncommon lesions such as Crohn's disease.

Patients with upper gastro-intestinal bleeding have traditionally undergone endoscopy whether as an emergency or on the next available list. Most patients do not require endoscopy and in those at low risk, endoscopy and admission to hospital can be avoided by application of a scoring system. The most widely used is the Rockall risk scoring system which includes endoscopic findings to predict poor outcome. Pre-endoscopic scoring systems are available (Stanley et al., 2009) such as the abbreviated Rockall score or the Glasgow–Blatchford score (GBS) which identify low-risk patients who can be managed safely without endoscopy or admission to hospital.

Wireless capsule endoscopy is also available to investigate NSAID-induced ulceration of the small intestine causing gastro-intestinal haemorrhage and is preferable to radiological imaging.

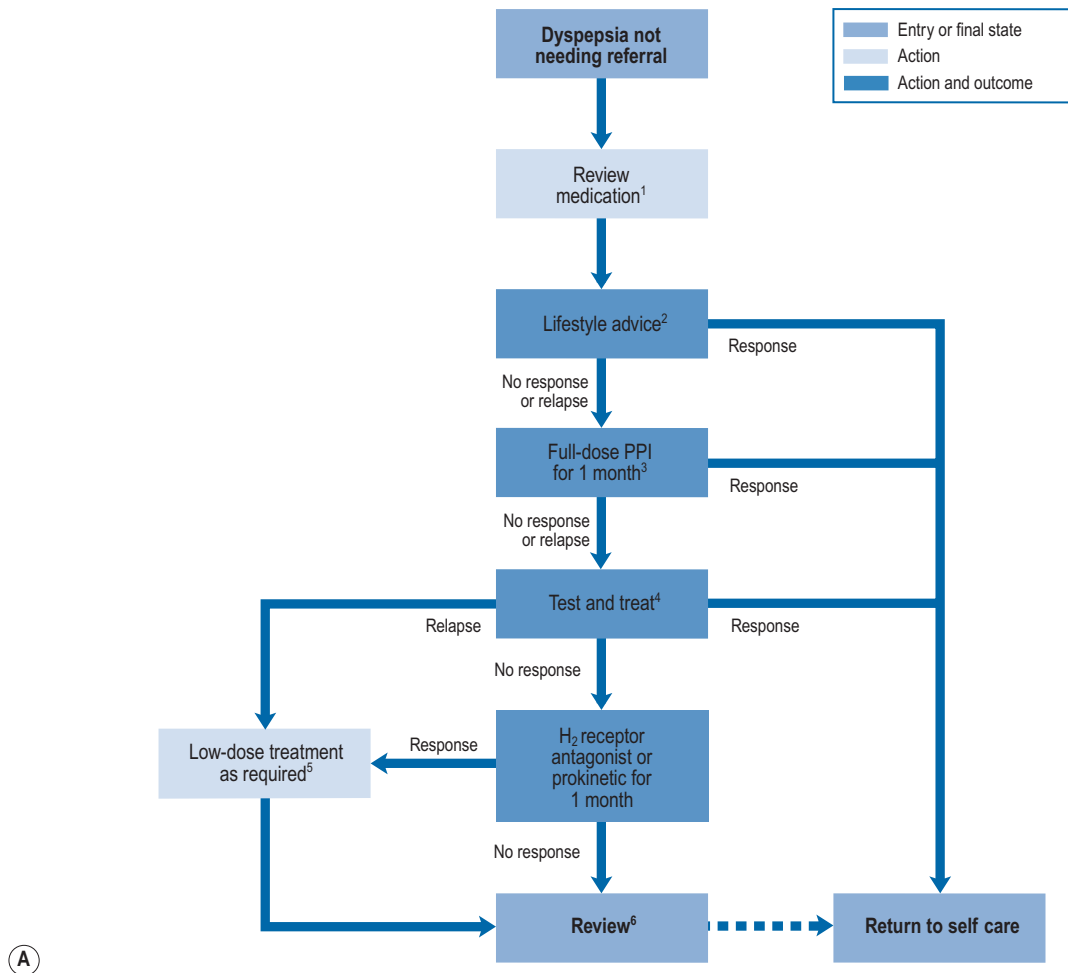
Radiology

Double-contrast barium radiography should detect 80% of peptic ulcers. However, endoscopy is more accurate and almost always preferred. A Gastrograffin® meal is used to diagnose peptic perforation in patients presenting with an acute abdomen, if a plain abdominal X-ray is not diagnostic.

H. pylori detection

There are several methods of detecting *H. pylori* infection. They include non-invasive tests such as serological tests to detect antibodies, [^{13}C] urea breath tests and stool antigen tests. Urea breath tests have a sensitivity and specificity over 90% and are accurate for both initial diagnosis and confirmation of eradication. The breath test is based on the principle that urease activity in the stomach of infected individuals hydrolyses urea to form ammonia and carbon dioxide. The test contains carbon-labelled urea which, when hydrolysed, results in production of labelled carbon dioxide which appears in the patient's breath. The stool antigen test uses an enzyme immunoassay to detect *H. pylori* antigen in stool. This test also has a sensitivity and specificity over 90% and can be used in the initial diagnosis and also to confirm eradication. However, the

breath test is preferable and more convenient. Serological tests are based on the detection of anti-*H. pylori* IgG antibodies but are not able to distinguish between active or previous exposure to infection. Near patient serology tests are not recommended (Malfertheiner et al., 2007) as they are inaccurate.

Invasive tests requiring gastric antral biopsies include urease tests, histology and culture. Of these, the biopsy urease test is widely used. Agar-based biopsy urease tests are designed to be read at 24h, whereas the strip-based biopsy urease tests can be read at 2h following incubation with the biopsy material.


(A)

1   Review medications for possible causes of dyspepsia, for example, calcium antagonists, nitrates, theophyllines, bisphosphonates, steroids and NSAIDs.

2   Offer lifestyle advice, including advice on healthy eating, weight reduction and smoking cessation, promoting continued use of antacid/alginates.

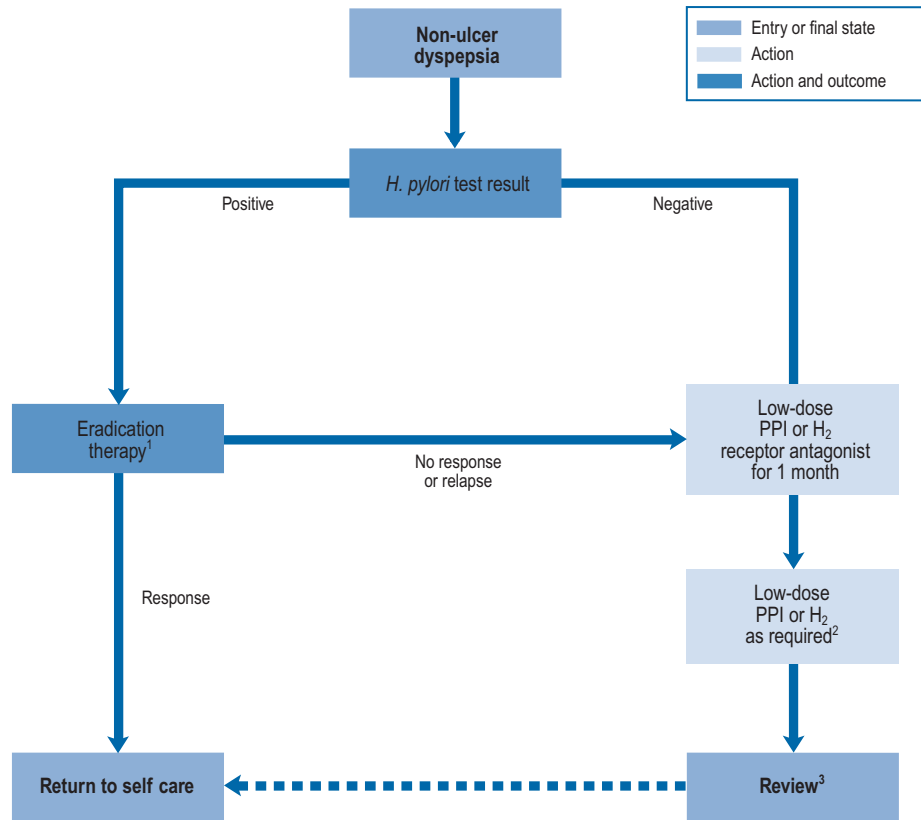
3   There is currently inadequate evidence to guide whether full dose PPI (proton pump inhibitor) for 1 month or *H. pylori* test and treat should be offered first. Either treatment may be tried first with the other offered if symptoms persist or return.

4   Detection: use carbon-13 urea breath test, stool antigen test or, when performance has been validated, laboratory based serology.
Eradication: use PPI, amoxicillin, clarithromycin 500 mg (PAC_{500}) regimen or a PPI, metronidazole, clarithromycin 250 mg (PAC_{250}) regimen.
Do not retest even if dyspepsia remains unless there is a strong clinical need.

5   Offer low-dose treatment with a limited number of repeat prescriptions. Discuss the use of treatment on an as-required basis to help patients manage their own symptoms.

6   In some patients with an inadequate response to therapy it may become appropriate to refer to a specialist for a second opinion. Emphasise the benign nature of dyspepsia. Review long-term patient care at least annually to discuss medication and symptoms.

Fig. 12.4   (A) Decision algorithm for management of uninvestigated dyspepsia.

Fig. 12.4, cont'd (B) Decision algorithm for management of non-ulcer dyspepsia.


[1] Use a proton pump inhibitor (PPI), amoxicillin, clarithromycin 500 mg (PAC$_{500}$) regimen or a PPI, metronidazole, clarithromycin 250 mg (PAC$_{250}$) regimen. Do not retest unless there is a strong clinical need.

[2] Offer low-dose treatment, possibly on an as-required basis, with a limited number of repeat prescriptions.

[3] In some patients with an inadequate response to therapy or new emergent symptoms it may become appropriate to refer to a specialist for a second option. Emphasise the benign nature of dyspepsia. Review long-term patient care at least annually to discuss medication and symptoms.

Increasing the number of biopsy samples increases the sensitivity of the test as infection can be patchy. The accuracy of the urea breath test or biopsy urease test can be reduced by drug therapy; therefore, it is recommended to discontinue PPIs at least 2 weeks before testing and discontinue antibiotics at least 4 weeks before testing to reduce the risk of false-negative results.

The faecal occult blood test is not specific for or sensitive to detection of NSAID-induced gastric damage. A full blood count may provide evidence of blood loss from peptic ulcer.

Treatment

Complications of peptic ulcer disease

Bleeding peptic ulcer

Peptic ulcer is the most common cause of non-variceal upper gastro-intestinal bleeding. Most patients with bleeding peptic ulcer are clinically stable and stop bleeding without any intervention, whereas other outcomes include re-bleeding and mortality. Endoscopy allows identification of the severity of disease as well as endoscopic haemostatic therapy which is successful in reducing mortality. Endoscopic therapy is necessary only in patients who exhibit high-risk stigmata (active bleeding, non-bleeding visible vessel, adherent clot) on endoscopy.

A number of pharmacological agents have been used for endoscopic injection therapy such as 1:10,000 adrenaline (epinephrine), human thrombin and fibrin glue. Mechanical endoscopic treatment options include thermocoagulation using a heater probe or endoscopic clipping. Combination therapies are superior to monotherapy and a combination of adrenaline 1:10,000 with either thermal or mechanical treatment is recommended (SIGN, 2008; Barkun et al., 2010). Need for surgery, re-bleeding rates and mortality are reduced but bleeding recurs in about 10% of patients and can cause death. Patients with uncontrolled bleeding should receive repeat endoscopic treatment, arterial embolisation

or surgery. The risk of recurrent bleeding following endoscopic therapy is reduced by increasing intragastric pH during the first 3 days after the initial bleed and eradication of *H. pylori*. Biopsies taken at the time of endoscopy are used to detect *H. pylori*, or the urea breath test can be used once oral intake is established and *H. pylori* eradication therapy is indicated in those who test positive. Successful eradication of *H. pylori* reduces the rate of re-bleeding to a greater extent than antisecretory non-eradicating therapy (Gisbert et al., 2004). Following successful *H. pylori* eradication and healing of the ulcer, there is no need to continue maintenance antisecretory therapy beyond 4 weeks unless required for prophylaxis of ulcer complications in those continuing to take aspirin or NSAIDs (SIGN, 2008).

Acid suppression reduces the re-bleeding rate and should be given to those patients at high risk of re-bleeding following endoscopic haemostatic therapy. The rationale for this is based on the fact that gastric acid inhibits clot formation and if intragastric pH is maintained above 6 during the first 3 days after the initial bleed, there is opportunity for clot stabilisation and haemostasis. Meta-analysis suggests PPIs significantly reduce re-bleeding rates compared with H_2-receptor antagonists and are the preferred choice of treatment (Leontiadis et al., 2006). In similar dosage regimens, there is no data to suggest any PPI is more efficacious than another. The optimal dose and route of PPI is unknown in this indication, although reduction in mortality is observed in high-risk patients when high dose PPI therapy is given (e.g. 80 mg bolus omeprazole, pantoprazole or esomeprazole followed by 8 mg/h for 72 h) following endoscopic haemostasis (Leontiadis et al., 2007; SIGN, 2008; Barkun et al., 2010).

The use of intravenous PPI therapy before endoscopy in patients with upper gastro-intestinal bleeding does not affect clinical outcome such as re-bleeding, need for surgery or mortality (Dorward et al., 2006). However, this may reduce the need for endoscopic therapy (Lau et al., 2007) as demonstrated in Asian patients in whom PPIs are more effective. Its benefits are not clear and it is not possible to identify patients with a greater likelihood of being at high risk. Therefore, the use of PPIs is not recommended prior to diagnosis by endoscopy (SIGN, 2008) but may be beneficial if early endoscopy is delayed (Barkun et al., 2010).

In those patients at low risk for re-bleeding and in whom endoscopic therapy is not indicated, usual therapeutic doses of oral PPI are given for 4 weeks to heal the ulcer. Aspirin or NSAIDs should be avoided but if strongly indicated, these patients are given concomitant PPI therapy following successful eradication of *H. pylori*. The effect of *H. pylori* eradication on the risk of recurrent ulcer bleeding is greater in patients taking low-dose aspirin than in those taking NSAIDs (Chan et al., 2001). A possible explanation (Lanza et al., 2009) for this might be that aspirin provokes bleeding in *H. pylori* ulcers and after healing, aspirin is less likely to cause ulceration.

In patients for whom there is a clear indication to continue aspirin therapy, addition of a PPI is of benefit in the prevention of recurrent bleeding in aspirin users (Lai et al., 2002). Clopidogrel alone is not a safer alternative than this combination in terms of prevention of recurrent ulcer bleeding. Cardiovascular and gastro-intestinal risks must be taken into consideration when deciding how long aspirin should be discontinued after a gastro-intestinal bleed. In some cases, low-dose aspirin can be restarted with concurrent PPI treatment within 7 days (Barkun et al., 2010). When the combination of aspirin and clopidogrel is indicated, concomitant PPI therapy is recommended in patients at high risk of gastro-intestinal complications despite the potential drug interaction between PPIs and clopidogrel. An increased risk of myocardial infarction has been observed with the combination of clopidogrel and PPIs (MHRA, 2009). Causality is unclear but it is suggested that through competitive enzyme inhibition, PPIs metabolised by CYP2C19 reduce the conversion of clopidogrel to its active metabolite. Concomitant use is discouraged but if necessary, separation of dosage timing is recommended (Laine and Hennekens, 2010).

Pyloric stenosis

Malignancy is the most common cause of gastric outlet obstruction. Peptic ulcer disease is the underlying cause in about 10% of cases. There is limited anecdotal evidence that incomplete gastric outlet obstruction may improve within several months of successful *H. pylori* eradication. Conventional treatment with acid-suppressive therapy may also help. If medical therapy fails to relieve the obstruction, endoscopic balloon dilation or surgery may be required.

Zollinger–Ellison syndrome

This rare syndrome consists of a triad of non-β islet cell tumours of the pancreas that contain and release gastrin, gastric acid hypersecretion and severe ulcer disease. Extrapancreatic gastrinomas are also common and may be found frequently in the duodenal wall. A proportion of these patients have tumours of the pituitary gland and parathyroid gland (multiple endocrine neoplasia type I). Surgical resection of the gastrinoma may be curative. Medical management consists of greater than standard doses of PPIs. The somatostatin analogue octreotide is also effective but has no clear advantage over PPIs. Patients with idiopathic peptic ulcer disease should be investigated for Zollinger–Ellison syndrome and gastrinoma.

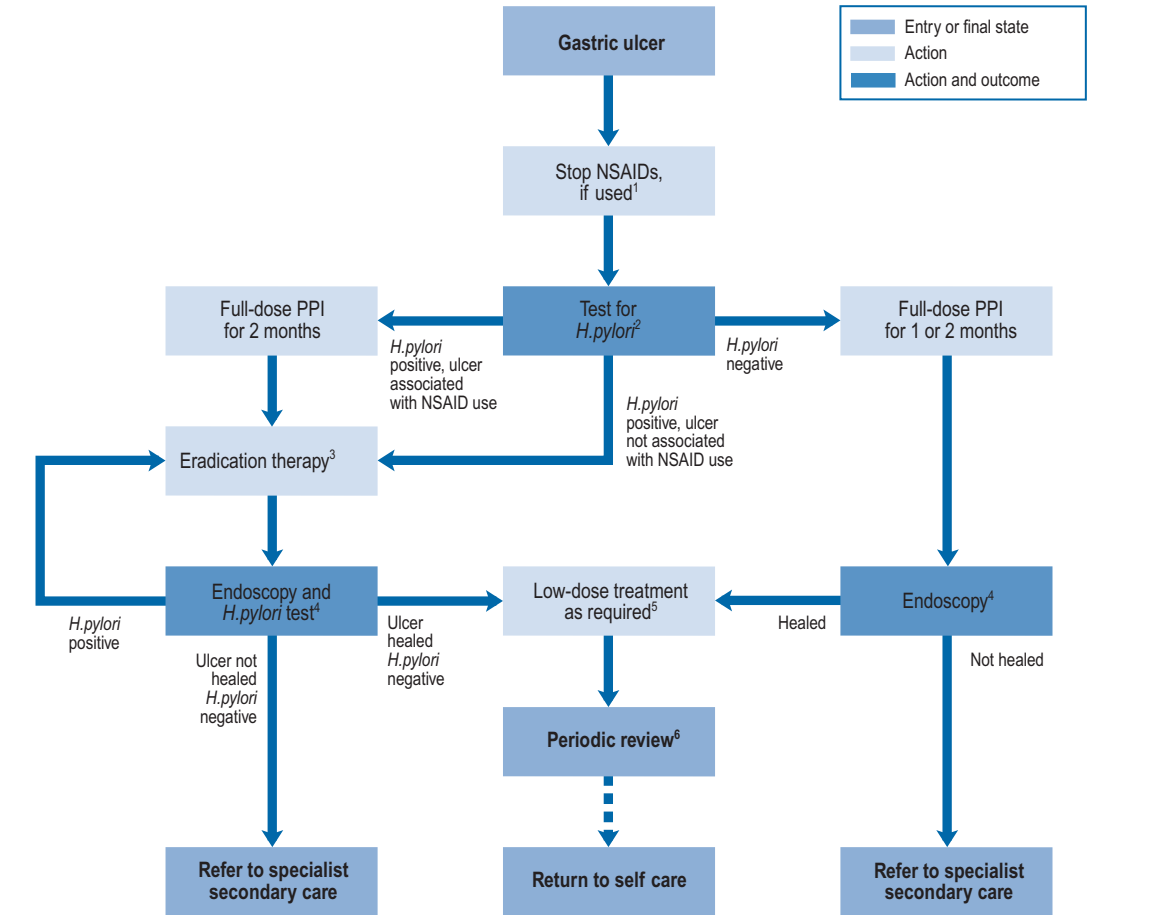
Stress ulcers

Severe physiological stress such as head injury, spinal cord injury, burns, multiple trauma or sepsis may induce superficial mucosal erosions or gastroduodenal ulcerations. These may lead to haemorrhage or perforation. Mechanical ventilation and the presence of coagulopathies place patients at particular risk of stress-related mucosal bleeding and may warrant prophylactic treatment (Quenot et al., 2009). Diminished blood flow to the gastric mucosa, decreased cell renewal, diminished prostaglandin production and, occasionally, acid hypersecretion are involved in causing stress ulceration. Intravenous acid-suppression therapy, histamine H_2-receptor antagonists and PPIs, and nasogastric tube

administration of sucralfate (4–6 g daily in divided doses) have been used to prevent stress ulceration in the intensive care unit until the patient tolerates enteral feeding. The most commonly used regimen is intravenous ranitidine 50 mg every 8 h reducing to 25 mg in severe renal impairment. Current evidence does not support routine use of prophylaxis and reports of complications associated with bacterial overgrowth in the gastro-intestinal tract in patients receiving acid suppressants should limit use only to those at high risk. Complications include association with hospital acquired

Clostridium difficile diarrhoea (Dial et al., 2004) and pneumonia (Herzig et al., 2009).

Uncomplicated peptic ulcer disease

Treatment of endoscopically proven uncomplicated peptic ulcer disease has changed dramatically in recent years (Fig. 12.5A and B). Curing of *H. pylori* infection and discontinuation of NSAIDs are key elements for the successful management of peptic ulcer disease.


[1] If NSAID continuation is necessary, after ulcer healing offer long-term gastric protection or consider substitution to a newer COX-2-selective NSAID.

[2] Use a carbon-13 urea breath test, stool antigen test or, when performance has been validated, laboratory-based serology.

[3] Use a proton pump inhibitor (PPI), amoxicillin, clarithromycin 500 mg (PAC_{500}) regimen or a PPI, metronidazole, clarithromycin 250 mg (PMC_{250}) regimen.
Follow guidance found in the *British National Formulary* for selecting second-line therapies.
After two attempts at eradication manage as *H. pylori* negative.

[4] Perform endoscopy 6 to 8 weeks after treatment. If re-testing for *H.pylori* use a carbon-13 urea breath test.

[5] Offer low-dose treatment, possibly used on an as-required basis, with a limited number of repeat prescriptions.

[6] Review care annually, to discuss symptoms, promote stepwise withdrawal of therapy when appropriate and provide lifestyle advice. In some patients with an inadequate response to therapy it may become appropriate to refer to a specialist.

H. pylori eradication

It is known that *H. pylori* infection is associated with over 90% of duodenal ulcers and 80% of gastric ulcers. Cure of this infection with antibiotic therapy and simultaneous treatment with conventional ulcer-healing drugs facilitates symptom relief and healing of the ulcer and reduces the ulcer relapse rate. Antibiotics alone, or acid-suppressing agents alone, do not eradicate *H. pylori*. Both therapies act synergistically as growth of the organism occurs at elevated pH and antibiotic efficacy is enhanced during growth. Additionally, increasing intragastric pH may enhance antibiotic absorption. Recent

studies limited to one country (Italy) suggest that sequential antibiotic treatment may be advantageous in overcoming emerging antibiotic resistance but the complexity of sequential regimens has the potential to affect adherence (Jafri et al., 2008)

High eradication rates are achieved by a short course of triple therapy consisting of a PPI, clarithromycin and amoxicillin or metronidazole in a twice-daily simultaneous regimen. European guidelines recommend 1 week of therapy, whereas the US guidelines recommend 10–14 days of therapy and achieve 7–9% better eradication rates (Malfertheiner et al., 2007).

Triple therapy consists of:

- OCA: omeprazole 20 mg, clarithromycin 500 mg and amoxicillin 1 g or
- OCM: omeprazole 20 mg, clarithromycin 250 mg and metronidazole 400 mg.

A lower dose of clarithromycin (250 mg twice daily) is effective and recommended when combined with metronidazole (NICE, 2004). However, some prescribers prefer to recommend 500 mg twice daily to achieve consistency and avoid prescribing errors.

Omeprazole may be replaced with any of the other PPI drugs. Local resistance rates determine the most appropriate first-line regimen, with OCA preferred in areas of high metronidazole resistance. In the UK, resistance to metronidazole has been reported in about 50% of *H. pylori* isolates, and resistance to clarithromycin in about 10%, although this is rising. Resistance to amoxicillin is rare. Sensitivity testing is of little value as *in vitro* resistance to either drug does not preclude eradication when those drugs are used as part of a triple therapy regimen. In patients with hypersensitivity to penicillin, the OCM regimen or substitution of amoxicillin from the OCA regimen with tetracycline 500 mg twice daily is used. If patients have recently received antibiotic treatment for any indication, a regimen avoiding that antibiotic is preferred.

Failure of a first-line regimen to achieve eradication will necessitate treatment with another triple therapy regimen or with a bismuth-based quadruple regimen. Recommended second-line triple therapy regimens include a PPI, amoxicillin or tetracycline and metronidazole. Most four-drug regimens contain bismuth subsalicylate, metronidazole, tetracycline or amoxicillin and a PPI and are generally not as well tolerated by patients as triple therapy regimens. Quadruple therapy may be used first-line where there is high prevalence of clarithromycin resistance. The indication should be reviewed in patients who are refractory to conventional as well as quadruple eradication therapies, to determine the importance of eradication before proceeding to endoscopic biopsies and determination of antibiotic sensitivity after culture. This strategy is rarely justified in dyspepsia.

Successful eradication relies upon patients adhering to their medication regimen. It is, therefore, important to educate patients about the principles of eradication therapy and also about coping with common adverse effects associated with their regimen. Diarrhoea is the most common adverse effect and should subside after treatment is complete. In rare cases, this can be severe and continue after treatment. If this happens, patients should be advised to return to their doctor as rare cases of antibiotic-associated colitis have been reported. If drugs are not taken as intended, then non-adherence may result in antibiotic resistance, should the antibiotic concentration at the site of infection decrease to a level where resistance may emerge.

If eradication is successful, uncomplicated active peptic ulcers heal without the need to continue ulcer-healing drugs beyond the duration of eradication therapy (Gisbert et al., 2004). Patients with persistent symptoms after eradication therapy should have their *H. pylori* status rechecked. This should be carried out no sooner than 4 weeks after discontinuation of therapy to avoid false-negative results due to suppression rather than eradication of the organism. If the patient is *H. pylori* positive, an alternative eradication regimen should be given. If eradication was successful but symptoms persist, gastro-oesophageal reflux or other causes of dyspepsia should be considered.

Patients who have had a previous gastro-intestinal bleed from a gastric ulcer should continue ulcer-healing therapy for a further 3 weeks in addition to eradication therapy. *H. pylori* eradication should be confirmed. The need for routine endoscopy to confirm ulcer healing is unclear but should be undertaken where malignancy is suspected.

Other accepted indications for *H. pylori* eradication include mucosal-associated lymphoid tissue (MALT) lymphoma of the stomach, severe gastritis, and in patients with a high risk of gastric cancer such as those with family history of the disease.

Treatment of NSAID-associated ulcers

NSAID-associated ulcers may be *H. pylori* positive. Although the presence of *H. pylori* may enhance the efficacy of acid suppression, eradication is generally recommended in infected patients with NSAID-associated ulcers as it is difficult to differentiate between *H. Pylori* or NSAID as the cause of the ulcer (Malfertheiner et al., 2009). If NSAIDs are discontinued, most uncomplicated ulcers heal using standard doses of a PPI, H_2-receptor antagonist, misoprostol or sucralfate. Healing is impaired if NSAID use is continued. Studies have demonstrated conflicting results, in terms of the comparative healing rates between PPIs and H_2-receptor antagonists, in this situation (Yeomans et al., 2006; Goldstein et al., 2007). PPIs demonstrate higher healing rates at 4 weeks but similar healing rates to H_2-receptor antagonists at 8 weeks. There is no evidence that high-dose PPI is better than treatment with the standard dose. Although effective, misoprostol use is limited by treatment-related adverse events.

Prophylaxis of NSAID ulceration

NSAIDs should be avoided in patients who are at risk of gastro-intestinal toxicity (see Box 12.1). However, some patients with chronic rheumatological conditions may require long-term NSAID treatment, in which case the lowest effective dose should be used. Dyspepsia is not a risk factor for ulcer complications but in those patients at high risk of ulcer complication, the NSAID should be stopped and investigation undertaken if dyspepsia develops.

Data suggests that *H. pylori* increases, has no effect on or decreases ulcer risk in NSAID users (Malfertheiner et al., 2007, 2009). The value of eradication of *H. pylori* in chronic NSAID users is, therefore, unclear but there may be some benefit in screening and eradicating *H. pylori* in patients about to start NSAIDs. The benefit is less apparent in those patients at low risk of peptic ulcer. In patients with a history of bleeding or non-bleeding ulcer, guidelines recommend screening for and eradicating *H. pylori* before starting low-dose aspirin (Bhatt et al., 2008). When using NSAIDs in patients with a previous bleeding ulcer, PPI maintenance therapy is more

effective secondary prophylaxis than *H. pylori* eradication alone, but a combination of both treatments is additive.

Treatment options for ulcer prophylaxis in patients at risk of peptic ulcer but who require NSAIDs, include co-therapy with acid-suppressing agents or a synthetic prostaglandin analogue, or substitution of a selective COX-2 inhibitor for a non-selective NSAID (Hooper et al., 2004). Comparison of study outcomes requires interpretation of whether ulcers are detected symptomatically or by endoscopy. The prostaglandin analogue, misoprostol at a dose of 800 µcg daily is effective at reducing NSAID-associated ulcer complications and symptomatic ulcers. Adverse effects, primarily diarrhoea, abdominal pain and nausea, limit its use as lower doses are less effective. PPIs are effective at reducing endoscopically diagnosed ulcers and dyspepsia symptoms but the effect on symptomatic ulcers is unclear. Studies have not demonstrated any advantage in using higher than standard doses of PPIs to reduce risk of ulcers. Standard doses of H_2-receptor antagonists are effective at reducing the risk of endoscopic duodenal ulcers. However, reduction in the risk of gastric ulcers requires double this dose. Gastroprotective agents licensed for prophylaxis of NSAID ulceration are listed in Table 12.1.

In low-dose aspirin users, standard-dose PPIs are more effective than high dose H_2-receptor antagonists in preventing recurrent ulcer bleeding following ulcer healing and eradication of *H. pylori* (Ng et al., 2010). However, in those patients who do not have a history of peptic ulcer bleeding, high-dose H_2-receptor antagonists might be an alternative to PPIs (Taha et al., 2009).

Given the contraindications to selective COX-2 inhibitors, their use is limited and further studies are required to clarify their place in minimising risk of ulcers in both primary and secondary prophylaxis. In patients with no history of peptic

ulcer bleeding but with risk factors, a combination of COX-2 inhibitor with a PPI was similar in efficacy to a combination of non-selective NSAID with a PPI (Scheiman et al., 2006). In patients with a history of ulcer bleeding, a combination of selective COX-2 inhibitor with a PPI reduced recurrent ulcer bleeding compared to COX-2 inhibitor alone (Chan et al., 2007). This was not compared to a combination of a non-selective NSAID and a PPI. Although an earlier study suggested COX-2 inhibitors alone offered similar protection to that offered by a combination of non-selective NSAID with PPI (Lai et al., 2005), results suggest that in high-risk patients with a history of gastro-intestinal bleeding in whom an NSAID is indicated where alternative analgesic therapies have failed and in whom there are no contraindications to selective COX-2 inhibitors, a combination of PPI with a selective COX-2 inhibitor may be the safest strategy.

H. pylori-negative, NSAID-negative ulcers

Ulceration in the absence of *H. pylori* infection or NSAID or aspirin use is rare and validation of negative medication history and *H. pylori* status should be confirmed using biopsy samples and a careful medication history including over the counter preparations. Many analgesics contain aspirin or NSAIDs and some patients purchase low-dose aspirin.

Gastro-oesophageal reflux disease

GORD is the term used to describe any symptomatic clinical condition or histopathological alteration resulting from episodes of reflux of acid, pepsin and, occasionally, bile into the oesophagus from the stomach (Moayyedi and Talley, 2006). Heartburn is the characteristic symptom, and the patient may also complain of acid regurgitation and dysphagia. Complications include oesophageal stricture, oesophageal ulceration and formation of specialised columnar-lined oesophagus at the gastro-oesophageal junction known as Barrett's oesophagus (Shaheen and Richter, 2009). The mechanism of acid reflux is multifactorial and involves transient lower oesophageal sphincter relaxations, reduced tone of the lower oesophageal sphincter, hiatus hernia and abnormal oesophageal acid clearance. The severity of inflammation of the oesophageal mucosa is described as categories of oesophagitis (Los Angeles A–D). However, approximately two-thirds of patients with GORD have normal mucosa on endoscopy. Hypersensitivity to normal acid exposure may be the cause of symptoms in this group of patients. Progression from non-erosive reflux disease to erosive oesophagitis and Barrett's oesophagus is rare.

Management of GORD focuses on symptom control rather than endoscopic findings, and therefore careful symptom evaluation is required (Box 12.5). Patients with alarm features or those who fail to respond to medical treatment should be referred for endoscopic investigation. *H. pylori* eradication is not recommended in the management of GORD (Malfertheiner et al., 2007).

Strategies for initial treatment include lifestyle measures such as weight loss and smoking cessation in combination

Table 12.1 Drugs for prophylaxis for NSAID-induced ulceration

Drug	Licensed indication	Prophylaxis dose
Omeprazole	Prophylaxis of further DU or GU	20 mg every day
Esomeprazole	Prophylaxis of DU or GU	20 mg every day
Lansoprazole	Prophylaxis of DU or GU	15–30 mg every day
Pantoprazole	Prophylaxis of DU or GU	20 mg daily
Misoprostol	Prophylaxis of DU or GU	200 µcg 2–4 times a day
Ranitidine	Prophylaxis of DU	150 mg twice a day
Ranitidine	Prophylaxis of DU (unlicensed)	300 mg twice day
DU, duodenal ulcer; GU, gastric ulcer.

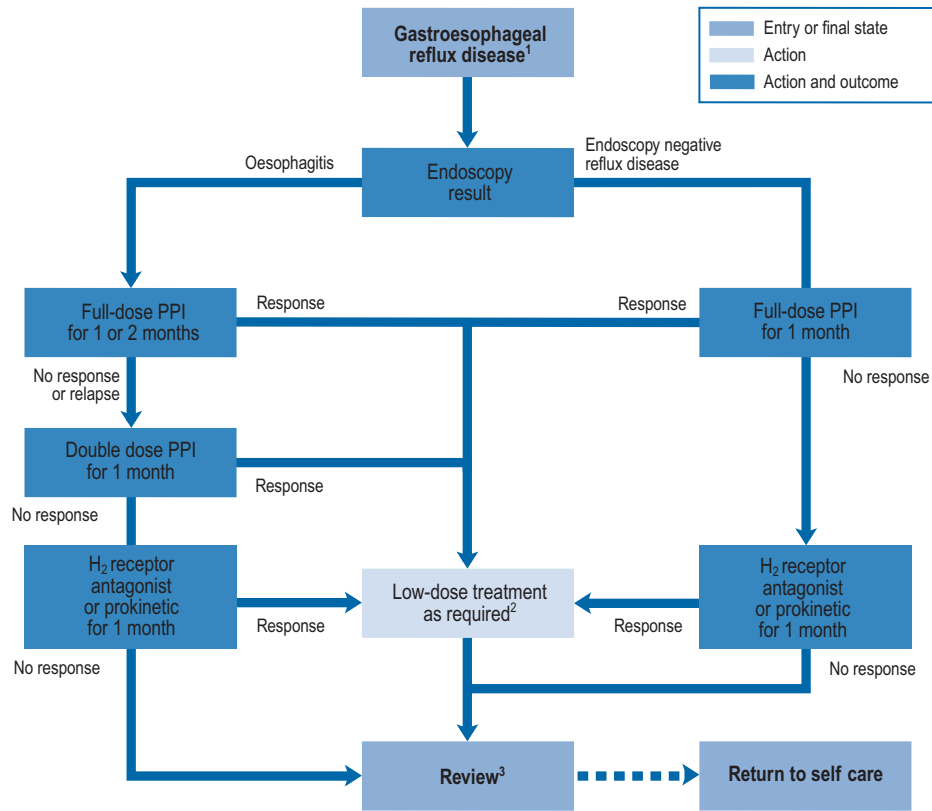
with antacids. These measures may be effective in patients with no significant impairment of quality of life. When quality of life is impaired, acid-suppression therapy is the basis of effective treatment. A course of standard-dose PPI therapy is most effective for symptom relief, healing of oesophagitis and maintenance of remission in patients with GORD (Fig. 12.6).

Compared with erosive oesophagitis, there is a diminished response to acid suppression in non-erosive reflux disease but PPIs remain the most effective agents. Most patients respond after 4 weeks' treatment and after initial control of symptoms, therapy can be withdrawn. If symptoms return, intermittent courses can be given or, alternatively, on-demand single doses can be taken immediately as symptoms occur. Patients who relapse frequently may require continuous maintenance therapy using the lowest dose of acid suppression which provides effective symptom relief.

Escalating doses can be used in the small number of patients who do not respond to initial treatment. These patients should be investigated to confirm diagnosis. Those with a normal upper endoscopy may require pH monitoring or motility tests. Twice-daily dosing may be required in patients with persistent symptoms. A selected group of patients may benefit from anti-reflux surgery rather than the escalation of acid-suppressing


1 GORD refers to endoscopically determined oesophagitis or endoscopy-negative reflux disease. Patients with uninvestigated 'reflux-like' symptoms should be managed as patients with uninvestigated dyspepsia.
   There is currently no evidence that *H. pylori* should be investigated in patients with GORD.
2 Offer low-dose treatment, possibly used on an as-required basis, with a limited number of repeat prescriptions.
3 Review long-term patient care at least annually to discuss medication and symptoms.
   In some patients with an inadequate response to therapy or new emergent symptoms it may become appropriate to refer to a specialist for a second opinion.
   A minority of patients have persistent symptoms despite proton pump inhibitor (PPI) therapy and this group remains a challenge to treat.
   Therapeutic options include doubling the dose of PPI therapy, adding an H_2 receptor antagonist at bedtime and extending the length of treatment.

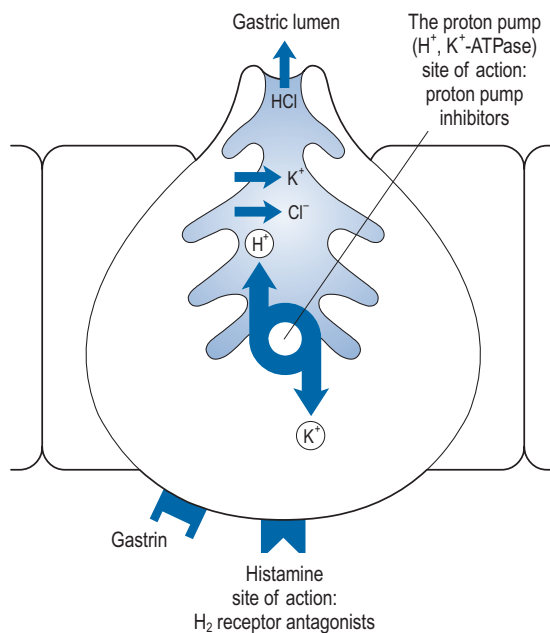
Fig. 12.6 Management algorithm for gastro-oesophageal reflux disease.

treatment. Patients with endoscopically severe oesophagitis (Los Angeles class C or D) should be kept on standard-dose PPIs long-term to maintain symptom relief and prevent the development of complications such as Barrett's oesophagus or oesophageal adenocarcinoma.

Ulcer-healing drugs

Proton pump inhibitors

The PPIs are all benzimidazole derivatives that control gastric acid secretion by inhibition of gastric H^+, K^+-ATPase, the enzyme responsible for the final step in gastric acid secretion from the parietal cell (Fig. 12.7).

The PPIs are inactive prodrugs that are carried in the bloodstream to the parietal cells in the gastric mucosa. The prodrugs readily cross the parietal cell membrane into the cytosol. These drugs are weak bases and therefore have a high affinity for acidic environments. They diffuse across the secretory membrane of the parietal cell into the extracellular secretory canaliculus, the site of the active proton pump (see Fig. 12.7). Under these acidic conditions the prodrugs are converted to their active form, which irreversibly binds the proton pump, inhibiting acid secretion. Since the 'active principle' forms at a low pH it concentrates selectively in the acidic environment of the proton pump and results in extremely effective inhibition of acid secretion. The different PPIs (omeprazole, esomeprazole, lansoprazole, pantoprazole and rabeprazole) bind to different sites on the proton pump, which may explain their differences in potency on a milligram per milligram basis.


PPIs require an enteric coating to protect them from degradation in the acidic environment of the stomach. This delays absorption and a maximum plasma concentration is reached after 2–3 h. Different formulations have been developed for patients with swallowing difficulties but these still rely upon some form of enteric coating (Table 12.2). New immediate-release formulations are under development which may overcome problems with enteric-coated granules blocking enteral feeding tubes.

Since these drugs irreversibly bind to the proton pump they have a sustained duration of acid inhibition which does not correlate with the plasma elimination half-life of 1–2 h. The apparent half-life is approximately 48 h. This prolonged duration of action allows once-daily dosing of PPIs, although twice-daily dosing is recommended in some cases of erosive oesophagitis or Barrett's oesophagus when a sustained gastric pH of greater than 4.0 is required. All PPIs are most effective if taken about 30 min before a meal as they inhibit only actively secreting proton pumps. Meals are the main stimulus to proton pump activity. The optimal dosing time is 30–60 min before the first meal of the day.

Intravenous PPIs are most frequently used to prevent recurrent ulcer bleeding in high-risk patients. Intravenous preparations are therapeutically equivalent to oral preparations. In the UK, omeprazole, pantoprazole and esomeprazole can be given intravenously.

PPIs are metabolised in the liver to various sulphate conjugates that are extensively eliminated by the kidneys (80%). With the exception of severe hepatic dysfunction, no dose adjustments are necessary in liver disease or in renal disease. Apart from minor differences in bioavailability in the first few days of oral dosing, pharmacokinetics are similar among all PPIs. The antisecretory effect is also similar among all agents when administered chronically in equivalent standard doses.

Adverse drug reactions

Experience suggests that PPIs are a remarkably safe group of drugs. The most commonly reported side effects are diarrhoea, headaches, abdominal pain, nausea, fatigue and dizziness which resolve on drug discontinuation (Table 12.3). Possible mechanisms for diarrhoea include bacterial overgrowth, changes in intestinal pH and bile salt abnormalities. Diarrhoea is most commonly associated with lansoprazole, particularly in the elderly. Some cases of persistent chronic watery diarrhoea associated with lansoprazole have been diagnosed as microscopic colitis. This may be explained by the unique ability of lansoprazole to inhibit colonic proton pumps which may have an effect on colonic secretion and pH. Apart from the association between lansoprazole and diarrhoea, the incidence of adverse reactions is similar among the drugs in this group.

Loss of gastric acidity has been associated with colonisation of the normally sterile upper gastro-intestinal tract. Associations with increased risk of respiratory tract infections and *C. difficile*-associated disease have prompted more judicious use of PPIs. Long-term use may also decrease bone density and increase risk of hip fractures.

Drug interactions

The cytochrome P450 enzyme system is classified into a number of subgroups, several of which are involved in drug metabolism. All PPIs are metabolised to varying degrees by the same cytochrome P450 isoenzymes, CYP2C19 and CYP3A. All except rabeprazole are metabolised primarily via the CYP2C19 isoenzyme. This suggests rabeprazole may be less influenced by other drugs metabolised through this system or by genetic changes in hepatic metabolism. The affinity of individual PPIs for these enzymes influences the incidence of clinically relevant drug interactions.

- Pantoprazole has lower affinity for the enzyme system than the other PPIs and is also metabolised by a sulphotransferase which is non-saturable and not part of the cytochrome P450 system. Rabeprazole is also metabolised through a non-enzymatic pathway.
- Omeprazole inhibits CYP2C9 and 2C19, the isoenzymes involved in the metabolism of, for example, phenytoin (2C9), *S*-warfarin (2C9), diazepam (2C19) and *R*-warfarin (2C19). Omeprazole 40 mg daily can decrease the clearance of phenytoin, but phenytoin levels were unchanged after a dose of 20 mg of omeprazole daily. Therefore, phenytoin plasma concentrations should be monitored when omeprazole is taken concomitantly. Omeprazole may increase the coagulation time in patients receiving warfarin therapy, especially if doses higher than 20 mg daily are given. Changes in the plasma concentration of the less potent (*R*) enantiomer of warfarin have been observed; therefore, monitoring of the international normalised ratio (INR) is recommended during concomitant therapy. The metabolism of benzodiazepines, particularly diazepam, may be decreased by omeprazole. Similar interactions are likely with esomeprazole.
- Lansoprazole is a weak inducer of CYP1A2 and concurrent administration results in increased theophylline clearance.

Other isolated interactions have been reported:

- Omeprazole can increase the concentration of ciclosporin.
- Clarithromycin increases esomeprazole concentrations; however, omeprazole has also increased clarithromycin concentration.
- Lansoprazole has reduced the efficacy of the oral contraceptive pill.
- Clarithromycin has increased plasma lansoprazole concentration.
- Lansoprazole has increased plasma concentration of tacrolimus.
- Omeprazole has increased the concentration of escitalopram.
- Omeprazole has decreased renal elimination of methotrexate.

Approximately 3% of the Caucasian and 20% of the Asian population are poor metabolisers of PPIs due to genetic polymorphism associated with CYP2C19. High plasma concentrations are achieved and the relative capacity for metabolism by other isoenzymes may alter and result in drug interactions. In practice, the genotype of a patient is unknown. The relative contribution of CYP2C19 to PPI metabolism is greatest with omeprazole and least with rabeprazole. The observation of decreased clopidogrel activity and increased cardiovascular events has been linked to competitive inhibition of CYP2C19 possibly caused by concomitant treatment with PPIs.

Table 12.3 Common adverse reactions to ulcer-healing drugs

Proton pump inhibitors	H$_2$-receptor antagonists	Sucralfate
Diarrhoea	Diarrhoea	Constipation
Headache	Headache	
Abdominal pain	Abdominal pain	
Nausea	Confusion	
Fatigue		
Dizziness		

The use of symptom-driven, on-demand PPI therapy may prove problematic if used concomitantly with warfarin or phenytoin. Careful monitoring should be undertaken. All acid-suppressing drugs potentially decrease the absorption of some drugs by increasing gastric pH. Reduction in absorption of ketoconazole and increased absorption of digoxin have been reported with PPIs. The absorption of drugs formulated as pH-dependent, controlled-release products may also be altered. Very few clinically important drug interactions have been reported despite the widespread use of these agents.

Clinical use

PPIs relieve symptoms and heal peptic ulcers faster than H_2-receptor antagonists. They also heal ulcers that are refractory to H_2-receptor antagonists. All PPIs provide similar *H. pylori* eradication rates and ulcer healing when used at their recommended doses. Standard doses of PPIs are used concomitantly with non-selective NSAIDs and with low-dose aspirin in patients at risk of peptic ulcers or ulcer bleeding. High dose intravenous PPIs are used to prevent recurrent bleeding in high-risk patients (active bleeding or non-bleeding visible vessel) during the initial 72h after a bleed. In GORD, PPIs heal oesophagitis and control symptoms more rapidly than H_2-receptor antagonists. Differences between PPIs in terms of speed of symptom relief are observed only in the first few days of treatment. Patients with severe oesophagitis should continue long-term PPI therapy, whereas those with milder GORD should be stepped down in terms of acid suppression and therapy withdrawn if symptoms are controlled. On-demand therapy is used to maintain symptom control. Patients with functional dyspepsia should not routinely receive long-term treatment with PPIs. PPIs can be purchased over the counter for short-term relief of heartburn.

H_2-receptor antagonists

The H_2-antagonists are all structural analogues of histamine. They competitively block the histamine receptors in gastric parietal cells, thereby preventing acid secretion. Pepsinogen requires acid for conversion to pepsin and so when acid output is reduced, pepsin generation is, in turn, also reduced.

All the available drugs (cimetidine, ranitidine, famotidine, nizatidine) have similar properties. Maximum plasma concentration is reached within 1–3h after administration. First-pass hepatic metabolism varies, ranitidine being most extensively metabolised which explains the difference between the intravenous and oral dose. All H_2-antagonists are eliminated to a variable and significant extent via the kidneys, and all require dosage reduction in moderate-to-severe renal impairment. They are equally effective at suppressing daytime and nocturnal acid secretion while they do not cause total achlorhydria. The evening dose of a H_2-antagonist is particularly important because during the daytime, gastric acid is buffered for long periods by food; however, during the night this does not occur and the intragastric pH may fall below 2.0 for several hours. For healing oesophagitis, intragastric pH must remain above 4.0 for 18h or more per day. H_2-receptor antagonists

are, therefore, not effective in healing oesophagitis. Adding a bedtime dose of H_2-receptor antagonist to PPI therapy may enhance nocturnal gastric pH control in patients in whom nocturnal gastric acid breakthrough is problematic.

The role of H_2-receptor antagonists in the management of peptic ulcer disease has diminished. H_2-receptor antagonists are less effective than PPIs in eradication regimens, in treating ulcers when NSAIDs are continued, and in prophylaxis of NSAID-induced ulcers. H_2-receptor antagonists do effectively heal ulcers in patients who discontinue their NSAID and they also have a role in continuing acid suppression for symptomatic treatment following eradication therapy. Their main role is in the empirical management of dyspepsia symptoms. If patients with mild symptoms gain adequate relief, it is not necessary to use a PPI. H_2-receptor antagonists are preferred over PPIs in the second-line treatment of heartburn in pregnancy, although there is growing evidence to support safe use of PPIs in those not controlled by H_2-receptor antagonists. H_2-receptor antagonists can be purchased in doses lower than those prescribed for the management of heartburn and indigestion.

Adverse drug reactions

H_2-receptor antagonists are a remarkably safe group of drugs with a lower risk of side effects than PPIs. The risk of any adverse reaction is below 3% and serious adverse reactions account for less than 1%. Diarrhoea and headache are the most common and occasionally mental confusion and rashes have been reported (see Table 12.3). Hepatotoxicity is a rare adverse effect. Cimetidine, due to its antiandrogenic effects, has been associated with gynaecomastia and impotence when used in high doses.

Drug interactions

Although many drug interactions have been suggested with cimetidine, many have only been demonstrated *in vitro* and are of doubtful clinical significance. Cimetidine inhibits the activity of cytochrome P450 and consequently retards oxidative metabolism of some drugs. This interaction is potentially important for drugs with a narrow therapeutic index. The clearance of theophylline is reduced to about 40% of normal, and raised plasma levels occur as a result. Phenytoin metabolism is reduced, and toxicity is theoretically possible. The metabolism of a number of benzodiazepines, including diazepam, flurazepam and triazolam, is impaired and levels are raised.

The interaction with warfarin has frequently been cited as justification to change to an alternative H_2-antagonist which binds less intensively to the CYP 450 system; however, careful investigation has shown that this interaction is complex. The metabolism of (*R*)-warfarin is affected to a greater degree than that of (*S*)-warfarin. As the (*S*) enantiomer is the more potent, the pharmacodynamic effects of the interaction may be modest, although the plasma warfarin concentrations may be increased. Current opinion suggests that warfarin may safely be added with appropriate monitoring when patients are already taking cimetidine in regular daily doses. Other H_2-antagonists should be used in patients who are difficult to stabilise on warfarin or for whom frequent monitoring is not feasible.

All acid-suppressing drugs potentially decrease the absorption of drugs such as ketoconazole and other pH-dependent controlled-release products by increasing gastric pH.

Bismuth chelate

Bismuth has been included in antacid mixtures for many decades but fell from favour because of its neurotoxicity. Bismuth chelate is a relatively safe form of bismuth that has ulcer-healing properties comparable to those of H_2-antagonists. Its mode of action is not clearly understood but it is thought to have cytoprotective properties. Bismuth is toxic to *H. pylori* and was one of the first agents to be used to eradicate the organism and reduce ulcer recurrence. Tripotassium dicitratobismuthate in combination with tetracycline, metronidazole and a PPI is used in quadruple therapy regimens in patients resistant to triple therapy.

Adverse drug reactions

Small amounts of bismuth are absorbed from bismuth chelate, and urinary bismuth excretion may be raised for several weeks after a course of treatment. The risks of bismuth intoxication are small if these products are used at the recommended dose and for short courses of treatment. Bismuth may accumulate in patients with impaired renal function. The most commonly reported events are nausea, vomiting, blackened tongue and dark faeces.

Sucralfate

Sucralfate is the aluminium salt of sucrose octasulphate. Although it is a weak antacid, this is not its principal mode of action in peptic ulcer disease. It has mucosal protective effects including stimulation of bicarbonate and mucus secretion and stimulation of mucosal prostanoids. At pH less than 4.0 it forms a sticky viscid gel that adheres to the ulcer surface and may afford some physical protection. It is capable of adsorbing bile salts. These activities appear to reside in the entire molecular complex and are not due to the aluminium ions alone. Sucralfate has no acid-suppressing activity. At a dose of 2 g twice daily, sucralfate is effective in the treatment of NSAID-induced duodenal ulcers, if the NSAID is stopped. However, it is not effective in the treatment and prevention of NSAID-related gastric ulcers. It has also been used in the prophylaxis of stress ulceration. The liquid formulation is often used as the tablets are large and difficult to swallow.

Adverse drug reactions

Constipation appears to be the most common problem with sucralfate, and this is thought to be related to the aluminium content (see Table 12.3). About 3–5% of a dose is absorbed, and therefore there is a risk of aluminium toxicity with long-term treatment. This risk is correspondingly greater in patients with renal impairment. Caution is required to avoid oesophageal bezoar formation around a nasogastric tube in patients managed in the intensive care unit.

Drug interactions

Sucralfate may bind to other agents in the gastro-intestinal tract and reduce the absorption of other drugs. Therefore, it should be taken at least 2 h following other medicines.

Antacids

Antacids have a place in symptomatic relief of dyspepsia, in particular symptoms associated with GORD. They have a role in the management of symptoms which sometimes remain for a short time after *H. pylori* eradication of uncomplicated duodenal ulcer.

The choice of antacid lies between aluminium-based and magnesium-based products, although many proprietary products combine both. Calcium-based products are unsuitable as calcium stimulates acid secretion. Antacids containing sodium bicarbonate are unsuitable for regular use because they deliver a high sodium load and generate large quantities of carbon dioxide. It should be noted that magnesium trisilicate mixtures contain a large amount of sodium bicarbonate. Some products contain other agents such as dimeticone or alginates. Products containing sodium alginate with a mixture of antacids are effective in relief of symptoms in GORD but are not particularly effectual antacids.

Aluminium-based antacids cause constipation, and magnesium-based products cause diarrhoea. When combination products are used, diarrhoea tends to predominate as a side effect. Although these are termed 'non-absorbable', a proportion of aluminium and magnesium is absorbed and the potential for toxicity exists, particularly with coexistent renal failure.

Antacids provide immediate symptom relief and a more rapid response is achieved with liquid preparations. They have a limited duration of action and need to be taken several times a day, usually after meals and at bedtime. Administration should be separate from drugs with potential for chelation, such as tetracycline and ciprofloxacin, and also pH-dependent controlled-release products.

Patient care

Patient education

Patients who present with symptoms of dyspepsia should be assessed in terms of risk of serious disease. Referral for investigation is indicated if they exhibit alarm features. Patients with predominant reflux-like symptoms are likely to respond to antacid/alginate medicines. In those with reflux-like symptoms, lifestyle should be assessed as weight loss is known to improve reflux symptoms in obese patients and raising the head of the bed may improve nocturnal symptoms of heartburn. A medication history, including purchased medicines, should be undertaken to identify likely or possible drug-induced causes of symptoms. Symptoms of dyspepsia are associated with many medicines including aspirin, NSAIDs and corticosteroids. Other agents are associated with gastro-oesophageal reflux and include those with antimuscarinic

effects, for example, tricyclic antidepressants, or those which relax muscle tone, for example, calcium channel blockers and nitrates, or those which cause oesophageal mucosal damage, for example, biphosphonates. Clinical medication review allows assessment of the benefits and risks associated with medicines and referral to the prescriber may be necessary. Patients who do not respond to 2 weeks of symptomatic relief medication should be referred to the primary care doctor.

Patients should be advised to seek the pharmacist's advice when purchasing over-the-counter analgesic preparations. Patients with risk factors for peptic ulcer disease should be advised to avoid over-the-counter aspirin and NSAIDs and to use paracetamol-based products. Taking aspirin or NSAIDs with or after food may decrease the risk of dyspepsia symptoms but does not decrease the risk of ulcer complications. Before prescribing NSAID or aspirin therapy, patients should be assessed in terms of both cardiovascular and gastro-intestinal risk. Benefits must outweigh risks in NSAID users and if NSAIDs are necessary in those at risk of ulcer complications, prophylaxis should be prescribed. Consideration should be given to screening for *H. pylori*. Patients should be aware of the optimum time of administration of PPIs, the dose and duration of therapy. Misoprostol should not be used in pregnant women, and women of childbearing age should be warned appropriately.

Patients with diagnosed peptic ulcer disease need to be educated about the current principles of therapeutic management determined by the diagnosis and, if appropriate, the balanced risks associated with continued aspirin or NSAID therapy. Uncomplicated disease requires a short course of treatment which may or may not include eradication of *H. pylori*. Patients need to know the importance of adherence to eradication therapy for successful treatment and to avoid development of resistance to antibiotics. Previous adverse reactions should be established; for example, patients who are sensitive to penicillin need an eradication regimen which does not include amoxicillin. Patients should be warned of the specific side effects to be expected from the regimen chosen for them and advised what to do should they experience

any of these effects. Patients taking metronidazole must avoid alcohol as they might have a disulfiram-like reaction with sickness and headache. Patients also need to know how their therapy will be followed up. In most patients, a single treatment course is required and there is no need for maintenance therapy unless they require prophylaxis treatment to reduce risks associated with continued NSAID or low-dose aspirin therapy.

Patient monitoring

Treatment success in uncomplicated peptic ulcer disease is measured by review of the patient in terms of symptom control. Patients with complicated ulcers or those who continue to have symptoms will receive a urea breath test and/or an endoscopy to confirm successful eradication of *H. pylori*. Very few patients require follow-up endoscopy. Patients should be aware of what their review will entail and when their review will take place. If patients comply with their medication the review process may be kept to a minimum.

Following eradication therapy, some patients continue to experience symptoms of abdominal pain. Patients should be reassured that these symptoms will resolve spontaneously, but if necessary an antacid preparation can be recommended to relieve symptoms until review. Patients receiving treatment for NSAID-induced ulceration should continue their ulcer-healing therapy for 4 weeks. If the NSAID or aspirin has been discontinued there is no need to continue ulcer treatment therapy once the ulcer has healed unless the NSAID or aspirin must also be continued.

Patients with iron-deficiency anaemia following a bleeding ulcer may be prescribed oral iron therapy. If patients suffer side effects such as constipation or diarrhoea, the dose of iron should be reduced. Treatment with iron should be for at least 3 months. Iron preparations are best absorbed from an empty stomach but if gastric discomfort is felt, the preparation should be taken with food.

Some common therapeutic problems in the treatment of peptic ulcer disease are summarised in Table 12.4.

Table 12.4 Common therapeutic problems in peptic ulcer disease

	Comments
Ulcer-like symptoms of dyspepsia are not specific for peptic ulcer disease and are often present in functional (non-ulcer) dyspepsia	Predominant heartburn differentiates GORD from dyspepsia. Patients with GORD are likely to respond to antisecretory therapy
In uncomplicated patients with ulcer-like symptoms of dyspepsia, there is controversy about whether a 1-month course of acid suppression or test and for *H. pylori* should be carried out initially	Identification and eradication of *H. pylori* will benefit those with ulcers and a small proportion of *H. pylori*-positive patients with functional dyspepsia. A course of acid suppression will have similar outcomes but ulcers may relapse. Eradication of *H. pylori* plays no role in management of GORD
A test and treat policy is cost-effective compared with initial endoscopy in patients with uncomplicated dyspepsia	There is no evidence to support widespread eradication of *H. pylori* in primary care
Patients on proton pump inhibitors (PPIs) can have false-negative results for *H. pylori*	PPIs should be withdrawn at least 2 weeks before urea breath test or biopsy urease testing (endoscopy)

Continued

Table 12.4 Common therapeutic problems in peptic ulcer disease—cont'd

	Comments
Following a 7-day eradication therapy regimen, antisecretory therapy can normally be stopped	Longer courses of acid-suppressive therapy should be reserved for patients with active ulcers complicated by bleeding and/or NSAID use
First-line eradication therapy comprises twice-daily PPI, amoxicillin 1 g and clarithromycin 500 mg	Metronidazole can be substituted in those patients allergic to amoxicillin and for second-line therapy. When combined with metronidazole, the dose of clarithromycin can be reduced to 250 mg
Use of high dose intravenous PPIs	Intravenous PPI use is not recommended before endoscopic diagnosis in gastro-intestinal bleeding. High dose intravenous PPI is recommended for 72 h after endoscopic haemostatic therapy in patients at high risk of re-bleeding from peptic ulcer
In patients with NSAID-associated active peptic ulcer disease who test positive for _H. pylori_, the cause of the ulcer may not be confirmed	The ulcer should be healed with a PPI for 4 weeks and _H. pylori_ eradicated. Eradication of _H. pylori_ reduces the risk of recurrent bleeding
The treatment of NSAID-associated ulcers may differ depending upon whether or not the NSAID must be continued	If NSAIDs are withdrawn, healing rates at 4 weeks are best with PPIs and are similar between H_2-receptor antagonists and PPIs after 8 weeks. PPIs are continued only if NSAIDs are continued
Patients in whom low-dose aspirin is indicated but have risk factors for peptic ulcer disease	Use of aspirin should be considered carefully, especially for primary prophylaxis of cardiovascular disease. Enteric coating does not reduce this risk. Clopidogrel is not a safer alternative than aspirin in combination with a PPI
There is an increased risk of bleeding with dual antiplatelet therapy	PPIs are thought to decrease conversion of clopidogrel to active metabolite, thus decreasing efficacy of clopidogrel. If dual antiplatelet therapy is indicated after PCI, use H_2 receptor antagonist unless high risk (previous gastro-intestinal bleed), when PPI indicated
NSAID use in elderly patients	Patients over 65 years of age are at increased risk of peptic ulcer disease associated with NSAIDs and often present with 'silent ulcers'. NSAIDs (prescription and non-prescription) should be avoided in the elderly
Patients who are candidates for COX-2 inhibitors	COX-2 inhibitors are associated with less gastro-intestinal toxicity than non-selective NSAIDs. COX-2 inhibitors are contraindicated in cardiovascular disease. The reduction in gastro-intestinal risk associated with COX-2 inhibitors is similar to reduction in risk associated with non-selective NSAIDs in combination with gastroprotective agents
Criteria and regimens to administer for stress ulcer prophylaxis are unclear	Intravenous H_2-receptor antagonist therapy is given to patients at risk until enteral feeding is tolerated. Definite risk factors include mechanical ventilation, presence of coagulopathy and spinal cord injury. Controversial risks include head injury, sepsis, burns, multiple trauma, steroid therapy
Patients who require long-term PPI therapy	Those in whom long-term NSAIDs or low-dose aspirin are indicated and who have risk factors for associated upper gastro-intestinal complications. Patients with endoscopically diagnosed GORD who either have severe erosive oesophagitis or severe symptoms which can only be controlled with maintenance therapy

PCI, percutaneous coronary intervention.

Case studies

Case 12.1

A 62-year-old man (Mr BD) presented to A&E following haematemesis and melaena. He suffered no pain. His past medical history included non-ST-elevated myocardial infarction (NSTEMI) for which he had undergone percutaneous coronary intervention (PCI)

and bare metal stent insertion 4 months previously. Mr BD stopped smoking 2 years previously, drinks alcohol in moderation and is not obese. He was taking the following prescribed medicines:

Aspirin (dispersible) 75 mg
Clopidogrel 75 mg
Ramipril 2.5 mg twice daily
Simvastatin 40 mg daily
Atenolol 100 mg
GTN spray prn

On investigation Mr BD's haemoglobin concentration was 8 g/dL (11.5–16.5 g/dL) with an MCV of 90 fL (83–101 fL). His blood pressure was 98/60 mmHg with a heart rate of 120 beats per minute and respiratory rate of 20 beats per minute. There was no jaundice or stigmata of liver disease. Plasma urea was 18 mmol/L (3.1–7.9 mmol/L) with a creatinine of 87 µmol/L (75–155 µmol/L). INR was 1.0. Serum sodium was 142 mmol/L (135–145 mmol/L) and serum potassium was 4.3 mmol/L (3.4–5.0 mmol/L). Endoscopy revealed an actively bleeding gastric ulcer.

Questions

1. What immediate treatment should Mr BD receive?
2. What treatment should he receive at the time of endoscopy?
3. Why should biopsies be taken at the time of endoscopy?
4. What pharmacological treatment should be given to reduce the risk of re-bleeding following endoscopic haemostatic therapy?
5. What was the likely cause of the bleeding ulcer?
6. When should antiplatelet therapy be restarted and with which agent(s)?
7. Is gastroprotection indicated following ulcer healing?
8. Summarise Mr BD's educational needs in terms of his medicines.

Answers

1. Mr BD's age, comorbidity and clinical signs of shock place him at risk of death and in need of emergency hospital admission for aggressive resuscitation with intravenous fluids and red cell transfusion. Either colloid or crystalloid solutions can be used for volume restoration prior to administering blood products. Sodium chloride 0.9% is appropriate fluid replacement. Following resuscitation, early endoscopic examination should be undertaken, within 24 h of presentation. There is no evidence to support the use of intravenous PPIs prior to diagnosis by endoscopy. The most frequent cause of upper gastro-intestinal bleeding is peptic ulcer disease. If Mr BD is nauseated, an antiemetic should be prescribed.
2. The clinical markers suggest urgent endoscopy is indicated. Patients who are shocked and have active peptic ulcer bleeding are at high risk of continuing to bleed and should receive haemostatic endoscopic therapy. Endoscopic treatment is indicated only for those with high-risk lesions (active bleeding, non-bleeding visible vessels or adherent blood clot). Endoscopic injection of large volume (at least 13 mL) 1:10,000 adrenaline achieves haemostasis through vasoconstriction and haemostasis is sustained if this is combined with thermal coagulation or mechanical endoscopic clipping. The patient should receive combination endoscopic therapy.
3. The presence of *H. pylori* should be sought at the time of endoscopy. Biopsies should be taken from the antrum and the body of the stomach. Samples are sent for testing for the presence of malignant cells and samples are used for the rapid urease test for *H. pylori*. The presence of bleeding may reduce the sensitivity of the rapid urease test and if negative results are obtained, a urea breath test can be undertaken once oral intake is established.
4. In high-risk patients who have received endoscopic haemostatic therapy, high dose intravenous PPI therapy reduces the risk of re-bleeding. The optimum dose and route is unclear but improved mortality is observed in high-risk patients when a dose of 80 mg bolus followed by 8 mg/h infusion for 72 h is given. Maintaining intragastric pH above 6 is considered to stabilise clot formation and prevent re-bleeding.

   If a positive test for *H. pylori* was obtained, oral eradication therapy should be given, although there is no evidence to suggest this must be given in the acute phase so should wait until oral intake is established. *H. pylori* eradication therapy is effective in prevention of re-bleeding from peptic ulcer. Ulcer healing can be achieved with an additional 3 weeks treatment with standard-dose PPI.

5. Mr BD was taking dual antiplatelet therapy to reduce the risk of myocardial infarction and cardiovascular death. These agents act synergistically through different pathways. Aspirin is a thromboxane A_2 inhibitor and clopidogrel is an adenosine diphosphate (ADP) inhibitor. Both these agents carry an increased risk of bleeding events, the risk being additive with dual therapy. Mr BD did not have any additional risk factors for peptic ulcer disease but it is important to take a careful medication history to identify if he had been taking NSAID analgesics and ensure he avoids such medicines in the future. The bleeding peptic ulcer was likely caused by the combination of aspirin and clopidogrel.
6. In patients with NSTEMI, most benefit is gained from the addition of clopidogrel to aspirin therapy in the first 3 months. Prolonged treatment for 12 months is indicated if a drug-eluting stent is inserted but as this patient had a bare metal stent inserted 4 months previously, the benefit from the addition of clopidogrel does not outweigh the gastro-intestinal bleeding risk and consideration should be given to discontinuation of clopidogrel. Aspirin should be continued at a dose of 75 mg daily. There is no evidence to suggest enteric coating is of any benefit, so the dispersible formulation should be continued. It is suggested that aspirin should be restarted within 7 days of discontinuation to maintain cardiovascular secondary prevention.
7. Standard dose of PPI should be continued as maintenance therapy in this patient to reduce the risk of further aspirin induced gastro-intestinal bleeding.
8. Mr BD needs to be aware of both his cardiovascular and gastro-intestinal risks. He does need to continue aspirin but he should be aware of the need to discontinue clopidogrel now as it is 4 months following his NSTEMI and the benefit does not outweigh the risk. He should not to take any other aspirin or NSAID containing medicines.

   Mr BD should be prescribed 7 days treatment with twice-daily omeprazole 20 mg, amoxicillin 1 g and clarithromycin 500 mg after ascertaining he is not penicillin sensitive. The importance of this treatment in prevention of re-bleeding should be emphasised to encourage adherence to the prescribed course which he may complete after discharge from hospital. Aspirin will be restarted and the dose of omeprazole will be reduced to 20 mg daily. A repeat endoscopy will be undertaken only if malignancy was suspected. Mr BD will return for a breath test to confirm eradication of *H. pylori,* although there is a risk of a false-negative result with concomitant omeprazole therapy.

   The anaemia associated with the acute bleed was treated with a blood transfusion and should not require additional oral iron therapy which is indicated in the case of microcytic anaemia more commonly caused by chronic bleeding

Case 12.2

A 57-year-old woman (Mrs MG) presents with symptoms of epigastric pain which has interfered with her normal activities over the previous few weeks. Medication history reveals that Mrs MG takes no prescribed medicines and occasional paracetamol as an analgesic for minor ailments. Although she has occasional heartburn, this is not the predominant symptom. Mrs MG has not vomited and does not have difficulty or pain on swallowing. She has not lost weight recently and has normal stools with no evidence of bleeding. The pain is not precipitated by exercise and does not radiate to the arms and neck. Mrs MG is a non-smoker and only takes a small quantity of alcohol on social occasions. She has an allergy to penicillin.

Questions

1. How should Mrs MG be treated?
2. Which *H. pylori* test should be used in primary care?

Answers

1. It is important to ascertain if Mrs MG has alarm features which should be investigated particularly as her age places her at higher risk of gastro-intestinal cancer. However, cancer is very rare in the absence of alarm features, and therefore initial management strategies are suggested prior to referral for investigation. Symptom assessment also suggests the pain is not cardiac in nature. Most patients with ulcer-like epigastric pain have functional dyspepsia but a small proportion have peptic ulcer disease. Her symptoms are affecting her quality of life, so an initial strategy of testing for *H. pylori* would be appropriate and if positive a 7-day course of twice-daily eradication therapy of omeprazole 20 mg, metronidazole 400 mg and clarithromycin 250 or 500 mg can be prescribed. Mrs MG should be advised to complete the course of therapy to avoid eradication failure and/or resistance to antibiotics. The potential interaction between metronidazole and alcohol should be explained to the patient in terms of the risk of nausea, vomiting, flushing and breathlessness which may occur during and for a few days after discontinuing metronidazole. Patients should also be alerted to the common adverse effect of diarrhoea associated with triple therapy. Patients should be encouraged to cope with the inconvenience but report symptoms to their doctor if they continue after the course of treatment is finished. If Mrs MG has an uncomplicated ulcer, it should heal with this treatment and if she has functional dyspepsia, a small proportion of patients obtain symptom relief. If Mrs MG tests negative for *H. pylori*, a 4-week course of standard-dose PPI can be given for symptomatic relief. If symptoms persist despite eradication therapy, successful eradication should be confirmed 4 weeks after treatment and eradication repeated if necessary. If patients over 55 years of age do not respond to either of these initial management strategies, referral for further investigation should be undertaken.
2. The most accurate non-invasive *H. pylori* test is the carbon-13 urea breath test. Alternative tests are the stool antigen test and a laboratory-based serology test. Local facilities and costs determine the choice of tests. Serology tests based on measurement of serum antibody are commonly used for initial detection of *H. pylori* but cannot be used to confirm eradication since circulating antibody remains for several weeks after removal of antigen.

Case 12.3

A 68-year-old woman (Ms WR) presents for review of her medication. Her medical history includes hypertension and osteoarthritis of the knees. Ms WR receives a regular prescription for:

Bendroflumethiazide 2.5 mg
Naproxen 500 mg twice daily

Ms WR stopped smoking 4 years previously and drinks no more than 10 units of alcohol per week. She is overweight with a BMI of 30 kg/m². Ms WR occasionally purchases an antacid to treat symptoms of heartburn if she's eaten a large meal at night. Her blood pressure was 148/92 mmHg with a pulse of 82 beats per minute.

Routine blood tests revealed:

		Reference range
Sodium	138 mmol/L	135–145 mmol/L
Potassium	3.9 mmol/L	3.4–5.0 mmol/L
Creatinine	110 µmol/L	75–155 µmol/L
Blood glucose	6.8 mmol/L	<11.1 mmol/L
Total cholesterol	4.5 mmol/L	<4.0 mmol/L
Haemoglobin	12.0 g/dL	11.5–16.5 g/dL

Questions

1. What is the mechanism for NSAID-induced peptic ulcer disease?
2. What are the risks associated with NSAID use in this patient?
3. What are the options for treating her pain and minimising the risk of peptic ulceration?

Answers

1. NSAIDs cause superficial erosions, but the main mechanism for causing ulcers in through their systemic inhibition of mucosal prostaglandin production. COX-1 is the enzyme responsible for synthesis of prostaglandins responsible for gastro-intestinal mucosal protection through maintenance of blood flow and production of mucus and bicarbonate. Another isoform of COX, COX-2 is involved in the inflammatory response and the prostaglandins produced are associated with pain and inflammation. The anti-inflammatory action of NSAIDs is thought to be as a result of inhibition of COX-2. Inhibition of COX-1 is thought to be responsible for the gastro-intestinal and renal adverse effects of NSAIDs.
2. Age-related reduction in the synthesis of prostaglandins and secretion of bicarbonate from the gastro-intestinal mucosa is the probable reason for the age-related increase in incidence of peptic ulcer bleeding. Patients over 60 years of age are at higher risk of peptic ulcer complications than their younger counterparts and the risk is much higher in those above 75 years of age. Other risk factors include a previous history of peptic ulcer disease, in particular peptic ulcer bleeding. Dyspepsia symptoms do not correlate with those who develop peptic ulcer disease and are, therefore, not a risk factor and can be treated symptomatically. Concomitant drug therapy such as aspirin, corticosteroids and anticoagulants increase the risk of peptic ulcer complications. In this case, the patient's age places her at risk, and therefore the benefits of the NSAID should be weighed against the risks and potential options for risk management considered.

   Age is also a risk factor for NSAID-induced decrease in renal perfusion caused by inhibition of prostaglandin-stimulated renal blood flow, a compensatory mechanism which is activated when renal perfusion is impaired. Withdrawal of NSAID therapy can improve renal perfusion and associated haemodynamic effects such as hypertension
3. The safest option for Ms WR is to manage the pain with regular use of a paracetamol-based product and to withdraw the NSAID thus removing the risk of peptic ulcer disease but also removing the potential detrimental effect the NSAID may have on blood pressure since the patient is just above the target for blood pressure control. Weight loss may also help to reduce the burden on her knees and may also have some positive effect on her blood pressure.

   The relative risk of ulcer complications has been compared among groups of NSAIDs with naproxen being of intermediate risk. Different NSAIDs vary in their selectivity for COX isoenzymes and may account for the relative toxicities observed. Selective COX-2 inhibitors are associated with low risk but are contraindicated in patients with

cardiovascular disease as they have been associated with an increased incidence of myocardial infarction. However, some other non-selective NSAIDs have also been associated with thrombotic risk, although naproxen seems to have the lowest risk and so is an appropriate choice of NSAID if indicated in this patient. There is no clear evidence to test for and eradicate *H. pylori* in chronic NSAID users.

An assessment of Ms WR's pain should be undertaken and the risks associated with naproxen use should be explained to the patient who may be willing to change to regular paracetamol with the addition of codeine if necessary. Otherwise adding a standard dose of PPI to naproxen reduces the gastro-intestinal risks but not the renal risks.

Inflammatory bowel disease 13

S. E. Cripps

Key points

- Ulcerative colitis and Crohn's disease are the two most common inflammatory bowel diseases (IBD) of the gut. Both are chronic relapsing conditions with a high morbidity and remain largely incurable.
- Ulcerative colitis and Crohn's disease are similar but there are contrasting features which relate to the site of involvement and extent of inflammation across the bowel wall. Ulcerative colitis is limited to the large bowel and the mucosa, whereas Crohn's disease frequently involves the small intestine with inflammation extending through the bowel wall to the serosal surface.
- The aims of treatment are to control acute attacks promptly and effectively, induce remission, maintain remission and identify patients who will benefit from surgery.
- Choice and route of therapy will depend on site, extent and severity of the disease together with knowledge of current or previous treatment.
- A reduction in inflammation with corticosteroids and aminosalicylates is the mainstay of treatment, with immunosuppressants (e.g. azathioprine, methotrexate, ciclosporin) and biologic agents (e.g. infliximab and adalimumab), reserved for more severe and refractory cases.
- The management of IBD poses a challenge to the multidisciplinary team both clinically and economically.
- National standards for IBD aim to ensure patients receive consistent, high-quality care and IBD services throughout the UK are evidence based, engaged in local and national networking, based on modern IT and meet specific minimum standards.

Introduction

Inflammatory bowel disease (IBD) can be divided into two chronic inflammatory disorders of the gastro-intestinal tract, namely Crohn's disease (CD) and ulcerative colitis (UC). Crohn's disease affects any part of the gastro-intestinal tract whereas ulcerative colitis affects the colon and rectum only. Current available treatment for IBD is not curative. IBD follows a relapsing and remitting course that is unpredictable and causes disruption to a patient's lifestyle and places a burden on the workplace and healthcare setting. The management of IBD patients poses a challenge to the multidisciplinary team both clinically and economically.

Epidemiology

The incidence of IBD is greater in North America, Europe, Australia and New Zealand, although the incidence in Africa, Asia and South America is rising steadily. This increase in developing countries may be due to improved sanitation and vaccination programmes along with a decreased exposure to enteric infections. Jewish and Asian people living in USA and UK are more commonly affected by IBD than those living in Israel and Asia. There appears to be no association between IBD and social class. The peak incidence of IBD occurs between 10 and 40 years, although it can occur at any age, with 15% of cases diagnosed in individuals over the age of 60 years. The incidence appears equal between males and females, although some studies in Crohn's disease show a slight female predominance. Up to 240,000 people are affected by IBD in the UK.

The incidence of new cases of ulcerative colitis in Europe and USA is 2–8 per 100,000 per year with a prevalence of 40–80 per 100,000 per year. The incidence has remained fairly static over the last 40 years. In the UK, Crohn's disease occurs with a similar frequency to ulcerative colitis with around 4 per 100,000 per year and a prevalence of 50 per 100,000. The rates in central and southern Europe are lower. In South America, Asia and Africa, Crohn's disease is uncommon but appears to be on the rise (Mpofu and Ireland, 2006).

Aetiology

The causative agents of IBD are largely unknown, although a number of factors are thought to play a role.

Environmental

Diet

Evidence that dietary intake is involved in the aetiology of IBD is inconclusive, although several dietary factors have been associated with IBD, including fat intake, fast food ingestion, milk and fibre consumption, and total protein and energy intake. A large number of case-control studies have reported a causal link between the intake of refined carbohydrates and Crohn's disease (Gibson and Shepherd, 2005). The mechanism for diet as a trigger is very poorly understood.

During the course of the disease, patients are able to identify foods which aggravate or exacerbate their symptoms, for example, milk or spicy foods. Up to 5% of patients with ulcerative colitis improve by avoiding cow's milk, whilst patients with Crohn's disease improve if they start to take elemental (amino acid based), oligomeric (peptides) and polymeric (whole protein) feeds, although symptoms may return when their normal diet is reintroduced.

Those that are breastfed as infants have a reduced risk of developing IBD (Mpofu and Ireland, 2006).

Smoking

There is a higher rate of smoking amongst patients with Crohn's disease than in the general population, with up to 40% of patients with the disease being smokers. Smoking worsens the clinical course of the disease and increases the risk of relapse and the need for surgery. Fewer patients with ulcerative colitis smoke (approximately 10%). Former smokers are at the highest risk of developing ulcerative colitis, while current smokers have the least risk. Stopping smoking can provoke the emergence of ulcerative colitis. This indicates that smoking may help to prevent the onset of the disease. The explanation for this is unclear. However, it is thought that in addition to its effect on the inflammatory response, the chemicals absorbed from cigarette smoke affect the smooth muscle inside the colon, potentially altering gut motility and transit time. In some studies, nicotine has been shown to be an effective treatment for ulcerative colitis (Guslandi, 1999).

Infection

Exposure to *Mycobacterium paratuberculosis* has been considered a causative agent of Crohn's disease, although current evidence indicates it is not an aetiological factor.

Ulcerative colitis may present after an episode of infective diarrhoea, but overall there is little evidence to support the role of a single infective agent.

Enteric microflora

Enteric microflora plays an important role in the pathogenesis of IBD because the gut acts as a sensitising organ that contributes to the systemic immune response. Patients with IBD show a loss of immunological tolerance to intestinal microflora and consequently antibiotics often play a role in the treatment of IBD. More recently, manipulating the intestinal flora using probiotics, prebiotics and symbiotic has proven to be an effective therapeutic strategy. Probiotics such as *Bifidobacteria* and *Lactobacilli* alter the intestinal microflora balance favourably. Prebiotics stimulate the growth of specific, beneficial microorganisms in the colon whilst synbiotics, a combination of both prebiotics and probiotics, have been successfully used.

Drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) such as diclofenac have been reported to exacerbate IBD (Felder et al., 2000). It is thought this may result from direct inhibition of the synthesis of cytoprotective prostaglandins. Antibiotics may also precipitate a relapse in disease due to a change in the enteric microflora. The risk of developing Crohn's disease is thought to be increased in women taking the oral contraceptive pill, possibly caused by vascular changes.

MMR vaccine. There has been much debate about the link between bowel disease and measles, measles vaccine or combined measles, mumps and rubella (MMR) immunisation. However, current evidence has indicated no proven correlation.

Appendicectomy

Appendicectomy has a protective effect in both Crohn's disease and ulcerative colitis (Radford-Smith et al., 2002). It is unclear whether this protective effect is immunologically based or whether individuals who develop appendicitis and consequently have an appendicectomy are physiologically, genetically or immunologically distinct from the population that is predisposed to IBD.

Stress

Some patients find that stress triggers a relapse in their IBD and this has been reproduced in animal models. It is thought that stress activates inflammatory mediators at enteric nerve endings in the gut wall. In addition to stress as a trigger factor, living with IBD can also be stressful. Its chronic nature, lack of curative treatment, distressing symptoms and impact on lifestyle make it difficult for patients to cope.

Genetic

Fifteen percent of first degree relatives have IBD. There is mounting evidence that Crohn's disease and ulcerative colitis result from an inappropriate response of the immune system in the mucosa of the gastro-intestinal tract to normal enteric flora (Ahmad et al., 2004). Since the mid-1990s there has been considerable progress in understanding the contribution of genetics to IBD susceptibility and phenotype.

Mutations of the gene CARD15/NOD2 located on chromosome 16 have been associated with small intestinal Crohn's disease in white but not oriental populations. Two other genes have been recently linked with Crohn's disease (OCTN1 on chromosome 5 and DLG5 on chromosome 10).

Genetic studies in ulcerative colitis have shown human lymphocyte antibody (HLA) is more strongly linked. Genotype related to pattern of disease (HLA-DRI*103) is 5–11 times more common in patients who have undergone colectomy.

Ethnic and familial

Jews are more prone to IBD than non-Jews, with Ashkenazi Jews having a higher risk than Sephardic Jews. In North America, IBD is more common in whites than blacks. First-degree relatives of those with IBD have a 10-fold increase in

risk of developing the disease. A familial link is supported from research showing a 15-fold greater concordance for IBD in monozygotic (identical) than dizygotic (non-identical) twins (Jess et al., 2005).

Pathophysiology

In individuals with IBD, trigger factors typically cause a severe, prolonged and inappropriate inflammatory response in the gastro-intestinal tract and the ongoing inflammatory reaction leads to an alteration in the normal architecture of the digestive tract. Genetically susceptible individuals seem unable to downregulate immune or antigen non-specific inflammatory responses. It is thought that chronic inflammation is characterised by increased activity of effector lymphocytes and pro-inflammatory cytokines that override normal control mechanisms. Others, however, have suggested that IBD may result from a primary failure of regulatory lymphocytes and

cytokines, such as interleukin-10 and transforming growth factor-β, to control inflammation and effector pathways. In Crohn's disease, it is also thought that T-cells are resistant to apoptosis after inactivation. Non-pathogenic bowel flora appears to be an essential factor.

Disease location

The character and distribution, both macroscopic and microscopic, of chronic inflammation define and distinguish ulcerative colitis and Crohn's disease. Table 13.1 shows the differences in location and distribution of ulcerative colitis and Crohn's disease. Figure 13.1 details the histological differences.

Crohn's disease

Crohn's disease can affect any part of the gut from the mouth to the anus. Approximately 45% of patients have ileocaecal disease, 25% colitis only, 20% terminal ileal disease, 5% small

Table 13.1   Location and distribution of ulcerative colitis and Crohn's disease

	Ulcerative colitis	Crohn's disease
Location	Colon and rectum 40% proctitis 20% pancolitis 10–15% backwash ileitis	Entire gut (mouth to anus, rectal sparing) 45% ileocaecal disease 25% colitis only 20% terminal ileal disease 5% small bowel disease 5% anorectal, gastroduodenal, oral disease
Distribution	Continuous, diffuse No granulomas Inflammation of mucosa Ulceration if fine and superficial	Often discontinuous and segmental 'skip lesions' Full thickness (transmural) Granulomatous inflammation Deep ulceration with mucosal extension
Fissures, fistulae and stricture	Absent	Common
Perianal disease	Absent	Present

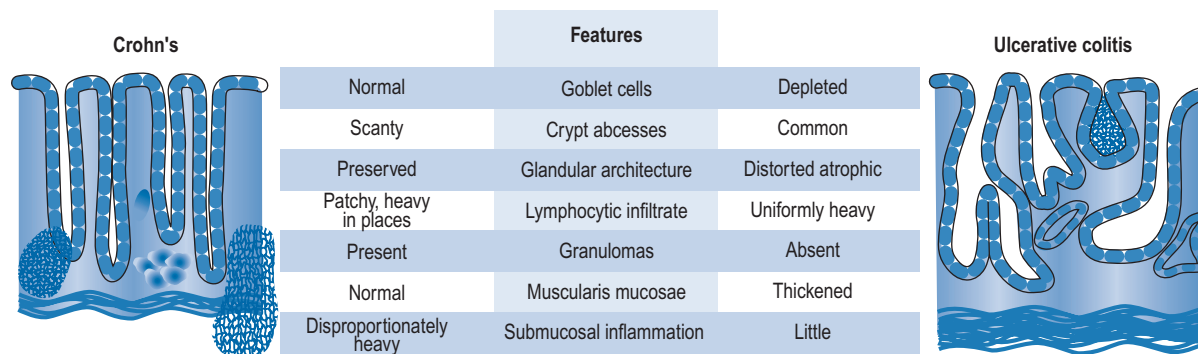
Crohn's	Features	Ulcerative colitis
Normal	Goblet cells	Depleted
Scanty	Crypt abcesses	Common
Preserved	Glandular architecture	Distorted atrophic
Patchy, heavy in places	Lymphocytic infiltrate	Uniformly heavy
Present	Granulomas	Absent
Normal	Muscularis mucosae	Thickened
Disproportionately heavy	Submucosal inflammation	Little


Fig. 13.1   Histological features in the rectal biopsy that help to distinguish between ulcerative colitis and Crohn's disease (from Misiewicz et al., 1994, with kind permission from Blackwell Scientific Publications, Oxford).

bowel disease and 5% anorectal, gastroduodenal or oral disease. Crohn's disease can involve one area of the gut or multiple areas, with unaffected areas in between being known as 'skip lesions'. The areas of the small bowel affected are typically thickened and narrow. A 'red ring' is often the first visible abnormality seen on colonoscopy. This is a lymphoid follicular enlargement with a surrounding ring of erythema, which develops into aphthoid ulceration and may progress to deep fissuring ulcers with a cobblestone appearance, fibrosis and strictures. Intestinal strictures arise from chronic and extensive inflammation and fibrosis and bowel obstruction may arise. Local gut perforation may cause abscesses which may also lead to fistulae.

Microscopically, inflammation extends through all layers of the bowel. Inflammatory cells are seen throughout, resulting in ulceration and microabscess formation. Non-caseating epithelioid cells, sometimes with Langhans' giant cells, are seen in about 25% of colonic biopsies and in 60% of surgically resected bowel. Chronic inflammation in the small intestine, colon, rectum and anus leads to an increased risk of carcinoma.

Ulcerative colitis

At first presentation, ulcerative colitis is confined to the rectum (proctitis) in 40% of cases, the sigmoid and descending colon (left-sided colitis) in 40% and the whole colon (total ulcerative colitis or pancolitis) in 20% of cases. Proctitis extends to involve more of the colon in a minority, with 15–30% of patients developing more extensive disease over 10 years. The reason why some patients have extensive disease and some have limited disease is unknown. In severe total ulcerative colitis, there may also be inflammation of the terminal ileum. This is known as 'backwash ileitis' but is not clinically significant. The colon appears mucopurulent, erythematous and granular with superficial ulceration that in severe cases leads to ulceration. As the colon heals by granulation, post-inflammatory polyps may form.

Microscopically, superficial inflammation is seen with inflammatory cells infiltrating the lamina propria and crypts. Crypt abscesses occur, the crypt structure is lost and goblet cell depletion arises as mucin is lost. Dysplasia, which can potentially progress to carcinoma, may be seen in biopsies taken from patients with long-standing total colitis.

Other types of colitis

Crohn's disease yet to be classified (sometimes referred to indeterminate colitis) is when chronic colitis persists, yet the pathology of the disease has not been identified as either Crohn's disease or ulcerative colitis. In microscopic colitis, the main feature is watery diarrhoea in the presence of a normal colonoscopy and chronic inflammation in the absence of crypt architectural distortion on mucosal biopsies. Drugs such as NSAIDs and proton pump inhibitors (PPIs) are implicated as the cause in up to 50% of cases of microscopic colitis. Diversion colitis is when inflammation occurs in the defunctioned loop of a colostomy causing a mucous discharge. Pseudomembranous colitis is caused by *Clostridium difficile*, usually after prolonged or multiple antibiotics. The use of PPIs predisposes patients to infection. It is diagnosed by sigmoidoscopy and detection of *C. difficile* toxin in the stool.

Clinical manifestation

The clinical differences between Crohn's disease and ulcerative colitis are described in Table 13.2.

Crohn's disease

The clinical features of Crohn's disease depend largely on the site of the bowel affected, the extent, severity and the pathological process in each patient. Crohn's disease tends to be more disabling than ulcerative colitis with 25% of patients unable to work 1 year after diagnosis. The predominant symptoms in Crohn's disease are diarrhoea, abdominal pain and weight loss. Weight loss occurs in most patients, irrespective of disease location. Ten to twenty percent of patients will have weight loss greater than 20%. The main cause is decreased oral intake, although malnutrition is also common. There is a slight increase in mortality in patients with extensive Crohn's disease.

Small bowel, ileocaecal and terminal ileal disease

Patients present with pain and/or a tender palpable mass in the right iliac fossa with weight loss and diarrhoea, which usually contains no blood. Diarrhoea is caused by mucosal inflammation, bile salt malabsorption that causes steatorrhoea or bacterial growth proximal to a stricture. Small bowel obstruction may also occur as a consequence of inflammation, fibrosis and stricture formation. Patients often describe a more generalised intermittent pain which is colicky with loud gurgling bowel sounds (borborygmi), abdominal distension, vomiting and constipation. When inflammation or abscesses are the predominant pathology, many patients present with constant pain and fever. Enteric fistulae occur and may involve the skin, bladder or vagina. Although rare, perforation of the gut may present with an acute abdomen and peritonitis. Vitamin B_{12} and folic acid deficiencies predispose patients with disease of the terminal ileum to macrocytic anaemia, while bile acid malabsorption also occurs in such patients and predisposes them to cholesterol gallstones and oxalate renal stones.

Colitis

The main symptoms are abdominal pain, profuse and frequent diarrhoea (more than six loose stools per day) with or without blood, and weight loss. Patients also complain of lassitude, anorexia and nausea and appear thin, tachycardic, anaemic, malnourished and febrile. Colitis may present

Table 13.2 Clinical differences between ulcerative colitis and Crohn's disease

Symptom	Ulcerative colitis	Crohn's disease
Prominent symptom	Bloody diarrhoea	Diarrhoea, abdominal pain, weight loss 30%, no gross bleeding
Fever	++	++
Abdominal pain	Variable	++
Diarrhoea	+++	+++
Rectal bleeding	+++	++
Weight loss	+	++
Sign of malnutrition	+	++
Abdominal mass	–	++
Dehydration	+++	++
Iron-deficiency anaemia, raised CPR/ESR, hypoalbuminaemia	++	++

CPR, C-reactive protein; ESR, erythrocyte sedimentation rate; +, the likelihood this symptom will be present; –, symptom absent in patient.

insidiously with minimal discomfort. Patients with severe involvement of the colon or the terminal ileum often have electrolyte abnormalities, hypoalbuminaemia and iron-deficiency anaemia. Extra-intestinal complications are more common in those patients with large bowel disease.

Perianal disease

Patients may present with an anal fissure, fistula or a perirectal abscess. These symptoms can have a significant impact on the patient's lifestyle.

Gastroduodenal and oral disease

These are both rare conditions. Gastroduodenal Crohn's disease presents as dyspepsia, pain, weight loss, anorexia, nausea and vomiting. Oral disease is very painful and may cause chronic ulceration resulting in anorexia.

Stricturing Crohn's disease

Patients presenting with pain, vomiting and constipation and a diagnosis of stricturing disease can lead to perforation if not surgically treated, although this is rare (see Fig. 13.2)

Ulcerative colitis

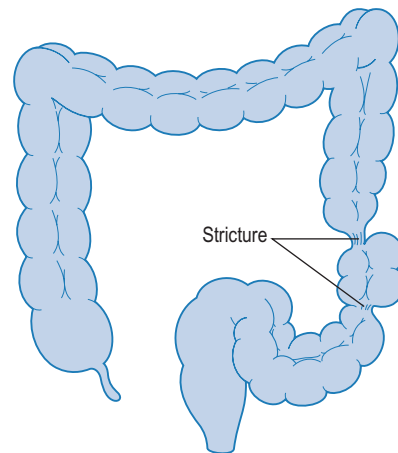
Typical symptoms of ulcerative colitis include bloody diarrhoea (the most predominant symptom) with mucus, abdominal pain with fever, and weight loss in severe cases. The typical


Fig. 13.2 Stricture formation in Crohn's disease.

appearance of a patient diagnosed with Crohn's disease is low BMI, malabasorption, weight loss and growth retardation. Frank blood loss is more common in ulcerative colitis than Crohn's disease. The symptoms of ulcerative colitis are similar to Crohn's colitis with patients being tachycardic, anaemic, febrile, fatigued, dehydrated and thin. Approximately 50% of patients with ulcerative colitis have some form of relapse each year, and severe attacks can be life-threatening. Up until the 1960s, one-third of ulcerative colitis patients died from the condition; with advances in medical and surgical treatment death is now extremely rare.

Acute severe disease

In addition to the typical symptoms of ulcerative colitis, patients with acute severe disease may present with more than six bloody stools per day (10–20 liquid stools per day is not unusual), with a fever (>37.8 °C), tachycardia (>90 bpm), anaemia (Hb < 10.5 g/dL) or elevated inflammatory markers (ESR > 30 mm/h; CRP > 8). Severity is commonly assessed using the Truelove and Witts criteria (see investigations).

Moderately active disease

Stool frequency is less than six motions each day with diarrhoea, mucus and rectal bleeding. Moderately active disease is more common in 'left-sided' disease. Toxic megacolon is rare in patients with rectosigmoidal involvement, and the incidence of colon cancer is much lower in these patients than those with total colitis.

Proctitis

The manifestations of active proctitis are less severe. These are tenesmus, pruritus ani, rectal bleeding and mucous discharge. Patients are often constipated.

Toxic dilatation

This can occur in untreated severe ulcerative colitis. There is a high risk of perforation with a mortality of 50%.

Extra-intestinal complications of IBD

Around 20–30% of patients with IBD will present with extra-intestinal manifestations. They are more commonly seen in patients where IBD affects the colon. Complications affect the joints, skin, bone, eyes, liver and biliary tree and are more common in active disease. Figure 13.3 highlights some of the extra-intestinal features of IBD.

Joints and bones

Arthropathies occur in 10% of patients with IBD, are more common in women and are a well-recognised complication of IBD. Patients with pauciarticular disease, characterised by arthritis limited to five or fewer joints, often experience a flare in the arthropathy when there is an exacerbation of the IBD symptoms. When the IBD relapse is treated, the arthropathy improves. In contrast, in polyarticular arthropathy, a chronic condition which affects more than five joints, a flare of the IBD appears not to be temporally related to the activity of the arthropathy. About 5% of patients with IBD also have ankylosing spondylitis. This is thought to be immunologically mediated and not associated with IBD activity. Osteopenia, potentially leading to osteoporosis, is often seen in patients with IBD because of chronic steroid use (particularly when the cumulative dose of prednisolone exceeds 10 g) and/or malabsorption.

Skin

Both erythema nodosum and pyoderma gangrenosum are associated with IBD. Erythema nodosum appears as tender, hot, red nodules that subside over a few days to leave a brown

Extra–intestinal features
- Uveitis
- Liver disease
- Ankylosing spondylitis
- Peripheral arthritis
- Finger clubbing
- Pyoderma gangrenosum
- Erythema nodosum

Malnutrition
Growth retardation
↓ Zinc: taste impaired

↓ Iron: anaemia
Osteoporosis
Emaciation
↓ Vitamin K: bruises
↓ Potassium: lethargy, ileus
↓ Calcium and magnesium: tetany
↓ Vitamin C: scurvy
Hypoproteinaemia: oedema

Fig. 13.3 Some of the extra-intestinal illnesses and features of malnutrition found in patients with inflammatory bowel disease (from Misiewicz et al., 1994, with kind permission from Blackwell Scientific Publications, Oxford).

skin discolouration. Disease flares are normally directly related to IBD activity in the 8% of patients affected.

Pyoderma gangrenosum presents as a discrete pustule that develops into an ulcer. In the 2% of patients affected, IBD activity does not appear to be directly related to the pyoderma gangrenosum, which may begin or worsen when the IBD is quiescent.

Sweet's syndrome (an acute febrile neutrophillic dermatosis) which has some similarity to erythema nodosum may also be associated with IBD.

Eye

Ocular complications are infrequent, occurring in less than 10% of cases. Episcleritis (intense burning and itching with localised area of blood vessels) is the most common complication of IBD. Scleritis, which involves more of the eye, may impair vision. Uveitis (headache, burning red eye, blurred vision) is often associated with joint and skin manifestations of IBD. Conjunctivitis is frequently seen in IBD patients but is not specific and no true association has been demonstrated.

Hepatobiliary

Biliary complications of IBD are gallstones and sclerosing cholangitis which occurs in 5% of patients with ulcerative colitis but less frequently in those with Crohn's disease. Conversely the prevalence of IBD (mostly ulcerativ colitis) in patients with sclerosing cholangitis is 70–80%. Sclerosing cholangitis, found predominantly in males, is a chronic cholestatic condition characterised by inflammation and fibrosis of the intrahepatic and extrahepatic bile ducts. Patients present with obstructive jaundice, cholangitis and raised liver enzymes (alkaline phosphatase and γ-glutamyltranspeptidase). Endoscopic retrograde cholangiopancreatography (ERCP) is useful in diagnosing and aiding the stenting of strictures. There is an increased risk of cholangiocarcinoma, with a liver transplant the only cure. Hepatic complications of IBD include fatty liver, pericholangitis, chronic active hepatitis and cirrhosis.

Thromboembolic

Thromboembolic complications occur in around 1–2% of IBD patients. The most common cause of death in hospitalised IBD patients is pulmonary embolism (Solem et al., 2004).

Anaemia

Around one-third of patients have haemoglobin levels below 12 g/dL. The main causes are chronic intestinal bleeding with iron loss (bowel inflammation) which causes a microcytic anaemia whereas the chronic inflammatory disease can cause normocytic anaemia giving rise to mixed features anaemia. Folate, iron, vitamin B_{12} malabsorption are also common. The side effects of commonly used drugs in IBD, for example, methotrexate and azathioprine can give rise to symptoms of anaemia.

Investigations

Radiological, pathological and clinical investigations help to confirm diagnosis, disease recurrence and response to treatment. Differential diagnoses of IBD include carcinoma, infection, drug-induced colitis, ischaemia, radiation damage, irritable bowel syndrome and diverticulitis.

Endoscopy

The key diagnostic investigation in IBD is lower gastrointestinal tract endoscopy (sigmoidoscopy and colonoscopy), which allows direct visualisation of the large bowel and histopathological assessment from biopsies. The risk of developing colorectal cancer is 7–10% after 20 years in patients with colonic disease. Therefore, routine surveillance colonoscopy is essential in the early detection of colorectal cancer. Treatment response to biologics, for example infliximab, can be assessed via mucosal healing seen at colonoscopy.

In patients with severe symptoms, it is sometimes necessary to delay a full colonoscopy because of the increased risk of perforation. Wireless capsule endoscopy is a relatively new procedure where the small bowel can be viewed and can be useful in patients with non-stricturing Crohn's disease.

Radiology

Radiological imaging is complementary to clinical and endoscopic assessment. It is used in the initial evaluation or diagnosis, preoperative review, to highlight the presence of complications during exacerbations and to evaluate extraintestinal manifestations. Radiological examination still plays a key role in IBD affecting the small bowel, although endoscopy has generally replaced conventional X-ray examinations of the colon.

Computed tomography (CT scan) and magnetic resonance imagery (MRI) are the best radiological methods for locating and defining fistulae and abscesses in active Crohn's disease.

Radiolabelled leucocyte scans that utilise autologous leucocytes labelled with [99]technetium-hexamethylenamine oxime may provide further information of disease site and severity.

Laboratory findings

Although not diagnostic, active disease is suggested in patients with raised inflammatory markers that include erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) in addition to a low haemoglobin and raised platelet count. Vitamin B_{12} may be low in patients with chronic terminal ileal disease. Low red cell folate and serum albumin, magnesium, calcium, zinc and essential fatty acids also indicate chronic inflammation and malabsorption. Anti-*Saccharomyces cerevisiae* antibodies (ASCA) are more likely to be present in Crohn's disease. Serology can be used to exclude infection as a cause of diarrhoea.

Malabsorption, indicated by low serum trace elements, for example, magnesium and zinc, is not seen in ulcerative colitis. Low albumin may indicate relapse in active disease. Patients with sclerosing cholangitis often present with altered liver function tests.

Stool tests

Red and white blood cells can be seen on microscopic examination of fresh stools. Microscopic identification of infective cells such as amoeba may also be visualised. *C. difficile* toxin can be assessed through culture and toxin assay. Stool tests do not diagnose IBD but contribute to excluding alternative diagnoses.

Clinical assessment tools

The Crohn's Disease Activity Index (CDAI) or the Harvey–Bradshaw Index (HBI) is used in most clinical trials to define remission in Crohn's disease. However, in clinical practice the CDAI is rarely used as it needs to be measured prospectively and is complex. The HBI is a simple measure of stool frequency, pain and other clinical features that is increasingly used to document selection for and response to biologic therapy. A CDAI of <150 or an HBI ≤3 suggests patient is in remission (NICE, 2010).

The Truelove and Witts criteria is a useful tool in defining the severity of ulcerative colitis (see Table 13.3). A severe attack is defined as more than six bloody stools a day plus one or more of the following: pulse >90 beats/min, temperature >37.8 °C, haemoglobin <10.5 g/dL or ESR >30 mm/h. In this case, the patient should be admitted to hospital.

Remission in ulcerative colitis is defined as complete resolution of symptoms with a normal bowel pattern (<3 stools/day), no urgency and no visible bleeding. Mucosal healing is confirmed by endoscopy. Steroid-free remission is the goal of therapy.

Table 13.3 Truelove and Witts criteria for assessing severity of ulcerative colitis (Travis et al., 2008)

Feature	Mild	Moderate	Severe
Motions per day	<4	4–6	>6
Rectal bleeding	Little	Moderate	Large amounts
Temperature	Apyrexial	Intermediate	>37.8 °C on 2 of 4 days
Pulse rate	Normal	Intermediate	>90 bpm
Haemoglobin	Normal	Intermediate	<10.5 g/dL
ESR	Normal	Intermediate	>30 mm/h

ESR, erythrocyte sedimentation rate.

Treatment of inflammatory bowel disease

At present there is no cure for IBD since the exact cause of the condition is unknown. A wide range of drugs and nutritional supplements are available to maintain the patient in long periods of remission in both Crohn's disease and ulcerative colitis. However, surgical intervention will eventually become necessary when the patient relapses and fails to respond to drug therapy. Since the majority of people with IBD are diagnosed under the age of 30, effective treatment and avoidance of relapses is of paramount importance in this chronic long-term condition.

Nutritional therapy

Nutritional therapy can be considered as an adjunctive or primary treatment. Although a potential problem for all patients with IBD, patients with Crohn's disease are at particular risk of becoming malnourished and developing a variety of nutritional deficiencies (Fig. 13.3). It is, therefore, important for patients to receive optimal nutrition and dietary manipulation as needed. Low-fibre diets help to reduce clinical symptoms of intestinal obstruction in Crohn's disease (Fernandes-Banares et al., 1999). Functional and structural damage to the small bowel can cause malabsorption problems and occasionally patients may require a low-lactose diet. Patients with poor oral intake and loss of appetite often respond to supplemental enteral feeds. Enteral nutrition in the form of an elemental or polymeric diet can be used as primary therapy and is widely employed in paediatrics (Heuschkel and Walker-Smith, 1999).

Patients who have extensive small bowel resection may experience many nutritional deficiencies because of malabsorption. Iron depletion, hypoproteinaemia, deficiencies in water- and fat-soluble vitamins, trace elements and electrolytes may all occur and must be corrected using a suitable replacement regimen.

Where appropriate, and when enteral nutrition is not indicated or adequate, a total parenteral nutrition (TPN) regimen may be prescribed. Some patients receive concurrent enteral and parenteral feeding.

Drug treatment

The main goals of drug treatment are to treat acute attacks promptly and effectively, induce and maintain remission, limit drug toxicity, modify the pattern of disease, avoid and/or manage complications and select patients who will benefit from surgery. Morbidity and mortality can also be reduced by the prompt use of effective and appropriate drug therapy. The choice of drug and route of administration depends on the site, extent and severity of the disease together with the individual's treatment history. Drug therapy is often required for many years and patient preference, acceptability and possible side effects not only affect choice but will impact on medication adherence. There is a need for therapeutic strategy and consistency in the management of patients with IBD.

Corticosteroids, aminosalicylates and immunosuppressive agents (immunomodulators) such as azathioprine are the mainstays of treatment. Immunomodulators are not licensed for use in IBD but are routinely used.

Modern advances in treatment, such as the use of humanised monoclonal antibody preparations and other biologic agents which modify the affected biochemical inflammatory pathways, now have a significant role in treatment of the disease. These are likely to be the main area of future development.

Other drugs such as antibiotics, for example, metronidazole, are helpful in some cases, while colestyramine, thalidomide, sodium cromoglicate, bismuth and arsenical salts, nicotine, lidocaine, sucralfate, new steroid entities, cytoprotective agents, aloe vera, probiotics and fish oils are rarely used. However, for some patients they provide alternative or supplemental therapy.

The choice of drug treatment is dependent on whether it is prescribed to induce remission or as maintenance therapy. The majority of patients are managed successfully as hospital outpatients or by their primary care doctor. Only severe extensive or fulminant disease requires hospitalisation and the use of parenteral therapy and/or surgical intervention. Oral medication can be given to most patients for maintenance of moderate disease.

The route of administration is a particularly important factor in IBD. In contrast to most other conditions, minimal systemic absorption and maximal intestinal wall drug levels are required with oral therapy. Several delivery strategies have been used to achieve this including the chemical modification of drug molecules, delayed and controlled-release formulations and the use of bioadhesive particles.

Disease confined to the anus, rectum or left side of the colon is more appropriately treated with rectally administered topical preparations where the drug is applied directly to the site of inflammation (Table 13.4).

These topical preparations have reduced systemic absorption and fewer side effects. Choice of formulation depends on the site of inflammation and also consideration of presentation, acceptability, patient preference and cost. Adherence to topical therapy is generally poor and good patient education is required for effective benefit.

Proctitis is best treated with suppositories. Where inflammation affects the rectum and sigmoid colon (up to 15–20 cm), foam enemas are preferred. In more extensive disease extending to the splenic flexure (30–60 cm), liquid enemas are the agents of choice. However, patients often require a combination of different rectal preparations because, for example, over 90% of liquid enemas bypass the rectum and thereby exert no therapeutic benefit at that site. As a consequence, a suppository may also be required to treat rectal inflammation. The propellant action of foam applicators also results in some preparations by-passing the rectal mucosa. Enemas or suppositories should be administered just before bedtime in a supine position as this allows a much longer retention time. Liquid enemas can be warmed and should be inserted while lying in the left lateral position.

An algorithm for drug treatment in IBD is shown in Fig. 13.4.

Table 13.4 Comparison of commercially available preparations for rectal administration in inflammatory bowel disease

Generic name (proprietary name)	Formulation	Site of release
Sulfasalazine (Salazopyrin®)	Suppositories	Rectum
	Retention enema	Transverse, descending colon and rectum
Mesalazine (Pentasa®, Salofalk®)	Retention enema	Transverse, descending colon and rectum
Mesalazine (Asacol®, Salofalk®)	Foam enema	Rectum and rectosigmoid colon
Mesalazine (Asacol©®, Pentasa®, Salofalk®)	Suppositories	Rectum
Prednisolone sodium phosphate (Predsol®)	Retention enema	Transverse, descending colon and rectum
	Suppositories	Rectum
Prednisolone sodium metasulphobenzoate (Predenema®)	Retention enema	Transverse and descending colon
Prednisolone sodium metasulphobenzoate (Predfoam®)	Foam enema	Rectum and rectosigmoid colon
Prednisolone sodium phosphate (Predsol®)	Retention enema	Transverse and descending colon
Hydrocortisone acetate (Colifoam®)	Foam enema	Rectum and rectosigmoid colon
Budesonide (Entocort©®)	Retention enema	Rectum and rectosigmoid colon

Corticosteroids

The glucocorticoid properties of hydrocortisone and prednisolone are the mainstay of treatment in active ulcerative colitis and Crohn's disease. Prednisolone administered orally or rectally is the steroid of choice, although in emergency situations hydrocortisone or methylprednisolone is used when the parenteral route is required. Corticosteroids have direct anti-inflammatory and immunosuppressive actions which rapidly control symptoms. They can be used either alone or in combination, with a suitable mesalazine (5-aminosalicylic acid, 5-ASA) formulation or immunosuppressant, to induce remission.

Oral corticosteroids should not be used for maintenance treatment because of serious long-term side effects, and abrupt withdrawal should be avoided. Patients should be maintained on aminosalicylates or immunosuppressants, as appropriate, or referred for surgery.

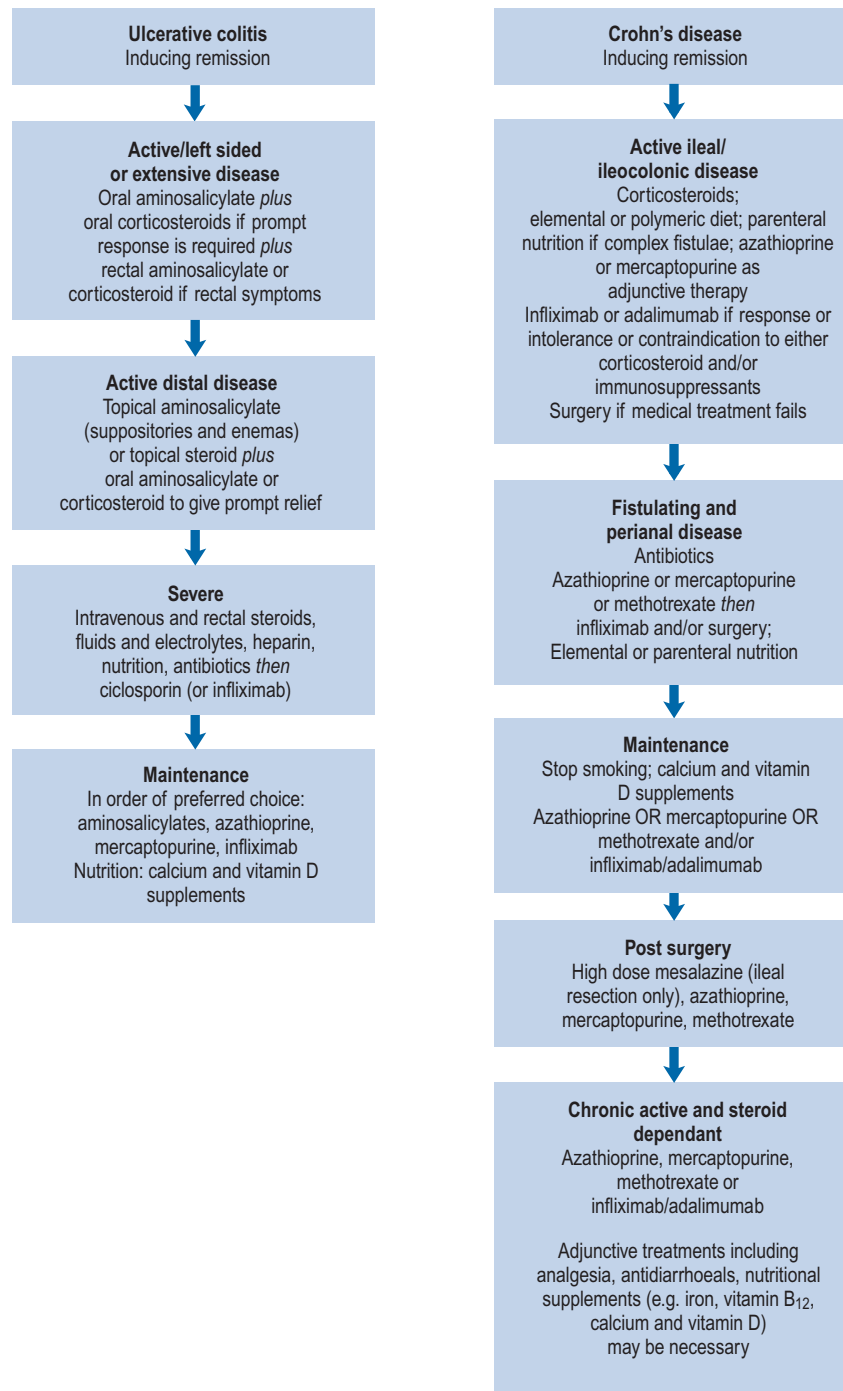
Formulations. Oral prednisolone will control mild and moderate IBD and 70% of patients improve after 2–4 weeks of 40 mg/day. This is gradually reduced over the next 4–6 weeks


Fig. 13.4 Drug treatment algorithm for inflammatory bowel disease.

to prevent acute adrenal insufficiency and early relapse. An example of a reducing oral prednisolone regime is detailed in Box 13.1.

Oral corticosteroids should be taken in the morning to mimic the diurnal rhythm of the body's cortisol secretion and prevent sleep disturbance. Uncoated steroid tablets are suitable for most patients while enteric-coated preparations do not offer any proven advantage and should be avoided in patients with short bowel or strictures because of poor absorption and bolus release at stricture sites.

Box 13.1 An example of a reducing regimen for oral steroids

40 mg/day for 1 week
30 mg/day for 1 week
20 mg/day for 4 weeks
15 mg/day for 1 week
10 mg/day for 1 week
5 mg/day for 1 week then stop

Local regimen used at the Oxford Radcliffe Hospitals NHS Trust

Severe extensive or fulminant disease requires hospitalisation. Patients are given either hydrocortisone sodium succinate, administered intramuscularly or intravenously at doses of 100 mg three or four times a day, or methylprednisolone 15–20 mg three or four times a day, for 5 days. No additional benefit is gained after 7–10 days. Additional therapy used in severe disease may include intravenous fluid and electrolyte replacement, blood transfusion, topical therapy for rectal and/or colonic involvement, prophylactic heparin (IBD is associated with increased coagulopathy), antibiotics and nutritional support, including possible parenteral nutrition. Oral prednisolone therapy is normally introduced as soon as possible and withdrawn over the following 6–8 weeks. Too rapid reduction is associated with relapse.

Prednisolone at doses higher than 40 mg/day increases the incidence of adverse effects and has little therapeutic advantage. Short-term side effects include moon face, acne, sleep and mood disturbance, dyspepsia, hypokalamia, hypernatraemia and glucose intolerance. Prolonged use can cause cataracts, osteoporosis and increased risk of infection. Doses below 20 mg are not generally effective in active disease (St Clair Jones, 2006). A typical treatment algorithm for the management of an acute attack of IBD is presented in Fig. 13.5.

Rectal corticosteroid preparations are available as suppositories, foam and liquid enemas. In the acute setting, some hospitals make up their own liquid enemas using 100 mg hydrocortisone sodium succinate injection in 100 mL sodium chloride 0.9%. This unlicensed preparation is administered via a burette and soft catheter over 30 min. It is often well tolerated and gives better therapeutic results compared with commercial preparations.

The distribution and absorption characteristics of rectally administered steroids vary greatly. Hydrocortisone (e.g. Colifoam®) is readily absorbed from the rectal mucosa with high peak concentrations compared to prednisolone sodium metasulphobenzoate (e.g. Predenema®) and, to a lesser extent, Predfoam®. Topical preparations may play a role either alone or in combination with oral steroids.

Other steroids

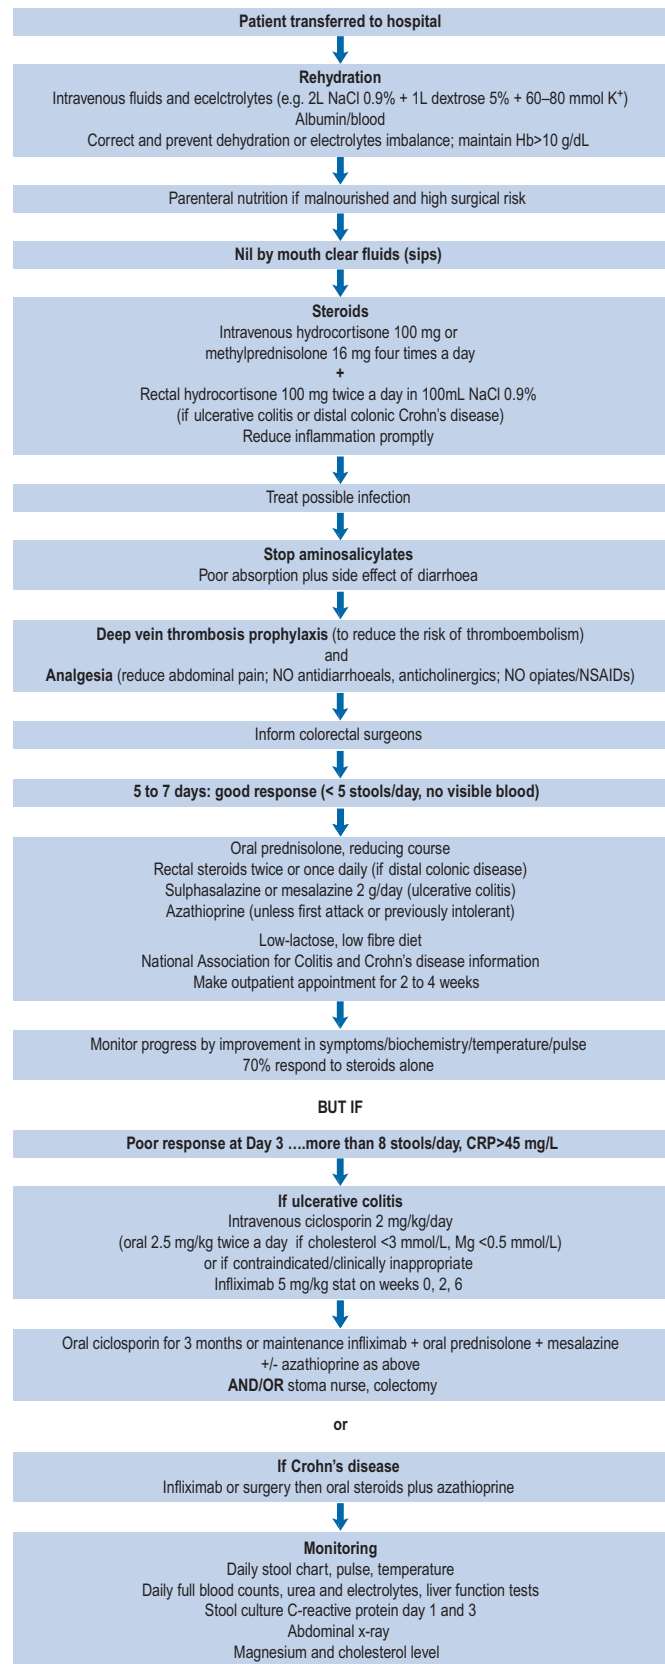
Budesonide, available orally and rectally, is currently licensed for Crohn's disease affecting the ileum and descending colon. It is less effective than conventional corticosteroids in inducing remission in active Crohn's disease, but has fewer side effects than prednisolone because of its rapid and extensive first-pass metabolism. However, the absorbed drug has a higher affinity for glucocorticoid receptors 50–100 times that of prednisolone and so long-term treatment is not advocated. Budesonide has shown to be of benefit in microscopic colitis (Travis et al., 2005). Budesonide enemas are effective in inducing remission in distal ulcerative colitis and are comparable to conventional steroids but probably less effective than mesalazine enemas (Marshall and Irvine, 1997).


Fig. 13.5 Treatment algorithm for a severe attack of inflammatory bowel disease.

Aminosalicylates

The aminosalicylates currently licensed for the treatment of IBD include sulphasalazine, mesalazine, olsalazine and balsalazide. Their mode of action is unclear but a local effect on epithelial cells by a variety of mechanisms to moderate the release of lipid mediators, cytokines and reactive oxygen species is proposed. Different formulations deliver variable amounts of the active component, mesalazine (5-ASA), to the gut lumen where it exerts a predominantly local action independent of blood levels. The dissolution profile and site of ulceration determine the effectiveness of different preparations.

Diagnosis, disease location, activity, side effect profile, efficacy and cost all affect the choice of aminosalicylate. Available as oral or rectal preparations, aminosalicylates can be used in combination with steroids to induce and maintain remission, in mild to moderate ulcerative colitis. Sulfasalazine is considerably cheaper but the newer aminosalicylates are generally used (Sutherland and MacDonald, 2006). Aminosalicylate maintenance therapy with doses of 1.2 g and above appears to reduce the risk of colorectal cancer by up to 75% (Van Staa et al., 2005).

The use of aminosalicylates in Crohn's disease is less well established (Dignass et al., 2010). There is evidence of patient benefit with high-dose mesalazine (over 2 g/day) in reducing relapse post-small bowel resection.

Sulfasalazine consists of sulfapyridine diazotised to mesalazine. It is broken down by bacterial azoreductase in the colon to mesalazine and sulfapyridine. Sulfapyridine is absorbed in the colon, metabolised by hepatic acetylation or hydroxylation followed by glucuronidation and excreted in urine. Mesalazine is partly absorbed, metabolised by the liver and excreted via the kidneys as *n*-acetyl 5-ASA. However, the majority is acetylated as it passes through the intestinal mucosa. Sulfasalazine itself is poorly absorbed and that which is absorbed is recycled back into the gut, via the bile, either unchanged or as the *n*-acetyl metabolite.

Elimination of sulfapyridine depends on the patient's acetylator phenotype. Those who inherit the 'slow' acetylator phenotype experience more side effects. The dissolution profile of the drug and the site of ulceration determine effectiveness (Fig. 13.6). The optimal dose of sulfasalazine to achieve and maintain remission is usually in the range of 2–4 g per day in 2–4 divided doses. Acute attacks require 4–8 g per day in divided doses until remission occurs, but at these doses associated side effects are often observed.

About 30% of patients taking sulfasalazine experience adverse effects which are either dose related and dependent on acetylate phenotype or idiosyncratic and not dose related. Dose-related side effects include nausea, vomiting, abdominal pain, diarrhoea, headache, metallic taste, haemolytic anaemia, reticulocytosis and methaemoglobinaemia. Side effects which are not dose related include rashes, aplastic anaemia, agranulocytosis, pancreatitis, hepatic and pulmonary dysfunction, renal impairment, peripheral neuropathy and oligospermia. In 3% of patients, acute intolerance may be seen. This often resembles colitis and includes bloody diarrhoea. Adverse effects usually occur during the first 2 weeks of therapy, the majority being related to plasma sulfapyridine levels. Sulfasalazine metabolites are responsible for the yellow colouration of bodily fluids and staining of soft contact lenses.

Mesalazine is tolerated by 80% of patients who are intolerant of sulphasalazine. Many of the sulphonamide-related adverse
Fig. 13.6 Physiological and formulation problems encountered with mesalazine and delivery systems.

effects of sulfasalazine are avoided by using one of the newer aminosalicylate formulations. However, mesalazine alone can still cause side effects, including blood disorders, pancreatitis, renal dysfunction and lupoid phenomenon. Patients should be counselled on how to recognise and report blood dyscrasias and if they occur, treatment should be stopped.

Formulations. Mesalazine is unstable in acid medium and rapidly absorbed from the gastro-intestinal tract. To increase stability and/or alter the site of release, 5-ASA is modified by different delivery systems (see Fig. 13.6). Mesalazine dose is more important than the delivery system and the lowest systemic absorption preparation should be used. The different delivery systems developed are:

- acrylic resin-coated mesalazine tablet that releases drug pH-dependently;
- ethyl cellulose-coated mesalazine granules that release drug in a time controlled manner;
- diazotisation of mesalazine to itself or to an inert carrier.

All mesalazine preparations are licensed for UC, however only Mesren® MR and Asacol® MR are licensed for Crohn's disease. There are six modified release oral preparations currently licensed in the UK. Asacol® MR, Ipacol®, Mesren® MR and Mezavant® XL contain mesalazine coated with an acrylic resin, Eudragit-S. Mesren® MR and Ipacol® are generic versions of Asacol® MR. Mezavant® XL, recently licensed, is a modified release mesalazine formulation with a patented multi-matrix release system allowing less frequent dosing which may be beneficial in patients experiencing difficulty with a high tablet burden. Salofalk® contains mesalazine coated with

Eudragit-L. All these preparations provide pH-dependant release of mesalazine at the mid to terminal ileum and the colon, at pH 7 (Asacol® MR, Mesren® MR, Mezavant® XL) and pH 6 (Ipacol®, Salofalk®). As dissolution occurs at a lower pH with Ipacol® and Salofalk®, this results in a lower ileocolonic mucosal concentration of mesalazine compared with the other pH-dependant release products. There is little clinical difference between the available pH-dependant products Asacol® MR, Mesren® MR and Mezavant® XL. However, cost may contribute to initiating new patients with the cheaper generic. Pentasa® tablets and granules comprise ethyl cellulose-coated granules of mesalazine which are released in the stomach. Mesalazine is leached slowly and continuously from the granules throughout the gastro-intestinal tract at all physiological pH.

It is very important to maintain patients on the same brand of mesalazine as some may relapse because of the different release profiles of the active drug. Therefore, mesalazine should always be prescribed by brand.

Evidence suggests that there is no difference in splitting the dose of mesalazine products as licensed, compared to taking the total dose once daily.

Dipentum® 250 mg capsules and 500 mg tablets contain olsalazine sodium, a dimer of mesalazine. Like sulfasalazine, it remains intact until it reaches the colon where it undergoes bacterial cleavage, releasing two molecules of mesalazine. Olsalazine-induced diarrhoea may help patients with distal disease and proximal constipation. Colazide® 750 mg capsules contain balsalazide sodium, a pro-drug of mesalazine, which relies on bacterial cleavage in the colon, releasing mesalazine from 4-aminobenzoyl β-alanine, the inert carrier molecule.

Table 13.5 Comparison of available oral aminosalicylate preparations for patients with IBD

Generic (proprietary) name	Formulation	Release profile	Site of release
Sulfasalazine (Salazopyrin®)	Compressed tablet, plain and film coated	Azo-linked, independent of pH	Terminal ileum and colon
Mesalazine (Asacol®)	Compressed tablet, acrylic coating	Acrylic coating dissolving at pH 7	Terminal ileum and colon
Mesalazine (Mesren®)	Compressed tablet, acrylic coating	Acrylic coating dissolving at pH 7	Terminal ileum and colon
Mesalazine (Salofalk®)	Compressed tablet and/or capsule, acrylic coating	Acrylic coating dissolving at pH 6	Terminal ileum and colon
Mesalazine (Mezavant® XL)	Compressed tablet, acrylic coating	Multi-matrix release system	Terminal ileum and colon
Mesalazine (Ipacol®)	Compressed tablet and/or capsule, acrylic coating	Acrylic coating dissolving at pH 6	Mid-jejunum ileum and colon
Mesalazine (Pentasa®)	Microgranules coated with ethyl cellulose and compressed into tablets. Granules also available	Disintegration not dependent on pH. Slow dissolution rate	Stomach, duodenum, jejunum, ileum and colon
Olsalazine (Dipentum®)	Hard gelatin capsules and tablets, uncoated	Azo-linked disintegration independent of pH	Terminal ileum and colon
Balsalazide (Colazide)	Hard gelatin capsules	Azo-linked disintegration independent of pH	Terminal ileum and colon

Table 13.5 compares the oral aminosalicylate preparations currently available.

Mesalazine enemas (1 g in 100 mL), foam enemas (1 g per application) or suppositories (250 mg, 500 mg and 1 g) are effective alternatives for treating distal ulcerative colitis and proctitis. The optimum rectal dose is 1 g. Rectal administrations of 5-ASA formulations are significantly better than rectal corticosteroids in inducing remission in ulcerative colitis but steroids are considerably cheaper (Travis et al., 2008). In severe ulcerative colitis, oral and topical formulations should be combined to give prompt symptom relief. Topical and oral 5-ASA is better than either alone (Marteau et al., 2005).

Immunosuppressants

Azathioprine, 6-mercaptopurine, methotrexate, ciclosporin and mycophenolate are immunosuppressants used in patients unresponsive to steroids and aminosalicylates or who relapse when steroids are withdrawn. They are used to induce and maintain remission. All are unlicensed for use in IBD but are routinely used. Treatment may be for up to 5 years because earlier withdrawal increases the rate of relapse. They can take several weeks to work and require regular monitoring.

Thioguanines (azathioprine, mercaptopurine). Azathioprine is metabolised to 6-mercaptopurine by the liver. Both azathioprine and 6-mercaptopurine have steroid-sparing properties. Although the action in IBD is unclear, their active metabolites inhibit purine ribonucleotide synthesis which may in turn inhibit lymphocyte function, primarily T-cells. Mercaptopurine is further metabolised to 6-thioguanine nucleotides.

The main indications for thioguanines are when patients

- require two or more steroid courses in 1 year;
- have chronic active disease unresponsive to steroids or 5-ASAs;
- relapse when steroids are withdrawn (within 3 months) or when the dose is reduced below 15 mg;
- require post-operative prophylaxis of complex Crohn's disease (fistulising or extensive disease).

Oral maintenance doses for azathioprine are usually 2–2.5 mg/kg/day and for mercaptopurine, 1–1.5 mg/kg/day. Doses are adjusted to patient response, tolerance, white cell and platelet counts. Patients are usually prescribed a reducing dose of corticosteroid in addition because mercaptopurine and azathioprine can take several weeks to show a therapeutic benefit.

Seventy percent of patients will tolerate azathioprine. Of the remaining 30%, most will tolerate mercaptopurine. The most common side effects occur within 2–3 weeks of starting treatment and rapidly stop on withdrawal. These include flu-like symptoms (myalgia, headache), nausea and diarrhoea. Nausea is reduced by taking the medicine with food. Although rare (<3%), leucopenia can develop suddenly and unpredictably. Hepatotoxicity and pancreatitis have also been reported in less than 5% of patients. Thioguanine has been used but is associated with a greater risk of hepatotoxicity. There is no evidence that the incidence of lymphoma increases with the use of these agents (St Clair Jones, 2006).

The value of assessing thiopurine methyl transferase (TPMT) activity and genotype, especially prior to initiating treatment, is debatable. Patients who develop leucopenia and are TPMT deficient have a greater risk of myelotoxicity. However, this may not apply in IBD. Some gastroenterologists measure TPMT if a patient has relapsed on doses greater than 2 mg/kg/day to identify fast metabolisers who may respond to higher doses. Measuring TPMT activity to identify the 0.3% of non-metabolisers who are at high risk of rapid leucopenia has also been recommended (Carter et al., 2004).

One of the most significant drug interactions is with allopurinol which inhibits the principal pathway for detoxification of azathioprine and mercaptopurine. Patients receiving these drugs concomitantly should have their dose of azathioprine reduced to approximately one-third to a quarter of the usual dose.

Methotrexate. A low-dose regimen of methotrexate is effective in inducing and maintaining remission in patients with chronically active Crohn's disease. Patients receive once-weekly doses of methotrexate ranging from 15 to 25 mg on the same day each week. These can be given orally or by subcutaneous or intramuscular injection. Oral medication is more practical, although parenteral administration may be more effective and better tolerated. Methotrexate is reserved for patients intolerant or unresponsive to thioguanines.

Methotrexate metabolites inhibit dihydrofolate reductase, although this cytotoxic action does not explain the drug's anti-inflammatory effect. Inhibition of cytokine and eicosanoid synthesis and modification of adenosine levels probably contribute.

Adverse effects associated with methotrexate are essentially gastro-intestinal (nausea, vomiting, diarrhoea and stomatitis). These may also be reduced by prescribing weekly doses of folic acid 5 mg. Folic acid should not be taken on the same day as the methotrexate. Monitoring is undertaken because of the serious side effects of hepatotoxicity, bone marrow suppression and pneumonitis.

Methotrexate is teratogenic and all male and female patients should be counselled about using contraception while taking the medication and also for 3 months after therapy is withdrawn. Guidance to improve the safety of methotrexate use and minimise the potential risk of overdose has been issued (NPSA, 2006). Measures include the issue of patient hand-held monitoring cards detailing dose and blood test results, comprehensive written and verbal medicines information, dispensing one strength of tablet (2.5 mg) and ensuring inpatient medication charts clearly state once-weekly dosing and the number and strength of tablets routinely used. An aide memoire commonly recommended to patients to remember dose frequency is to take methotrexate on Mondays and folic acid on Fridays.

Ciclosporin. Ciclosporin is a calcineurin inhibitor that acts at an early stage on precursors of helper T-cells by interfering with the release of interleukin-2. This inhibits the formation of the cytotoxic lymphocytes which cause tissue damage. Both controlled and uncontrolled studies suggest that ciclosporin is

effective rescue therapy for severe ulcerative colitis failing to respond to intravenous steroids (Campbell et al., 2005). Its use in Crohn's disease is unproven.

The effectiveness of ciclosporin at doses of 2–5 mg/kg/day in treating IBD has been studied in patients refractory to conventional drug therapy (Van Assche et al., 2003). A dose of 2 mg/kg has been shown to be as effective as 4 mg/kg. Patient response to this treatment has varied, with adverse effects causing withdrawal of treatment in some cases. However, some patients have stopped concurrent steroid therapy and have remained in remission for some time.

When patients with severe colitis fail to show a response to treatment with parenteral steroids, then ciclosporin at an intravenous dose of 2 mg/kg/day should be considered. If patients respond to parenteral ciclosporin they can subsequently be maintained on an oral dose for 3–6 months. If the patient has a low plasma magnesium (< 0.5 mmol/L) or low cholesterol (<3 mmol/L), they are at an increased risk of ciclosporin-induced seizures when given intravenously. In these circumstances, treatment with an oral ciclosporin preparation, for example, Neoral®, at a dose of 5 mg/kg/day is preferred. Ciclosporin therapy is used for many patients, but normally as a bridge to colectomy or starting maintenance treatment with azathioprine or mercaptopurine. Infliximab is an alternative 'rescue therapy' for acute severe colitis (NICE, 2008a) if ciclosporin is contraindicated or clinically inappropriate. A multi-centre randomised controlled trial (CONSTRUCT) is underway comparing the clinical and cost-effectiveness of infliximab and ciclosporin in the treatment of steroid resistant acute severe colitis.

Forty percent of patients who receive ciclosporin develop minor side effects such as tremor, paraesthesia, headache, gum hyperplasia, burning sensations of the hands and feet and hirsutism. Major complications include nephrotoxicity, neurotoxicity, hepatotoxicity and hypertension. There has been 1–2% mortality reported in some case series. Ciclosporin blood levels should be monitored and maintained within the range of 100–200 ng/mL. Grapefruit juice, macrolide antibiotics (mainly erythromycin and clarithromycin), ketoconazole, fluconazole, itraconazole, diltiazem, verapamil, oral contraceptives and protease inhibitors are just some of the drugs that increase ciclosporin levels and toxicity.

In severe proctitis, refractory to standard treatments, ciclosporin enemas have been used with some success at a dose of 250 mg at night for 1 month. No commercial preparation is available.

Tacrolimus. Tacrolimus is an alternative calcineurin inhibitor to ciclosporin that has shown some benefit in inducing remission in ulcerative colitis. It is of limited value in Crohn's disease.

Mycophenolate. It has been suggested that mycophenolate mofetil is effective and well tolerated in IBD. Although used if other treatments have failed, there is little evidence regarding its use in clinical practice.

Monitoring of immunosuppressants. Major concerns about the use of immunosuppressive agents are related to bone marrow suppression and hepatotoxicity. Therefore, patients should be monitored regularly and have routine blood counts and liver function tests including plasma bilirubin and alkaline phosphatase. These should be undertaken every 2–3 weeks for the first 2–3 months and then bimonthly. Although often advised, there is no evidence that more frequent monitoring is more effective. Patients should be taught to recognise the signs of bone marrow suppression and educated about the need for earlier blood tests and the increased risk of infection due to immunosuppression. It is recommended that all patients initiated or maintained on immunosuppressants are provided with a record card detailing current dose and blood test results. This should be shown to their doctor and pharmacist at each visit. There should be good shared care policies in place between primary and secondary care in the management of patients on immunomodulators.

The incidence of lymphomas in patients receiving immunosuppressants when compared with other treatments is of concern. Patients should be advised to avoid live vaccines while taking immunosuppressants, including corticosteroids. Guidance on appropriate action following abnormal blood results is provided in Box 13.2.

Biologic agents

Since their introduction over a decade ago, biological therapy targeting tumour necrosis factor alpha (TNF-α) has revolutionised the management of IBD. These agents are efficacious in treating signs and symptoms of Crohn's disease and ulcerative colitis, reducing corticosteroid requirements and draining fistulae, achieving mucosal healing and reducing the need for major abdominal surgery or hospitilisation. They are indicated for patients who have failed or are intolerant or who have contraindications to conventional therapy including corticosteroids and immunomodulators. Not all patients will require biological therapy which is expensive and is a significant cost to the Health Service. Some patients may derive greater benefit from early use of these agents such as patients who are steroid dependant or who have complex fistulising disease.

Biologic agents that are licensed for use in IBD are infliximab (Remicade®) and adalimumab (Humira®). At present there are no direct comparative studies of the two agents. Certolizumab pegol (Cimzia®) has also shown benefit and is an alternative in some cases; however, it is currently not licensed for use in IBD. All these monoclonal antibodies inhibit the functional activity of the pro-inflammatory cytokine TNF-α which damages cells lining the gut, causing pain, cramping and diarrhoea. Colonic biopsies post-treatment with these agents show a substantial reduction in TNF-α and a reduction in the commonly elevated plasma inflammatory marker C-reactive protein. Table 13.6 summarises the anti-TNF agents used. All appear to have similar efficacy, although there are more data on infliximab than adalimumab or certolizumab. Natalizumab, another monoclonal antibody, has also shown promise in treating active Crohn's disease. It works by inhibiting the migration of leucocytes into the CNS thereby reducing inflammation. It is unlicensed in IBD.

Box 13.2 Guidance on dealing with abnormal blood results for patients on immunosuppressant therapy

Baseline U&Es, LFTs and FBC should be carried out prior to initiation of therapy. These should be repeated at 2 weeks, 4 weeks then every 2–3 months.

Methotrexate should be *stopped* and the relevant expert advice obtained if any of the following occur:

WBC	$<4 \times 10^9 \, L^{-1}$
Neutrophils	$<2 \times 10^9 \, L^{-1}$
Platelets	$<150 \times 10^9 \, L^{-1}$
AST/ALT	$>3 \times$ normal range

- Unexplained respiratory symptoms, for example, dyspnea, dry cough, especially if accompanied by fever and sweats
- Renal impairment
- Mouth or throat ulceration/rash/unexplained bleeding/fever/alopecia/recurrent sore throats, infections, fever or chills/nausea/vomiting/diarrhoea

Azathioprine or mercaptopurine should be *stopped* and the relevant expert advice obtained if any of the following occur:

WBC	$<4 \times 10^9 \, L^{-1}$
Neutrophils	$<2 \times 10^9 \, L^{-1}$
Platelets	$<150 \times 10^9 \, L^{-1}$
AST/ALT	$>3 \times$ normal range

- Significant reduction in renal function
- Mouth or throat ulceration/rash/unexplained bleeding/fever/upper abdominal or back pain/alopecia/recurrent sore throats, infections, fever or chills/nausea/vomiting/diarrhoea
- Nausea may be relieved by taking the dose with/after food or in divided doses

Ciclosporin should be *stopped* and the relevant expert advice obtained if any of the following occur:
- High blood levels (will require dose adjustment)
- Significant reduction in renal function
- Uncontrolled hypertension

Drug blood levels should be done at similar intervals to FBC. A 12-h trough level should be taken, that is, before a dose. Target level within the range of 100–200 ng/mL. It takes 2–3 days to reach steady state after dose change

U&Es, urea and electrolytes; LFTs, liver function tests; FBC, full blood count; WBC, white blood cells; ALT, alanine transaminase; AST, aspartate transaminase.

Table 13.6 Summary of anti-TNF agents used in IBD

Agent	Licensed/(unlicensed) indication	Dose
Infliximab	*Crohn's disease*	
	Induction of remission in severe active disease	5 mg/kg intravenously at weeks 0 and 2
	Maintenance treatment	5 mg/kg intravenously 6 weeks after initial dose then every 8 weeks or further dose of 5 mg/kg if signs and symptoms recur
	Fistulising	5 mg/kg intravenously at weeks 0, 2 and 6 (consult product literature)
Infliximab	*Ulcerative colitis*	
	Induction of remission in moderate to severe active disease	5 mg/kg intravenously at weeks 0, 2 and 6
	Maintenance of remission in severe active disease	5 mg/kg intravenously every 8 weeks; discontinue if no response 14 weeks after initial dose
	Extra-intestinal manifestations (unlicensed)	5 mg/kg intravenously
Adalimumab	*Crohn's disease*	
	Induction of remission in severe active disease	80 mg subcutaneously at week 0, 40 mg at week 2 and or accelerated regime of 160 mg at week 0, 80 mg at week 2
	Maintenance treatment	40 mg subcutaneously on alternate weeks, increasing to weekly if loss of response
Certolizumab pegol	*Crohn's disease (unlicensed)* Used in moderate to severe disease when patients who have lost response to or are intolerant of infliximab or adalimumab	
	Induction	400 mg subcutaneously at weeks 0, 2 and 4
	Maintenance treatment	400 mg subcutaneously every 4 weeks

National guidance has been issued on the use of infliximab in ulcerative colitis (NICE, 2008a,b) and infliximab and adalimumab in the treatment of Crohn's disease (NICE, 2010). The latter guidance indicates treatment should be started with the less expensive drug, taking into account drug administration costs, required dose and product price per dose. This may need to be varied for individual patients due to differences in the method of administration and treatment schedules.

A combination of infliximab with azathioprine has been shown to be superior to monotherapy in inducing remission and mucosal healing in Crohn's patients naïve to both agents. The rate of infliximab-related infusion reactions was also less with combination treatment and there was no significant difference seen with the rate of serious infection (Colombel et al., 2010). For scheduled treatment, the concomitant immunomodulator should be reviewed and stopped after 6–12 months. It remains unclear whether the same applies to other anti-TNF agents. In practice, the same principles apply with other immunomodulators such as methotrextate.

Natalizumab should not be combined with an immunosuppressant or prolonged steroids as this may increase the risks of progressive multifocal leucoencephalopathy (D'Haens et al., 2010).

There is currently no specific guidance on how long anti-TNF agents should be continued for. Preliminary evidence suggests that many patients in clinical remission for greater than 1 year, with a normal C-reactive protein and complete mucosal healing on endoscopy will remain in remission during the following year after stopping treatment. Whether remission is then sustained or whether the behaviour of disease is altered in the long term is currently unknown (D'Haens et al., 2010). NICE guidance on the treatment of Crohn's disease recommends that infliximab or adalimumab treatment should be given until treatment failure (including the need for surgery) or until 12 months after initiation of treatment, whichever is shorter. Patients should then have their disease reassessed and continue treatment if there is clear evidence of ongoing active disease and treatment is still clinically appropriate. Treatment can be restarted if patients subsequently relapse.

Loss of response or intolerance to anti-TNF agents can be managed by optimising dosing regimes, switching to agents or switching class, for example, to natalizumab. Reasons for a loss of response should be assessed.

Monoclonal antibodies are contraindicated in patients with tuberculosis (TB) and, therefore, all patients should have a chest X-ray prior to administration to exclude latent TB. Infliximab increases the risk of TB five-fold. Other contraindications include moderate to severe cardiac failure, history of malignancy (excluding non-melanoma skin cancer), sepsis (including pelvic or perianal), optic neuritis. Intestinal stricturing is a relative contraindication (obstruction may be exacerbated through rapid healing at the stricture site) along with chronic hepatitis B/C carriers, primary failure or absence of inflammatory activity (normal C-reactive protein). Patients who receive live vaccines should not receive biological therapy for 3 months. Patients on biologics should be vaccinated against tetanus, pneumococcus species, influenza and hepatitis B. Young females should also be vaccinated for the human papilloma virus.

Anti-TNF agents should only be prescribed by a gastroenterologist with experience of IBD, and in the case of infliximab, administered in a setting where there are adequate resuscitation facilities available and patients are closely monitored. Patients self-administering adalimumab at home should be counselled on how to recognise signs of infection, for example, fever, productive cough, toothache, stinging on passing urine or if neurological symptoms develop.

Infliximab. Infliximab is a chimeric human murine monoclonal antibody, licensed for treating severe active Crohn's disease (with or without fistulae) which is refractory or intolerant to corticosteroids or conventional immunosuppressants alone or if surgery is inappropriate. Treatment may be repeated if the condition responded to the initial course but subsequently relapsed. Infliximab is also licensed for moderate to severe active ulcerative colitis (acute exacerbation) requiring hospitilisation and/or possible surgical intervention and if unresponsive to conventional treatments. Infliximab may half the need for colectomy in steroid refractory patients with acute ulcerative colitis. It remains to be determined whether infliximab is superior to ciclosporin (D'Haens et al., 2010).

In severe active Crohn's disease, infliximab is administered by intravenous infusion, at a dose of 5 mg/kg over a 2-h period, repeated after 2 weeks. If a clinical response is seen, then a maintenance dose of 5 mg/kg every 8 weeks should be given. Alternatively, a dose could be given when signs and symptoms recur. Fixed interval dosing may be superior to intermittent dosing because of the reduced risk of immunogenicity (NICE, 2010).

In active fistulising Crohn's disease where disease has not responded to conventional therapy (including antibiotics, drainage and immunosuppressive therapy) or who are intolerant or have contraindications to conventional therapy, an initial dose of 5 mg/kg is given, repeated at 2 and 6 weeks after the first infusion is given. If no response is seen after three doses, no further treatment should be given (NICE, 2010).

Trials in inflammatory Crohn's disease have shown an 81% response rate at 4 weeks. After 12 weeks, 48% of patients still had a response. In fistulising disease, 68% of patients experienced a 50% reduction in the number of draining fistulas at two or more consecutive visits. If a loss of response is seen the dose can be increased to 10 mg/kg (unlicensed) or the dosing interval shortened. An alternative is to switch treatment to adalimumab.

In treatment-refractory, moderate to severe acute exacerbation of ulcerative colitis, the licensed dose regimen is 5 mg/kg at weeks 0, 2 and 6. The optimal maintenance strategy after induction therapy is currently unknown. Treatment should be discontinued if no response is seen after 14 weeks. In azathioprine naïve patients responding to infliximab induction, azathioprine is an option instead of infliximab for maintenance (Travis et al., 2008). Although unlicensed, infliximab has shown to be of benefit in extra-intestinal manifestations such as pyoderma gangrenosum and peripheral and axial naturopathies

All doses should be preceded with intravenous corticosteroid (hydrocortisone 200 mg) unless the patient has been taking an immunosuppressant for more than 3 months.

In some patients, infliximab has been associated with either infusion (during or shortly after infusion) or delayed hypersensitivity reactions. It may also affect the normal body immune responses in a significant number of patients. Other side effects include headache, dizziness, nausea, rash, raised liver function tests, abdominal pain, fatigue, etc.

Adalimumab. Adalimumab is a fully humanised anti-TNF monoclonal antibody which is licensed for the treatment of severe active Crohn's disease in patients who are refractory or intolerant to corticosteroids and conventional immunomodulators. It may also be used in those patients who have primary or secondary non-response to infliximab or developed a hypersensitivity reaction. Unlike infliximab it is not licensed for acute ulcerative colitis.

As adalimumab is fully humanised it is less immunogenic than infliximab. It also has the advantage of being given as a subcutaneous injection which enables patients to self-administer at home, therefore reducing nursing time and hospital bed occupancy. This also lends itself to supply by home delivery services. The licensed dose is an initial induction of 80 mg followed by 40 mg at week 2 and then 40 mg on alternate weeks thereafter as maintenance. An accelerated dose of 160 mg followed by 80 mg and then 40 mg on alternate weeks maintenance is more commonly used, particularly in those patients who have previously been on infliximab. The maintenance dose can be increased to 40 mg weekly if a diminished or suboptimal response is seen but treatment should be stopped if no response is seen within 12 weeks of the initial dose.

Infliximab may be of benefit in patients initiated on adalimumab as the first-line anti-TNF agent but who lose response to, or develop adverse effects. The efficacy of infliximab in patients with no initial response to adalimumab needs to be evaluated.

Certolizumab. Certolizumab is a pegylated monoclonal antibody fragment TNF-α antibody. It is currently used for those patients who have lost response to or have become intolerant to infliximab or adalimumab. It is given at an induction dose of 400 mg subcutaneously at weeks 0, 2 and 4 and then if a response is seen, once every 4 weeks as maintenance.

Antibiotics

Metronidazole has been used in Crohn's disease associated with perianal disease, sepsis associated with fistulae, perforation and bacterial overgrowth in the small bowel. Doses of 0.6–1.5 g/day are typically used and well tolerated. Metronidazole appears to be ineffective in ulcerative colitis. The associated paraesthesia appears to be dose related, occurring frequently with treatment of greater than 3 months duration. In such patients, doses should be gradually reduced or the drug alternated with another antibiotic, for example, ciprofloxacin, tetracycline or rifabutin, which have shown some limited benefit. The metabolite of metronidazole has a free nitro group and this is probably responsible for the drug's local activity. It also inhibits phospholipase A, contributing to a reduction in damage induced by polymorphonuclear leucocytes.

Other antibacterials are used if specifically indicated, especially when the causative bacterial agents have been identified.

Pseudomembranous colitis caused by *C. difficile* usually occurs after prolonged or multiple antibiotics. This can be distinguished from other causes of colitis by biopsy and stool culture. If it is unclear whether a patient has pseudomembranous or acute colitis, treatment with metronidazole or vancomycin and steroids is advised. A colonoscopy can be performed once symptoms resolve.

Other treatments

Thalidomide. The use of thalidomide, under specialist supervision, is restricted to refractory cases of Crohn's disease. Thalidomide acts as a TNF-α inhibitor and probably stabilises lysosomal membranes. At therapeutic doses it also inhibits the formation of superoxide and hydroxyl radicals, both potent oxidants capable of causing tissue damage. Daily doses in the range of 50–400 mg have proved beneficial when used for periods of 1 week to several months. Side effects during treatment include sedation, dry skin and reduced libido. Thalidomide is teratogenic and should never be used in women of child-bearing age.

Antidiarrhoeals. Codeine diphenoxylate and loperamide should be used with caution to treat diarrhoea and abdominal cramping in IBD. Their use may mask inflammation, infection, obstruction or colonic dilation, thereby delaying correct diagnosis.

Colestyramine. Colestyramine has been used in Crohn's disease following ileal resection to reduce diarrhoea associated with bile acid malabsorption caused by the decrease in small bowel absorptive surface area and the cathartic effect of bile salts on the colon. Doses of up to 4 g three times a day inhibit the secretion of water and electrolytes stimulated by bile acids.

Fish oils (omega-3 fatty acids). Fish liver oils containing eicosapentaenoic and docosahexaenoic acids have been used with some success in the treatment of both ulcerative colitis and Crohn's disease. These products cause unpleasant regurgitation which renders them unpalatable in long-time use. Enteric-coated preparations have reduced this problem. It is thought that fish oils work by diverting fatty acid metabolism from leukotriene B4 to the formation of the less inflammatory leukotriene B5.

Miscellaneous treatments. There are many limited trials, studies and case series in the literature evaluating other therapies for ulcerative colitis and Crohn's disease. These include probiotics, sodium cromoglicate, bismuth and arsenic salts, sucralfate, nicotine, oxygen-derived free radical scavengers, somatostatin analogues, lidocaine, chloroquine, d-penicillamine, carbomers, antituberculous agents, heparin, aloe vera, probiotics and worm therapy (helminths). In general, these treatments are not recommended, although the variety illustrates the limitations of current therapy. When a patient is not responding to conventional agents, consideration should be given to referral to a specialist centre for a review of current therapy and a plan of future management. Alternative and complementary treatments, for example, acupuncture, aromatherapy may have a role.

Leukapheresis has been shown to have some benefit in patients with IBD. It involves removal of leucocytes from the blood, either through an adsorptive system or by centrifugation. In each system, venous blood is removed in a continuous flow, anticoagulated, processed to deplete the leukocytes and returned to the circulation (see NICE, 2005). Table 13.7 summarises the pharmacological profile of drugs used in adults with IBD.

Future treatments

Future therapy is focusing on the ability of drugs to target a specific point in the inflammatory process, such as TNF, interleukins (IL-10, 11, 12), T-cell surface antigens and stem cell transplantation.

Table 13.7 Pharmacological profile of drugs used in adults with inflammatory bowel disease

Pharmacological group	Daily dose	$t^{1/2}$ (h)	Metabolism
Steroids			
Hydrocortisone	125–250 mg as foam enema 100–400 mg in 0.9% w/v in sodium chloride intravenously	1.5	Hepatic metabolism 70% and 30% unchanged
Prednisolone	20–60 mg orally 20 mg as foam or liquid enema 5–10 mg as suppositories	3	Hepatic metabolism 70% and 30% unchanged
Budesonide	3–9 mg orally 20 mg as enema	2.8	90% hepatic metabolism
Aminosalicylates			
Mesalazine	500 mg–1.5 g as suppositories 1 g as enema 1.2–2.4 g orally	0.7–2.4	Local and systemic Hepatic acetylation, glucuronidation
Olsalazine	1–3 g orally	1.0	Local and systemic Hepatic acetylation, glucuronidation
Sulfasalazine	3 g as enema 1–2 g as suppositories 4–8 g orally	5–8	Colonic azo-reduction Local and systemic acetylation Hepatic glucuronidation
Balsalazide	3–6.75 g orally	1.0	Local and systemic hepatic acetylation
Antibiotics			
Metronidazole	600 mg–1.2 g orally 1.5 g intravenously	6–24	Hepatic metabolism
Immunosuppressants			
Azathioprine	2–2.5 mg/kg orally	3	Hepatic metabolism to 6-mercaptopurine
6-Mercaptopurine	1–1.5 mg/kg orally	1.5	Hepatic metabolism to inactive metabolite
Methotrexate	15–25 mg by intramuscular or subcutaneous injection weekly 15–25 mg orally weekly	3–10	Insignificant metabolism at low doses
Ciclosporin	2 mg/kg intravenously 5 mg/kg orally	19–27	Mainly hepatic metabolism
Monoclonal antibody			
Infliximab	5 mg/kg intravenous infusion every 8 weeks (maintenance)	8–9 days	Unknown
Adalimumab	40 mg subcutaneous injection every 2 weeks	10–19 days	Unknown
Certolizumab	400 mg subcutaneous injection every 4 weeks	14 days	Unknown
Miscellaneous			
Arsenic salts	250 mg–1 g rectally	72	Tissue deposition excreted unchanged
Bismuth salts	200 mg–1.2 g rectally	60–80	Tissue deposition excreted unchanged
Fish oils	3–4 g	None	Used in the arachidonic acid cycle
Sodium cromoglicate	200–800 mg orally 100–400 mg rectally	Unknown	Poorly absorbed, excreted unchanged in urine and bile
Nicotine	5–15 mg transdermally	0.5–2.0	Hepatic oxidation to cotinine 5% excreted unchanged
Lidocaine	200–800 mg rectally	1–2	Hepatic de-ethylation and hydrolysis 3% excreted unchanged Largely excreted unchanged
Human growth hormone	1.5–5 mg daily by subcutaneous injection	0.5–4	Unknown
Thalidomide	100–400 mg orally	7–16	Hydrolysis
Colestyramine	4–12 g orally		Not absorbed
Probiotics, for example, VSL#3	1–2 sachets daily orally		Poorly absorbed

Surgical treatment

Fifty to eighty percent of Crohn's disease patients will require surgery within 5–10 years of diagnosis. In contrast, 20–30% of ulcerative colitis patients will usually undergo colectomy with 5 years.

In ulcerative colitis, surgical colectomy, temporary ileostomy and ileoanal pouch construction are all curative. These are the surgical interventions of choice, although proctocolectomy and permanent ileostomy also have a role. Curative surgery is not possible in Crohn's disease as recurrence elsewhere in the gut is inevitable. Complications in the course of their illness result in about 70% of patients with Crohn's disease requiring at least one surgical procedure. If a significant length of gut is removed this can result in short gut syndrome which may require long-term parenteral nutrition and medication to control a high-output stoma if present, for example, PPIs, loperamide, codeine phosphate, isotonic fluids.

Patient care

The impact of a diagnosis of IBD should not be underestimated. In general, most patients are diagnosed when they are relatively young and the disease can have a significant effect on the rest of their life. In addition to managing symptoms, the condition can result in loss of education and difficulty in gaining employment or insurance. In young patients, it can cause psychological problems and growth failure or retarded sexual development. Anxiety and loss of self-esteem are commonly described. In addition to pharmacological treatments, psychological support is also important. Medical treatment with corticosteroids and immunosuppressants causes secondary health problems such as infection and surgery may result in complications such as intestinal failure. The care of patients with IBD is, therefore, a challenge for the multidisciplinary team.

All patients should be educated about their illness and medication and reminded that even in periods of remission it is important to continue taking prescribed therapy. This should take the form of verbal and written information. Drug use is invariably lifelong and patients are likely to receive several different treatments during the course of their illness due to intolerance or lack of response. Certain patients such as female or those newly diagnosed patients may require more tailored information about the condition or treatment. Patients with poor dexterity may find the use of rectal preparations difficult and these preparations may, therefore, be poorly tolerated. Leaflets about IBD and insurance or employment for patients with IBD have been prepared by the National Association for Colitis and Crohn's Disease (www.nacc.org.uk). Patients should also be warned about unreliable information sources.

Patients and primary care doctors may require additional reassurance as several of the treatments used, for example, azathioprine, are unlicensed for IBD. Regular blood monitoring of aminosalicylates and immunosuppressants is essential to ensure patients avoid toxicity associated with these drugs.

All patients taking steroids must be issued with a steroid card. Shared care policies between primary care doctors, gastroenterologists and patients may also be appropriate.

If relapse occurs in some patients, they are advised to increase the dose of their current oral therapy and/or commence rectal administration of a corticosteroid before contacting their doctor. If symptoms do not improve within 48 h they should arrange a review with their specialist.

Effective home treatment of proctitis is important because tenesmus and occasional faecal incontinence, apart from being distressing, limit further treatment. Good counselling on the administration of topical therapy is important to ensure effectiveness and adherence.

IBD affects young adults, so pregnancy is not uncommon. Poorly controlled IBD can affect fertility and pregnancy. Good nutrition, stopping smoking and adherence to medication is important. Active disease is a risk factor for pre-term delivery and low birth weight. Infertility associated with sulfasalazine therapy would indicate the use of alternative aminosalicylate therapy. With the exception of methotrexate, which is contraindicated in pregnancy, most drugs used in the treatment of IBD do not present a significant hazard. However, patients are strongly advised to first discuss any plans for pregnancy with their gastroenterologist. Care of pregnant women should be done jointly by a gastroenterologist and obstetrician.

Encouraging patients to stop smoking, especially those with Crohn's disease, can have a significant impact on the course of the disease.

Long-term steroid use and underlying IBD both contribute to a higher risk of developing osteoporosis. This is prevalent in up to 50% of the patient population with IBD. Patients with Crohn's disease appear more susceptible to osteoporosis than those with ulcerative colitis. Regular DEXA-scanning should be considered and preventive treatment with bisphosphonate and/or calcium and vitamin D supplements may be necessary. Guidance for the treatment of osteoporosis in IBD has been published by the British Society of Gastroenterology.

IBD patients often develop microcytic anaemia because of malabsorption and chronic blood loss. Assessment of the blood film and serum ferritin can differentiate between iron deficiency and anaemia of chronic disease. Oral iron supplements are generally poorly tolerated and parenteral iron may be required. Guidance of the treatment of iron-deficiency anaemia in IBD has been published (Gasche et al., 2007). Megaloblastic anaemias are uncommon, although vitamin B_{12} and folate deficiencies occur and may benefit from appropriate supplementation.

The European Crohn's and Colitis Organisation have published evidence-based consensus guidelines on the prevention, diagnosis and management of opportunistic infections in IBD (Rahier et al., 2009). These highlight which vaccinations should be offered on diagnosis of IBD. UK practice currently recommends influenza, and pneumococcal vaccine in immunosupressed patients only, along with HPV vaccines for females aged 12–18 years in line with other national guidelines. IBD patients in the UK are also advised to receive the swine flu vaccine if immunocompromised.

In 2009, National IBD Standards were published by key stakeholders involved in the care of patients with IBD to improve the service provided for people with a diagnosis of IBD across the UK. The aim of the standards is to ensure patients receive consistent, high-quality care and that IBD services throughout the UK are evidence based, engaged in local and national networking, based on modern IT and audit, meet specific minimum standards. The delivery of patient-focused care requires a multidisciplinary approach which should comprise medical gastroenterologist, nurse specialist, pharmacist, dietician, psychologist, colorectal surgeon, primary care doctor, radiologist and histopathologist.

Case studies

Case 13.1

Miss A has been receiving maintenance treatment with infliximab for Crohn's disease for the last 6 months but is now losing response and the decision is made to switch her to adalimumab. She weighs 65 kg and is currently taking azathioprine 100 mg daily and Adcal D$_3$ two tablets daily. She is hoping to start a family within the next year.

Questions

1. What dose of adalimumab (Humira®) should be prescribed?
2. For how long should combination treatment with azathioprine and adalimumab (Humira®) continue?
3. What advice would you give regarding immunisation for patients on biologic agents?
4. Is adalimumab (Humira®) safe in pregnancy and breastfeeding?

Answers

1. The licensed dosing schedule for severe active Crohn's disease is 80 mg, then 40 mg 2 weeks after initial dose or an accelerated regimen (more commonly used in practice) of 160 mg followed by 80 mg 2 weeks after initial dose; the maintenance dose is 40 mg on alternate weeks, increased if necessary to 40 mg weekly. Treatment should be reviewed if no response is seen within 12 weeks of the initial dose. Adalimumab is administered by subcutaneous injection.
2. The risk of developing immunogenicity and loss of response to adalimumab must be balanced against potential toxicities of combining biologic agents with immunosuppressants such as azathioprine. There is no definitive duration of overlap but a period of 6 months is common and then the immunomodulator can be stopped.
3. Patients should have annual vaccination against influenza (seasonal flu) and swine flu. Pneumococcal polysaccharide vaccine (doses at 0 and 3 years) is also recommended as anyone who gets a viral pneumonia when they are immunocompromised is at high risk of pneumococcal co-infection.
4. As adalimumab is a relatively new drug, little is known about its effect in pregnancy. The manufacturer advises to avoid and take adequate contraception during and for at least 5 months after the last dose. Patients should be advised that if they are planning a pregnancy or are already pregnant and are receiving adalimumab then they must inform their specialist. Adalimumab has been assigned to pregnancy category B by the FDA. Animal studies have revealed no teratogenic, embryotoxic or fetotoxic effects.

There are no controlled data in human pregnancy. Adalimumab is only recommended for use during pregnancy when benefit outweighs risk. To monitor outcomes of pregnant women exposed to adalimumab, a pregnancy registry has been established.

The priority is to keep the mother well and in remission. Although very low amounts of adalimumab may be transferred into breast milk, there is no risk to the baby, because adalimumab is a protein that is digested, so cannot be absorbed. The benefits of breastfeeding generally outweigh any theoretical risk while using adalimumab. Information changes rapidly, so it is important to discuss this with a specialist gastroenterologist.

Case 13.2

Miss B, a 30-year-old woman has a known history of ulcerative colitis and presents with bloody diarrhoea (12 motions/day), pyrexia, CRP 84 mg/L, platelets 545 × 10^9 L^{-1}, haemoglobin 10.5 g/dL. She is admitted to hospital for intensive medical management with intravenous and rectal steroids, fluid and electrolyte replacement and subcutaneous heparin.

Questions

1. What is the rationale for prescribing Miss B intravenous steroids and what biochemical monitoring should be undertaken?
2. Miss B is complaining of abdominal pain and the doctor is considering starting codeine phosphate or diclofenac. What advice would you give them?

   By day 3 of intensive therapy, Miss B is still passing more than six stools a day and her C-reactive protein remains greater than 45 mg/L. The decision is made to start infliximab. The patient weighs 65 kg.
3. What assessments should be made prior to administering infliximab?
4. What dose would you recommend and what advice would you give the nursing staff about administration?

Answers

1. Intravenous administration is appropriate as absorption of oral steroids could be erratic and unpredictable in severe inflammation or in patients who are systemically unwell. A parenteral steroid also ensures rapid attainment of drug levels. The mineralocorticoid properties of hydrocortisone may cause sodium and water retention, and hypokalaemia and glucocorticoid property may produce a rise in blood sugar levels. In case the patient requires second-line treatment with ciclosporin, a magnesium level and cholesterol level should be done.
2. Regular use of opiates such as codeine phosphate should be avoided as the resulting reduction in gastro-intestinal motility may precipitate a toxic megacolon and perforation. For this reason, antidiarrhoeal agents such as loperamide should also be avoided. NSAIDs, by reducing cyclo-oxygenase enzyme activity, may potentially increase production of proinflammatory leukotrienes and increase bleeding. Paracetamol is safe and may be prescribed. The anti-inflammatory action of the intravenous steroids should also reduce pain. However, pain is uncommon in ulcerative colitis because the inflammation is mucosal. The patient should be reviewed to ensure perforation is not overlooked.
3. Definite contraindications to anti-TNF therapy are sepsis, including pelvic or perianal sepsis, TB, optic neuritis or other demyelinating disorders, infusion reactions (previous sensitivity to either agent or murine products), cancer (past or present) or cardiac failure (moderate to severe NYHA III or IV – marked limitation of physical activity). Relative contraindications are pregnancy or breastfeeding, obstructive structuring disease

or surgery potentially inappropriate, chronic hepatitis B or C carriers, primary failure or loss of response, absence of inflammatory activity, that is, normal C-reactive protein.

A chest X-ray should be carried out +/− Mantoux test to rule out latent TB as infliximab increases the risk of TB five-fold. Indian or African ethnicity escalates the risk.

4. A 5 mg/kg dose should be prescribed (5 × 65 kg = 300 mg to the nearest whole vial) and infused over 2 h.

Rare infusion-related side effects are hypotension, shortness of breath and flushing. Blood pressure and pulse should be monitored every 30 min. Stopping the infusion temporarily often resolves the symptoms or they can be treated with antihistamines and paracetamol. Anaphylactic reactions are very rare but have been reported. If anaphylaxis occurs then future infusions are not advised. The patient is already receiving IV steroids to minimise the risk of hypersensitivity. Other side effects include lower respiratory tract infection and fatigue.

Case 13.3

Mr C was diagnosed with ulcerative colitis 12 months ago. His past medical history includes surgical resection and radiotherapy for squamous cell carcinoma of the mouth. As a result of this the patient has a Peg-J tube inserted for administration of enteral feed and medication. He is currently prescribed Pentasa® 2 g/day and a reducing course of prednisolone.

Question

1. Is Pentasa® suitable for administration via a Peg-J tube?

Answer

1. Pentasa® MR tablets disperse in water to give M/R granules which are slightly smaller than those in the sachets. However, the tablet contents can only be drawn into a catheter-tipped syringe owing to their size and will only flush down a 16 fr tube without blockage. The granules must not be crushed as this will destroy the modified release mechanism. As Peg-J tubes are typically smaller than 16 fr this preparation is unsuitable for Mr C as are all other oral modified release 5-ASA preparations. An alternative would be topical preparations if clinically appropriate or to consider changing to sulfasalazine liquid preparation.

Case 13.4

Mrs D is admitted to hospital for colectomy and formation of an ileostomy, following unsuccessful medical management of her ulcerative colitis. Her regular drug therapy on admission includes:
Pentasa® 1 g three times a day
Azathioprine 100 mg daily
Prednisolone 5–15 mg/day
Digoxin 125 μcg daily
Aspirin 75 mg daily

Questions

1. Following her operation, Mrs D's ileostomy output is high. What treatment approaches are available for managing high-output stomas?
2. What changes, if any, would you recommend to her current prescription?

Answers

1. High-output stomas lead to dehydration and metabolic disturbance, for example, hypokalaemia, hypernatraemia.

Drinking more can make the situation worse since this flushes the small intestinal contents through and exacerbates dehydration. Food and drink can promote secretion and increase volume.

The causes of high-output stomas need to be considered and may include high lactose intake, partial obstruction, gastric hypersecretion, inappropriate diet, laxatives and diuretics. Treatment options should include high-dose PPI to reduce gastric acid hypersecretion and codeine phosphate (180–240 mg/day) and/or loperamide to reduce gut motility. In the absence of a colon, a dose of loperamide that exceeds 16 mg/day can be used without adverse effect. Octreotide has been used as an alternative to the antimotility drugs but would appear to offer limited benefit and is best reserved for when other measures have been tried. Intake of isotonic fluids with a sodium concentration >90 mmol/L, to allow the jejunum to absorb water, may also be of benefit.

2. As ulcerative colitis is confined to the colon, following colectomy, the patient will no longer require medical treatment for maintenance of her ulcerative colitis, that is, Pentasa® and azathioprine and these can be stopped. Depending on how long the patient has been taking prednisolone, this should be reduced slowly to prevent withdrawal. If the stoma output remains high, careful monitoring of potassium levels should be taken to prevent digoxin toxicity. If potassium supplementation is given, oral modified release preparations should be avoided.

Case 13.5

Mr E was diagnosed with Crohn's disease 4 years ago and also suffers from gout. Although relatively well, during the last year he has required two courses of prednisolone. However, when the dose has been reduced, his symptoms have flared. The decision has been made to start Mr F on azathioprine. He weighs 70 kg.

Questions

1. What dose of azathioprine would you recommend for this patient to re-establish remission?
2. Are there any drugs Mr F should avoid while taking azathioprine?

Answers

1. A dose of 2–2.5 mg/kg should be recommended (150–175 mg). As azathioprine is a steroid-sparing agent this should enable prednisolone to be withdrawn.
2. One of the most significant drug interactions is with allopurinol which inhibits the principal pathway for detoxification of azathioprine and mercaptopurine. Patients receiving allopurinol concomitantly should have their dose of azathioprine reduced to approximately one-third to a quarter of the usual dose. NSAIDs which are often used to treat an acute flare of gout should be avoided in Crohn's disease.

Case 13.6

Mrs F, a 36-year-old woman, is unable to tolerate azathioprine or mercaptopurine for her Crohn's disease and has been started on oral methotrexate 25 mg once weekly.

Questions

1. What counselling points would you discuss with the patient regarding her methotrexate treatment?

2. What is the rationale for also prescribing folic acid?
3. Mrs F asks you if it is safe to become pregnant while taking methotrexate. What advice would you give her?

Answers

1. Methotrexate is effective in maintaining remission in Crohn's disease in patients who do not respond to or tolerate azathioprine or mercaptopurine. Like the thioguanines it has inflammatory and immunosuppressive properties which help to reduce the damage to the bowel wall which is responsible for the symptoms of Crohn's disease. It can take several weeks before patients start to feel the effects.

   Methotrexate should be taken once a week, on the same day of the week. Methotrexate is never taken every day. Methotrexate comes in tablet form in two different strengths: 2.5 and 10 mg. The two strengths are different shapes but are a similar colour. It is important that patients keep an up to date record of the dose they are taking and always check the strength of the tablet they have been given each time they get a prescription. To reduce the risk of confusion and possible overdose, many pharmacies only stock 2.5 mg strength tablets. If patients have problems swallowing large numbers of tablets (in this case 10 × 2.5 mg), they can be dispersed in water. As recommended by the NPSA (2006) in their 'Improving compliance with oral methotrexate' guidelines, patients should be given a monitoring card which details the dose, strength and quantity of tablets to be taken each week and blood test results.

   The most frequent side effects are nausea and vomiting (especially at start of treatment) which can be reduced by taking the dose with food; inflammation and soreness of the mouth, diarrhoea and rash or generalised itchiness. Hair loss can also occur but is reversible on stopping treatment.

   Mrs F should also be advised about the need for regular blood tests as methotrexate suppresses the bone marrow and can affect liver function. If they feel generally unwell or develop unexplained bruising, bleeding, sore throat, fever or malaise, they should contact their doctor. Methotrexate can cause inflammation in the lung tissue leading to a feeling of breathlessness or persistent cough. Although very rare, it should be reported to a doctor as soon as possible.

   Immunisation with live vaccines should also be avoided. Patient should receive vaccination for influenza, pneumococcal and swine flu.
2. Methotrexate is a folate antagonist. In patients who experience gastro-intestinal side effects, folic acid helps to reduce their frequency. It should be taken once weekly, 4 days after the methotrexate. As an aide memoire patients are often advised to take it on a Friday if they take methotrexate on a Monday.
3. It is not safe to take methotrexate during pregnancy. It is essential that men and women of child-bearing potential use a reliable form of contraception during treatment and for at least 3 months after treatment is stopped as methotrexate can damage the developing fetus. If patients are planning a family it is essential they discuss it with their doctor first.

Case 13.7

Mr G is newly diagnosed with mild ulcerative colitis. His abdominal X-ray suggests predominantly disease of the rectum and sigmoid colon. His past medical history includes joint stiffness due to rheumatoid arthritis. He presents at the pharmacy with a prescription for sulphasalazine tablets and Predfoam® one at night.

Questions

1. What advice would you give Mr G about the administration of Predfoam® enemas?
2. What are the side effects associated with the use of topical steroids?

   Mr G expresses concerns to the primary care doctor about the possibility of sulphasalazine impairing fertility as he and his wife hope to start a family. The primary care doctor decides to switch Mr G to mesalazine tablets, 800 mg taken three times a day.
3. Mesalazine 400 mg tablets are available in several different brands. Does it matter which brand is supplied?
4. Does mesalazine cause problems with fertility?

Answers

1. Rectal therapy is appropriate for mild left-sided disease. Enemas are best administered just before bedtime when the supine position allows longer retention times. Predfoam® comes in an aerosol can and the drug is delivered by attaching some plastic rectal tubes to the canister. A new tube is used for each dose. Patients with rheumatoid arthritis may have difficulty in using enemas and this may affect adherence and treatment success. The aerosol canister is flammable and care should be taken.
2. Prednisolone sodium metasulphobenzoate (Predfoam®) is poorly absorbed and the systemic side effects are minimal.
3. Once initiated, patients should remain on the same brand of mesalazine as different brands have different release profiles. Relapse of disease can occur if patients are inadvertently switched to another brand. Prescribers are encouraged to prescribe by brand and not by generic name.
4. Mesalazine does not cause problems with fertility, only sulfasalazine is associated with infertility and this only affects men. Sulfasalazine affects sperm but is reversible on stopping treatment.

Constipation and diarrhoea 14

P. Rutter

Key points

Constipation

- About 90% of people defaecate between three times a day and once every 3 days.
- Constipation is considered infrequent bowel action when it happens twice a week or less that involves straining to pass hard stools accompanied by a sensation of pain or incomplete evacuation.
- Constipation is usually not caused by a serious disease and is corrected by non-drug treatment.
- Non-drug treatment involves increasing fibre intake, increasing fluid intake and encouraging exercise.
- The four main groups of drugs used to treat constipation (bulk forming, stimulant, osmotic and faecal softener) all have proven efficacy compared to placebo.

Diarrhoea

- Diarrhoea is the passage of loose or watery stools, at least three times in a 24-h period, which may be accompanied by anorexia, nausea, vomiting, abdominal cramps or bloating.
- Gastroenteritis is the most common cause of diarrhoea in all age groups.
- In the UK, rotavirus and small round structured virus (SRSV) are the most common causes of gastroenteritis in children.
- In adults, Campylobacter followed by rotavirus are the most common causes.
- Blood in diarrhoea is classed as dysentery and indicates the presence of an invasive organism such as Campylobacter, Salmonella, Shigella or *Escherichia coli* O157.
- Dehydration is the main complication of acute diarrhoea. Oral rehydration solution is the mainstay of treatment, particularly in children and the elderly.
- Antimotility agents, for example, loperamide, diphenoxylate, codeine, may be given to adults with mild-to-moderate diarrhoea but are not recommended for use in children.

Constipation and diarrhoea are two of the most common disorders of the gastro-intestinal tract. Most adults will suffer from these disorders at some time in their life and while they are often self-limiting, they can cause significant morbidity or occur as a secondary feature to a more serious disorder. For example, constipation may be secondary to hypothyroidism, hypokalaemia, diabetes, multiple sclerosis or gastro-intestinal obstruction. Likewise, diarrhoea may be secondary to ulcerative colitis, Crohn's disease, malabsorption or bowel carcinoma.

Both constipation and diarrhoea can also be drug induced and this should be considered when trying to identify a likely cause and determine effective management.

Constipation

In Western populations, 90% of people defaecate between three times a day and once every 3 days. It is clear, therefore, that to base a definition of constipation on frequency alone is problematic. What is perceived to be constipation by one individual may be normal to another. Most definitions of constipation include infrequent bowel action of twice a week or less that involves straining to pass hard faeces and which may be accompanied by a sensation of pain or incomplete evacuation. A pragmatic definition would simply be the passage of hard stools less frequently than the patient's own normal pattern. Standard criteria for the diagnosis of diarrhoea are available (Longstreth et al., 2006), although they are seldom used in practice.

Incidence

Constipation affects all age groups but is more common in the elderly: up to 20% of elderly people, compared to 8% of middle-aged and 3% of young people, seek medical advice for constipation. In the elderly, poor diet, insufficient intake of fluids, lack of exercise, concurrent disease states and use of drugs that predispose to constipation have all been identified as contributory factors.

Constipation is reported to be twice as common in women than men, although this probably reflects the greater likelihood that they seek medical advice. Constipation is, however, common in late pregnancy (up to 40% of women) due to increased circulating oestrogens, reduced gastro-intestinal motility and delayed bowel emptying caused by displacement of the uterus against the colon. It has also been reported that between 5% and 10% of children have constipation and it is more common in formula-fed babies.

Aetiology

The digestive system can be divided into the upper and lower gastro-intestinal tract. The upper gastro-intestinal tract starts at the mouth and includes the oesophagus and stomach and is
Fig. 14.1 The lower gastro-intestinal tract.

responsible for the ingestion and digestion of food. The lower gastro-intestinal tract consists of the small intestine, large intestine (colon), rectum and anus (Fig. 14.1) and is responsible for the absorption of nutrients, conserving body water and electrolytes, drying the faeces and elimination.

The remains of undigested food are swept along the gastro-intestinal tract by waves of muscular contractions called peristalsis. These peristaltic waves eventually move the faeces from the colon to the rectum and induce the urge to defaecate. By the time the stool reaches the rectum it generally has a solid consistency because most of the water has been absorbed.

Normally there is a net uptake of fluid in the intestine in response to osmotic gradients involving the absorption and secretion of ions, and the absorption of sugars and amino acids. This process is under the influence of the autonomic nervous system (sympathetic and parasympathetic). In those situations where absorption increases, this will generally lead to constipation, whereas a net secretion will result in diarrhoea.

Agents that alter intestinal motility, either directly or by acting on the autonomic nervous system, affect the transit time of food along the gastro-intestinal tract. Since the extent of absorption and secretion of fluid from the gastro-intestinal tract generally parallels transit time, a slower transit time will lead to the formation of hard stools and constipation. Motility is largely under parasympathetic (cholinergic) control, with stimulation bringing about an increase in motility while antagonists such as anticholinergics, or drugs with anticholinergic side effects, decrease motility and induce constipation. This mechanism is distinct from that of the other major group of drugs that induce constipation, the opioids. Opioids cause constipation by maintaining or increasing the tone of smooth muscle, suppressing forward peristalsis, raising sphincter tone at the ileocaecal valve and anal sphincter, and reducing sensitivity to rectal distension. This delays passage of faeces through the gut, with a resultant increase in absorption of electrolytes and water in the small intestine and colon.

It is normally the lower section of the gastro-intestinal tract that becomes dysfunctional during constipation. For convenience, many classify constipation as originating from within the colon and rectum, or externally. Causes directly attributable to the colon or rectum include obstruction from

neoplasm, Hirschsprung's disease (absence of neurons in the diseased segment of the internal anal sphincter), outlet obstruction due to rectal prolapse or damage to the pudendal nerve, typically during childbirth. Causes of constipation outside the colon include poor diet, inadequate fibre intake, inadequate water intake, excessive intake of caffeine, use of medicines with constipating side effects or systemic disorders such as hypothyroidism, diabetic autonomic neuropathy, spinal cord injury, cerebrovascular accident, multiple sclerosis or Parkinson's disease.

Differential diagnosis

Constipation is a symptom and not a disease and can be caused by many different factors (Table 14.1) but the overwhelming majority of cases in non-elderly patients will be due to lack of dietary fibre. To aid diagnosis, questions need to be asked about the frequency and consistency of stools, nausea, vomiting, abdominal pain, distension, discomfort, mobility, diet and other concurrent symptoms or disorders the patient may be experiencing. It may also be necessary to ask about access to a toilet or commode. The individual with limited mobility may suppress the urge to defaecate because of difficulty in getting to the toilet. Likewise, lack of privacy or dependency on a nurse or carer for toileting may result in urge suppression that precipitates constipation or exacerbates an underlying predisposition. Patients with unexplained constipation of recent onset or a sudden aggravation of existing constipation associated with abdominal pain and the passage of blood or mucus, and long-standing constipation unresponsive to treatment require further investigation. Investigations include sigmoidoscopy/colonoscopy, barium enema, full blood count and biochemical monitoring including thyroid function tests (Fig. 14.2).

General management

In uncomplicated constipation, education and advice on diet and exercise are the mainstays of management and may adequately control symptoms in many individuals. Typically this advice will include reassurance that the individual does not have cancer, that the normal frequency of defaecation varies widely between individuals, and that mild constipation is not in itself harmful.

If the patient is taking medication for a concurrent disorder this must be assessed for its propensity to cause constipation. In the UK, over 700 medicinal products, including ophthalmic preparations, have constipation listed as a possible side effect. Common examples of medicines involved are presented in Table 14.2.

Non-drug treatment

Non-drug treatment is advocated as first-line therapy for all patient groups, except those who are terminally ill. This often includes advising an increase in fluid intake at the same time as reducing strong or excessive intake of tea or coffee, since these act as a diuretic and serve to make constipation worse.

Table 14.1   Causes of constipation

Cause	Comment
Poor diet	Diets high in animal fats, for example, meats, dairy products, eggs, and refined sugar, for example, sweets, but low in fibre predispose to constipation
Irritable bowel syndrome	Spasm of colon delays transit of intestinal contents. Patients have a history of alternating constipation and diarrhoea
Poor bowel habit	Ignoring and suppressing the urge to have a bowel movement will contribute to constipation
Laxative abuse	Habitual consumption of laxatives necessitates increase in dose over time until intestine becomes atonic and unable to function without laxative stimulation
Travel	Changes in lifestyle, daily routine, diet and drinking water may all contribute to constipation
Hormone disturbances	For example, hypothyroidism, diabetes. Other clinical signs should be more prominent, for example, lethargy and cold intolerance in hypothyroidism and increased urination and thirst in diabetes
Pregnancy	Mechanical pressure of womb on intestine and hormonal changes, for example, high levels of progesterone
Fissures and haemorrhoids	Painful disorders of the anus often lead patients to suppress defaecation, leading to constipation
Diseases	Many disease states may have constipation as a symptom, for example, scleroderma, lupus, multiple sclerosis, depression, Parkinson's disease, stroke
Mechanical compression	Scarring, inflammation around diverticula and tumours can produce mechanical compression of intestine
Nerve damage	Spinal cord injuries and tumours pressing on the spinal cord affect nerves that lead to intestine
Colonic motility disorders	Peristaltic activity of intestine may be ineffective, resulting in colonic inertia
Medication	See Table 14.2
Dehydration	Insufficient fluid intake or excessive fluid loss. Water and other fluids add bulk to stools, making bowel movements soft and easier to pass
Immobility	Prolonged bedrest after an accident, during an illness or general lack of exercise
Electrolyte abnormalities	Hypercalcaemia, hypokalaemia

It is generally recommended that fibre intake in the form of fruit, vegetables, cereals, grain foods, wholemeal bread, etc. be increased to about 30 g/day. The amounts of fibre in commonly eaten foods have been published (MeReC, 2004). Such a diet should be tried for at least 1 month to determine if it has an effect. Most will notice an effect within 3–5 days. Unfortunately, a high-fibre diet is not without problems, with patients complaining of flatulence, bloating and distension, although these effects should diminish over a period of several months. Patients who increase their fibre intake must also be advised to drink 2 L of water a day. Where an intake of this volume cannot be ingested it will be necessary to avoid increasing dietary fibre. An increased level of exercise should also accompany the raised fibre intake as this is thought to help relax and contract the abdominal muscles and help food move more efficiently through the gut.

A high-fibre diet is not recommended in those with megacolon or hypotonic colon/rectum because they do not respond to bulk in the colon. Similarly, a high-fibre diet may not be appropriate in those with opioid-induced constipation.

Drug treatment

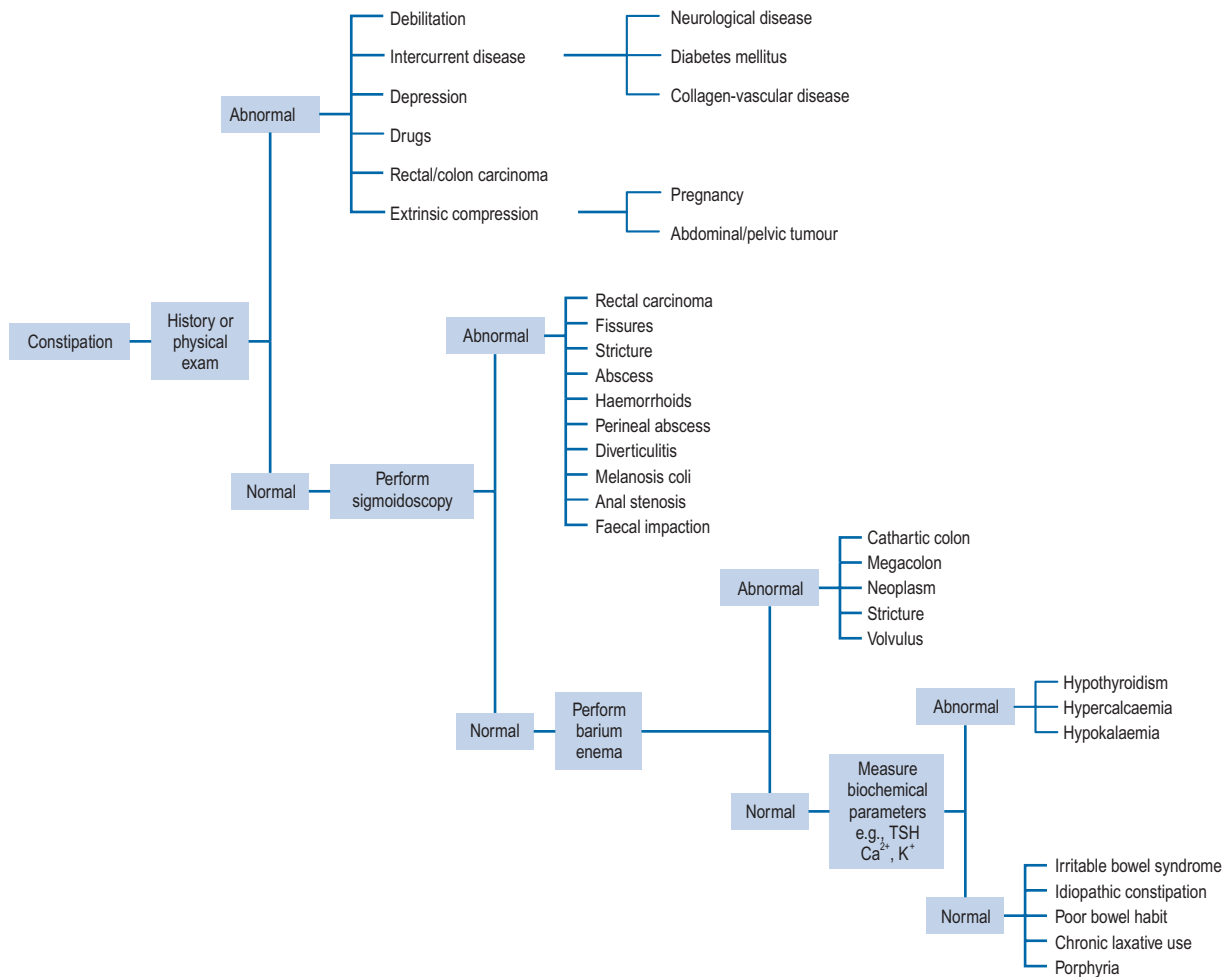
Drug treatment is indicated where there is faecal impaction, constipation associated with illness, surgery, pregnancy, poor diet, where the constipation is drug induced, where bowel strain is undesirable, and as part of bowel preparation for surgery. The various laxatives available can be classified as bulk forming, stimulant, osmotic and faecal softeners. A systematic review (Tramonte et al., 1997) identified 36 trials involving 1815 participants that met their inclusion criteria. Twenty of the trials compared laxative against placebo or regular diet, 13 of which demonstrated statistically significant increases in bowel movement. The remaining 16 trials compared different types of laxatives with each other. The review concluded that laxative use was superior to placebo but due to a lack of comparative data could not conclude which laxative group was most efficacious. Further, more recent reviews have found good evidence that macrogols are effective, as are ispaghula husk and bisacodyl, although data is still lacking on which laxative is best (Frizelle and Barclay, 2007).


Fig. 14.2 A diagnostic algorithm for constipation.

In general, the fit, active, elderly person should be treated as a younger adult. In contrast, management of constipation in children is often complex. Early treatment is required in children to avoid developing a megarectum, faecal impaction and overflow incontinence. Encouraging the child to use the toilet after meals and increasing dietary fibre have a role alongside oral drug treatment. Depending on circumstances, behavioural therapy may be indicated. In pregnancy, if drug treatment is required, bulk-forming laxatives are first choice, but if stools remain hard then either changing to or adding in lactulose or a macrogol is advocated. Conversely, if stools are soft but the woman still finds difficulty in passing stools then a stimulant laxative should be considered.

Bulk-forming agents. Ispaghula, methylcellulose, sterculia and bran are typical bulk-forming agents and are usually taken as granules, powders or tablets. Their use is most appropriate in situations where dietary intake of fibre cannot be increased and the patient has small hard stools, haemorrhoids or an anal fissure.

The mechanism of action for bulk-forming agents involves polysaccharide and cellulose components that are not digested and which retain fluid, increase faecal bulk and stimulate peristalsis. They may also encourage the proliferation of colonic bacteria and this helps further increase faecal bulk and stool softness. Following ingestion it usually takes 12–36 h before any effect is seen but it may take longer. An adequate volume of fluid should also be ingested to avoid intestinal obstruction. Bulk-forming agents can be used safely long term, during pregnancy or breast feeding but many users will experience problems with flatulence and distension. The use of bulk-forming agents is not recommended in patients with colonic atony, intestinal obstruction or faecal impaction and they are less effective, or may even exacerbate constipation, in those who lack mobility.

Stimulant laxatives. Drugs in this group include bisacodyl, senna and dantron. They directly stimulate colonic nerves that cause movement of the faecal mass, reduce transit time and result in the passage of stool within 8–12 h. As a consequence of their time to onset, oral dosing at bedtime is generally recommended. For a rapid action (within 20–60 min), suppositories can be used. Abdominal cramps are common as an immediate side effect of stimulant laxatives, while electrolyte disturbances and an atonic colon may result from chronic use.

In the elderly, atonic colon is of less concern and prolonged use may be appropriate in a few cases. Stimulant laxatives should be avoided in patients with intestinal obstruction, and

Table 14.2 Examples of medicines known to cause constipation (frequency defined as very common [>10%] or common [1–10%])

α-Blocker	Prazosin
Antacid	Aluminium and calcium salts
Anticholinergic	Trihexyphenidyl, hyoscine, oxybutynin, procyclidine, tolterodine
Antidepressant	Tricyclics, SSRIs, reboxetine, venlafaxine, duloxetine, mirtazepine
Antiemetic	Palonosetron, dolasetron, aprepitant
Antiepileptic	Carbamazepine, oxcarbazepine
Antipsychotic	Phenothiazines, haloperidol, pimozide and atypical antipsychotics such as amisulpride, aripiprazole, olanzapine, quetiapine, risperidone, zotepine, clozapine
Antiviral	Foscarnet
β-Blocker	Oxprenolol, bisoprolol, nebivolol; other β-blockers cause constipation more rarely
Bisphosphonate	Alendronic acid
CNS stimulant	Atomoxetine
Calcium channel blocker	Diltiazem, verapamil
Cytotoxic	Bortezomib, buserelin, cladribine, docetaxel, doxorubicin, exemestane, gemcitabine, irinotecan, mitozantrone, pentostatin, temozolomide, topotecan, vinblastine, vincristine, vindesine, vinorelbine
Dopaminergic	Amantadine, bromocriptine, carbegolide, entacapone, tolcapone, levodopa, pergolide, pramipexole, quinagolide
Growth hormone antagonist	Pegvisomant
Immunosuppressant	Basiliximab, mycophenolate, tacrolimus
Lipid-lowering agent	Colestyramine, colestipol, rosuvastatin, atorvastatin (other statins uncommon) gemfibrozil
Iron	Ferrous sulphate
Metabolic disorder	Miglustat
Muscle relaxant	Baclofen
NSAID	Meloxicam; other NSAIDs, for example, aceclofenac, and COX-2 inhibitors reported as uncommon
Smoking cessation	Bupropion
Opioid analgesic	All opioid analgesics and derivatives
Ulcer healing	All proton pump inhibitors, sucralfate

dantron alone, or in combination with a faecal softener, is restricted for use in constipation in terminally ill patients of all ages, because animal studies have demonstrated that it has carcinogenic and genotoxic properties.

 Osmotic laxatives. Osmotic laxatives include magnesium salts, phosphate enemas, sodium citrate enemas, lactulose and macrogols. These agents retain fluid in the bowel by osmosis or change the water distribution in faeces to produce a softer, bulkier stool. Their ingestion should be accompanied by an appropriate fluid intake.

Rectal preparations of phosphates and sodium citrate are useful for quick relief, within 30 min, and bowel evacuation before abdominal radiological procedures, sigmoidoscopy and surgery. Oral magnesium salts such as the sulphate are also indicated for rapid bowel evacuation and have an effect within 2–5 h.

Lactulose is a semisynthetic disaccharide, which is not absorbed from the gut. It increases faecal weight, volume and bowel movement and must be taken regularly. It may take 48 h or longer to work. It is also useful in the treatment of hepatic

encephalopathy since it produces an osmotic diarrhoea of low faecal pH that discourages the growth of ammonia-producing organisms. Macrogols are inert polymers of ethylene oxide which induce a laxative effect by sequestering fluid in the bowel and like lactulose may take 48 h or more to exert an effect.

Faecal softeners/emollient laxatives. Docusate sodium is a non-ionic surfactant that has stool-softening properties. It reduces surface tension, increases the penetration of intestinal fluids into the faecal mass and has weak stimulant properties. Rectal docusate has a rapid onset of action but should not be used in individuals with haemorrhoids or anal fissure.

The classic lubricant, liquid paraffin, has no place in modern therapy. It seeps from the anus and is associated with granulomatous reactions following absorption of small quantities, lipoid pneumonia following aspiration and malabsorption of fat-soluble vitamins.

Diarrhoea

Diarrhoea is defined as the increased passage of loose or watery stools relative to the person's usual bowel habit. It may be accompanied by anorexia, nausea, vomiting, abdominal cramps or bloating. It is not a disease but a sign of an underlying problem such as an infection or gastro-intestinal disorder. The most likely cause of diarrhoea in all age groups is viral or bacterial infection; therefore, the following section primarily focuses on acute infective gastroenteritis but also includes reference to drug-induced diarrhoea. Diarrhoea can be associated with other conditions, for example, irritable bowel syndrome, inflammatory bowel disease, colorectal cancer and malabsorption syndromes, but these will not be covered here.

Acute gastroenteritis is most common in children but the precise incidence is not known because many cases are self-limiting and not reported. Nevertheless, diarrhoeal illness in children leads to high consultation rates with primary care doctors and accounts for one in five consultations in the 0–4 age group. It has been estimated that children under the age of 5 years have between one and three bouts of diarrhoea per year. Children in the same age range account for over 5% of consultations to primary care doctors, with 18,000 children a year in England and Wales being admitted to hospital with rotavirus infection.

The incidence of diarrhoea in adults is, on average, just under one episode per person each year. Many of these cases are thought to be food related, with 22% of those consulting a doctor claiming to have 'food poisoning'. Traveller's diarrhoea is another common cause of diarrhoea. For high-risk travel to areas such as Africa, Asia and South America, the reported incidence is more than 20%. Over recent years, *Escherichia coli* O157 has gained prominence because of a number of outbreaks in different communities associated with severe disease and even death. It is, however, an uncommon cause of diarrhoea, accounting for only 0.1% of all cases.

Aetiology

In the UK, rotavirus and small round structured virus (SRSV) are the most common identified causes of gastroenteritis in children. In adults, Campylobacter followed by rotavirus are the most common causes, although rates of norovirus have reported to be on the increase. Other identified causes include: the bacteria *E. coli*, Salmonella, Shigella, *Clostridium perfringens* enterotoxin; viruses such as adenovirus and astrovirus; and the protozoa Cryptosporidium, Giardia and Entamoeba. These pathogens produce diarrhoea via a number of methods: for example, enterotoxigenic *E. coli* produce enterotoxins that affect gut function with secretion and loss of fluids; by interfering with normal mucosal function, for example, adherent enteropathogenic *E. coli*; or by causing injury to the mucosa and deeper tissues, for example, enteroinvasive *E. coli* or enterohaemorrhagic *E. coli* such as *E. coli* O157. Other organisms, for example, *Staphylococcus aureus* and *Bacillus cereus*, produce preformed enterotoxins which on ingestion induce rapid-onset diarrhoea and vomiting that usually last less than 12 h.

So-called traveller's diarrhoea frequently affects people travelling from an area of more developed standards of hygiene to a less developed area. In many instances, the cause remains unknown, even after stool culture, but where a pathogen is identified, bacterial infection is responsible in over 80% of cases, and associated with ingestion of contaminated food or water and occurs during or shortly after travel. Bacterial pathogens commonly isolated include *E. coli*, Shigella, Salmonella, Campylobacter, Vibrio and Yersinia species. Viruses (10–15% of cases) and parasites (2–10% of cases), such as norovirus, Giardia, Cryptosporidium and Entamoeba, account for the remainder.

Many medicines, particularly broad-spectrum antibiotics such as ampicillin, erythromycin and neomycin, induce diarrhoea secondary to therapy (Table 14.3). With these antibiotics the mechanism involves the overgrowth of antibiotic-resistant bacteria and fungi in the large bowel after several days of therapy. The diarrhoea is generally self-limiting. However, when the overgrowth involves *Clostridium difficile* and the associated production of its bacterial toxin, life-threatening pseudomembranous colitis may be the outcome.

Signs and symptoms

Acute-onset diarrhoea is associated with loose or watery stools that may be accompanied by anorexia, nausea, vomiting, abdominal cramps, flatulence or bloating. When there is blood in the diarrhoea this is classed as dysentery and indicates the presence of an invasive organism such as Campylobacter, Salmonella, Shigella or *E. coli* O157.

The history of symptom onset is important. The duration of diarrhoea, whether other members of the family and contacts are ill, recent travel abroad, food eaten, antibiotic use and weight loss are all important factors to elucidate. The possibility of underlying diseases such as AIDS or infective proctitis in homosexual men must also be considered.

Dehydration is a common problem in the very young and frail elderly and the signs and symptoms must be recognised.

Table 14.3 Examples of medicines known to cause diarrhoea (defined as very common [>10%] or common [1–10%])

α-Blocker	Prazosin
ACE inhibitor	Lisinopril, perindopril
Angiotensin receptor blocker	Telmisartan
Acetylcholinesterase inhibitor	Donepezil, galantamine, rivastigmine
Antacid	Magnesium salts
Antibacterial	All
Antidiabetic	Metformin, acarbose
Antidepressant	SSRIs, clomipramine, venlafaxine
Antiemetic	Aprepitant, dolasetron
Antiepileptic	Carbamazepine, oxcarbagepine, tiagabine, zonisamide, pregabalin, levtiracetam
Antifungal	Caspofungin, fluconazole, flucytosine, nystatin (in large doses), terbinafine, voriconazole
Antimalarial	Mefloquine
Antiprotozoal	Metronidazole, sodium stibogluconate
Antipsychotic	Aripiprazole
Antiviral	Abacavir, emtricitabine, stavudine, tenofovir, zalcitabine, zidovudine, amprenavir, atazanavir, indinavir, lopinavir, nelfinavir, saquinavir, efavirinez, ganciclovir, valganciclovir, adefovir, oseltamivir, ribavrin, fosamprenavir
β-Blocker	Bisoprolol, carvedilol, nebivolol
Bisphosphonate	Alendronic acid, disodium etidronate, ibandronic acid, risedronate, sodium clodronate, disodium pamidronate, tiludronic acid
Cytokine inhibitor	Adalimumab, infliximab
Cytotoxic	All classes of cytotoxics
Dopaminergic	Levodopa, entacapone
Growth hormone antagonist	Pegvisomant
Immunosuppressant	Ciclosporin, mycophenolate, leflunomide
NSAID	All
Ulcer healing	All proton pump inhibitors
Vaccine	Pediacel (5 vaccines in 1), haemophilus, meningococcal
Miscellaneous	Calcitonin, strontium ranelate, colchicine, dantrolene, olsalazine, anagrelide, nicotinic acid, pancreatin, eplerenone, acamprosate

In children, the severity of dehydration is most accurately determined in terms of weight loss as a percentage of body weight prior to the dehydrating episode. Unfortunately, in the clinical situation pre-illness weight is rarely known; therefore, clinical signs of dehydration must be assessed. National Institute for Health and Clinical Excellence (2009) has issued guidance on assessing the level of dehydration in children under 5 years of age and appropriate fluid management depending on the level of dehydration. Symptoms that could indicate mild dehydration are vague and include tiredness, anorexia, nausea and light-headedness.

Symptoms become more prominent in moderate dehydration and include dry mucous membranes, sunken eyes, decreased

skin turgor (pinch test of 1–2 s or longer), tachycardia, apathy, dizziness and postural hypotension. In severe dehydration, the above symptoms are more marked and may also include hypovolaemic shock, oliguria or anuria, cold extremities, a rapid and weak pulse and low or undetectable blood pressure.

Investigations

Before any investigations are undertaken a medication history is required to eliminate antibiotic- and other drug-induced diarrhoeas, or the possibility of a laxative overuse-induced diarrhoea. Testing for *C. difficile*-induced pseudomembranous colitis is indicated in those with severe symptoms or where hospitalisation or antibiotic therapy with lincomycins, broad-spectrum β-lactams or cephalosporins has occurred within the preceding 6 weeks.

In general, stool culture is required in patients who are immunocompromised, with bloody diarrhoea, severe symptoms, where there is no improvement within 48 h. Stool culture is also required when there is a history of recent overseas travel to non-Western countries.

Where the diarrhoea persists for more than 10 days, further investigation should be undertaken to exclude parasites such as Giardia, Entamoeba and Cryptosporidium. Acute, severe or persistent diarrhoea in a homosexual male or patient with AIDS warrants referral for specialist advice.

Treatment

Acute infective diarrhoea, including traveller's diarrhoea, is usually a self-limiting disorder. However, depending on the causative agent, a number of complications may have to be dealt with. Dehydration and electrolyte disturbance can be readily treated but may, if severe, progress to acidosis and circulatory failure with hypoperfusion of vital organs, renal failure and death. Toxic megacolon due to infective colitis has been documented; associated arthritis or Reiter's syndrome may complicate the invasive diarrhoeas of Campylobacter and Yersinia; Salmonella species may infiltrate bones, joints, meninges and the gallbladder; and *E. coli* infection may, for example, be complicated by haemolytic uraemic syndrome.

General measures

Patients should be advised on handwashing and other hygiene-related issues to prevent transmission to other family members. Promotion of handwashing has been shown to decrease diarrhoeal episodes by approximately one-third (Ejemot et al., 2008). Exclusion from work or school until the patient is free of diarrhoea is advised. In acute, self-limiting diarrhoea, children, healthcare workers and food handlers should be symptom free for 48 h before returning to school or work. More exacting criteria for return to work, such as testing for negative stool samples, are rarely required.

In both children and adults, normal feeding should be restarted as soon as possible. In weaned and non-weaned children with gastroenteritis, early feeding after rehydration has been shown to result in higher weight gain, no deterioration or prolongation of the diarrhoea and no increase in vomiting or lactose intolerance (Conway and Ireson, 1989, Sandhu et al., 1997). Similarly, breast-feeding infants should continue to feed throughout the rehydration and maintenance phases of therapy. Avoidance of milk or other lactose-containing food is seldom justified.

Dehydration treatment

Since diarrhoea results in fluid and electrolyte loss, it is important to ensure the affected individual maintains adequate fluid intake. Most patients can be advised to increase their intake of fluids, particularly fruit juices with their glucose and potassium content, and soups because of their sodium chloride content. High-carbohydrate foods such as bread and pasta can also be recommended because they promote glucose and sodium co-transport.

Young children and the frail elderly are prone to diarrhoea-induced dehydration and use of an oral rehydration solution (ORS) is recommended. The formula recommended by the World Health Organization (WHO) contains glucose, sodium, potassium, chloride and bicarbonate in an almost isotonic fluid. A number of similar preparations are available commercially in the form of sachets that require reconstitution in clean water before use (Table 14.4). Glucose concentrations between 80 and 120 mmol/L are needed to optimise sodium absorption in the small intestine. Glucose concentrations in excess of 160 mmol/L will cause an osmotic gradient that will result in increased fluid and electrolyte loss. High sodium solutions, in excess of 90 mmol/L, may lead to hypernatraemia, especially in children, and should be avoided. Until recently, the WHO ORS contained 90 mmol/L sodium, as cholera is more common in developing countries and associated with rapid loss of sodium and potassium. However, a systematic review of trials using a reduced osmolarity ORS (Hahn et al., 2002) concluded that solutions with a reduced

Table 14.4	Composition of oral rehydration solutions					
	Osmolarity (mOsm/L)	Glucose (mmol/L)	Sodium (mmol/L)	Chloride (mmol/L)	Potassium (mmol/L)	Base (mmol/L)
Dioralyte®	240	90	60	60	20	Citrate 10
Electrolade®	251	111	50	40	20	Bicarbonate 30
WHO ORS	245	75	75	65	20	Citrate 10

osmolarity compared to the standard WHO formula were associated with fewer unscheduled intravenous infusions, a trend towards reduced stool output and less vomiting in children with mild-to-moderate diarrhoea. Based on this and other findings, the WHO ORS now has a reduced osmolarity of 245 mOsm/L and contains 75 mmol of sodium.

Commercially available solutions in the UK contain lower sodium concentrations as diarrhoea tends to be isotonic, and therefore replacement of large quantities of sodium is less important and indeed may be harmful. The presence of potassium prevents hypokalaemia occurring in the elderly, especially in those taking diuretics. ORS should be routinely used in both primary and secondary care settings. There appears to be no significant difference between intravenous and oral rehydration (Gavin et al., 1996).

For healthy adults, an appropriate substitute for a rehydration sachet is 1 level teaspoonful of table salt plus 1 tablespoon of sugar in 1 L of drinking water. The volume of ORS to be taken in treating mild-to-moderate diarrhoea is dependent on age. In adults, 2 L of oral rehydration fluid should be given in the first 24 h, followed by unrestricted normal fluids with 200 mL of rehydration solution per loose stool or vomit. For children, 30–50 mL/kg of an ORS should be given over 3–4 h. This can be followed with unrestricted fluids, either with normal fluids alternating with ORS or normal fluids with 10 mL/kg rehydration solution after each loose stool or vomit (Murphy, 1998). The solution is best sipped every 5–10 min rather than drunk in large quantities less frequently.

Care is required in diabetic patients who may need to monitor blood glucose levels more carefully.

Drug treatment

Antimotility agents. In acute diarrhoea, antimotility agents such as loperamide, diphenoxylate and codeine are occasionally useful for symptomatic control in adults who have mild-to-moderate diarrhoea and require relief from associated abdominal cramps. Antimotility agents are not recommended for use in children as trial results appear contradictory and any benefits are small with unacceptable levels of side effects observed. Management should initially focus on prevention or treatment of fluid and electrolyte depletion before antimotility agents are considered.

Antimotility agents should be avoided in severe gastroenteritis or dysentery because of the possibility of precipitating ileus or toxic megacolon. All appear to have comparable efficacy but loperamide is the drug of choice given its low incidence of CNS effects.

Diphenoxylate. Diphenoxylate is a synthetic opioid available as co-phenotrope in combination with a subtherapeutic dose of atropine. The atropine is present to discourage abuse but may cause atropinic effects in susceptible individuals. Administration of co-phenotrope at the recommended dosage carries minimal risk of dependence. However, prolonged use or administration of high doses may produce a morphine-type dependence. Its adverse effect profile resembles that of morphine.

In cases of suspected overdose, signs may be delayed for up to 48 h. Young children are particularly susceptible to diphenoxylate overdose where as few as 10 tablets of co-phenotrope may be fatal.

Concurrent use of diphenoxylate with monoamine oxidase inhibitors can precipitate a hypertensive crisis, while the action of CNS depressants such as barbiturates, tranquillisers and alcohol is enhanced.

Loperamide. Loperamide is a synthetic opioid analogue that exerts its action by binding to opiate receptors in the gut wall, reducing propulsive peristalsis, increasing intestinal transit time, enhancing the resorption of water and electrolytes, reducing gut secretions and increasing anal sphincter tone. In uncomplicated diarrhoea, it may have an effect within 1 h of oral administration. It is relatively free of CNS effects at therapeutic doses, although CNS depression may be seen in overdose, particularly in children. As it undergoes hepatic metabolism it should be used with caution in patients with hepatic dysfunction.

Codeine and morphine. The constipating side effect of the opioid analgesics codeine and morphine may be used to treat diarrhoea. Both are susceptible to misuse and, given in large doses, may induce tolerance and psychological and physical dependence. Morphine may still be obtained in combination with agents such as the adsorbent kaolin, for example, kaolin and morphine. However, it has no evidence of efficacy in the treatment of diarrhoea and should not be recommended.

Bismuth subsalicylate. Bismuth subsalicylate is an insoluble complex of trivalent bismuth and salicylate that has been shown to be effective in reducing stool frequency. It possesses antimicrobial activity on the basis of its bismuth content while the salicylate is considered to confer antisecretory properties. At therapeutic doses it is relatively free from side effects, although it may cause blackening of the tongue and stool. The relatively large quantity of the liquid preparation that has to be consumed is seen as a disadvantage.

Antimicrobials. Antibiotics are generally not recommended in diarrhoea associated with acute infective gastroenteritis. Inappropriate use will only contribute further to the problem of resistant organisms. There is, however, a place for antibiotics in patients with positive stool culture where the symptoms are not receding or for travellers' diarrhoea (De Bruyn et al., 2000). In patients presenting with dysentery or suspected exposure to bacterial infection, treatment with a quinolone, for example, ciprofloxacin, may be appropriate. However, quinolones are not without their problems: they may cause tendon damage or induce convulsions in epileptics, in situations that predispose to seizures, and in patients taking NSAIDs. Their use in adolescents is also not recommended because of an association with arthropathy.

Where Campylobacter is the suspect causative organism, patients with severe symptoms or dysentery should receive early treatment with erythromycin or ciprofloxacin. Severe symptoms or dysentery associated with Shigella can also be treated with ciprofloxacin. Nalidixic acid can be used in children and trimethoprim may be appropriate in pregnant women where resistance is not a problem.

The use of antibiotics in patients with Salmonella is not generally recommended because of the likelihood that excretion

is prolonged. Antibiotics may, however, be indicated in the very young and the immunocompromised. The benefit of antibiotic use in enterohaemorrhagic infection, for example, *E. coli* O157, is less clear. In this situation, there is evidence that antibiotics cause toxins to be released which may lead to haemolytic uraemic syndrome.

In both amoebic dysentery and giardiasis, metronidazole is the drug of choice. Diloxanide is also used in amoebic dysentery to ensure eradication of the intestinal disease. Antibiotics are not indicated in the treatment of cryptosporidiosis in immunocompromised individuals.

Probiotics. Probiotics have been defined as components of microbial cells or microbial cell preparations that have a beneficial effect on health. Well-known probiotics include lactic acid bacteria and the yeast Saccharomyces. The rationale for their use in infectious diarrhoea is that they act against enteric pathogens by competing for available nutrients and binding sites, making gut contents acid and increasing immune responses. A Cochrane review (Allen et al., 2003) concluded that whilst probiotics in individual studies appeared moderately effective as adjunctive therapy, there were insufficient studies of specific probiotic regimens to inform the development of evidence-based treatment guidelines.

Zinc. The use of zinc has been reviewed in the treatment of diarrhoea in children in developing countries (Lazzerini et al., 2008). In this context, zinc has been shown to be of value in children older than 6 months, probably because they have some prior, underlying deficiency of zinc.

Rotavirus vaccine. Rotavirus vaccine has been shown to protect against the most common strains of rotavirus (G1 and G3), although the benefits of the vaccine are dependant on the type of vaccine used, with rhesus and human rotavirus the most efficacious (Soares-Weiser, 2004).

Some of the common therapeutic problems in the management of individuals with constipation and diarrhoea are outlined in Table 14.5.

Table 14.5 Common therapeutic problems in constipation and diarrhoea

Problem	Comment
Constipation	
Bulk laxative, for example ispaghula, taken at bedtime	Drugs such as ispaghula should not be taken before going to bed because of risk of oesophageal blockage
Urine changes colour	Anthraquinone glycosides, for example senna, are excreted by the kidney and may colour urine yellowish-brown to red colour, depending on pH
Patient claims dietary and fluid advice ineffective in resolving constipation	May find high-fibre diet difficult to adhere to, socially unacceptable, and expect result in less than 4 weeks
Patient taking docusate complains of unpleasant aftertaste or burning sensation	Advise to take with plenty of fluid after ingestion
Sterculia as Normacol® and Normacol Plus® granules or sachets	The granules should be placed dry on the tongue and swallowed immediately with plenty of water or a cool drink. They can also be sprinkled onto and taken with soft food such as yoghurt
Methylcellulose (Celevac®)	Each tablet should be taken with at least 300 mL of liquid
Diarrhoea	
Antimotility agent requested for a young child	Antimotility agents must be avoided in young children or patients with severe gastroenteritis or dysentery
Antimotility agent requested by patient with persistent diarrhoea (>10 days)	Antimotility agent inappropriate. Stool culture required to exclude parasitic infection such as Giardia, Entamoeba and Cryptosporidium
Adult with diarrhoea stops eating and drinking to allow diarrhoea to settle	Patient should eat and drink as normally as possible. Plenty of fluids required to prevent dehydration. Fruit juice (glucose and potassium), soup (salt), bread and pasta (carbohydrate) are of particular benefit
Reconstitution of oral rehydration solution	Each sachet of Diorolyte® and Electrolade® requires 200 mL of water. They should be discarded after 1 h after preparation unless stored in a fridge when they may be kept for 24 h

Case studies

Case 14.1

Mr J, a man in his 30s, asks to speak to the pharmacist. He has constipation and has taken some medicine, lactulose, but he is still finding it difficult to go to the toilet. He asks for a stronger laxative.

Question

What further information do you need to obtain to be in a position to help Mr J?

Answer

Constipation is rarely a symptom of sinister pathology in someone of Mr J's age. The most likely cause is a diet low in fibre and inadequate fluid intake. Establish the duration and nature of the problem and discuss with Mr J his usual diet. Determine if there has been any change to his diet recently, which may have precipitated the constipation. Social factors also play a role in constipation, so it is prudent to ask if there have been any life changes such as a loss of job or difficulties with family life. If his replies to the questions raise no suspicion of underlying medical problems then dietary advice only may be needed. However, since he has already taken lactulose it is likely he will persist in his request for a suitable laxative. Question Mr J on how he took the lactulose and for how long. Patients often have misconceptions on how quickly a medicine will work. A stimulant laxative may be a suitable alternative for Mr J as it has a quicker onset of action.

Case 14.2

Mr A's mother has recently moved in with his family following the death of his father 4 months ago. Although she was formerly a sprightly 78 year old, she is now withdrawn, eats little of the meals prepared for her and no longer goes for her daily walks. Mr A knows she is taking medicine for a long-standing heart complaint and has recently started taking antidepressants. She is complaining of constipation.

Question

Mr A would like to know if there is any medicine suitable to help his mother.

Answer

Constipation is a common problem in the elderly. Activity levels often diminish and many also suffer from medicine-induced constipation exacerbated by reduced muscle tone. Pain on defaecation associated with haemorrhoids is also a common contributory factor. The elderly often have poor dental status or false teeth and consequently avoid high-fibre foods because they are more difficult to chew.

In the case of Mr A's mother, the history provides little insight into the duration of the problem, although there are a number of factors that warrant further investigation. Clearly, a reduction in physical activity has occurred and her diet and fluid intake may have changed. The death of her husband and loss of independence are significant lifestyle issues for Mr A's mother that cannot readily be addressed and probably account for the recent introduction of antidepressants. The identity of her 'heart medicine' may reveal a drug-induced factor that could have been enhanced by the recent prescription for antidepressants. It is also unclear whether she has been constipated previously.

Appropriate exercise, proper diet and sufficient fluid may be the only key actions that need to be taken.

Case 14.3

Mr B is a busy 45-year-old executive who works for a large multinational company. He has noted blood in his stools over the past 2 weeks and for 3 days has had continuous abdominal discomfort. He has discussed his symptoms with his wife and they suspect haemorrhoids are the cause. Mr B is going away on business in 6 days and seeks your advice on a suitable treatment.

Question

What advice should be given to Mr B?

Answer

Blood in the stool is not necessarily serious. If the blood appears fresh and can only be seen on the surface of the stool it is likely the source is the anus or distal colon. It is probably caused by straining and bleeding from haemorrhoids or an anal fissure. Similarly, if the blood appears as specks or as a smear on the toilet paper after defaecation, this is also likely to indicate haemorrhoids, particularly if such a diagnosis has been made previously following clinical examination.

If the blood is mixed with the faeces and has a dark or 'tarry' appearance then a more serious underlying cause is possible. The darker the faeces, the more suggestive they are that there has been an upper GI bleed or a substantial loss of blood from the large bowel. If this is the case the patient should have a proper clinical examination.

Iron or bismuth tablets can cause darkened stools, so it is important to take a medication history from the patient.

However, given Mr B's age, recent onset of symptoms and the presence of continuous abdominal pain accompanying the constipation, a thorough clinical examination is required to eliminate sinister pathology such as bowel obstruction caused by a tumour or diverticular disease.

Case 14.4

A 7-year-old boy in previous good health was admitted to hospital with bloody diarrhoea and dehydration 4 days after attending a children's birthday party. He was treated with intravenous fluids and given nothing by mouth. The day after admission to hospital a colonoscopy revealed haemorrhagic colitis. His diarrhoea seemed to be improving up to day 5 when he experienced a generalised convulsion following which he was transferred to a children's intensive care bed. He was irritable, pale and hypertensive, and an emergency laboratory report revealed thrombocytopenia, hyponatraemia and hyperkalaemia.

Questions

1. What is the likely diagnosis in this child?
2. What specific therapy is required?

Answers

1. This patient probably has haemolytic uraemic syndrome caused by *E. coli* O157. Haemolytic uraemic syndrome is the most common form of acquired renal insufficiency in young children. It is characterised by nephropathy, thrombocytopenia and microangiopathic haemolytic anaemia. Although there are a number of potential causative factors, the most common is the toxin-producing O157 strain of *E. coli*. In 1996, 21 people died from *E. coli* O157 after eating contaminated meat from a butcher's shop in Scotland. In 2001, 13 Girl Guides and their leader contracted *E. coli* O157 after camping in a field in Inverclyde, Scotland, previously grazed by sheep and in 2005 more than 158 children from 42 schools in South Wales were affected by eating contaminated meat, one of whom died.

    The syndrome typically has a pro-drome of bloody diarrhoea occurring 5–7 days before onset of renal insufficiency. Colonoscopy is usually non-specific and shows haemorrhagic colitis. At diagnosis most children are pale and very irritable. Hypertension and hyponatraemia may be associated with convulsions and are generally a consequence of a disorder of fluid and salt balance. Laboratory findings may include anaemia and thrombocytopenia, hyponatraemia, hyperkalaemia, hypocalcaemia and metabolic acidosis. The kidney typically shows signs of glomerular endothelial injury. Capillary thrombosis is quite prominent but with no evidence of immune complex deposition. Similar findings can usually be seen in all other organs including the brain, liver and intestine.

2. Treatment is usually supportive. Fluid and electrolyte balance need to be corrected and the hypertension controlled. In cases with prolonged oliguria or anuria, peritoneal dialysis may be used. Approximately 85% of patients recover normal renal function.

Case 14.5

Mr G is planning to travel to Mexico on business. He was last there 6 months ago but was incapacitated with diarrhoea for 3 of 6 days in a busy work schedule. He does not want a repeat experience on his forthcoming visit and seeks advice about taking a course of antibiotics with him to use as empirical treatment should the need arise.

Questions

1. Is there any evidence that antibiotics are of benefit in traveller's diarrhoea?
2. Are there any problems associated with empirical use of antibiotics in traveller's diarrhoea?

Answers

1. The empirical use of antibiotics has been shown to increase the cure rate in individuals suffering from traveller's diarrhoea. Studies in travellers including students, package tourists, military personnel and volunteers have compared antibiotic use against placebo (De Bruyn et al., 2000). The antibiotics studied have included aztreonam, ciprofloxacin, co-trimoxazole, norfloxacin, ofloxacin and trimethoprim given for durations varying from a single dose to a 5-day treatment course. Overall, antibiotics increased the cure rate at 72 h (defined as cessation of unformed stools or less than one unformed stool/24 h) without additional symptoms.

2. The use of antibiotics in the treatment of traveller's diarrhoea does have problems. Adverse effects in up to 18% of recipients have been reported with gastro-intestinal (cramp, nausea, anorexia), dermatological (rash) and respiratory (cough, sore throat) symptoms the most frequently reported. Antibiotic-resistant isolates have also been reported following the use of ciprofloxacin, co-trimoxazole and norfloxacin. In the USA but not the UK, rifaximin, a semi-synthetic rifamycin derivative that is little absorbed from the gastro-intestinal tract, is licensed for the treatment of traveller's diarrhoea.

15 Adverse effects of drugs on the liver

B. E. Featherstone

Key points

- Approximately 20–30% of acute liver failure cases are attributed to drugs.
- Risk of drug-induced liver disorders increases with age and is generally more common in women.
- Generally, drug-induced liver damage is either dose-related or idiosyncratic.
- Drugs can cause all types of liver disorder and should always be considered in patients presenting with liver-related problems.
- The clinical features of drug-induced hepatotoxicity vary widely, depending upon the type of liver damage caused.
- Treatment of drug-induced hepatotoxicity relies on correct diagnosis, prompt withdrawal of the causative agent and supportive therapy.
- Patients given potentially hepatotoxic drugs should be monitored regularly and taught how to recognise signs of liver dysfunction and advised to report symptoms immediately.
- Drugs causing dose-related hepatic toxicity may do so at lower doses in patients with liver disease than in patients with normal liver function and idiosyncratic reactions may occur more frequently in patients with existing liver disease.
- Any new drug has the potential to cause hepatotoxicity. Post-marketing surveillance is important to highlight new potential hepatotoxic effects.

An adverse drug reaction (ADR) is an effect that is unintentional, noxious and occurs at doses used for diagnosis, prophylaxis and treatment. A hepatic drug reaction is an ADR which predominantly affects the liver.

Drugs can induce almost all forms of acute or chronic liver disease, with some drugs producing more than one type of hepatic reaction. Although not a particularly common form of ADR, drugs should always be considered as a possible cause of liver disease.

Epidemiology

The incidence of drug-induced liver disease (DILD) has continued to rise steadily since the late 1960s, although the incidence of idiosyncratic reactions for most drugs remains low, occurring at therapeutic doses from 1 in every 1000 patients to 1 in every 100,000 patients. DILD is not usually life-threatening; however, for the small number of patients who develop drug-induced acute liver failure (ALF) the prognosis is poor, with a 60–80% mortality rate, unless they receive a liver transplant. The incidence and severity of DILD is shown in Fig. 15.1. It is estimated that 15–40% of ALF cases may be attributable to drugs. Classification of ALF suggests three classes: hyperacute, acute and subacute (Table 15.1).

In the early 1990s, acute overdose with paracetamol accounted for 30,000–40,000 hospital admissions and over half the cases of ALF referred to liver units. It is the definite cause of approximately 100 deaths a year in the UK. ALF induced by paracetamol has become an important indication for liver transplantation. Hepatotoxicity induced by such drugs as halothane, the antituberculous agents (isoniazid and rifampicin), psychotropics, antibiotics and cytotoxic drugs still continue to cause concern.

Many drugs cause elevated liver enzymes with apparently no clinically significant adverse effect, although in a few patients there may be significant hepatotoxicity. For example, isoniazid

Table 15.1 Characteristics of the different types of acute liver failure (Richardson and O'Grady, 2002)

Characteristic	Hyperacute	Acute	Subacute
Transition time from jaundice to encephalopathy	0–7 days	8–28 days	29–84 days
Cerebral oedema	Common	Common	Rare
Renal failure	Early	Late	Late
Ascites	Rare	Rare	Common
Coagulation disorder	Marked	Marked	Modest
Prognosis	Moderate	Poor	Poor

Table 15.2 Examples of drugs that elevate liver enzymes

Drug	Percentage of patients with increase in transaminases
Cefaclor	11%
Cefixime	0.7%
Ciprofloxacin	5%
Chlorpromazine	50%
Diclofenac	15%
Donepezil	MHRA reports[a]
Efavirenz	4%
Heparin/LWMH	5%
Isoniazid	10–36%
Naproxen	4%
Norfloxacin	0.1%
Nevirapine	12%
Niacin	50%
Rifampicin	15–30%
Sodium valproate	11%
SSRIs	MHRA reports[a]
Statins	1–2%
Sulphonamides	10%

[a]Available at: http://www.mhra.gov.uk

causes elevated liver enzymes in 10–36% of patients taking the drug as a single agent. However, only 1% suffer significant hepatotoxicity, with the liver function tests (LFTs) of the majority returning to normal if therapy is discontinued. Other examples of drugs that elevate liver enzymes are shown in Table 15.2.

Although it is not possible to identify patients who will suffer ADRs manifesting in hepatic toxicity, a number of risk factors have been identified.

Risk factors

Pre-existing liver disease

Pre-existing liver disease may increase the risk of developing drug-induced hepatic injury with agents such as methotrexate, cytotoxic agents, aspirin and sodium valproate. In general, patients with liver disease are more likely to suffer ADRs. A past medical history of DILD from any medication has been shown to be a predictor of future DILD from other drugs.

Age

It is generally accepted that the elderly are at an increased risk of ADRs. There are multiple reasons for this, including higher exposure rates and decreased metabolism. Drug-induced hepatic injury is more likely to occur in elderly patients than in those under 35 years of age. Similarly, halothane hepatitis and isoniazid or chlorpromazine hepatotoxicity are more likely in patients over 40 years of age. The severity of the reactions also appears to increase with age, especially in those over 60 years. Sodium valproate toxicity, on the other hand, demonstrates an increased risk of developing serious or fatal hepatotoxicity in those under 3 years, with risk decreasing as age advances. Aspirin is an example of another drug causing hepatotoxicity, specifically in children. Reye's syndrome in children has been linked to the use of aspirin following a viral illness; it is life-threatening and associated with coma, seizures and liver failure. A cholestatic presentation of DILD is more common in older patients and hepatocellular damage is generally more common in younger patients.

Gender

The frequency of drug-induced hepatotoxicity is thought to be more common in females than males, particularly with halothane, isoniazid, flucloxacillin, chlorpromazine, erythromycin and nitrofurantoin. However, evidence from a recent series of more than 600 cases of DILD found that female gender was not a risk factor. There is weak evidence of a gender difference in toxicity of sodium valproate, being more common in boys before puberty and in females after puberty. Cholestatic jaundice associated with co-amoxiclav has been reported to be more common in males than females.

Genetics

Genetic differences that affect an individual's ability to metabolise certain drugs may predispose to DILD. For example, both fast and slow acetylators may be more susceptible to isoniazid-induced liver damage. The conventional view is that rapid acetylators are at risk of increased toxic reactions due to transformation of acetylhydrazine by cytochrome P450 into a reactive metabolite; other studies suggest slow acetylation may result in toxicity due to formation of hydrazine, which is toxic in itself. When starting, isoniazid monitoring of LFTs is recommended monthly for the first 3 months, as toxicity is most likely to occur early in therapy.

Halothane-induced injury has been reported for multiple family members.

It is thought that a genetic predisposition to allergic forms of drug hypersensitivity could be a factor in some types of liver disease. Flucloxacillin liver injury has been associated with the human leukocyte antigen B*5701. Having this HLA haptotype confers an 80-fold increase in susceptibility to liver injury with flucloxacillin.

Enzyme induction

Alcohol, rifampicin and other drugs that induce cytochrome P450 isoenzyme 2El potentiate the risk of hepatotoxicity with other drugs such as paracetamol, isoniazid and halothane. The role of alcohol as a risk factor for DILD is, however, not clear-cut and acute and chronic alcohol consumption may have different effects.

Concomitant therapy with other anticonvulsants, particularly phenytoin and phenobarbital, is a risk factor for toxicity with sodium valproate, where 90% of cases of liver injury are associated with combination therapy.

Polypharmacy

A typical example of this is seen with NSAIDs. The risk of liver disease with NSAIDs is normally extremely low but is increased when NSAIDs are used with other hepatotoxic drugs.

Concurrent diseases and pregnancy

Pre-existing renal disease, diabetes, pregnancy and poor nutrition may all affect the ability of the liver to metabolise drugs effectively and may put the patient at risk of developing liver damage. Table 15.3 summarises the host factors that may predispose a patient to drug hepatotoxicity.

Aetiology

Drug-induced hepatotoxicity may present as an acute insult that may or may not progress to chronic disease, or it can present as an insidious development of chronic disease. The type of lesion may be cytotoxic (cellular destruction) or cholestatic (impaired bile flow). Cytotoxic damage may be further classified as necrotic (cell death) or steatic (fatty degeneration). The liver damage resulting from drug toxicity often presents as a mixed picture of cytotoxic and cholestatic injury.

Table 15.3 Examples of host factors that predispose to drug hepatotoxicity

Host factor	Drug example
Pre-existing liver disease	Methotrexate, aspirin, sodium valproate

Age
  Older
  Younger
	
	Halothane, isoniazid, chlorpromazine, co-amoxiclav, nitrofuratoin
	Aspirin, sodium valproate

Gender
  Female
  Male
	
	Halothane, isoniazid, nitrofurantoin, flucloxacillin, chlorpromazine, erythromycin
	Sodium valproate (in prepubescent boys), co-amoxiclav

Genetics	Halothane, chlorpromazine, phenytoin, carbamazepine, phenobarbital, paracetamol, flucloxacillin
Enzyme induction	Paracetamol, halothane, isoniazid, sodium valproate
Polypharmacy	NSAIDs if used with other hepatotoxic drugs Isoniazid with rifampicin or pyrazinamide Sodium valproate with phenytoin Paracetamol with zidovudine

Concurrent diseases
  Diabetes mellitus
  Renal failure
  Malnutrition
	
	Methotrexate
	Allopurinol, i.v. tetracycline
	Paracetamol

HIV positive with hepatitis C or B co-infection	Antiretroviral agents

Table 15.4 Characteristics of intrinsic and idiosyncratic hepatotoxic reactions

	Intrinsic toxicity		Idiosyncratic toxicity
Mechanism	Direct toxicity	Metabolic abnormality	Hypersensitivity reaction
dose-dependent	Yes	No	No
Predictable	Yes	No	No
Latency	Hours	Weeks to months	1–5 weeks
Type of injury	Usually necrosis	Any	Any
Clinical features	Acute liver failure	Increased liver enzymes, hepatitis, jaundice	Fever, rash, eosinophilia, arthralgias, hepatitis

The mechanisms of drug-induced hepatic damage can be divided into intrinsic (type A) and idiosyncratic (type B) hepatotoxicity (Table 15.4). Intrinsic hepatotoxicity is predictable, dose-dependent and usually has a short latency period ranging from hours to weeks. The majority of individuals who take a toxic dose are affected and exhibit the same type of injury. Examples are paracetamol, salicylates, methotrexate and tetracycline. Other examples are presented in Table 15.5. Toxicity may be avoided by ensuring the doses listed are not exceeded.

Idiosyncratic reactions occur at a low frequency, typically less than 1 in 100 individuals who are exposed to the drug. The latency period is variable, ranging from 5 to 90 days from the initial ingestion of the drug. The type of injury is less predictable and not dose-related. This type of reaction may be due to either drug hypersensitivity or a metabolic abnormality. Examples of drugs that induce idiosyncratic reactions are chlorpromazine, halothane and isoniazid.

The precise mechanisms resulting in DILD are often not completely understood, although injury to the hepatocytes may result directly from interference with intracellular function, membrane integrity or indirectly by immune-mediated damage to cells.

Necrosis

Necrosis is characterised by cytotoxic cellular breakdown (hepatocellular destruction) and is generally associated with a poor prognosis. Drugs commonly associated with DILD have a variable propensity to cause hepatic necrosis. For example, hepatic necrosis has been reported in 3% of cases with co-amoxiclav DILD compared to 89% in individuals with halothane-induced liver injury cases.

Paracetamol causes hepatic necrosis when its normal metabolic pathway is saturated. Subsequent metabolism occurs by an alternative pathway that produces a toxic metabolite which covalently binds to liver cell proteins and causes necrosis.

Steatosis

In steatosis, hepatocytes become filled with small droplets of lipid (microvesicular fatty liver) or occasionally with lipid droplets that are much larger (macrovesicular fatty liver).

Table 15.5 Examples of dose-related drug-induced hepatotoxicity

Drug	Toxic dose
Paracetamol	Single dose >10 g
Tetracycline	>2 g daily (oral), increased risk of toxicity in pregnancy and renal failure
Methotrexate	Weekly dose >15 mg Cumulative dose >2 g in 3 years, increased risk of toxicity in pre-existing liver disease, alcohol abuse, diabetes
6-Mercaptopurine	>2.5 mg/kg
Vitamin A	Chronic use of 40,000 units daily
Cyclophosphamide	Daily dose >400 mg/m^2
Salicylates	Chronic use >2 g daily
Anabolic steroids	High dose >1 month
Oral contraceptive	Increased risk with higher oestrogen content, older preparations Duration of treatment
Iron	Single dose >1 g

Tetracyclines are thought to cause steatosis by interfering with synthesis of lipoproteins that normally remove triglycerides from the liver.

Cholestasis

Some drugs injure bile ducts and cause partial or complete obstruction of the common bile duct, resulting in retention of bile acids and the condition known as cholestasis. Cholestasis caused by anabolic and contraceptive steroids is due to inhibition of bilirubin excretion from the hepatocyte into the bile.

The penicillins, although commonly associated with allergic drug reactions, are a very rare cause of liver disease. The

isoxazoyl group present in the synthetic β-lactamase resistant oxypenicillins has been implicated as a cause of liver injury. Acute cholestatic hepatitis has increasingly been reported during treatment with flucloxacillin, and in some countries this has become the most important cause of drug-induced cholestatic hepatitis. The incidence appears to be about twice that of the related isoxazoyl penicillins cloxacillin and dicloxacillin. Moreover, there is likely to be underreporting due to a delay in onset of up to 42 days after stopping treatment. Female sex, age over 55 years, longer courses and high daily doses also seem to be associated with a higher risk of liver reaction to flucloxacillin.

Rifampicin causes hyperbilirubinaemia by inhibiting uptake of bilirubin by the hepatocyte as well as inhibiting bilirubin excretion into bile. This is generally not an indication for interrupting rifampicin therapy, although liver function will need to be closely monitored. Other therapeutic agents affect sinusoidal or endothelial cells, which may result in veno-occlusive disease or fibrosis. Vitamin A affects the fat storing cells, causing toxicity that leads to fibrosis.

Pathophysiology

The range of DILDs is illustrated in Table 15.6. Increased serum level of hepatobiliary enzymes without clinical liver disease occurs with variable frequency between drugs but for some agents it may occur in up to half the patients who receive a drug. This may reflect subclinical liver injury.

Hepatocellular necrosis

In severe cases, acute hepatocellular necrosis presents with jaundice and LFT abnormalities, including a modestly raised alkaline phosphatase and a markedly elevated alanine aminotransferase level of up to 200 times the upper limit of the reference range. Prolongation of the prothrombin time occurs but depends on the severity of the injury, increasing dramatically in severe cases. Microscopy reveals necrosis of the hepatocytes in a characteristic pattern.

Steatosis

Steatosis (fatty liver) is the accumulation of fat droplets within liver cells and is associated with abnormal LFTs, although the elevation of alanine aminotransferase is not as high as that seen in acute hepatocellular necrosis. Hyperammonia, hypoglycaemia, acidosis and clotting factor deficiency may also be present. Histologically, the liver damage resembles the acute fatty liver of pregnancy. Fat distribution within the hepatocyte is either microvesicular, as occurs with tetracycline, aspirin and sodium valproate, or macrovesicular where the hepatocyte cell nucleus is displaced to the periphery by a single large fat droplet. This type of damage occurs typically with steroids, methotrexate, alcohol and amiodarone.

A less severe, more chronic form of fatty liver, steatohepatitis, also occurs. Steatohepatitis differs from diffuse fatty

Adverse reaction	Drugs associated with reaction
Hepatocellular necrosis	Paracetamol Propylthiouracil Salicylates Iron salts Allopurinol Dantrolene Halothane Ketoconazole Isoniazid Mithramycin Cocaine 'Ecstasy' (methylenedioxymetamphetamine, MDMA)
Fatty liver	Amiodarone Tetracyclines Steroids Sodium valproate L-Asparaginase
Cholestasis	Oral contraceptives Carbimazole Anabolic steroids Ciclosporin
Cholestasis with hepatitis	Chlorpromazine Tricyclic antidepressants Erythromycin Flucloxacillin Co-amoxiclav ACE inhibitors Sulphonamides Sulphonylureas Phenytoin NSAIDs Cimetidine Ranitidine Trazodone
Granulomatous hepatitis	Phenytoin Allopurinol Carbamazepine Clofibrate Hydralazine Sulphonamides Sulphonylureas
Acute hepatitis	Dantrolene Isoniazid Phenytoin
Chronic active hepatitis	Methyldopa Nitrofurantoin Isoniazid
Fibrosis and cirrhosis	Methotrexate Methyldopa Vitamin A (dose-related)
Vascular disorders	Azathioprine Dactinomycin Dacarbazine

Table 15.6 Examples of adverse drug reactions on the liver

change. Notably, the clinical symptoms and biochemistry resemble chronic parenchymal disease and the histology is similar to that seen in alcoholic hepatitis. Amiodarone is an example of a drug that can cause chronic steatohepatitis associated with phospholipidosis.

Cholestasis

Cholestasis without hepatitis is associated with a raised bilirubin and a normal or minimally raised alanine aminotransferase level. No inflammation or hepatocellular necrosis is seen. In contrast, cholestasis associated with hepatitis presents with raised bilirubin, alanine aminotransferase and alkaline phosphatase levels and a certain amount of liver damage.

Granulomatous hepatitis

Granulomatous hepatitis occurs with modestly elevated LFTs and, usually, normal synthetic liver function. Histology reveals granulomas and tissue eosinophilia.

Acute hepatitis

Acute hepatitis resembles viral hepatitis with LFTs raised in proportion to the severity of the hepatocellular damage. The best indicator of severity is the prothrombin time. Histologically, necrosis and cellular degeneration are seen in combination with an inflammatory infiltrate.

Chronic active hepatitis

Chronic active hepatitis may present as an acute injury or progress to cirrhosis. Serum transaminases are usually raised and albumin is low. The histology resembles that of autoimmune chronic active hepatitis and is associated with circulating autoantibodies. Methyldopa is an example of a drug that can cause chronic active hepatitis.

Fibrosis

In patients with fibrosis, the serum transaminase levels may be only slightly raised, and are not good predictors of hepatic damage. Microscopy shows deposition of fibrous tissues. Fibrosis may proceed to cirrhosis. Such damage may be seen with long-term methotrexate use.

Vascular disorders

A variety of drugs can cause veno-occlusive disease, which is characterised by non-thrombotic narrowing of small centrilobular veins, and is typically caused by cytotoxic agents and some herbal remedies. Use of oral contraceptives or cytotoxic agents may exacerbate an underlying thrombotic disorder and increase the risk of the Budd–Chiari syndrome (obstruction of the large veins) developing.

Tumours

Drugs have been associated with a variety of hepatic tumours. The drugs most commonly linked to malignancy are the oral contraceptives, anabolic steroids and danazol.

Clinical manifestations

The clinical features of drug-induced hepatotoxicity vary widely, depending on the type of liver damage caused.

Acute hepatocellular necrosis

In acute hepatocellular necrosis caused by paracetamol, early symptoms include anorexia, nausea and vomiting, malaise and lethargy. Abdominal pain may be the first indication of liver damage but is not usually apparent for 24–48 h. A period of apparent recovery precedes the development of jaundice and production of dark urine. If the liver injury is severe, deterioration follows, with repeated vomiting, hypoglycaemia, metabolic acidosis, bruising and bleeding, drowsiness and hepatic encephalopathy. Oliguria (diminished urine output) and anuria (complete cessation of urine production) may result from acute tubular necrosis. Renal failure may occur even in the absence of severe liver disease. In addition to acute renal failure, myocardial injury and pancreatitis have also been reported. In fatal cases, death from acute hepatic failure occurs between 4 and 18 days after ingestion.

Steatosis

A patient presenting with steatosis generally shows fatigue, nausea, vomiting, hypoglycaemia and confusion. Jaundice is present in severe cases.

Acute hepatitis

Acute hepatitis may present with a prodromal illness with non-specific symptoms or include features of drug allergy followed by anorexia, nausea and vomiting, dark urine, pale stools and jaundice. Jaundice tends to be present in severe cases. Weight loss may also be a feature of acute hepatitis. Fatalities occur in 5–30% of jaundiced patients. Acute hepatitis is second only to paracetamol self-poisoning as a cause of DILD.

Chronic active hepatitis

Drug-induced chronic active hepatitis may present with tiredness, lethargy and malaise, in a manner similar to other types of chronic liver disease. The symptoms may evolve over many months. Gastro-intestinal symptoms are usually present, and patients may show one or more complications of severe liver disease, including ascites, bleeding oesophageal varices or hepatic encephalopathy. If the ADR has an allergic component, a skin rash and other extrahepatic features of a drug allergy such as lymphadenopathy, evidence of bone marrow suppression (particularly petechial haemorrhages) may be present.

Cholestasis

The main clinical feature of pure cholestasis is severe pruritus, with or without other features, according to the severity, such as dark urine, pale stools and jaundice.

Drug-induced cholestatic hepatitis usually presents with gastro-intestinal symptoms following an influenza-like illness. Abdominal pain with typical features of cholestasis then occurs. The pruritus is generally less severe than with pure cholestasis.

Veno-occlusive disease

Veno-occlusive disease may present with painful hepatomegaly, ascites and jaundice along with other features of liver insufficiency. It has been reported following chemotherapy with drugs such as cyclophosphamide, doxorubicin and dacarbazine. It has also been reported as a common complication of bone marrow transplantation.

Hepatic tumours

In general, patients with hepatic tumours present in a similar manner. Abdominal pain may or may not be reported, together with a feeling of fullness after eating. Weight loss, fatigue, anorexia, nausea and, occasionally, vomiting can occur, especially in advanced cases.

Investigations

Various types of investigation are used in the diagnosis of drug-induced hepatotoxicity, with the number and type of tests depending on the clinical presentation. Unfortunately, available laboratory tests do not provide ideal markers for DILD and the diagnosis is generally one of exclusion.

Biochemical tests

Routine LFTs are measured, which generally include total bilirubin, alanine transaminase and alkaline phosphatase. Impairment of the synthetic function of the liver is detected by total protein, albumin and the prothrombin time. Other biochemical tests may include measurement of γ-glutamyl transpeptidase which may be elevated in all forms of liver disease, including drug-induced disease. α-Fetoprotein may be measured to exclude malignancy. Conjugated bilirubin may be measured to establish if there is biliary obstruction.

Serological markers

Serological markers for hepatitis A, B and C and other viruses such as the Epstein–Barr virus should be determined in patients with symptoms of hepatitis with appropriate risk factors to exclude an infective cause.

Radiological investigations

Radiological investigations, such as ultrasound, computed tomography, percutaneous cholangiograms and endoscopic retrograde cholangiopancreatography (ERCP), are used to look for physical obstruction of bile ducts by gallstones, masses or strictures.

Liver biopsy

Liver biopsy is seldom helpful for diagnosis but certain drugs can cause characteristic lesions, such as the distribution of microvesicular fat droplets seen with tetracyclines. Specific diagnostic tests for drug-induced disease exist for few drugs, with halothane being a notable exception.

Other causes of liver dysfunction such as autoimmune chronic active hepatitis, acute severe cholestasis, ischaemic hepatic necrosis, pregnancy-related liver disease, the Budd–Chiari syndrome, rare metabolic disorders or liver disease related to alcohol abuse must also be excluded.

Treatment

The aim of treatment for drug-induced hepatotoxicity is complete recovery. This relies on correct diagnosis, withdrawal of any and all suspected drugs, and supportive therapy, which may include liver transplantation where appropriate.

Diagnosis

Drug-induced hepatic injury should be suspected in every patient with jaundice while ruling out other causes of liver disease by the clinical history and the results of investigations. The typical process in screening patients presenting with jaundice is outlined in Fig. 15.2 and the general approach to the differential diagnosis of acute hepatitis is set out in Fig. 15.3.

Drugs that are commonly prescribed, such as NSAIDs, antimicrobials and antihypertensive agents, are more likely to be implicated in DILD, although the frequency for the individual agents is low. Identifying the causative agent and stopping it is important in reducing the morbidity and mortality associated with DILD. Recovery normally follows discontinuation of a hepatotoxic drug. Serious toxicity or ALF may result if the drug is continued after symptoms appear or the serum transaminases rise significantly. Failure to discontinue the drug may give grounds for claims of negligence.

A detailed and thorough drug history, including use of oral contraceptives, over-the-counter medicines, vitamins, herbal preparations and illicit drug use, should be obtained. Examples of herbal and dietary preparations implicated in causing liver damage are listed in Box 15.1. Attention to the duration of treatment with a specific drug and the relationship to the onset of symptoms is important. The likelihood of a drug-related disease is greatest when the abnormality begins between 5 and 90 days after taking the first dose and within 15 days of taking the last dose. The latent period, that is, the time between starting therapy and the appearance of

JAUNDICE

Consider drugs as a cause for all cases of jaundice

| Relevant drug history? | Presence of rash, fever, eosinophilia? | No other causes of jaundice found |

Drug history to include over-the-counter preparations, illicit drugs, herbal preparations and vitamins
Jaundice occurred between 5 and 90 days of starting or within 15 days of finishing drug

Presence increases likelihood of drug induced disease, but absence does not exclude it

NO

YES

STOP SUSPECTED DRUG

IS AN IMPROVEMENT SEEN?

YES   NO

Drug unlikely to be the cause of jaundice
Examples of other causes include: infection, neoplasm, haemolysis, Wilson's disease, gallstones, pregnancy, α_1-antitrypsin deficiency

LIKELIHOOD OF DRUG INDUCED JAUNDICE IS HIGH

COMPLETE YELLOW CARD REPORT TO MHRA

Jaundice usually reversible on stopping drug

Treat symptomatically

NAUSEA ANOREXIA DIARRHOEA

Consider antiemetics, low fat, high carbohydrate diet

PRURITIS

Cool the skin e.g. with calamine lotion, tepid baths, moisturizers
Consider giving: anion binding resin (e.g. colestyramine), antihistamine (e.g. chlorphenamine), ursodeoxycholic acid

Fig. 15.2 General approach to the diagnosis and management of drug-induced jaundice.

symptoms, may vary but for many drugs is sufficiently reproducible to be of some diagnostic value.

Predisposing factors for liver toxicity should also be noted. If the liver injury is accompanied by fever, rash and eosinophilia, the likelihood of drug-induced disease increases, although lack of these features does not exclude it. Unequivocal diagnosis cannot be made in most circumstances, and improvement on withdrawal of the implicated drug may provide the strongest evidence for drug-induced disease. Time for resolution of the abnormalities is dependent on the individual drug and type of liver disease. In some cases, several months may elapse.

Idiosyncratic reactions may also need to be considered and the literature consulted for previous reports. A key component of secondary prevention is the reporting of all suspected hepatic drug reactions to the appropriate monitoring agency, particularly for newer agents with fewer published cases. Many drugs are approved and licensed before the idiosyncratic reactions are identified as there is little chance of detecting the reaction in the phase III studies which typically involve 300 patients. To detect a single case of clinically significant hepatic injury due to a drug with 95% confidence, the number of patients included in the trial must be about three times the incidence of the reaction. Idiosyncratic reactions occur in about 1 in 10,000 patients so to detect the reaction, the clinical trial would have to study 30,000 patients. Practice points for diagnosing DILD are shown in Box 15.2.

Withdrawal

Once drug-induced hepatotoxicity has been recognised as a possibility, therapy should be stopped. If the patient is receiving more than one potentially hepatotoxic drug, all drugs

Passion flower (*Passiflora incarnata*)
Ubiquinone
Valerian (*Valeriana officinalis*)

Box 15.2 Practice points for the diagnosis of drug-induced liver disease

- Consider drugs as a cause for all cases of liver damage in patients presenting with liver disease.
- Take a careful drug history include prescription, over the counter, herbal and alternative medicines
- Has the drug implicated been previously reported to cause drug-induced liver disease?
- Does the patient have risk factors for drug-induced liver disease?
- Consider the temporal relation (onset of symptoms between 5 and 90 days after initial exposure?)
- Is there improvement on discontinuation of the suspected agent?
- Rechallenge with the suspected drug is not recommended; however, a positive rechallenge is the most definite evidence of drug-induced disease.

Box 15.3 Examples of drugs associated with the development of chronic liver disease

Amiodarone
Chlorpromazine
Diclofenac
Isoniazid
Methotrexate
Nitrofurantoin

should be stopped. Withdrawal of the agent usually results in recovery that begins within a few days. However, LFTs may take many months or even years to return to normal. Co-amoxiclav and phenytoin are examples of drugs that have been associated with a worsening of the patient's condition for several weeks after withdrawal, and a protracted recovery period of several months. Examples of drugs associated with chronic liver injury are shown in Box 15.3.

Rechallenge

When drug-induced hepatotoxicity has been confirmed by improvement on drug withdrawal, subsequent use in the patient is generally contraindicated. Rechallenge is not normally justified as this is potentially dangerous for the patient, although a positive rechallenge is the most definitive confirmation of drug-induced disease. Inadvertent rechallenge may occur. If the rechallenge is negative, this is usually taken to indicate that the patient may resume using the drug. Another adverse reaction on re-exposure to the drug precludes any further use.

Management

If clinical or laboratory signs of hepatic failure appear, hospitalisation is mandatory.

After withdrawal of the drug, attempts to remove it from the body are only relevant for acute hepatotoxins such as paracetamol, metals or toxic mushrooms such as *Amanita phalloides* (death cap).

If patients present a few hours post-ingestion, any unabsorbed drug may best be removed by gastric lavage, rather than by use of emetics.

Antidotes

Specific antidotes are acetylcysteine and methionine for paracetamol, and desferrioxamine for iron overdose. Desferrioxamine 5–10 g in 50–100 mL of water is administered orally as soon as possible after ingestion for acute iron poisoning. Parenteral desferrioxamine is indicated in addition to oral administration, to chelate absorbed iron where the plasma levels exceed 89.5 μmol/L, where the plasma levels exceed 62.6 μmol/L and there is evidence of free iron, and in patients with signs and symptoms of acute iron poisoning.

Corticosteroids

Immunosuppression with corticosteroids has been used in the management of drug-induced hepatotoxicity, but evidence indicates their use does not affect survival of patients with ALF. However, there have been anecdotal reports of impressive responses to corticosteroids that are persuasive, and it may be appropriate to conduct a short trial in rare types of drug-induced disease.

Supportive treatment

For most patients there is no specific treatment available. General supportive treatment is necessary in liver failure, with appropriate attention to fluid and electrolyte balance.

Nutritional support should be along conventional medical lines. Some patients find that a low-fat, high-carbohydrate diet provides relief from the anorexia, nausea and diarrhoea that may accompany cholestasis.

Pruritus

The main symptom of drug-induced cholestasis is pruritus due to high systemic concentrations of bile acids deposited in tissues. General measures include light clothing (avoid wool) and cooling the skin with tepid baths or calamine lotion, and a general moisturising agent such as aqueous cream. The management of liver-induced pruritus is discussed in more detail in Chapter 16.

Coagulation disorders

Coagulation disorders should be treated by correcting vitamin K deficiency with intravenous phytomenadione injection. This should correct the prothrombin time within 3–5 days. Oral phytomenadione is ineffective in cholestasis. Menadiol sodium phosphate, the water-soluble vitamin K analogue, may be effective in an oral dose of 10 mg daily. If bleeding occurs, infusion of fresh frozen plasma or clotting factor concentrates will be indicated. The administration of other fat-soluble vitamins may also be necessary. Liver transplantation is often considered the treatment of choice for patients with acute hepatic failure induced by drugs.

Long-term treatment

When the DILD is under control, consideration will have to be given to the treatment of the original condition for which the implicated drug was prescribed. In many cases, drug therapy will still be required and caution must, therefore, be exercised, as drugs with similar chemical structures may cause similar hepatotoxicity (Table 15.7).

Hepatotoxicity may occur with different derivatives of a drug. Erythromycin-induced cholestatic hepatitis has been more frequently reported with the estolate preparation than with other erythromycin esters (ethylsuccinate, stearate, propionate and lactobionate). It is not clear which part of the drug is responsible for hypersensitivity.

Table 15.7 Examples of cross-sensitivity within drug groups

	Problem	Action
Phenothiazines	Cross-sensitivity	Avoid
Tricyclics	Cross-sensitivity	Avoid
NSAIDs	Cross-sensitivity	Avoid
Isoniazid, pyrazinamide	Chemically-related	Avoid
Halothane	Avoid enflurane	Isoflurane appears safe

Paracetamol-induced hepatotoxicity

Paracetamol causes a dose-related toxicity resulting in centrilobular necrosis. It normally undergoes the phase II reactions of glucuronidation and sulphation. However, paracetamol is metabolised by cytochrome P450 2E1 to *N*-acetyl-*p*-benzoquinoneimine (NABQI) if the capacity of the phase II reactions is exceeded or if cytochrome P450 2E1 is induced. After normal doses of paracetamol, NABQI is detoxified by conjugation with glutathione to produce mercaptopurine and cysteine conjugates. Following overdose, tissue stores of glutathione are depleted, allowing NABQI to accumulate and cause cell damage. Illness, starvation and alcohol deplete glutathione stores and increase the predisposition to paracetamol toxicity, while acetylcysteine and methionine provide a specific antidote by replenishing glutathione stores.

Ingestion of doses as low as 10–15 g of paracetamol have been reported to cause severe hepatocellular necrosis. Removal of unabsorbed paracetamol by gastric lavage may be worthwhile if more than 150 mg/kg body weight has been taken and the patient presents within 4 h of ingestion. Activated charcoal may also be administered to reduce further absorption of paracetamol and facilitate removal of unmetabolised paracetamol from extracellular fluids. This may lessen the effect of any methionine given. A plasma paracetamol concentration should be taken as soon as possible but not within 4 h of ingestion due to the fact that a misleading and low level may be obtained because of continuing absorption and distribution of the drug. The plasma concentration measured should be compared with a standard nomogram reference line of a plot of plasma paracetamol concentration against time in hours after ingestion. This may be a semilogarithmic (Fig. 15.4) or linear (Fig. 15.5) plot. Generally, administration of intravenous acetylcysteine is the treatment of choice for paracetamol overdose when the blood paracetamol level is in the range predictive of possible or probable liver injury (see Fig. 15.4). Patients allergic to acetylcysteine may receive oral methionine.

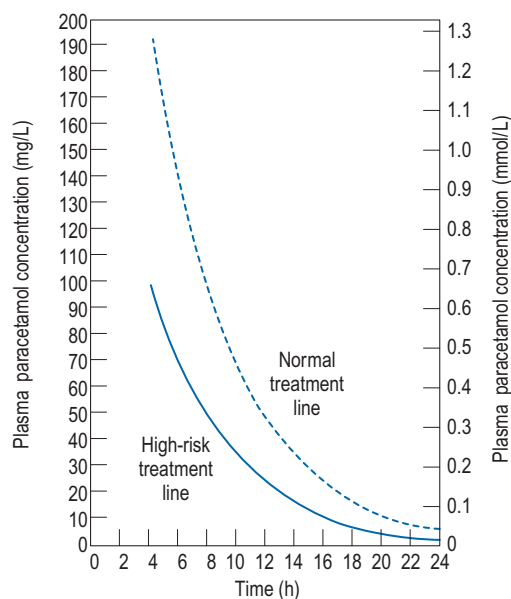
Acetylcysteine is most effective within 8 h of overdose. However, late administration in patients who present more than 16–24 h post-ingestion may be appropriate. Acetylcysteine administered at this stage will not counteract the oxidative effects of paracetamol but it may have a
Fig. 15.4 Semilogarithmic plot of plasma paracetamol concentration versus time in hours after ingestion.


Fig. 15.5 A linear plot of plasma paracetamol concentration versus time in hours after ingestion.

cytoprotective role in hepatic failure, and has been shown to reduce morbidity and mortality in patients who have already developed ALF.

Patient care

Patients may be at risk of drug-induced hepatotoxicity from prescribed drugs or from purchased drugs. Additionally, children may be at risk from medicines that are not stored properly. Parents should be reminded to store all medicines in child resistant containers and out of reach. Deaths from liver failure have occurred in children following overdose with drugs commonly available, such as iron tablets.

Patient counselling

Patients who purchase preparations containing paracetamol should be made aware of the danger of overdosing, which may occur if other preparations containing paracetamol are taken simultaneously. Since 1994 the European guidelines on package labelling have required products containing paracetamol to warn patients of the need to avoid other products containing paracetamol. The pack size of paracetamol sold from general sales outlets has been limited to 16 tablets or capsules (32 where paracetamol is sold under the supervision of a pharmacist) with the aim of limiting availability and reducing residual stocks in the home. This appears to have reduced the incidence of ALF secondary to paracetamol overdose.

All patients should be advised of potential side effects. This information needs to be reinforced with the use of patient information leaflets.

Patients and their carers should be helped to recognise signs of liver disorder and know to report immediately symptoms such as malaise, nausea, fever and abdominal discomfort that may be significant, although non-specific during the first few weeks of any change of therapy. If these are accompanied by elevated LFTs, the drug should be discontinued.

Patients who recover from drug-induced hepatotoxicity should be informed of the causative agent, warned to avoid it in the future, and advised to inform their doctor, dentist, nurse and pharmacist about the occurrence of such an event.

Parents of children commenced on sodium valproate should be warned to report side effects that may be suggestive of liver injury such as the onset of anorexia, abdominal discomfort, nausea and vomiting. Early features include drowsiness and disturbed consciousness. Fever may also be present. The time to onset is between 1 and 4 months in the majority of cases.

The challenge for all members of the health care team is to alert patients to the potentially toxic effects of drugs without creating so much concern that they fail to comply with vital medication. For the limited number of drugs presented in Table 15.8, careful monitoring of LFTs during the first 6 months of treatment is advisable, although not always practical. Thereafter, regular monitoring of LFTs is appropriate in patients who are at greater risk of hepatotoxicity. Such patients would include those with known liver disease, those taking other hepatotoxic drugs, those aged over 40 years, and heavy alcohol consumers. Surveillance should be particularly frequent in the first 2 months of treatment. In patients with no risk factors and normal pretreatment liver function, LFTs

Table 15.8 Examples of drugs where regular monitoring of liver function is recommended

Drug	Baseline measurement[a]	Frequency of monitoring
Anti-TB therapy (isoniazid, rifampicin, pyrazinamide)	Yes	Patients with pre-existing chronic liver disease: check LFTs regularly, every week for the first 2 weeks, then twice a week for the first 2 months. Patients with normal liver function tests and no evidence of pre-existing liver disease: regular monitoring is not necessary but LFTs repeated if signs of liver dysfunction develop, for example, fever, malaise, vomiting or jaundice. Patients with raised pretreatment hepatic transaminases: Two or more times normal: check LFTs weekly for 2 weeks, then twice a week until normal. Under two times normal: check LFTs at 2 weeks. If these transaminases have fallen, further tests are only needed if symptoms occur
Amiodarone	Yes	LFTs checked every 6 months
Cyproterone	Yes	Recheck if any symptoms
Dantrolene	Yes	Repeat LFTs after first 6 weeks of therapy
Itraconazole	Yes	Monitor LFTs if therapy continues for more than 1 month. Recheck if any symptoms
Ketoconazole	Yes	LFTs checked on weeks 2 and 4 of therapy and then every month
Methotrexate	Yes	LFTs checked every 2 weeks for the first 2 months, then monthly for 4 months, then every 3 months
Methyldopa	Yes	Check LFTs at intervals during the first 6–12 weeks of treatment
Micafungin	Yes	Periodic monitoring of LFTs recommended. Recheck if any symptoms
Nevirapine	Yes	Check LFTs every 2 weeks for the first 2 months, then at month 3 and then regularly
Pioglitazone	Yes	Periodic monitoring of LFTs recommended. Recheck if any symptoms

Table 15.8 Examples of drugs where regular monitoring of liver function is recommended—cont'd

Drug	Baseline measurement[a]	Frequency of monitoring
Rosiglitazone	Yes	Periodic monitoring of LFTs recommended. Recheck if any symptoms.
Sodium valproate	Yes	Check LFTs regularly during the first 6 months of therapy
Statins	Yes	LFTs checked 12 weeks after initiation or after a dose increase and periodically thereafter
Sulfasalazine	Yes	LFTs checked every 2 weeks for the first 2 months, then monthly for 4 months then every 3 months
Tipranavir	Yes	Check LFTs on weeks 2, 4 and 8 of treatment and then every 2–3 months
Vildagliptin	Yes	LFTs checked every 3 months for the first year and then periodically

[a]Baseline and subsequent liver function tests (LFTs) difficult to interpret in critically ill patients as LFTs will be affected by multiple factors

need only be repeated if fever, malaise, vomiting, jaundice or unexplained deterioration during treatment occurs.

Since many drugs cause elevation of LFTs there may be difficulty in assessing when to stop a drug, particularly when treating an individual for tuberculosis or epilepsy. An empirical guideline is that the drug should be stopped if the levels of alanine transaminase exceed three times the upper limit of the reference range. Any clinical features of liver disease or drug allergy would require immediate discontinuation of the drug. Conversely, a raised γ-glutamyl transpeptidase level and elevated alanine transaminase level in the absence of symptoms often reflect microsomal induction and would not indicate drug-induced injury.

It should be noted that monitoring of LFTs is not a complete safeguard against hepatotoxicity, as some drug reactions develop very quickly, and the liver enzymes are an unreliable indicator of fibrosis.

Minimising the risk of DILD

Cholestatic jaundice has been reported to occur in about 1 in 6000 patients treated with co-amoxiclav. The risk of acute liver injury with co-amoxiclav is approximately six times that of amoxicillin and increases with treatment courses above 14 days. Hence, the indications for co-amoxiclav have been restricted to cover infections caused by amoxicillin-resistant β-lactam-producing infections.

Patients admitted for procedures requiring a general anaesthetic should be questioned about past exposure and any previous reactions to halothane. Halothane is well known to be associated with hepatotoxicity, particularly if patients are re-exposed. Repeated exposure to halothane within a period of less than 3 months should be avoided, while some increase in risk persists regardless of the time interval since last exposure. Unexplained jaundice or delayed-onset post-operative fever in a patient who has received halothane is an absolute contraindication to future use in that individual. Patients with a family history of halothane-related liver injury should also be treated with caution.

The individuals at greatest risk of halothane hepatitis are obese, post-menopausal women. Halothane may be present in detectable amounts even in theatres equipped with scavenging devices, and it is possible for these small concentrations to provoke a reaction in a highly sensitised individual. If electing to avoid halothane, a halothane-free circuit and operating theatre should be used. Cross-hepatotoxicity with other haloalkanes is a possibility, and enflurane should also be avoided. Isoflurane appears to be safe, as no reports of cross-sensitivity have been published. Some anaesthetists would prefer to use total intravenous anaesthesia in patients who have had a reaction to halothane.

Although hepatic ADRs are rare for most drugs, when they do occur they can cause significant morbidity and mortality. Over 600 drugs have been associated with hepatotoxicity and any new drug released on to the market may have the potential to cause hepatotoxicity. Pemoline, troglitazone and tolcapone are examples of drugs withdrawn from the market due to reports of serious hepatic reactions. These examples help to highlight the importance of post-marketing surveillance and yellow card reporting.

Appropriate selection of drugs, an awareness of predisposing factors and avoidance of toxic dose thresholds and potentially hepatotoxic drug–drug interactions will minimise the risk to patients.

Practice points for patient care and minimising the risk of DILD are outlined in Box 15.4.

Box 15.4 Practice points for minimising the risk of drug-induced liver disease (DILD)

- Minimise DILD by ensuring appropriate monitoring of drugs associated with hepatotoxicity.
- Minimise DILD by following recommendations, for example, use co-amoxiclav for penicillin β-lactam resistant infections only, counsel all patients on paracetamol not to exceed 4 g/day and to be alert to other preparations containing paracetamol.
- Counsel all patients (or carers of patients) on potentially hepatotoxic medicines to recognise and report signs of liver damage.
- Inform all patients who have DILD of the causative agent, and the importance of avoiding this in future.

Case studies

Case 15.1

Mr V, a 39-year-old male, presented to his local hospital following a paracetamol overdose. He had recently separated from his wife, had not been eating properly, went on an alcohol binge and then on impulse had taken approximately 70 paracetamol tablets. He self-referred himself to his local hospital 28 h after the overdose. At presentation he was feeling nauseous and had right subcostal pain. His results at this time were:

	Actual value (normal range)
Paracetamol	18 mg/mL
Albumin	26 g/dL (30–50 g/L)
Alanine transaminase	5435 units/L (0–50 units/L)
Bilirubin	50 μmol/L (<17 μmol/L)
Alakline phosphatase	66 units/L (30–135 units/L)
Prothrombin time	57 s (9.8–12.6 s)
Creatinine	133 (35–125 μmol/L)
Urea	5.6 (0–7.5 mmol/L)

Other test results:
   Hepatitis screen negative
   Autoantibody screen negative

At this stage, supportive treatment was given. However, he deteriorated, with worsening test results and the development of encephalopathy. He was then transferred to a tertiary intensive care unit, with a diagnosis of ALF secondary to paracetamol overdose. His test results on admission to the intensive care unit were:

	Actual value (normal range)
Albumin	22 g/dL (30–50 g/L)
Alanine transaminase	12,477 units/L (0–50 units/L)
Bilirubin	71 μmol/L (<17 μmol/L)
Alakline phosphatase	73 units/L (30–135 units/L)
Prothrombin time	90.8 s (9.8–12.6 s)
Arterial pH	7.226 (7.350–7.450)
Lactate	6.9 (0.4–2.2 mmol/L)
Creatinine	336 (35–125 μmol/L)
Urea	7.4 (0–7.5 mmol/L)

He was put on the liver transplant urgent list and received an orthotopic liver transplant (OLT) the following day.

Questions

1. What risk factors does Mr V have which suggest a worse prognosis?
2. On initial presentation what treatment should be initiated?
3. What is the significance of the high creatinine result?
4. Can Mr V be prescribed paracetamol for pain relief?

Answers

1. The progression of paracetamol toxicity can be categorised into four stages: preclinical, hepatic injury, hepatic failure, and recovery. The prognosis varies depending upon the stage at presentation. Mr V's late presentation to hospital also increases his risk of a worse prognosis. He presented to hospital 28 h after the overdose, with raised ALT and some symptoms of liver injury, indicating that he was in the hepatic injury stage and progressed onto the liver failure stage with the development of encephalopathy. Patients presenting with liver injury have a variable prognosis but patients who present with hepatic failure have a mortality rate of 20–40%. Had he presented in the preclinical stage he would have been expected to make a full recovery with treatment.

   Although Mr V had acutely ingested alcohol at the time of paracetamol overdose, this is not a risk factor for a worse prognosis. Theoretically, acute alcohol ingestion competes with paracetamol for CYP2E1 metabolism resulting in lower formation of NAPQI and thus less toxicity. Chronic alcohol consumption induces the CYP2E1 enzyme resulting in increased NAPQI production and increased risk of hepatotoxicity.

   The fact that Mr V had not been eating properly may have resulted in depleted glutathione stores and a worse prognosis.

   Mr V developed hepatorenal syndrome, this is a poor prognostic indicator and has an associated mortality of 50–100%. A poor prognosis is also associated with the following:

Prothrombin time	>36 s
Creatinine	>200 μmol/L
pH	<7.3
Encephalopathy	Present
Cerebral oedema	Present
Time from onset of jaundice to encephalopathy	0–7 days

2. A plasma paracetamol level needs to be taken as soon as possible, although not within the first 4 h following paracetamol overdose. A toxic screen should be performed to exclude other drug overdoses. Supportive therapy with intravenous fluids and oxygen, if necessary, should be given. This patient should also be treated with *N*-acetylcysteine. Treatment with *N*-acetylcysteine is particularly beneficial when administered within 8 h of paracetamol overdose when the blood paracetamol level is in the range predictive of possible or probable liver injury (see Fig. 15.4). However, late administration in patients who present more than 16–24 h post-ingestion is also appropriate. Acetylcysteine administered at this stage will not counteract the oxidative effects of paracetamol but it may have a cytoprotective role in hepatic failure, improving haemodynamics and oxygen use. Late administration of *N*-acetylcysteine has been shown to reduce morbidity and mortality in patients who have already developed hepatic failure. Available data for use of *N*-acetylcysteine following paracetamol overdose suggests that, although the evidence for benefit is limited, it should be given to patients with overdose (Brok et al., 2006).
3. Mr V developed renal impairment secondary to the liver damage which is known as the hepatorenal syndrome (HRS). Other causes of renal impairment should be excluded. Where necessary drug doses should be adjusted for renal impairment. Once the liver recovers, or transplantation of the liver occurs, the kidneys are likely to recover.
4. Paracetamol should be avoided in the acute phase following an overdose. However, if following the acute phase, the patient needs either an analgesic or antipyretic, then paracetamol in small doses may be used. Following a liver transplant, standard paracetamol doses can be used as long as the patient is adequately nourished and does not have any psychological issues with the use of paracetamol.

Case 15.2

Ms B is a 43-year-old lady with type 2 diabetes who was commenced on simvastatin 10 mg at night 4 months ago. She has no other relevant past medical history. She does not drink alcohol and does not consume grapefruit. Drug history includes gliclazide MR 60 mg twice a day and aspirin 75 mg daily. A routine blood test revealed an increase in ALT from baseline (pre-simvastatin) of 21 to 197 units/L (0–50 units/L) at 4 months.

Questions

1. What are the likely causes of the increase in ALT?
2. Should liver function tests be routinely monitored in patients on a statin?
3. What action, if any, should be taken in this case?
4. Can statins be used in patients with pre-existing liver disease?

Answers

1. The most likely cause of the increase in ALT is the introduction of simvastatin 4 months previously. All statins are reported to cause elevations in transaminases, which may be transient or persistent. The incidence of transaminitis with statins is low, being reported to occur between 1 in 1000 and 1 in 10,000 patients. Other causes of liver disease should also be considered in this case, for example, non-alcoholic steatohepatitis (NASH) associated with diabetes.
2. Monitoring of liver function tests in patients taking a statin is recommended in the Summary of Product Characteristics, and hence should be monitored for medico legal reasons (McKenney et al., 2006). It is recommended to monitor liver function tests at baseline and then at 12 weeks or after a dose increase. However, the true value for monitoring liver function test is not clear as it does not identify those at risk of liver damage, is expensive and may lead to patient anxiety and unnecessary cessation of statin therapy. Moreover, hepatic function does not appear to be compromised by statin use and there is no apparent link between an elevation in liver function tests and the development of toxicity (McKenney et al., 2006).
3. Ms B had a single high ALT result. The general recommendation is that if the patient is asymptomatic and the transaminase levels are greater than three times the upper limit of normal the test should be repeated. If transaminases are still more than three times upper limit of normal the patient should have a full liver investigation.

    In this case, the simvastatin was switched to pravastatin before a repeat liver function test. Follow-up liver function tests showed that the ALT had returned to within the normal range. It is highly probable that this rise in ALT on simvastatin would have been transient and had the patient continued with simvastatin the ALT would have normalised. However, the patient was anxious, did not want to risk any progression of liver toxicity and was keen to switch to an alternative statin.
4. Statins are contraindicated in ALF and decompensated chronic liver disease. However, they can probably be used safely in liver disease where there is no, or mild, synthetic dysfunction. Statin use may actually improve elevations in transminases in patients with fatty liver disease (Gomez-Dominguez et al., 2006)

Case 15.3

Mr K, a 28-year-old HIV-infected male, was found to have elevated liver function tests on a routine monitoring sample following initiation of antiretroviral therapy. He had previously been diagnosed with HIV 6 months ago, with a CD count of 330 cells/mm³ and a viral load of 83,000 copies/mL. Relevant past medical history included psychiatric illness. He had been initiated on Kivexa® (abacavir and lamivudine) and nevirapine 5 months ago. He is not on any other medications. Mr K was recalled to the hospital clinic for urgent medication review. In the clinic, Mr K reported a 3-day history of general malaise, abdominal discomfort and nausea. Examination

in clinic showed to have a normal blood pressure, a temperature of 37.1 °C and slight visible jaundice. There were no signs of a hypersensitivity reaction. His routine liver function tests were:

	Actual value (normal range)
Albumin	30 g/dL (30–50 g/L)
Alanine transaminase	350 units/L (0–50 units/L)
Bilirubin	90 µmol/L (<17 µmol/L)
Alkaline phosphatase	180 units/L (30–135 units/L)

Questions

1. For which drug would Mr K be having routine liver function tests?
2. What is the significance of looking for signs of hypersensitivity?
3. Does Mr K have any risk factors for developing drug associated hepatotoxicity?
4. What actions should be taken in relation to this patient's antiretroviral therapy?

Answers

1. Hepatotoxicity among HIV-infected persons taking nevirapine is a well recognised adverse effect. The incidence of an asymptomatic increase in hepatic aminotransferase levels is reported as approximately 5–15%, with the incidence of clinically symptomatic hepatitis among persons taking nevirapine of approximately 4% (Martínez et al., 2001). It is recommended that all patients commencing on nevirapine undergo close monitoring during the first 18 weeks of treatment, with liver function tests performed at baseline, then every 2 weeks for the first 2 months again after a further 1 month and regularly thereafter.
2. Signs of hypersensitivity help to diagnose the type of nevirapine induced hepatotoxicty. Two distinct mechanisms and time courses of nevirapine-associated hepatotoxicity have been recognised. The first type is an immune-mediated hypersensitivity reaction, developing within 18 weeks of the start of nevirapine. Most patients with this type of early nevirapine associated hepatotoxicity will have concomitant flu-like symptoms (fever, myalgia, fatigue, malaise, nausea, and vomiting) with or without skin rash. The second, and much less frequent type, typically occurs after 18 weeks of nevirapine therapy and most likely represents an intrinsic toxic drug effect (Soriano et al., 2008).
3. Mr K does not have any risk factors. Risk factors for developing hepatotoxicity with nevirapine include female gender, higher CD4 cell count prior to starting nevirapine (greater than 250 cells/mm³ in females and greater than 400 cells/mm³ in males), chronic hepatitis B or C virus infection, alcoholic liver disease and abnormal baseline hepatic aminotransferase levels (Soriano et al., 2008).
4. In general, nevirapine should be discontinued when increases in hepatic aminotransferase levels occur associated with a rash. Mr K shows signs of clinical hepatitis with symptoms of general malaise, abdominal discomfort and nausea, in conjunction with a raised ALT. He does not show signs of hypersensitivity or rash. His nevirapine therapy should be suspended and his liver function monitored closely. Once his liver function has settled, nevirapine could be cautiously reintroduced with close monitoring. For patients who develop nevirapine-associated hepatitis, the risk of developing hepatitis from subsequent treatment with efavirenz or delavirdine remains unknown. As a consequence, efavirenz or delavirdine should be used with caution if initiated in a patient with prior nevirapine-associated hepatotoxicity.

16 Liver disease

P. Kennedy and J. G. O'Grady

Key points

- The liver is a complex organ central to the maintenance of homeostasis.
- The liver is notable for its capacity to regenerate unless cirrhosis has developed. There are now some data to suggest that cirrhosis is reversible in selected cases, for example treated hepatitis B virus.
- The spectrum of liver disease extends from mild, self-limiting conditions to serious illnesses which may carry significant morbidity and mortality.
- Liver disease is defined as acute or chronic on the basis of whether the history of disease is less than or greater than 6 months, respectively.
- Viral infections and paracetamol overdose are the leading causes of acute liver disease, but a significant number of patients have no defined aetiology (seronegative hepatitis).
- Alcohol abuse and chronic viral hepatitis (B and C) are the major causes of chronic liver disease.
- Cirrhosis may be asymptomatic for considerable periods of time.
- Ascites, encephalopathy, varices and hepatorenal failure are the main serious complications of cirrhosis.
- A careful assessment is required prior to the use of any drug in a patient with liver disease due to unpredictable effects on drug handling.

The liver weighs up to 1500 g in adults and as such is one of the largest organs in the body. The main functions of the liver include protein synthesis, storage and metabolism of fats and carbohydrates, detoxification of drugs and other toxins, excretion of bilirubin and metabolism of hormones, as summarised in Fig. 16.1. The liver has considerable reserve capacity reflected in its ability to function normally despite surgical removal of 70–80% of the organ or the presence of significant disease. It is noted for its capacity to regenerate rapidly. However, once it has been critically damaged multiple complications develop involving many body systems. The distinction between acute and chronic liver disease is conventionally based on whether the history is less or greater than 6 months, respectively.

The hepatocyte is the functioning unit of the liver. Heptocytes are arranged in lobules and within a lobule hepatocytes perform different functions depending on how close they are to the portal tract. The portal tract is the 'service network' of the liver and contains an artery and a portal vein delivering blood to the liver and bile duct which forms part of the biliary drainage system (Fig. 16.2). The blood supply to the liver is 30% arterial and the remainder is from the portal system which drains most of the abdominal viscera. Blood passes from the portal tract through sinusoids that facilitate exposure to the hepatocytes before the blood is drained away by the hepatic venules and veins. There are a number of other cell populations in the liver, but two of the most important are Kuppfer cells, fixed monocytes that phagocytose bacteria and particulate matter, and stellate cells responsible for the fibrotic reaction that ultimately leads to cirrhosis.

Acute liver disease

Acute liver disease is a self-limiting episode of hepatocyte damage which in most cases resolves spontaneously without clinical sequelae. This is a rare condition in which there is a rapid deterioration in liver function with associated encephalopathy (altered mentation) and coagulopathy. Acute liver failure (ALF) carries a significant morbidity and mortality and may require emergency liver transplantation.

Chronic liver disease

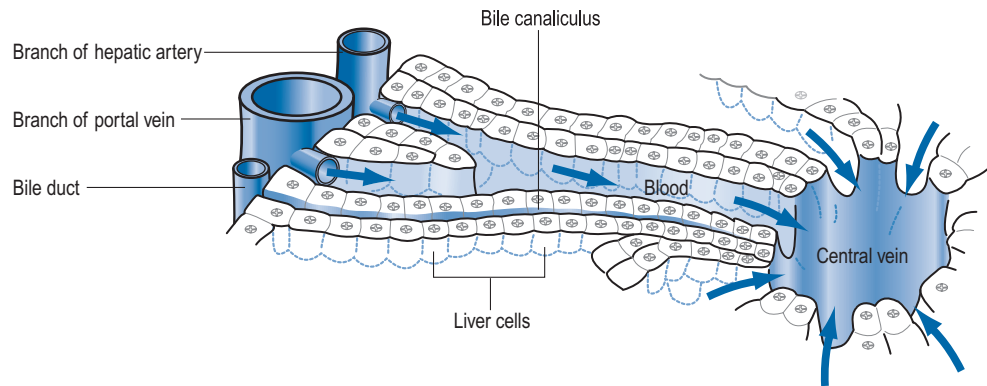
Chronic liver disease occurs when permanent structural changes within the liver develop secondary to long-standing cell damage, with the consequent loss of normal liver architecture. In many cases, this progresses to cirrhosis, where fibrous scars divide the liver cells into areas of regenerative tissue called nodules (Fig. 16.3). Conventional wisdom is that this
Fig. 16.1 Normal physiological functions of the liver, with examples of each.


Fig. 16.2 Illustration of the relationship between the three structures that comprise the portal tract, with blood from both the hepatic artery and portal vein perfusing the hepatocytes before draining away towards the hepatic veins (central veins). Each hepatocyte is also able to secrete bile via the network of bile ducts. (Reproduced with permission of McGraw-Hill from Vander, 1980.)
Fig. 16.3 The gross post-mortem appearance of (A) a normal and (B) a cirrhotic liver demonstrating scarring and nodule formation in part B.

process is irreversible, but therapeutic intervention in hepatitis B and haemochromatosis has now repeatedly documented cases of reversal of cirrhosis. Once chronic liver disease progresses, patients are at risk of developing liver failure, portal hypertension or hepatocellular carcinoma. Cirrhosis is a sequel of chronic liver disease of any aetiology and it develops over very variable time periods from 5 to 20 or more years.

Causes of liver disease

Viral infections

Viruses commonly affect the liver, resulting in a transient and innocuous hepatitis. Viruses which target the liver are primarily described as hepatotropic viruses, and each of these can lead to clinically significant hepatitis and in some cases to the development of chronic viral hepatitis with viral persistence. Five human viruses have been well described to date, including hepatitis A (HAV), B (HBV), C (HCV), D (HDV) and E (HEV). Each type of viral hepatitis causes a similar pathology with acute inflammation of the liver. Types A and E are classically associated with an acute and sometimes severe hepatitis which is invariably self-limited, but occasionally fatal. Hepatitis B causes acute hepatitis in adults and 5% of patients become chronic carriers, while 95% of patients infected in the neonatal period are chronically infected. Hepatitis C rarely causes an acute hepatitis but up to 85% of patients become chronic carriers. Both viruses cause chronic liver inflammation or hepatitis, cirrhosis and hepatocellular carcinoma.

Hepatitis A

Hepatitis A virus (HAV) is a non-enveloped RNA virus and a major cause of acute hepatitis worldwide, accounting for up to 25% of clinical hepatitis in the developed world. HAV is an enteric virus and the faecal oral route is the main mechanism of transmission. The virus is particularly contagious and constitutes a public health problem throughout the world. The virus may go unnoticed by the patient in the absence of an icteric episode, particularly in children. However, HAV can cause ALF in less than 1% of patients who are typically older adults. The virus is particularly prevalent in areas of poor sanitation, and often associated with water- and food-borne epidemics. Hepatitis A has a relatively short incubation period (2–7 weeks), during which time the virus replicates and abnormalities in liver function tests can be detected.

Hepatitis B

Up to 500 million people worldwide are chronically infected with the hepatitis B virus (HBV). Chronic HBV is defined as the presence of hepatitis B surface antigens (HBsAg) for a period of more than 6 months. In endemic areas of Africa and the Far East, up to 15–20% of the population are chronic carriers of HBV and exposure to HBV at birth (vertical transmission)

is the single most important risk factor for the development of chronic HBV infection. Acquisition of HBV in adulthood is often via sexual transmission and is usually associated with a discrete episode of hepatitis. HBV can also be transmitted parenterally, by the transfusion of blood or blood products from contaminated stocks and by intravenous drug use or needle sharing.

There are many factors that determine the outcome of HBV infection, ranging from age and genetic factors of the host to virus characteristics. Acute HBV infection has a peculiarly long incubation period of 3–6 months, which is generally self-limiting and does not require antiviral therapy. Most patients recover within 1–2 months of the onset of jaundice. The protracted incubation period and the ability of the virus to escape the host immune response contribute to the development of chronic HBV. Chronic HBV is associated with varying levels of viraemia and hepatic inflammation. The level of viraemia, and thus infectivity, was conventionally determined by the presence of the hepatitis Be antigen (HBeAg); and HBeAg loss resulted in a reduction in HBV viraemia and a more favourable outcome. However, HBeAg negative chronic hepatitis with significantly elevated levels of HBV DNA is now recognised as a growing health care problem and is associated with a poorer prognosis. HBeAg negative chronic HBV results as a consequence of the emergence of escape mutants from the core promoter or pre-core regions of the virus. It is estimated that 15–40% of HBV carriers will develop serious sequelae during their lifetime, namely liver cirrhosis and/or hepatocellular carcinoma, which can develop in chronic HBV in the absence of cirrhosis. Childhood infection is associated with a different disease outcome with a higher percentage of patients developing chronic HBV infection, and owing to the protracted exposure to the virus a higher proportion develop cirrhosis and hepatocellular carcinoma.

Hepatitis C

Over 170 million people worldwide are chronically infected with hepatitis C virus (HCV). HCV is a hepatotropic, non-cytopathic, predominantly blood borne virus with greater infectivity than the human immunodeficiency virus (HIV). It is estimated that more than 2.7 million people in the USA are chronically infected with HCV, where it is the leading cause of death from liver disease. The equivalent estimate for the UK is between 200,000 and 500,000, although a considerable proportion of these have not yet been diagnosed. HCV is transmitted parenterally, most commonly through intravenous drug use and the sharing of contaminated needles. Prior to its identification in 1990, HCV (previously known as Non-A, Non-B viral hepatitis) was also contracted through contaminated blood and blood products. The introduction of widespread screening of blood donors and pooled blood products has largely consigned blood transfusion as a mode of transmission to history. There remains a small risk of HCV infection associated with tattooing, electrolysis, ear piercing, acupuncture and sexual contact. The vertical transmission rate from HCV infected mother to child is less than 3%.

Hepatitis D

Hepatitis D virus (HDV) is an incomplete virus that can establish infection only in patients simultaneously infected by HBV. It is estimated that 5% of HBV carriers worldwide are infected with HDV. It is endemic in the Mediterranean basin and is transmitted permucosally, percutaneously or sexually. In other geographical areas, it is confined to intravenous drug users.

HCV infection is associated with the development of a recognised episode of acute hepatitis in only a small percentage of individuals. The majority of patients remain asymptomatic and so are often unaware of the infection or the timing of when they contracted the virus. Symptoms associated with HCV infection tend to be mild constitutional upset with malaise, weakness and anorexia being most commonly reported. Up to 85% of subjects exposed to HCV develop chronic disease, which can lead to progressive liver damage, cirrhosis and hepatocellular carcinoma. Unlike HBV, the risk of developing hepatocellular carcinoma is almost totally linked to the presence of cirrhosis. Approximately 20–30% of patients with chronic HCV infection progress to end-stage liver disease within 20–30 years and alcohol consumption is a recognised co-factor that accelerates disease progression. HCV infection is now the leading worldwide indication for liver transplantation.

Hepatitis E

Hepatitis E virus (HEV) is endemic in India, Asia, the Middle East and parts of Latin America. It is an RNA virus which is transmitted enterically and leads to acute hepatitis. The symptoms of HEV are no different from other causes of viral hepatitis, with an average incubation period of 42 days. It was previously thought that the risk of death was increased in pregnancy, especially in the final trimester, but more recent data do not support this belief.

Alcohol

Alcohol is the single most significant cause of liver disease throughout the Western world accounting for between 40% and 60% of cases of cirrhosis in different countries. In general, deaths from alcoholic liver disease in each country correlate with the consumption of alcohol per head of population, although additional factors can influence this trend. Liver disease related to recent alcohol consumption presents a broad spectrum, ranging from the relatively benign fatty liver disease to the development of alcoholic hepatitis, a condition with an immediate mortality of between 30% and 60%. An estimated 20% of alcohol abusers develop progressive liver fibrosis, which can eventually lead to alcoholic cirrhosis, typically after a period of 10–20 years of heavy indulgence.

The central event in the development of hepatic fibrosis is the transformation of hepatic stellate cells into matrix secreting cells producing pericellular fibrosis. This network of collagen fibres develops around the liver cells and gradually leads to hepatocyte cell death. The extent of fibrosis progresses and micronodular fibrotic bands develop characterising alcoholic cirrhosis. The anatomical changes within the liver increase

resistance to blood flow from the portal system, causing an increase in pressure within this system resulting in portal hypertension. As the number of normally functioning liver cells reduces further, because of continued liver cell failure and death, the clinical condition deteriorates progressively with the development of liver failure. The rate of disease progression, and indeed regression, is very strongly linked to whether or not patients continue to consume alcohol.

Non-alcohol related fatty liver disease

Liver pathology that is very similar to alcohol-induced disease is now well recognised in a number of settings including obesity, diabetes mellitus and the metabolic syndrome. As a result, the entities of non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH) have been introduced. It has been suggested that up to 25% of the U.S. population have NAFLD. The majority of cases of cryptogenic cirrhosis probably reflect the end stage of the NAFLD/NASH disease process even though by that stage the characteristic fatty infiltrate has disappeared.

Immune disorders

Autoimmune disease can affect the hepatocyte or bile duct and is characterised by the presence of auto-antibodies and raised immunoglobulin levels.

Autoimmune hepatitis (AIH)

AIH is an unresolving inflammation of the liver characterised by the presence of auto-antibodies (anti-smooth muscle [type 1] or anti-kidney, liver microsomal [type 2]), hypergammaglobulinemia and an interface hepatitis on liver histology. It is usually a chronic, progressive disease which can occasionally present acutely with a severe hepatitis. AIH typically occurs in young women, between 20 and 40 years, and often with a history or family history of autoimmune disorders.

Primary biliary cirrhosis (PBC)

PBC is an autoimmune disease of the liver which predominantly affects middle aged women (95% of cases are female). It is characterised by the presence of antimitochondrial antibodies and a granulomatous destruction of the interlobular bile ducts leading to progressive ductopenia, fibrosis and cirrhosis. The disease is progressive, albeit over a period of 20 years or longer if diagnosed at an early stage, and liver transplantation is the only effective treatment.

Primary sclerosing cholangitis (PSC)

PSC is an idiopathic chronic inflammatory disease resulting in intra- and extra-hepatic biliary strictures, cholestasis and eventually cirrhosis. There is a strong association with inflammatory bowel disease, particularly ulcerative colitis; 75% of PSC patients have ulcerative colitis and 5–8% of patients with ulcerative colitis develop PSC. It has a predeliction for young Caucasian males (mean age at presentation 39 years), but it can occur in infancy or childhood and can affect any race. Cholangiocarcinoma develops in up to 10% of patients with PSC.

Vascular abnormalities

The Budd–Chiari syndrome (BCS) is a rare, heterogeneous and potentially fatal condition related to the obstruction of the hepatic venous outflow tract. The prevalence of underlying thrombophilia is markedly increased in patients with BCS. Affected patients are commonly women with an average age at presentation of 35. Early recognition and immediate use of anticoagulation has vastly improved outcome. More advanced disease can be treated in a number of ways including venoplasty, transjugular intrahepatic portosystemic shunt (TIPS), surgical shunts or liver transplantation.

Metabolic and genetic disorders

There are various inherited metabolic disorders that can affect the functioning of the liver.

Haemochromatosis

Hereditary haemachromatosis (HH) is the most commonly identified genetic disorder in the Caucasian population. It is associated with increased absorption of dietary iron resulting in deposition within the liver, heart, pancreas, joints, pituitary gland and other organs. This can lead to cirrhosis and hepatocellular carcinoma.

Wilson's disease

Wilson's disease is an autosomal recessive disorder of copper metabolism. The disorder leads to excessive absorption and deposition of dietary copper within the liver, brain, kidneys and other tissues. Presentation can vary widely from chronic hepatitis, asymptomatic cirrhosis, ALF to neuropsychiatric symptoms with cognitive impairment.

α_1-Antitrypsin deficiency

This is an autosomal recessively inherited disease and is the most common genetic metabolic liver disease. The disease results in a reduction in α_1-antitrypsin which is protective against a variety of proteases including trypsin, chymotrypsin, elastase and proteases present in neutrophils. The homozygous form of the disease (ZZ phenotype) is associated with the development of liver disease and cirrhosis in 15–30% of both adult and paediatric patients.

Glycogen storage disease

Glycogen storage disease is a rare disease occurring in 1 in 100,000 births. Enzymatic deficiencies at specific steps in the pathway of glycogen metabolism cause impaired glucose production and accumulation of abnormal glycogen in the liver.

Gilbert's syndrome

Gilbert's syndrome is characterised by persistent mild unconjugated hyperbilirubinaemia. It is most frequently recognised in adolescents and young adults with an incidence of between 2% and 7% in the general population. Serum bilirubin levels fluctuate but can increase to 80–100 µmol/L during periods of stress, sleep deprivation, prolonged fasting, menstruation and intercurrent infections. Gilbert's syndrome is an asymptomatic condition requiring no therapy, although patients may inappropriately associate being jaundiced with the symptoms of the condition that triggered the increase in the bilirubin levels.

Drugs

Drugs are an important cause of abnormal liver function tests and acute liver injury, including ALF (DILI drug-induced liver injury). Drugs can also be relevant to a number of chronic liver diseases including steatosis, fibrosis/cirrhosis, autoimmune and vascular disease. In most situations, the drug is implicated because of an appropriate temporal relationship between the disease and drug exposure.

Clinical manifestations

Symptoms of liver disease

In patients who have liver disease, weakness, increased fatigue and general malaise are common but non-specific symptoms. Weight loss and anorexia are more commonly seen in chronic liver disease and loss of muscle bulk is a characteristic of very advanced disease. Abdominal discomfort may be described by patients with an enlarged liver or spleen while distension with ascites is usually the cause in more advanced disease. Abdominal pain is common in hepatobiliary disease, frequently localised to the right upper quadrant. This is often a feature of rapid or gross enlargement of the liver when the pain is thought to be a consequence of capsular stretching. Tenderness over the liver is a symptom of acute hepatitis, hepatic abscess or hepatic malignancy.

Jaundice is the most striking symptom of liver disease and can present with or without pain, depending on the underlying aetiology of disease. Pruritus can be a distressing symptom in cholestatic liver disease and patients usually complain that it is worse at night. Patients with acute and chronic liver disease can develop bleeding complications because of defective hepatic synthesis of coagulation factors and low platelet counts

Signs of liver disease

Cutaneous signs

Hyperpigmentation is common in chronic liver disease and results from increased deposition of melanin. It is particularly associated with PBC and haemachromatosis. Scratch marks on the skin suggest pruritus which is a common feature of cholestatic liver disease. Vascular 'spiders' referred to as spider naevi are small vascular malformations in the skin and are found in the drainage area of the superior vena cava, commonly seen on the face, neck, hands and arms. Examination of the limbs can reveal several signs, none of which are specific to liver disease. Palmar erythema, a mottled reddening of the palms of the hands, can be associated with both acute and chronic liver disease. Dupuytren's contracture, thickening and shortening of the palmar fascia of the hands causing flexion deformities of the fingers, was traditionally associated with alcoholic cirrhosis. It is now considered to be multifactorial in origin and not to reflect primary liver disease. Nail changes, highly polished nails or white nails (leukonychia) can be seen in up to 80% of patients with chronic liver disease. Leukonychia is a consequence of low serum albumin. Finger clubbing is most commonly seen in hypoxaemia related to hepato-pulmonary syndrome, but is also a feature of chronic liver disease (Table 16.1)

Abdominal signs

Abdominal distension, notably of the flanks, is suggestive of ascites which can develop in both acute (less commonly) and chronic liver disease. An enlarged liver (hepatomegaly) is a common finding in acute liver disease. In cirrhotic patients the liver may be large, but alternatively it may be small and shrunken reflecting end-stage chronic disease. An enlarged spleen (splenomegaly) in the presence of chronic liver disease is the most important sign of portal hypertension. Dilated abdominal wall veins are a notable finding in chronic liver disease with the detection of umbilical and para-umbilical veins, a feature of portal hypertension.

Jaundice

Jaundice is the physical sign regarded as synonymous with liver disease and is most easily detected in the sclerae. It reflects impaired liver cell function (hepatocellular pathology)

Table 16.1 Physical signs of chronic liver disease	
Common findings	**End-stage findings**
Jaundice	Ascites
Gynaecomastia & loss of body hair	Dilated abdominal blood vessels
Hand changes:	Fetor hepaticus
Palmar erythema	Hepatic flap
Clubbing	Neurological changes:
Dupuytren's contracture	Hepatic encephalopathy
Leuconychia	Disorientation
Liver mass reduced or increased	Changes in consciousness
Parotid enlargement	Peripheral oedema
Scratch marks on skin	Pigmented skin
Purpura	Muscle wasting
Spider naevi	
Splenomegaly	
Testicular atrophy	
Xanthelasma	
Hair loss	
Fig. 16.4 Common causes of jaundice. Obstructive: due to blockage of the bile ducts; Hepatocellular: due to drugs, hepatitis, chronic liver disease or tumour formation; Prehepatic: due to increased blood breakdown such as occurs in haemolysis.

or it can be cholestatic (biliary) in origin. Hepatocellular jaundice is commonly seen in acute liver disease, but may be absent in chronic disease until the terminal stages of cirrhosis are reached. The causes of jaundice are shown in Fig. 16.4.

Portal hypertension

The increased pressure in the portal venous system leads to collateral vein formation and shunting of blood to the systemic circulation. Portal hypertension is an important contributory factor to the formation of ascites and the development of encephalopathy due to bypassing of blood from the liver to the systemic circulation. The major, potentially life-threatening complication of portal hypertension is torrential venous haemorrhage (variceal bleed) from the thin walled veins in the oesophagus and upper stomach. Patients with portal hypertension are often asymptomatic, while others may present with bleeding varices, ascites and/or encephalopathy.

Ascites

Ascites is the accumulation of fluid within the abdominal cavity. The precise mechanism by which ascites develops in chronic liver disease is unclear, but the following are all thought to contribute:

- Activation of the renin–angiotensin–aldosterone axis as a consequence of central hypovolaemia, leading to a reduction in sodium excretion by the kidney and fluid retention. Reduced aldosterone metabolism due to reduced liver function may also contribute to increased fluid retention.
- A reduction in serum albumin and reduced oncotic pressure is thought to contribute to the collection of fluid in the third space. Peripheral oedema (swollen lower limbs) occurs through this mechanism in a manner similar to the development of ascites.
- Portal hypertension and splanchnic arterial vasodilation alters intestinal capillary pressure and permeability and so facilitates the accumulation of retained fluid in the abdominal cavity.

Sexual characteristics

Endocrine changes are well documented in chronic liver disease and tend to be more common in alcoholic liver disease. Hypogonadism is common in patients with cirrhosis and in males results in testicular atrophy, female body hair distribution and gynaecomastia. This is thought, in part, to occur because the cirrhotic liver cannot metabolise oestrogen, leading to feminisation in males. Gynaecomastia is particularly found in alcoholics but is also seen in those taking spironolactone, when there is usually associated tenderness of the nipples. In women with chronic liver disease menstrual irregularity, amenorrhoea and reduced fertility are encountered in those of reproductive age, but few detectable physical signs are seen as a result of gonadal atrophy.

Investigations

All patients with liver disease must undergo a comprehensive and thorough assessment to ascertain the underlying aetiology. Although causes of acute and chronic liver disease may differ, a similar approach is used to investigate both patient groups to ensure no primary cause or co-factor is overlooked.

Biochemical tests

Biochemical liver function tests (LFTs) are simple, inexpensive and easy to perform but usually cannot be used in isolation to make a diagnosis. Biochemical parameters provide very useful information in monitoring disease progression or response to therapy. The liver enzymes usually measured are the aminotransferases which reflect hepatocellular pathology and the cholestatic liver enzymes, alkaline phosphatase and γ-glutamyl transpeptidase. Aspartate transaminase (AST) and alanine transaminase (ALT) are two intracellular enzymes present in hepatocytes which are released into the blood of patients as a consequence of hepatocyte damage. Extremely high values, where transaminases are recorded in the thousands, occur in acute liver disease, for example, viral hepatitis or paracetamol overdose. In chronic hepatitis, serum transaminases are rarely more than five to eight times the normal upper limit. Alkaline phosphatase is present in the canalicular and sinusoidal membranes of the liver but is also present in other sites, especially bone. Concomitant elevation of the enzyme γ-glutamyl transpeptidase confirms the hepatic origin of an elevated alkaline phosphatase. The serum alkaline phosphatase activity may be raised by up to four to six times the normal limit in intrahepatic or extra-hepatic cholestasis. It can also be raised in conditions associated with liver infiltration, such as metastases.

Bilirubin is commonly elevated in hepatocellular pathology and especially in acute hepatitis and end-stage chronic disease. An increase in bilirubin concentration results in jaundice and is usually clinically apparent when the serum bilirubin level exceeds 50 μmol/L. In acute liver disease, the serum bilirubin reflects severity of disease but is of little prognostic value. In chronic liver disease, a gradual increase for no apparent reason usually reflects serious disease progression. Hepatocellular damage, cholestasis and haemolysis can all cause elevations in the serum bilirubin concentration.

Synthetic function capacity is very important in assessing liver disease. Prothrombin time (PT), international normalised ratio (INR) and other coagulation studies are useful short-term markers of the synthetic function, especially in acute liver insults where they reflect the severity of the liver injury. PT or INR are also important indicators of chronic liver disease when combined with albumin levels. Albumin is synthesised in the liver and serum albumin levels reflect liver function over the preceeding months rather than days as with coagulation studies. Alternative causes of hypoalbuminaemia need to be considered, especially proteinuria.

Laboratory investigation of aetiology

All individuals presenting with derangement of liver function should be tested for hepatitis A, B, and C as part of a routine liver disease screen. Auto-antibodies and immunoglobulins to screen for autoimmune disease are also relevant to both acute and chronic liver disease. Serum ferritin, caeruloplasmin (in patients under 40 years), α_1-antitrypsin phenotype and lipid profile are standard investigations in patients with evidence of chronic liver disease.

Imaging techniques

Ultrasound is a non-invasive, low-risk procedure that is pivotal in the preliminary assessment of liver disease as it assesses the size, shape and texture of the liver and screens for dilatation of the biliary tract. In patients with chronic liver disease, it assesses patency of the portal vein and may detect signs of portal hypertension (increased spleen size, ascites). It is also routinely used to screen for hepatocellular carcinoma and other hepatobiliary malignancies. Computed tomography (CT) and magnetic resonance (MR) scans are regularly used for more precise definition of any abnormalities identified on ultrasound.

Liver biopsy

Liver biopsy is an invasive procedure with an associated morbidity and mortality, albeit extremely low. Nevertheless, it remains the gold standard in establishing a diagnosis and assessing the severity of chronic liver disease. Progress has been made in developing techniques to assess liver fibrosis non-invasively and a technique called Fibroscan appears to be effective in patients with HCV. In some instances, liver histology will contribute to the decision-making process with regard to therapy, for example, whether to initiate antiviral therapy for HBV or HCV. In acute hepatic dysfunction, a liver biopsy is usually unnecessary, especially if the condition is self-limiting.

Patient care

Pruritus

Pruritus is a prominent and sometimes distressing symptom of chronic liver disease and tends to be most debilitating in the context of cholestatic conditions. The pathogenesis of pruritus in liver disease is poorly understood but the deposition of bile salts within the skin is considered to be central to its development. However, the concentration of bile salts in the skin does not appear to correlate with the intensity of pruritus. Management of pruritus is variable. Relief of biliary obstruction by endoscopic, radiological or surgical means is indicated in patients with obstructed biliary systems. In other cases, pharmacological agents are used initially but in some cases plasmapheresis, molecular absorbants recirculating system (MARS) or even liver transplantation may be needed.

Anion exchange resins

Colestyramine and colestipol act by binding bile acids and preventing their reabsorption. These anion exchange resins are the first line of therapy in the treatment of pruritus. Colestyramine is usually initiated at a dosage of 4 g once or twice daily, and the dose is then titrated to optimise relief without causing side effects (predominantly gastro-intestinal). Such adverse effects are common and include constipation, diarrhoea, fat and vitamin malabsorption. Palatability is variable and consequently adherence is often a problem. In order to enhance compliance, patients should be advised that the benefits of therapy may take time to become apparent and often up to a week. Anion exchange resins can reduce the absorption of concomitant therapy and such drugs should be taken 1 h prior to or 4 h after colestyramine or colestipol ingestion. Drugs which are susceptible to this interaction include digoxin, thyroxine, ursodeoxycholic acid (UDCA), chlorothiazide, propranolol and the antibiotics tetracycline and penicillin.

Antihistamines

Although frequently used, antihistamines are usually ineffective in the management of the pruritus caused by cholestasis and should not be considered first-line therapy. A non-sedating antihistamine such as cetirizine (10 mg once daily) or loratidine (10 mg once daily) is preferred as these avoid precipitating or masking encephalopathy. Antihistamines such as chlorphenamine or hydroxyzine provide little more than sedative properties, although they may be useful at night if the severity of pruritus is sufficient to prevent a patient from sleeping.

Ursodeoxycholic acid

The bile acid UDCA (10 mg/kg daily in two divided doses) has been used frequently in cholestatic liver disease and long-term use has been shown to be effective in the treatment of pruritus. However, in about 5% of cases it worsens the pruritus.

Rifampicin

Rifampicin induces hepatic microsomal enzymes, which may benefit some patients, possibly by improving bile flow. Rifampicin, administered at a dose of 600 mg/day may be effective in the treatment of pruritus, albeit over a more prolonged period of time (1–3 weeks). It is most commonly used in patients with PBC. Its use is restricted by its potential hepatotoxicity and drug interactions with other agents.

Opioid antagonists

A growing spectrum of opioid antagonists have been used to treat pruritus because it is believed that endogenous opioids in the central nervous system are potent mediators of itch. As a consequence the centrally acting opioid antagonists naloxone, naltrexone and nalmefene are thought to reverse the actions of these endogenous opioids. The use of such agents is limited by their route of administration. Naloxone is given by subcutaneous injection, while naltrexone and nalmefene are reported to be more substantially bioavailable after oral administration. A summary of drugs used in the management of pruritus is shown in Table 16.2.

Table 16.2   Drugs commonly used in the management of pruritus

Drug	Indication	Daily dose	Advantage	Disadvantage
Colestyramine	Cholestatic jaundice Itching (first line)	4–16 g (in two or three divided doses)	Reduce systemic bile salt levels	Poor patient adherence due to unpalatability Diarrhoea/constipation Increased flatulence Abdominal discomfort
Ursodeoxycholic acid	Cholestatic jaundice Itching	10–15 mg/kg (in two divided doses)		Variable response
Menthol 2% in aqueous cream	Itching	As required	Local cooling effect	Variable response
Chlorphenamine	Itching	4–16 mg (in three or four divided doses)	Sedative effects may be useful for night-time itching	May precipitate/aggravate encephalopathy
Hydroxyzine	Itching	25–100 mg (in three or four divided doses)	Sedative effects may be useful for night-time itching	May precipitate/aggravate encephalopathy
Cetirizine	Itching	10 mg (once daily)	Antihistamine with low incidence of sedation	Variable response
Naltrexone	Itching	50 mg/day	Shown to be beneficial in primary biliary cirrhosis	Opiate withdrawal symptoms, usually transient

Topical preparations

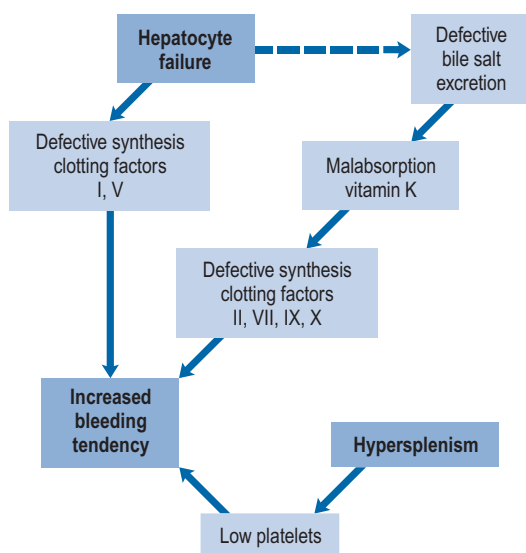
Topical therapy may benefit some patients. Calamine lotion or menthol 2% in aqueous cream are standard preparations, but improvement of pruritus with such agents is variable.

Clotting abnormalities

The relationship of liver disease to clotting abnormalities is shown diagrammatically in Fig. 16.5. Haemostatic abnormalities develop in approximately 75% of patients with chronic liver disease and 100% of patients with ALF. The majority of clotting factors (with the exception of factor V) are dependent on vitamin K. Patients with liver disease who develop deranged blood clotting should receive intravenous doses of phytomenadione (vitamin K), usually 10 mg daily for 3 days. Administration of vitamin K to patients with significant liver disease does not usually improve the prothrombin time because the liver is unable to utilise the vitamin to synthesis clotting factors. Oral vitamin K is less effective than the parenteral form and so, has little or no place in the management of clotting abnormalities and bleeding secondary to liver disease.

Aspirin, non-steroidal anti-inflammatory drugs (NSAIDs) and anticoagulants should be avoided in all patients with liver disease because of the risk of altering platelet function, causing gastric ulceration and bleeding. NSAIDs have also been implicated in precipitating renal dysfunction and variceal bleeding in patients with end-stage liver disease. Although COX-2 inhibitors may cause a lower incidence of bleeding complications, currently they are avoided in patients with liver disease as their use still poses a risk.

Ascites

The aim in the treatment of ascites is to mobilise the abnormal collection of third space fluid (intra-abdominal fluid) and this can be achieved by simple measures such as reduced sodium intake. A low-salt diet (60–90 mEq/day) may be enough to facilitate the elimination of ascites and delay reaccumulation of fluid. Salt reduction combined with fluid restriction (approximately 1–1.5 L/day) are practical measures taken to mobilise fluid and provide weight reduction and symptomatic relief.


Aggressive weight reduction in the absence of peripheral oedema should be avoided as it is likely to lead to intravascular fluid depletion and renal failure. Weight loss should not exceed 300–500 g/day in the absence of peripheral oedema and 800–1000 g/day in those with peripheral oedema to prevent renal failure. However, diuretics and/or paracentesis are the cornerstone in the management of moderate to large volume ascites. A sequential approach to the management of ascites is outlined in Box 16.1.

Diuretics

The aldosterone antagonist, spironolactone is usually used as a first-line agent in the treatment of ascites. In most instances, a negative sodium balance and loss of ascitic fluid can be achieved with low doses of diuretics. Spironolactone can be used alone or in combination with a more potent loop diuretic. The specific agents and dosages used are outlined in Table 16.3. Spironolactone acts by blocking sodium reabsorption in the collecting tubules of the kidney. It is usually commenced at 50–100 mg/day, but this varies, depending on the patient's clinical status, electrolyte levels and concomitant drug therapies. It can take many days to have a therapeutic effect, so dose augmentation should be conducted with caution and strict observation of renal parameters. The addition of a loop diuretic, furosemide 40 mg/day enhances the natriuretic activity of spironolactone, and should be used when ascites is severe or when spironolactone alone fails to produce acceptable diuresis.

The use of more potent diuretic combinations may result in excessive diuresis which can lead to renal failure of pre-renal origin. The initiation and augmentation of diuretic therapy should ideally be carried out in hospital. This allows strict urea and electrolyte monitoring to detect impending hyperkalaemia and/or hyponatraemia, which commonly occur with diuretic therapy. It also allows the

Table 16.3 Diuretics used in the management of ascites

Drug	Indication	Daily dose	Advantage	Disadvantage
Spironolactone	Fluid retention	50–400 mg	Aldosterone antagonist Slow diuresis	Painful gynaecomastia Variable bioavailability Hyperkalaemia
Furosemide	Fluid retention	40–160 mg	Rapid diuresis Sodium excretion	Nephrotoxic Hypovolaemia Hypokalaemia Hyponatraemia Caution in pre-renal uraemia
Amiloride	Mild fluid retention	5–10 mg	As K⁺-sparing agent or weak diuretic if spironolactone contraindicated	Lacks potency

baseline measurement of urinary sodium excretion, subsequent changes in the diuretic dose should be titrated against urinary sodium excretion. Aggressive and unchecked diuresis will precipitate the hepatorenal syndrome, which has a very poor prognosis. Generally, if the serum sodium level decreases to less than 130 mmol/L or if creatinine levels rise to greater than 130 µmol/L then dose escalation of diuretics should be stopped. Diuretic therapy can be complicated by encephalopathy, hypokalaemia, hyponatraemia and azotaemia. Gynaecomastia and muscle cramps are side effects of diuretic therapy.

Refractory ascites, which occurs in 5–10% of patients with ascites, is associated with a 1-year survival rate of 25–50%. Therapeutic strategies include repeated large volume paracentesis combined with the administration of plasma expanders or alternatively, TIPS. In some patients, liver transplantation may be indicated. Ascites is considered to be refractory or diuretic resistant if there is no response with once daily doses of 400 mg spironolactone and 160 mg furosemide. Again, urinary sodium excretion provides important information in terms of the response to or viability of dose augmentation with diuretic therapy. Patients on lower doses of diuretics are also considered to have refractory ascites if side effects are a problem, for example, hepatic encephalopathy, hyperkalaemia, hyponatraemia or azotemia.

Paracentesis

Repeated large volume paracentesis in combination with albumin administration is the most widely accepted therapy for refractory ascites. Patients generally require paracentesis every 2–4 weeks and the procedure is often performed in the outpatient setting. Paracentesis, however, does not affect the mechanism responsible for ascitic fluid accumulation and so early recurrence is common. Intravenous colloid replacement or plasma expanders are used to prevent adverse effects on the renal and systemic circulation. Colloid replacement in the form of 6–8 g albumin/L of ascites removed (equivalent to 100 mL of 20% human albumin solution [1 unit] for every 2.5 L of ascitic fluid removed) is a standard regimen.

Transjugular intrahepatic portosystemic shunting (TIPS)

TIPS is an invasive procedure, used to manage refractory ascites or control refractory variceal bleeding. It is carried out under radiological guidance. An expandable intrahepatic stent is placed between one hepatic vein and the portal vein by a transjugular approach (Fig. 16.6). In contrast to paracentesis, the use of TIPS is effective in preventing recurrence in patients with refractory ascites. It reduces the activity of sodium retaining mechanisms and improves the renal response to diuretics. However, a disadvantage of this procedure is the high rate of shunt stenosis (up to 30% after 6–12 months) which leads to recurrence of ascites. TIPS can also induce or exacerbate hepatic encephalopathy.

Spontaneous bacterial peritonitis (SBP)

Patients with ascites should be closely observed for SBP as it develops in 10–30% of patients and has a high mortality. Hepatorenal syndrome can complicate SBP in up to 30% of
Fig. 16.6 Intrahepatic stent shunt links the hepatic vein with the intraheptic portal vein.

patients and also carries a high mortality. Conventional signs and symptoms of peritonitis are rarely present in such patients and if suspected, treatment with appropriate antibiotics should be started immediately after a diagnostic ascitic tap has been taken. A polymorphonuclear leucocyte count of greater than 250 cells/mm^3 is diagnostic of this condition. The causative organism is of enteric origin in approximately three-quarters of infections, and originates from the skin in the remaining one-quarter. Cefotaxime (2 g, 8 hourly) is effective in 85% of patients with SBP and is commonly used as first-line antimicrobial therapy. Other antibiotic regimens have been used including co-amoxiclav, but third-generation cephalosporins are the treatment of choice. The quinolone, norfloxacin (400 mg/day), has a role in the prevention of recurrence of SBP, estimated as 70% at 1-year, and is recommended for long-term antibiotic prophylaxis. However, the emergence of quinolone-resistant bacteria is a growing problem in the management of SBP.

Hepatic encephalopathy

Hepatic encephalopathy is a reversible neuropsychiatric complication that occurs with significant liver dysfunction. The precise cause of encephalopathy remains unclear, but three factors are known to be implicated, namely portosystemic shunting, metabolic dysfunction and an alteration of the blood–brain barrier. It is thought that intestinally derived neuroactive and neurotoxic substances such as ammonia pass through the diseased liver or bypass the liver through shunts and go directly to the brain. This results in cerebral dysfunction. Ammonia is thought to increase the permeability of the blood–brain barrier, enabling other neurotoxins to enter the brain, and indirectly alter neurotransmission. Other substances implicated in causing hepatic encephalopathy include free fatty acids, γ-aminobutyric acid (GABA) and glutamate.

Clinical features of hepatic encephalopathy range from trivial lack of awareness, altered mental state to asterixis (liver flap) through to gross disorientation and coma. During low-grade encephalopathy, the altered mental state may present as impaired judgement, altered personality, euphoria or anxiety. Reversal of day/night sleep patterns is very typical of encephalopathy. Somnolence, semistupor, confusion and, finally, coma can ensue (Table 16.4).

Encephalopathy associated with cirrhosis and/or portal-systemic shunts may develop as a result of specific precipitating factors (Box 16.2) or spontaneously. Common precipitating factors include gastro-intestinal bleeding, SBP, constipation, dehydration, electrolyte abnormalities and certain drugs including narcotics and sedatives. Identification and removal of such precipitating factors is mandatory. Therapeutic management is then aimed at reducing the amount of ammonia or nitrogenous products in the circulatory system. Treatment with laxatives increases the throughput of bowel contents, by reducing transit time and also increases soluble nitrogen output in the faeces. Drug therapies for encephalopathy are summarised in Table 16.5.

Lactulose, a non-absorbable disaccharide, decreases ammonia production in the gut. It is widely used as it is broken down by gastro-intestinal bacteria to form lactic, acetic and formic

Table 16.4	Grading of hepatic encephalopathy
Grade 0	Normal
Subclinical	Abnormal psychometric tests for encephalopathy (e.g. number correction test)
Grade 1	Mood disturbance, abnormal sleep pattern, impaired handwriting +/− asterixis
Grade 2	Drowsiness, grossly impaired calculation ability, asterixis
Grade 3	Confusion, disorientation, somnolent but arousable, asterixis

acids. The effect of lactulose is to acidify the colonic contents which leads to the ionisation of nitrogenous products within the bowel, with a consequent reduction in their absorption from the gastro-intestinal tract. Lactulose is commenced in doses of 30–40 mL/day and titrated to result in two to three bowel motions each day. Patients unable to take oral medication or those with worsening encephalopathy are treated with phosphate enemas.

Antibiotics such as metronidazole or neomycin may also be used to reduce ammonia production from gastro-intestinal bacteria. Metronidazole has been the preferred option in the past, while the use of neomycin has largely been abandoned because of associated toxicity. Recent data has supported the use of the rifaximin, a minimally absorbed antibiotic, for the treatment of acute encephalopathy and the remission of chronic encephalopathy (Bass et al., 2010). Other therapies investigated for the treatment of encephalopathy include L-ornithine-L-aspartate (LOLA), sodium benzoate, L-dopa, bromocriptine and the benzodiazepine receptor antagonist, flumazenil.

Oesophageal varices

Variceal bleeding is the most feared complication of portal hypertension in patients with cirrhosis and there is a 30% lifetime risk of at least one bleeding episode among patients with cirrhosis and varices. Treatment of variceal bleeding includes

Table 16.5 Drugs commonly used in the management of encephalopathy

Drug	Dose	Comment	Side effects
Lactulose	15–30 mL orally 2–4 times daily	Aim for 2–3 soft stools daily	Bloating, diarrhoea
Metronidazole	400–800 mg orally daily in divided doses	Metabolism impaired in liver disease	Gastro-intestinal disturbance
Neomycin Used less frequently now	2–4 g orally daily in divided doses	Maximum duration of 48 h	Potential for nephro- and ototoxicity
Rifaxamin	550 mg twice daily	Benefit demonstrated over 6 months use	Allergic reactions, gastro-intestinal disturbance May permit overgrowth *Clostridium difficile*

endoscopic banding, or rarely sclerotherapy, of oesophageal varices in parallel with splanchnic vasoconsrictors and intensive medical care. Patients with variceal bleeding refractory to endoscopic intervention or patients bleeding from ectopic or uncontrolled gastric varices will need TIPS or surgical decompressive shunts. Refractory variceal bleeding should, therefore, be managed in centres with the appropriate expertise.

Initial treatment is aimed at stopping or reducing the immediate blood loss, treating hypovolaemic shock, if present, and subsequent prevention of recurrent bleeding. Immediate and prompt resuscitation is an essential part of treatment. Only when medical treatment has been initiated and optimised should endoscopy be performed. Endoscopy confirms the diagnosis and allows therapeutic intervention. Fluid replace-

ment is invariably required, and should be in the form of colloid or packed red cells and administered centrally. Saline should generally be avoided in all patients with cirrhosis. Fluid replacement must be administered with caution, as overzealous expansion of the circulating volume may precipitate further bleeding by raising portal pressure, thereby exacerbating the clinical situation. A flow chart for the management of bleeding oesophageal varices is shown in Fig. 16.7.

Endoscopic management

Variceal band ligation uses prestretched rubber bands applied to the base of a varix which has been sucked into the banding chamber attached to the front of an endoscope. Variceal
Fig. 16.7 Management of oesophageal variceal haemorrhage.

band ligation (VBL) controls bleeding in approximately 90% of cases. It is at least as effective as sclerotherapy, which it has largely superceded, and is associated with fewer side effects. Balloon tamponade with a Sengstaken–Blakemore balloon or Linton balloon may be used to stabilise a patient with actively bleeding varices by directly compressing the bleeding varices, until more definitive therapy can be undertaken. Balloon tamponade can control bleeding in up to 90% of cases but 50% rebleed when the balloon is deflated. Gastric varices develop in approximately 20% of patients with portal hypertension. The risk of gastric variceal bleeding is lower than that of oesophageal variceal bleeding, but bleeding from fundal varices is more difficult to manage and is associated with a higher mortality. The most effective treatment strategy for fundal varices is now considered to be variceal obturation with tissue adhesives or 'glue injection'. The use of cyanoacrylate injection in the treatment of fundal varices is associated with less rebleeding and is emerging as the treatment of choice in the hands of experienced endoscopists.

Drug treatment

Several pharmacological agents are available for the emergency control of variceal bleeding (Table 16.6). Most act by lowering portal venous pressure. They are generally used to control bleeding in addition to balloon tamponade and emergency endoscopic techniques. Vasopressin was the first vasoconstrictor used to reduce portal pressure in patients with actively bleeding varices. However, its associated systemic vasoconstrictive adverse effects limited its use. The synthetic vasopressin analogue, terlipressin, is highly effective in controlling bleeding and in reducing mortality. It can be administered in bolus doses every 4–6h and has a longer biological activity and a more favourable side effect profile. Once a diagnosis of variceal bleeding has been established, a vasoactive drug infusion (usually terlipressin) should be started without further delay and continued for 2–5 days. Somatostatin and the somatostatin analogue, octreotide, are reported to cause selective splanchnic vasoconstriction and reduce portal pressure. Although they are reported to cause less adverse effects on the systemic circulation, terlipressin remains the agent of choice.

Transjugular intrahepatic portosystemic shunt (TIPS)

TIPS is now established as the preferred rescue therapy in cases where endoscopic intervention has failed to control bleeding (Fig. 16.7). Recent data suggests the use of early

Table 16.6	Drugs used in the treatment of acute bleeding varices
Drug	Dosage and administration
Terlipressin	1–2 mg bolus 4–6 hourly for 48 h
Octreotide	50 μcg/h i.v. infusion for 48 h or longer if patient rebleeds

TIPS, within the first 48h, may be life saving in patients with advanced liver failure.

Prevention of rebleeding

Endoscopic band ligation (EBL) is performed at regular intervals (1–2 weeks) as part of an eradication programme to obliterate the varices. Once varices have been eradicated, endoscopic follow-up can be performed less frequently (3 monthly) for the first year, then twice yearly thereafter. If varices reappear they should be banded regularly until eradicated again. Non-selective β-blockers, such as propranolol, are the medication of choice to prevent rebleeding and can also be used as primary prophylaxis against variceal bleeding in patients with known varices. The mechanism of action is complex, but they reduce portal hypertension by causing splanchnic vasoconstriction and reduced portal blood flow. At higher doses they can have a more marked negative effect on cardiac output and so must be titrated accordingly.

Acute liver failure

ALF occurs when there is a rapid deterioration in liver function in previously healthy individuals resulting in encephalopathy and a coagulopathy. ALF is a multisystem disorder with cerebral oedema and renal impairment being particularly important complications. In the past, viral hepatitis was a major consideration in the aetiology of ALF. However, the development of a commercial vaccine for hepatitis B has seen a dramatic decline in the contribution of HBV to ALF in Western countries. The most common cause of ALF in the UK and USA is paracetamol (acetaminophen) toxicity. Seronegative hepatitis is the other common aetiological group. Management of ALF is complicated, involving supporting the central nervous system, cardiovascular and renal systems. All patients with ALF are at risk of infection, and prophylactic administration of broad spectrum antibiotics and antifungal agents is standard practice. Coagulopathy and bleeding resulting from liver failure are well-recognised life-threatening complications which require specialised monitoring and early correction.

Liver transplantation

Liver transplantation is the established treatment for selected patients with ALF, decompensated chronic liver disease, inherited metabolic disorders and primary liver cancer. HCV and alcohol-induced end-stage liver disease are the commonest indications for liver transplantation in Europe and the USA. Typical 1 year survival rates are around 90% for elective transplants. Remarkably few transplants fail because of rejection and, nowadays, technical problems, infection and multisystem failure account for most deaths in the first year. Recurrence of the primary disease, malignancy and death with a functioning graft account for most late deaths.

An increasing number of immunosuppressive agents are now available and this has enabled clinicians to tailor immunosuppression to achieve a balance of good graft function

and an acceptable side effect profile. The calcineurin inhibitors (CNIs), tacrolimus and ciclosporin remain the mainstay of immunosuppressive therapy. Corticosteroids are still commonly used, at least during the first 3 months after transplantation. The other drugs used regularly for long-term immunosuppression include azathioprine, mycophenolate, sirolimus and everolimus. Therapy is monitored closely and increasingly tailored to individual patients, with a particular emphasis on preserving renal function and reducing the risk of cardiovascular disease.

Disease specific therapies

Hepatitis B

The primary goal in the management of chronic HBV infection is to prevent cirrhosis, hepatic failure and hepatocellular carcinoma. The ideal outcome is eradication of HBV with HBsAg loss and the prevention of irreversible liver damage. However, the eradication of HBV is near impossible because of the presence of extra-hepatic reservoirs of HBV and the integration of HBV into the host genome and the presence of an intracellular conversion pathway which replenishes the pool of transcriptional templates in the hepatocyte nucleus without the need for reinfection. For this reason, the main treatment goal is continuous viral suppression and current therapies, specifically with oral antiviral agents, are judged by their ability to provide continuous viral suppression.

It is the persistence of covalently closed circular DNA (cccDNA) which is considered to preclude a 'cure' for HBV. Thus, therapies currently available for the treatment of chronic HBV are measured in terms of HBeAg seroconversion (in eAg positive disease), viral suppression, ALT normalisation and improvement in liver histopathology. More recently, there has been specific focus on HBsAg quantification, with loss of HBsAg considered a surrogate marker of cccDNA levels (Sung et al., 2005). Thus, all therapies in the treatment of HBV should be benchmarked against HBsAg loss, as a marker of drug utility and efficacy.

There is now consensus amongst the major liver disease authorities in terms of their clinical practice guidelines and the recommended agents available for the treatment of chronic HBV infection. Treatment strategies have broadened and include the potent oral antiviral agents tenofovir (Marcellin et al., 2008; National Institute for Health and Clinical Excellence, 2009) and entecavir (National Institute for Health and Clinical Excellence, 2008) as first-line monotherapies. While these two agents have emerged as the leading oral antivirals, the weaker and more outdated agents such as telbivudine, lamivudine and adefovir are still widely used. The use of lamivudine or adefovir as monotherapy is no longer recommended and should be avoided if at all possible, owing to the high rates of resistance reported with these drugs. Pegylated interferon (peginterferon) alfa-2a has re-emerged as a viable alternative to oral antiviral agents in the treatment of chronic HBV. This is due primarily to its potent immunomodulatory effects which gives it a clear advantage over oral antivirals. Significant rates of surface antigen (sAg) loss have been reported in both HBeAg positive and negative disease and the inclusion of surface antigen quantification has provided an objective tool to assess response to pegylated interferon. The advantages of interferon therapy, such as a finite treatment course, good rates of surface antigen loss in selected patients, must be weighed against the disadvantages associated with an injection-based therapy and the inherent side effect profile associated with interferons. Therefore, a careful and rational approach must be followed when considering treatment of chronic HBV. While reported rates of resistance is extremely low with entecavir, and none reported with tenofovir, the treatment landscape for chronic HBV has changed dramatically from the high rates of resistance previously seen with lamivudine and adefovir. However, when commencing oral antiviral agents, the patient must be aware they are potentially embarking on a lifelong course of treatment.

An issue which must be given further consideration is the potential side effect profile of these relatively new drugs, notwithstanding their potency and documented efficacy. The potential for unforeseen side effects must be considered unresolved, as safety data to date are limited by the relatively short period of time that these drugs have been used in clinical practice. Likewise, physicians will need to remain vigilant for the emergence of resistant virus, even with these potent agents with well-described high-genetic barriers to resistance.

Hepatitis C

The primary aim of treating patients with chronic HCV is viral clearance with sustained virologic response (SVR) defined as the absence of viraemia 6 months after antiviral therapy has been discontinued. Viral clearance improves the patient's quality of life and reduces the risk of progression to cirrhosis and hepatocellular carcinoma.

Pegylated interferon and ribavirin combination therapy are now the standard care of chronic HCV (National Institute for Health and Clinical Excellence, 2010). The SVR for treatment of naïve patients is of the order of 55% for genotypes 1 and 4 (48 weeks of therapy) and 80–85% for genotypes 2 and 3 (24 weeks of therapy). The treatment duration, however, can be individualised based on the baseline viral load and the speed of virological response during treatment. Patients failing to achieve a significant reduction in viral load after 12 weeks will normally have therapy discontinued. The current standard of care combination therapy is limited by the side effect profile, complications of therapy and poor patient tolerability. Side effects of therapy include influenza-like symptoms, decrease in haematological parameters (haemoglobin, neutrophils, white blood cell count and platelets), gastrointestinal complaints, psychiatric disturbances (anxiety and depression) and hypo- or hyperthyrodism. It is accepted that these side effects are a major obstacle preventing completion of therapy by hindering compliance or enforcing significant dose reductions. While growth factors (erythropoietin, GCSF) and antidepressants may alleviate some side effects,

there remains a clear need for better treatment strategies in chronic HCV infection.

Significant progress has been made in the development of new HCV-specific inhibitors. Data from recent trials have shown a marked improvement in SVR when these new protease inhibitors, telaprevir and boceprevir are given in combination with current standard of care, increasing response rates to 61–75% in genotype 1 HCV infection. It is anticipated that these agents will be available for clinical practice from 2011. Several new HCV-specific inhibitors are currently in clinical evaluation including protease inhibitors, nucleoside and non-nucleoside polymerase inhibitors as well as non-HCV compounds with anti-HCV activity. It is envisaged, as a result of this evolution of HCV therapies, that the treatment options for HCV will become more robust.

Autoimmune hepatitis

Corticosteroids and/or azathioprine are the standard therapy for AIH. Prednisone or prednisolone are administered at doses of 40–60 mg/day alone or at lower doses when combined with azathioprine. The steroid dose is reduced over a 6-week to 3-month period to a target maintenance dose of 7.5 mg/day or lower. The disturbance in aminotransferases usually normalises within 6–12 weeks, but histological remission tends to lag by 6–12 months. Azathioprine at a dose of 1–1.5 mg/kg/day is used as an adjunct to corticosteroid therapy. Azathioprine, used alone, is ineffective in treating the acute phase of AIH. In patients intolerant of azathioprine, or in cases of proven treatment failure, other immunosuppressants have been used, for example, tacrolimus and mycophenolate. Newer corticosteroids such as budesonide, with fewer systemic side effects, have also been used effectively and may have a greater role in the future treatment of AIH.

Primary biliary cirrhosis. Several therapies have been associated with short-term symptomatic improvements in liver function tests. UDCA, the only medication widely used to treat PBC, reduces the retention of bile acids and increases their hepatic excretion. Therefore, it is effective in protecting against the cytotoxic effects of dihydroxy bile acids which accumulate in PBC. However, UDCA does not appear to prevent ongoing bile duct injury and disease progression. Therefore, liver transplantation remains the only effective option in patients with end-stage disease. Immunosuppressive agents such as ciclosporin, azathioprine and methotrexate have also been assessed for the treatment of PBC but clinically significant adverse events outweigh the potential benefits.

Primary sclerosing cholangitis

There is no effective treatment for this condition. UDCA can be used to manage associated cholestasis, and doses as high as 15 mg/kg/day have been advocated despite the limited evidence that it alters the natural history of the disease. Studies with various immunosuppressive agents have been disappointing and transplantation remains the only effective treatment option in patients with advanced disease.

Wilson's disease

This rare autosomal recessive condition is usually managed with chelation therapy. Penicillamine is the agent of choice in Wilson's disease as it promotes urinary copper excretion in affected patients and prevents copper accumulation in presymptomatic individuals. Initial treatment of 1.5–2 g/day is given in divided doses. Initially, neurological symptoms may worsen because of deposition of mobilised copper in the basal ganglia, but symptomatic patients tend to improve over a period of several weeks. Other therapy-related adverse effects include renal dysfunction, haematological abnormalities and disseminated lupus erythematosis. Therefore, regular monitoring of full blood count and electrolytes is required as well as small doses of pyridoxine (25 mg) to counteract the antipyridoxine effect of penicillamine and the associated neurological toxicity. Patients unable to tolerate penicillamine may respond to trientine. This chelating agent is less potent than penicillamine but has fewer adverse effects. Oral zinc is also used but it too is less potent than penicillamine.

Case studies

Case 16.1

A 56-year-old man is admitted to hospital following haematemesis and melaena. He has a known history of alcoholic liver disease (stopped drinking alcohol 1 year ago) with marked ascites.
A provisional diagnosis of bleeding oesophageal varices is made.

A Sengstaken–Blakemore tube is inserted and the balloon inflated as a temporary measure to arrest bleeding. The patient is transferred 8 h later to a specialist regional centre for further management.

Laboratory data on admission are:

Na	124 (133–143 mmol/L)
K	3.0 (3.5–5.0 mmol/L)
Creatinine	131 (80–124 µmol/L)
Urea	14.3 (2.7–7.7 mmol/L)
Bilirubin	167 (3.15 µmol/L)
ALT	24 (0–35 IU/L)
PT	18.9 (13 s)
Albumin	24 (35–50 g/dL)
Hb	8.9 (13.5–18 g/dL)

Drugs on admission:

Spironolactone 200 mg one each morning.

Questions

1. What other action would you have recommended before the patient was transferred to the regional centre?
2. What options (drug and/or non-drug) are likely to be available at the regional centre for managing the patient's bleeding varices?
3. What further long-term measures would you recommend for this patient?

Answers

1. Initial restoration of circulating blood volume with colloid, followed by cross-matched blood. Fluid replacement is necessary to protect renal perfusion. In view of the patient's ascites, saline should be avoided. Dextrose 5% with added

potassium (hypokalaemia present) would be a reasonable choice. A pharmacological agent to reduce portal pressure, such as terlipressin 1–2 mg every 4–6 h or octreotide 50 μcg/h, should be started. Current evidence supports terlipressin over octreotide. Broad spectrum antibiotics such as cefuroxime and metronidazole should be started intravenously if there is suspicion of abdominal infection or sepsis. There is no evidence that gastric acid suppression is beneficial, but if the bleeding is caused by a gastric mucosal lesion, a proton pump inhibitor such as lansoprazole or omeprazole, or a histamine type-2 receptor antagonist such as ranitidine can be administered.

Spironolactone is likely to be either causing or exacerbating the low sodium and should be discontinued.

Vitamin K, 10 mg intravenously once daily for 3 days, should be administered to try to correct the raised prothrombin time. As the patient has severe liver disease with varices and ascites there is a possibility he may develop encephalopathy. It would be advisable to start lactulose or, if the patient is unable to take medicines orally, administer an enema such as a phosphate enema.

2. *Banding/ligation*: this has a similar efficacy to sclerotherapy but fewer complications. It involves mechanical strangulation of variceal channels by small elastic plastic rings mounted on the tip of the endoscope.

Transjugular intrahepatic portosystemic shunt (TIPS): this can be used to reduce portal pressure, but there is a risk of precipitating encephalopathy.

Banding is the first-line option for managing bleeding oesophageal varices. Patients who continue to bleed after two endoscopic treatments should be considered for TIPS. Surgery involving portal-systemic shunts or devascularisation are possible options if the above alternatives repeatedly fail. Extra-hepatic portal-systemic shunts are situated outside the liver and divert portal blood flow into the systemic circulation bypassing the liver. Devascularisation involves obliteration of the collateral vessels supplying blood to the varices.

3. Banding/ligation can be performed at regular intervals of 1–2 weeks to obliterate the varices. Once varices have been eradicated, endoscopic follow-up should be undertaken every 3 months for the first year then every 6–12 months thereafter. If varices reappear they should be banded regularly until eradicated again. Non-selective β-blockers such as propranolol are used in the prophylaxis of further bleeds, with the dose adjusted until the heart rate is reduced by 25%, but to not less than 55 beats/min.

Case 16.2

A 68-year-old woman with a long-standing history of alcoholic liver disease is admitted to hospital with a 2-week history of vomiting, confusion, increased abdominal distension and worsening jaundice.

On admission laboratory data are as follows:

Na	116 (133–143 mmol/L)
K	3.8 (3.5–5 mmol/L)
Urea	8.5 (3.3–7.7 mmol/L)
Cr	119 (80–124 μmol/L)
Bilirubin	459 (3–17 μmol/L)
Albumin	23 (35–50 g/L)
ALT	23 (0–35 iu/L)
Alk P	524 (70–300 iu/L)
PT	18.6 (13 s)

Drugs on admission are as follows:

Spironolactone: 300 mg each morning.
Temazepam: 10 mg at night.
Lactulose: 10 mL twice daily.

Questions

Discuss the initial treatment plan for the management of:
1. Ascites
2. Nausea and vomiting
3. Confusion

Answers

From the presenting features and LFTs on admission it is apparent that the patient's liver disease is getting progressively worse, probably as a result of continued alcohol intake. She is confused on admission and this suggests encephalopathy, a common complication of chronic liver disease.

1. *Ascites management.* The patient has increased abdominal distension on admission suggestive of worsening ascites. This might be due to poor adherence with spironolactone, or alternatively, her ascites may have become diuretic resistant.

The patient should be sodium restricted and confined to bed. Spironolactone therapy should be stopped in view of the low sodium and confusion, as overuse of diuretics can precipitate encephalopathy. Fluid restriction is necessary to reduce the ascites, but sufficient fluid is required to rehydrate the patient following vomiting.

Paracentesis should be used to manage the ascites. Every litre of ascitic fluid removed should be replaced with 6–8 g of albumin. A diagnostic ascitic tap should be taken to ensure there is no infection in the ascites.

2. *Nausea/vomiting management.* Urea is slightly raised, indicating possible dehydration as a result of vomiting. The patient should be rehydrated with dextrose 5%, not saline, as this will worsen the ascites. Additional potassium should be given to correct the low serum potassium. Note that if the patient has been taking the spironolactone there would normally be an increase in potassium, but in this case the vomiting has probably reduced this. The patient's nausea can be managed with a suitable antiemetic such as domperidone 10 mg four times a day initially and then titrated according to the response.

3. *Confusion.* Confusion may be an early sign of encephalopathy in this patient. Temazepam should be stopped. The patient is on an inadequate dose of lactulose for the management of encephalopathy, so this should be increased to produce 2–3 loose motions per day. A typical dose would be 20 mL three or four times daily. In view of the patient's confusion, it may be worth considering other agents in the management of the encephalopathy, such as metronidazole 400 mg twice daily.

Case 16.3

A 54-year-old woman with primary biliary cirrhosis has been complaining of increasing backache over the last 3 months. Her general condition has deteriorated over the past year during which she has suffered from ascites and encephalopathy. Her main complaint is of continuous back pain, which disturbs her sleep.

Question

How would you manage this patient's back pain?

Answer

Back pain secondary to osteoporosis-related vertebral fractures is common in patients with chronic liver disease, such as primary biliary cirrhosis. This is due to the fact that most patients with

primary biliary cirrhosis are postmenopausal women in their late 50s where bone thinning is likely, secondary to both menopausal and liver changes. Once the diagnosis has been confirmed, the patient should be counselled that the bone pain is chronic, tends to be intermittent, and takes several months to settle after each new fracture. Bed rest is useful in the acute situation, but prolonged bed rest can accelerate bone loss.

Although there have been rapid advances in recent years in the treatment of postmenopausal osteoporosis, very few studies have addressed the problems of treating osteoporosis in patients with chronic liver disease. Hormone replacement therapy has not been evaluated in patients with chronic liver disease, and oestrogen therapy is widely believed to be contraindicated in such patients, although there is little evidence to support this. Transdermal oestrogen preparations that avoid the first-pass metabolic effect may be a possible future option.

The patient should be advised to take adequate calcium supplementation of 1–1.5 g/day in addition to her normal diet. Vitamin D deficiencies are common in chronic liver disease and it would be advisable to administer 300,000 units intramuscularly every 3 months.

For symptomatic management of the pain a variety of analgesics are available. The choice of drug is influenced by both the severity of the pain and the degree of liver impairment.

For mild pain, paracetamol is the mainstay of treatment, and may be used in standard doses in the majority of patients with liver dysfunction. Patients pretreated with cytochrome P450 inducing drugs or patients with a history of alcohol abuse are at increased risk of paracetamol-induced liver injury and should receive only short courses at low doses (maximum of 2 g/day for an adult).

Opioid analgesics should usually be avoided in liver disease because of their sedative properties and the risks of precipitating or masking encephalopathy. If a patient has stable mild to moderate liver disease then short-term use of opioids can be considered. Moderate potency opioids, such as dihydrocodeine and codeine, are eliminated almost entirely by hepatic metabolism. Therapy should be initiated at a low dose, and the dosage interval titrated according to the response of the patient. Despite their low potency, these preparations may still precipitate encephalopathy.

In severe pain, the use of potent opioids is usually unavoidable. They undergo hepatic metabolism, and are therefore likely to accumulate in liver disease. To compensate for this it is important to increase the dosage interval when using these drugs. Morphine, pethidine or diamorphine should be administered at doses at the lower end of the dosage range at intervals of 6–8 h. The patient should be regularly observed and the dose titrated according to patient response. In any patient with liver disease receiving an opioid, it is advisable to coprescribe a laxative as constipation can increase the possibility of developing encephalopathy.

NSAIDs should be avoided in patients with liver disease. All NSAIDs can prolong bleeding time via their effects on platelet function. Impaired liver function itself can lead to a reduced synthesis of clotting factors and an increased bleeding tendency. NSAIDs may also be dangerous due to the increased risk of gastro-intestinal haemorrhage and potential to preciptate renal dysfunction.

Acute kidney injury 17

P. Cockwell, S. Stringer and J. Marriott

Key points

- Acute renal failure (ARF), or acute kidney injury (AKI), is diagnosed when the excretory function of the kidney declines rapidly over a period of hours or days and is usually associated with the accumulation of metabolic waste products and water.
- A wide range of factors can precipitate AKI, including trauma, obstruction of urine flow or any event that causes a reduction in renal blood flow, including surgery and medical conditions, for example, sepsis, diabetes, acute liver disease, rapidly progressive glomerulonephritis.
- Drug involvement in the development of AKI is common.
- There are no specific signs and symptoms of AKI. The condition is typically indicated by raised blood levels of creatinine and/or a low urine output.
- The clinical priorities in AKI are to manage life-threatening complications, correct intravascular fluid balance and establish the cause of the renal failure, reversing factors causing damage where possible.
- The aim of medical treatment is to remove causative factors and maintain patient well-being so that the kidneys have a chance to recover.
- Most measures of renal function are inaccurate when renal function deteriorates or improves rapidly as is usually the case in AKI.
- Treatment of AKI is essentially supportive, though there are conditions that cause AKI that are reversible with specific treatment.
- AKI is a serious condition with mortality rates up to 70%, varying according to cause and at its highest with concurrent failure of other organs.

Definition and incidence

Acute renal failure (ARF) is a common and serious problem in clinical medicine. It is characterised by an abrupt reduction (usually within a 48-h period) in kidney function. This results in an accumulation of nitrogenous waste products and other toxins. Many patients become oliguric (low urine output) with subsequent salt and water retention. In patients with pre-existing renal impairment, a rapid decline in renal function is termed 'acute on chronic renal failure'. The nomenclature of ARF is evolving and the term acute kidney injury (AKI) is being increasingly used in clinical practice.

The diagnostic criteria for AKI is based on an increase in serum creatinine or the presence of oliguria (see Table 17.1). Criteria have recently been introduced for the definition and staging of the condition; the acronym RIFLE is used (Risk, Injury, Failure, Loss and End-stage renal disease (ESRD)), which is now becoming established in clinical practice (see Fig. 17.1).

The large majority of cases of AKI occur in patients who are already hospitalised for other medical conditions; up to 7% of these sustain AKI and this increases to 30% or more in those who are critically ill. Most cases are caused by pre-renal AKI and are reversed with appropriate intervention. However, severe AKI, as defined by the requirement for dialysis treatment, is often associated with failure of one or more non-renal organs (this is called multi-organ failure); in this setting there is a mortality rate of 70% in patients with sepsis and AKI and 45% in patients without sepsis. AKI that occurs in the community is responsible for around 1% of all hospital admissions.

Classification and causes

AKI is not a single disease state with a uniform aetiology, but a consequence of a range of different diseases and conditions. The most useful practical classification comprises three main groupings: (i) pre-renal, (ii) renal, or (iii) post-renal. More than one category may be present in an individual patient. Common causes of each type of AKI are outlined in Table 17.1.

Table 17.1 Classification of acute kidney injury

Acute kidney injury type	Typical % cases	Common aetiology
Pre-renal	40–80	Reversible ↓ renal perfusion through hypoperfusion
Intra-renal (including ATN)	10–50	Renal parenchymal injury
Post-renal	<10	Urinary tract obstruction
ATN, acute tubular necrosis.		

	Glomerulor filtration rate criteria	Urine output criteria	
Risk	Increased creatinine ×1.5 or GFR decrease >25%	Urine output <0.5 mL/kg/h x6 h	High sensitivity
Injury	Increased creatinine × 2 or GFR decrease >50%	Urine output <0.5 mL/kg/h x12 h	
Failure	Increased creatinine × 3 or GFR decrease >75% or creatinine ≥ 4 mg per 100 mL (acute rise of ≥0.5 mg per 100 mL dL)	Urine output <0.3 mL/kg/h x24 h or anuria x12 h	High specificity
Loss	Persistent acute renal failure = complete loss of renal function >4 weeks		
End stage renal disease	End stage renal disease		

Fig. 17.1 The RIFLE criteria for the definition and staging of acute renal disease.

The kidneys are pre-disposed to haemodynamic injury owing to hypovolaemia or hypoperfusion. This relates to the high blood flow through the kidneys in normal function; the organs represent 5% of total body weight but receive 25% of blood flow. Furthermore, the renal microvascular bed is unique; firstly, the glomerular capillary bed is on the arterial side of the circulation; secondly, the peri-tubular capillaries are down-stream from the glomerular capillary bed. Finally, renal cells are highly specialised and are, therefore, pre-disposed to ischaemic and inflammatory injury.

Pre-renal acute kidney injury

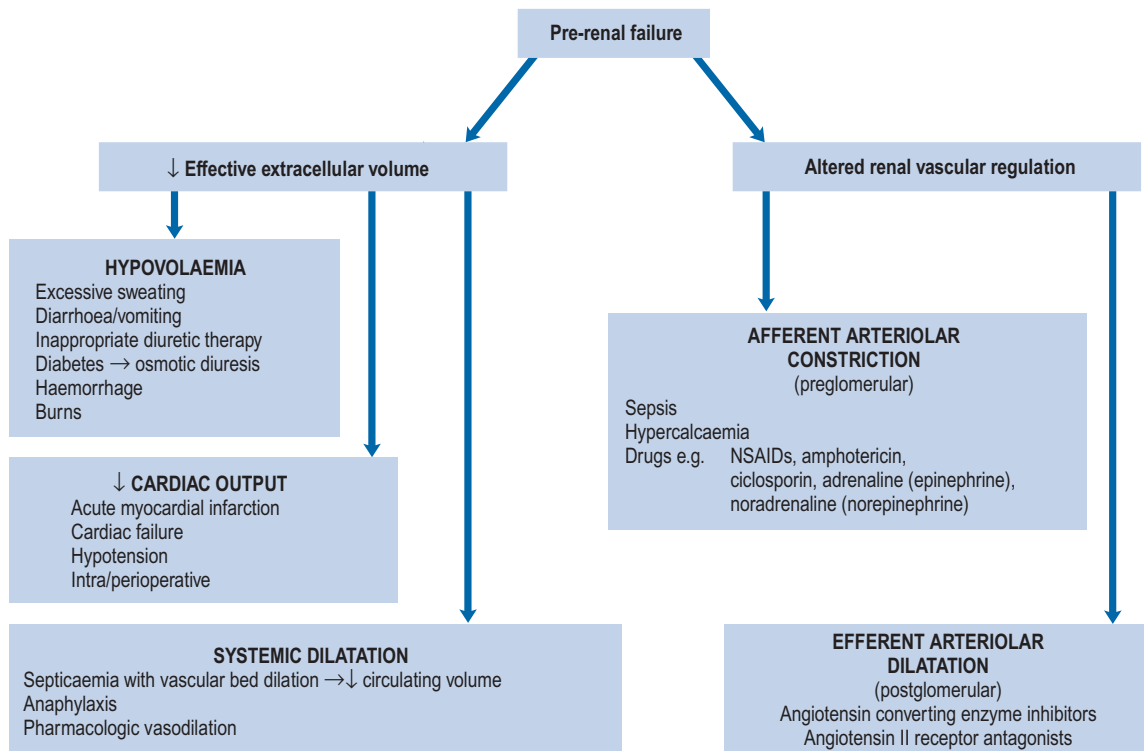
This is caused by impaired perfusion of the kidneys with blood, and is usually a consequence of decreased intravascular volumes (hypovolaemia) and/or decreased intravascular pressures. Some of the commonest causes of pre-renal AKI are summarised in Fig. 17.2. Perfusion of the kidneys at the level of the microvascular beds (glomerular and tubulo-interstitial) is usually maintained through wide variations in pressure and flow through highly efficient auto-regulatory pathways, such as the renin–angiotensin–aldosterone system (RAAS) and


Fig. 17.2 Causes of pre-renal failure.

regulated prostaglandin synthesis. However, when the systolic blood pressure (BP) drops below 80 mmHg, AKI may develop. In individuals with chronic kidney disease (CKD) or in the elderly, this may occur at higher levels of systolic BP. Drugs that inhibit the RAAS, such as angiotension converting enzyme inhibitors (ACE inhibitors) and angiotensin receptor blockers (ARBs), or block the production of prostaglandins, such as non-steroidal anti-inflammatory drugs (NSAIDs), can pre-dispose to the development of pre-renal AKI. These are discussed in more detail below.

Hypovolaemia

This results from any condition that causes intravascular fluid depletion, either directly by haemorrhage or indirectly to compensate for extravascular loss. Examples of this include diarrhoea and vomiting, burns and excessive use of diuretics. Hypotension is a secondary effect of significant hypovolaemia.

Hypotension

In addition to hypovolaemia, hypotension can result from pump (cardiac) failure, of which there are a number of causes, the most common of which is ischaemic heart disease. Another important cause is septic shock, where there is peripheral vasodilatation and low peripheral resistance which leads to profound hypotension despite a high cardiac output.

Intra-renal acute kidney injury

This is caused by a variety of causes (see Tables 17.1 and 17.2), most commonly (in >80% of cases) acute tubular necrosis (ATN). ATN occurs usually as a consequence of a combination of factors, including hypotension, often in the setting of sepsis and nephrotoxic agents including drugs or chemical poisons, or endogenous sources such as myoglobin or haemoglobin.

Acute tubular necrosis

ATN is a diagnosis made by renal biopsy; the findings can include damage to the proximal tubule and the ascending limb of the loop of Henle, interstitial oedema and sparse infiltrating inflammatory cells. Whilst severe and sustained hypoperfusion can lead to ATN, it usually develops when there is a combination of factors including the presence of one or more of a range of nephrotoxins. These may arise exogenously from drugs or chemical poisons, or from endogenous sources such as haemoglobin, myoglobin, crystals (uric acid, phosphate) and toxic products from sepsis or tumours (see Table 17.2). Some endogenous toxins may be released as a direct consequence of drug exposure. For example, myoglobin may be released (rhabdomyolosis) following muscle injury or necrosis, hypoxia, infection or following drug treatment, for example, with fibrates and statins, particularly when both are used in combination. The mechanism of the subsequent damage to renal tissue is not

Table 17.2	Common clinical factors known to cause acute tubular necrosis
Clinical factor	**Mechanism**
Hypoperfusion	Reduced oxygen/nutrient supply
Radiocontrast media	Medullary ischaemia may result from contrast media induced renal vasoconstriction. The high ionic load of contrast media may produce ischaemia particularly in diabetics and those with myeloma (who produce large quantities of light chain immunoglogulins)
Sepsis	Infection produces endotoxaemia and systemic inflammation in combination with a pre-renal state and nephrotoxins. The immunological response to sepsis involves release of vasoconstrictors and vasodilators (e.g. eicosanoids, nitric oxide) and damage to vascular endothelium with resultant thrombosis
Rhabdomyolysis	Damaged muscles release myoglobin, which can cause ATN through direct nephrotoxicity and by a reduction in blood flow in the outer medulla
Renal transplantation	The procedures and conditions encountered during renal transplantation can induce ischaemic ATN which can be difficult to distinguish from the nephrotoxic effects of immunosuppressive drug therapy used in these circumstances and rejection
Hepatorenal syndrome	Renal vasoconstriction is frequently seen in patients with end-stage liver disease. Progression to ATN is common
Nephrotoxins Aminoglycosides	Aminoglycosides are transported into tubular cells where they exert a direct nephrotoxic effect. Current dosage regimens recommend once daily doses, with frequent monitoring of drug levels, to minimise total uptake of aminoglycoside
Amphotericin	Amphotericin appears to cause direct nephrotoxicity by disturbing the permeability of tubular cells. The nephrotoxic effect is dose dependent and minimised by limiting total dose used, rate of infusion and by volume loading. These precautions also apply to newer liposomal formulations

Continued

Table 17.2 Common clinical factors known to cause acute tubular necrosis—cont'd

Clinical factor	Mechanism
Immunosuppressants	Ciclosporin and tacrolimus cause intra-renal vasoconstriction that may result in ischaemic ATN. The mechanism is unclear but enhanced by hypovolaemia and other nephrotoxic drugs
NSAIDs	Vasodilator prostaglandins, mainly E_2, D_2 and I_2 (prostacyclin), produce an increase in blood flow to the glomerulus and medulla. In normal circumstances, they play no part in the maintenance of the renal circulation. However, increased amounts of vasoconstrictor substances arise in a variety of clinical conditions such as volume depletion, congestive cardiac failure or hepatic cirrhosis associated with ascites. Maintenance of renal blood flow then becomes more reliant on the release of vasodilatory prostaglandins. Inhibition of prostaglandin synthesis by NSAIDs may cause unopposed arteriolar vasoconstriction, leading to renal hypoperfusion
Cytotoxic chemotherapy	For example, cisplatin
Anaesthetic agents	Methoxyflurane, enflurane
Chemical poisons/naturally occurring poisons	Insecticides, herbicides, alkaloids from plants and fungi, reptile venoms

understood fully but probably results from a combination of factors including hypoperfusion, haem-catalysed free radical tubular cytotoxicity and haem cast formation and precipitation leading to tubular injury.

The vascular bed and development of acute tubular necrosis. Regional blood flow within the kidney varies, resulting in relatively hypoxic regions such as the outer medulla. This area is also the site of highly metabolically active parts of the nephron. Owing to the relatively poor oxygen supply and high metabolic demands, the outer medulla is at risk of ischaemia, even under normal conditions. The regulation of regional blood flow in the kidney, and therefore the oxygen supply to these areas, relies upon vasomotor mechanisms mediated in part by adenosine. Adenosine appears to exert either vasoconstrictor or vasodilator effects within the kidney depending upon the relative distribution of A_1 and A_2 receptors.

Clearly, any circumstance that interferes with the delicate balance of blood flow and, therefore, oxygen supply within the kidney can result in ATN because of ischaemia and a greater vulnerability to nephrotoxins. The likelihood of ATN is increased by underlying conditions that pre-dispose to ischaemia such as pre-existing CKD of any cause, atheromatous renovascular disease and cholesterol embolisation from upstream atheromatous plaque rupture.

Common causes of acute tubular necrosis. Table 17.2 shows a summary of some of the common factors encountered clinically that may cause ATN.

Immune and inflammatory renal disease

The kidney is vulnerable to a range of immunological processes that can cause AKI. These are divided into glomerular causes (glomerulonephritis) and interstitial causes (interstitial nephritis). Rarely, acute pyelonephritis, which is an infection of renal parenchyma, usually as a consequence of ascending infection, can cause AKI.

Rapidly progressive glomerulonephritis

Glomerulonephritis refers to an inflammatory process within the glomerulus. If that process causes AKI it is called rapidly progressive glomerulonephritis (RPGN). This is an important cause of AKI occurring without a precipitating other illness. Most cases of RPGN are caused by a small vessel vasculitis; this gives a pattern of injury in the glomerulus that is called a focal segmental necrotising glomerulonephritis (FSNGN) with crescent proliferation; crescents are the presence of cells and extra-cellular matrix in Bowman's space. Most cases of FSNGN are caused by anti-neutrophil cytoplasmic antibody-associated small-vessel vasculitis (SVV). Anti-neutrophil cytoplasmic antibodies (ANCA) refer to the presence of circulating antibodies that are targeted against primary neutrophil cytoplasmic antigens (proteins including proteinase 3 and myeloperoxidase).

The two main types of anti-neutrophil cytoplasmic antibody-associated SVV are Wegener's granulomatosis and microscopic polyangiitis. Other important causes of RPGN include Goodpasture's disease, which is caused by antibodies against glomerular basement membrane (anti-GBM antibodies), Systemic lupus erythematosis (SLE) which usually affects young women and is more common with black ethnicity, and secondary vasculitis are triggered by drugs, infection and tumours. There are many drug triggers for secondary vasculitis; the commonest clinical presentation is a cutaneous vasculitis, secondary to immune complex deposition. Kidney involvement can occur and has been reported with a range of drugs.

Interstitial nephritis

Interstitial nephritis is thought to be a nephrotoxin-induced hypersensitivity reaction associated with infiltration of inflammatory cells into the interstitium with secondary involvement of the tubules. The nephrotoxins involved are usually drugs and/or the toxic products of infection. Drugs that have been

most commonly shown to be responsible include NSAIDs, antibiotics (especially penicillins, cephalosporins and quinolones), proton pump inhibitors such as omeprazole, furosemide, allopurinol and azathioprine, although many other drugs have been implicated.

Differentiating pre-renal from renal acute kidney injury

It is sometimes possible to distinguish between cases of pre-renal and renal AKI through examination of biochemical markers (see Table 17.3). In renal AKI, the kidneys are generally unable to retain Na^+ owing to tubular damage. This can be demonstrated by calculating the fractional excretion of sodium (FENa); in practice this is not often done because it lacks sensitivity and specificity and may be difficult to interpret in the elderly who may have pre-existing concentrating defects.

$$FENa = sodium\ clearance/creatinine\ clearance$$

$$FENa = \frac{urine\ sodium \times serum\ creatinine}{serum\ sodium \times urine\ creatinine}$$

If FENa <1%, this indicates pre-renal AKI with preserved tubular function; if FENa >1% this is indicative of ATN. This relationship is less robust if a patient with renal AKI has glycosuria, pre-existing renal disease, has been treated with diuretics, or has other drug-related alterations in renal haemodynamics, for example, through use of ACE inhibitors or NSAIDs. One potential use of urinary electrolytes is in the patient with liver disease and AKI; where the diagnosis of hepato-renal syndrome is being considered, one of the diagnostic criteria is a urinary sodium <10 mmol/L

Post-renal acute kidney injury

Post-renal AKI results from obstruction of the urinary tract by a variety of mechanisms. Any mechanical obstruction from the renal pelvis to the urethral orifice can cause post-renal AKI; these can be divided into causes within the ureters (e.g. calculi or clots), a problem within the wall of ureter (malignancies, benign strictures) and external compression (e.g. retroperitoneal tumours). It is extremely unusual for drugs to be responsible for post-renal AKI. Practolol-induced retroperitoneal fibrosis resulting in bilateral ureteric obstruction is a rare example.

Clinical manifestations

The signs and symptoms of AKI are often non-specific and the diagnosis can be confounded by coexisting clinical conditions. The patient may exhibit signs and symptoms of volume depletion or overload, depending upon the precipitating conditions, course of the disease and prior treatment.

Acute kidney injury with volume depletion

In those patients with volume depletion, a classic pathophysiological picture is likely to be present, with tachycardia, postural hypotension, reduced skin turgor and cold extremities (see Table 17.4). The most common sign in AKI is oliguria, where urine production falls to less than 0.5 mL/kg/h for several hours. This is below the volume of urine required to effectively excrete products of metabolism to maintain a physiological steady state. Therefore, the serum concentration of those substances normally excreted by the kidney will rise and differentially applies to all molecules up to a molecular weight of around 50 kDa. This includes serum creatinine, which at a molecular weight of 113 Da is normally freely filtered by the kidneys but with loss of kidney function the serum level climbs. Whilst the term uraemia is still in widespread use, it merely describes a surrogate for the overall metabolic disturbances that accompany AKI; these include excess potassium, hydrogen ions (acidosis) and phosphate in blood. Most cases of AKI are first identified by an abnormal blood test, though some patients may have symptoms that are specifically attributable to AKI; these include nausea, vomiting, diarrhoea, gastro-intestinal haemorrhage, muscle cramps and a declining level of consciousness.

Table 17.3 Differentiating pre-renal from renal acute kidney injury

Laboratory test	Pre-renal	Renal
Urine osmolality (mOsm/kg)	>500	<400
Urine sodium (mEq/L)	<20	>40
Urine/serum creatinine (µmol/L)	>40	<20
Urine/serum urea (µmol/L)	>8	<3
Fractional excretion of sodium (%)	<1	>2

Table 17.4 Factors associated with acute kidney injury

	Volume depletion	Volume overload
History	Thirst Excessive fluid loss (vomiting or diarrhoea) Oliguria	Weight increase Orthopnoea/nocturnal dyspnoea
Physical examination	Dry mucosae ↓ Skin elasticity Tachycardia ↓ Blood pressure ↓ Jugular venous pressure	Ankle swelling Oedema Jugular venous distension Pulmonary crackles Pleural effusion

Acute kidney injury with volume overload

In those patients with AKI who have maintained a normal or increased fluid intake as a result of oral or intravenous administration, there may be clinical signs and symptoms of fluid overload (see Table 17.4).

Diagnosis and clinical evaluation

In hospitalised patients, AKI is usually diagnosed incidentally by the detection of increasing serum creatinine and/or a reduction in urine output.

The assessment of renal function is described in detail in Chapter 18. However, unless a patient is at steady state, measurement of serum creatinine does not provide a reliable guide to renal function. For example, serum creatinine levels will usually rise by only 50–100 µmol/L per day following complete loss of renal function in a previously normal patient. These changes in serum creatinine are not sufficiently responsive to serve as a practical indicator of glomerular filtration rate, particularly in AKI in critical care scenarios.

In the hospital situation, when AKI is detected incidentally, the cause(s) of the condition, such as fluid depletion (hypovolaemia), infection or the use of nephrotoxic drugs, are often apparent on close examination of the clinical history. The development of AKI in this setting is more likely to occur in people with pre-existing CKD. People with normal baseline kidney function usually need to sustain at least two separate triggers for the development of AKI; for example, hypovolaemia will rarely cause AKI in this setting, but when hypovolaemia occurs in the presence of nephrotoxic drugs then AKI may occur. In patients with pre-existing CKD, AKI (i.e. acute on chronic renal failure) can occur in patients with one trigger. By definition, the worse the baseline kidney function, the smaller the trigger required for the development of AKI. Irrespective of the presentation of AKI, it is wise to consider the complete differential diagnosis in all people; active exclusion of post-renal AKI and immune and inflammatory AKI should be considered in all cases. In AKI without an obvious precipitating pre-or post-renal cause, there is a greater need to consider these causes. Although the majority of patients have ATN, other causes such as rapidly progressive glomerulonephritis, interstitial nephritis, multiple myeloma or urinary tract obstruction must be screened for and systematically excluded. In addition to supportive care that is generic for all causes of AKI, disease-specific treatment may also be required. The investigation of AKI is outlined in Fig. 17.3.

Various other parameters should be monitored through the course of AKI. Fluid balance charts that are frequently used may be inaccurate and should not be relied upon exclusively. Records of daily weight are more reliable but are dependent on the mobility of the patient.

Monitoring fluid balance in acute kidney disease

Maintaining appropriate fluid balance in AKI is a critical component of the clinical management of the patient. Detailed clinical assessment includes:

1. Measurement of BP which needs to be interpreted in respect of the baseline for the affected patient together with the patient's heart rate.
2. Auscultation of the heart for the presence of 3rd (and 4th) heart sounds; the presence of these indicate cardiac strain associated with fluid overload.
3. Presence of added sounds in the chest, in particular fine inspiratory crackles that are found in some patients with pulmonary oedema.
4. A chest X-ray for the presence of pulmonary oedema.
5. Pulse oximetry to assess arterial oxygen saturation.
6. Whilst the presence of pitting oedema of the legs or sacrum indicates longer term fluid overload, it may be a useful marker of overall endothelial function and the potential for extravascular fluid accumulation.
7. Decreased skin turgor is a sign of fluid loss.

Intravascular monitoring

Central venous pressure (CVP) can be measured following insertion of a central venous catheter, and is a measure of the pressure in the large systemic veins and the right atrium produced by venous return. CVP assesses circulating volume and, therefore, the degree of fluid deficit, and reduces the risk of pulmonary oedema following over-rapid transfusion. CVP should usually be maintained within the normal range of 5–12 cmH$_2$O.

Most patients with AKI do not require invasive monitoring to the extent described above and recover with supportive care based on careful clinical observations.

Monitoring key parameters in acute kidney disease

Serum electrolytes including potassium, bicarbonate, calcium, phosphate and acid–base balance should be measured on a daily basis. In patients with severe AKI, acid–base balance may need assessing every few hours as this may direct fluid replacement, respiratory support and dialysis treatment.

Course and prognosis

Pre-renal acute kidney injury

The majority of cases will recover within days of onset following prompt correction of the underlying causes. The urine output improves and waste products of metabolism are cleared by the kidneys. Whilst the kidney function usually stabilises to the pre-event baseline, in some patients long-term kidney function resets to lower than previous values.

ATN may be divided into three phases. The first is the oliguric phase where patients have sustained pre-renal AKI and move from the potential for early reversibility to a situation where uraemia and hyperkalaemia develop and the patient may die unless renal replacement therapy (RRT) with dialysis

Full history
including drug history

Clinical examination, including fluid balance assessment
Pre-renal cause: postural hypotension, ↓ skin turgor
Intra-renal cause: drug rash, vasculitic lesions
Post-renal cause: distended bladder most commonly identified by simply palpating the abdomen. Rectal and vaginal examination very rarely performed in this setting

Urinalysis
Pre-renal cause: concentrated urine
Intra-renal or obstructive cause: indicated by isotonic urine
Obstructive uropathy: anuria or crystalluria
ATN: abnormal urinary sediment with tubular epithelial cells and tubular casts
Glomerulonephritis or acute nephritis: proteinuria and haematuria
Microbiological culture/sensitivity
Biochemical analyses: urinary urea/creatinine concentration, osmolarity

Blood examination
Full haematology and renal biochemistry screen
Haematological tests: white cell counts, erythrocyte sedimentation rate (ESR)
Biochemical tests: serum creatinine, urea and albumin concentrations and serum osmolarity
Bacteriological and immunological tests are also of value

Renal immunology screen (ANCA, anti-GBM antibodies, serum and urine electrophoresis, immunoglobulins, complement, ANA)

Ultrasound scan of renal tract is mandatory
Ultrasound scan to exclude obstruction and to prepare for renal biopsy if indicated

ANCA – anti-neutrophil cytoplasmic antibodies
GBM – glomelular basement membrane
ANA – anti nuclear antibody

Fig. 17.3 The investigations of acute kidney injury.

is started. The oliguric phase is usually no longer than 7–14 days but may last for 6 weeks. This is followed by a diuretic phase, which is characterised by a urine output that rises over a few days to several litres per day. This phase lasts for up to 7 days and corresponds to the recommencement of tubular function. The onset of this phase is associated with an improving prognosis unless the patient sustains an intercurrent infection or a vascular event. Finally, the patient enters a recovery phase where tubular cells regenerate slowly over several months, although the glomerular filtration rate often does not return to initial levels. The elderly recover renal function more slowly and less completely.

The mortality rate of AKI varies according to the cause but increases when AKI occurs in patients with multi-organ failure, where mortality rates of up to 70% are seen. Higher mortality rates are seen in patients aged over 60 years.

Death resulting from uraemia and hyperkalaemia are very uncommon. Consequently, the major causes of death associated with AKI are septicaemia and intercurrent acute vascular events such as myocardial infarction and stroke. High

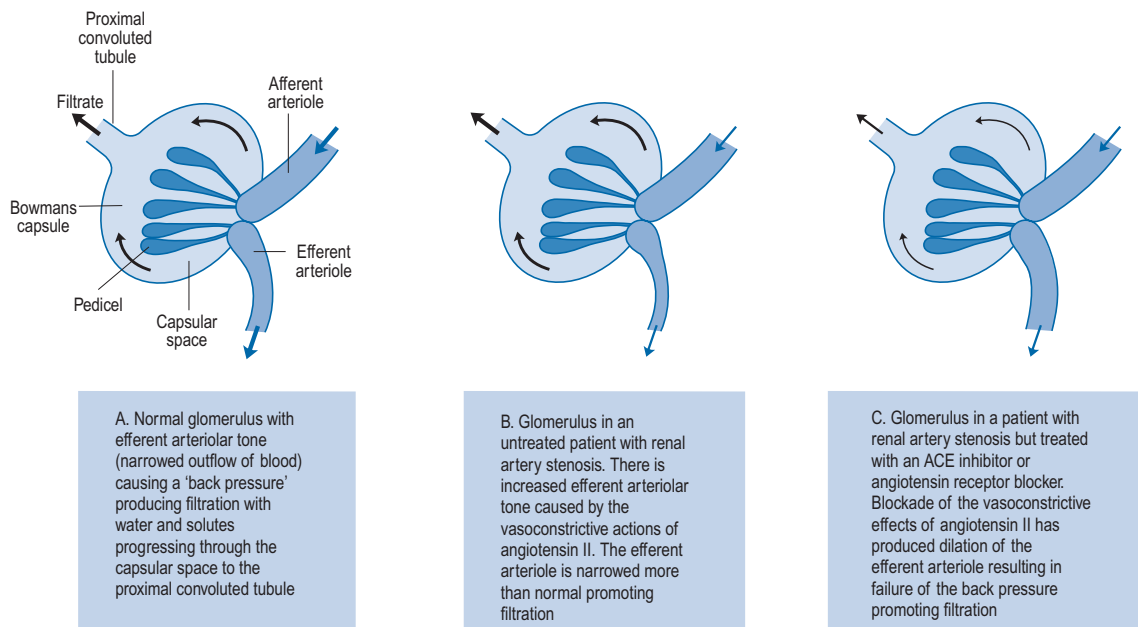
circulating levels of uraemic toxins that occur in AKI result in general debility. These, together with the significant number of invasive procedures such as bladder catheterisation and intravascular cannulation which are necessary in the management of AKI, leave such patients prone to infection and septicaemia. Uraemic gastro-intestinal haemorrhage is a recognised consequence of AKI, probably as a result of reduced mucosal cell turnover.

Post-renal acute kidney injury

Prompt identification and relief of the obstruction is important. The prognosis is then dependent on the underlying cause of the obstruction of the renal tract and the baseline to which the kidney function returns after the obstruction has been relieved. If the underlying problem is benign then there may be no long-term adverse consequences. However, if the cause of the obstruction is due to an underlying malignancy then long-term survival is dependent on whether this can be cured.

ACE inhibitors and angiotensin receptor blockers in acute kidney injury

ACE inhibitors and ARBs are not directly nephrotoxic and can be used in most patients with kidney disease. However, profound hypotension can occur if they are initiated in susceptible patients such as those who are receiving high dose diuretics as treatment for fluid overload. This might result in the development of pre-renal AKI. It is, therefore, wise to monitor BP and carefully titrate dosages whilst monitoring renal function in such patients. Nonetheless, it is common to see increases in serum creatinine levels of up to 20% on initiation of an ACE inhibitor or ARB and this is not necessarily a cause for discontinuing therapy with these agents.

ACE inhibitor use is, however, absolutely contraindicated when a patient has bilateral renal artery stenosis, or renal artery stenosis in a patient with a single functioning kidney. If an ACE inhibitor or ARB is initiated under these circumstances then pre-renal AKI may ensue. This may occur since the renin–angiotensin system is stimulated by low renal perfusion resulting from stenotic lesions in the arteries supplying the kidneys, most often at the origin of the renal artery from the abdominal aorta. Angiotensin II is produced which causes renal vasoconstriction, in part, through increased efferent arteriolar tone. This creates a 'back pressure' which paradoxically maintains glomerular filtration pressure in an otherwise poorly perfused kidney. If angiotensin II production is inhibited by an ACE inhibitor, or the effect is blocked by an ARB, then efferent arteriole dilatation will result. Since increased efferent vascular tone maintains filtration in such patients, then the overall result of ACE inhibitor or ARB therapy will be to reduce or shut down filtration at the glomerulus and put the patient at risk of pre-renal AKI (see Fig. 17.4).


Management

The aim of the medical management of a patient with AKI is to prolong life in order to allow recovery of kidney function. Effective management of AKI depends upon a rapid diagnosis. If the underlying acute deterioration in renal function is detected early enough, it is often possible to prevent progression. If the condition is advanced, however, management consists mainly of supportive strategies, with close monitoring and appropriate correction of metabolic, fluid and electrolyte disturbances. Patients with severe AKI usually require renal replacement therapy with dialysis. Specific therapies that promote recovery of ischaemic renal damage remain under investigation. Patients with immune-mediated causes of AKI should be treated with appropriate immunosuppressant regimens to treat the underlying cause of the AKI.

Early preventive and supportive strategies

Identification of patients at risk

Any patient who has concurrent or pre-existing conditions that increase the risk of development and progression of AKI must be identified and this includes those with pre-existing CKD, diabetes, jaundice, myeloma and the elderly. These patients either have baseline impaired renal function or are sensitised to the development of AKI by the co-morbid condition. Meticulous attention to fluid balance, assessment of infection and the use of drugs is crucial to minimise the risk of development of AKI.

Withdrawal and avoidance of nephrotoxic agents

Irrespective of whether the aetiology of the AKI directly involves nephrotoxic drugs, the drug and treatment regimens should be examined so that potential nephrotoxins are

A. Normal glomerulus with efferent arteriolar tone (narrowed outflow of blood) causing a 'back pressure' producing filtration with water and solutes progressing through the capsular space to the proximal convoluted tubule

B. Glomerulus in an untreated patient with renal artery stenosis. There is increased efferent arteriolar tone caused by the vasoconstrictive actions of angiotensin II. The efferent arteriole is narrowed more than normal promoting filtration

C. Glomerulus in a patient with renal artery stenosis but treated with an ACE inhibitor or angiotensin receptor blocker. Blockade of the vasoconstrictive effects of angiotensin II has produced dilation of the efferent arteriole resulting in failure of the back pressure promoting filtration

Fig. 17.4 The actions of ACE inhibition and angiotensin receptor blockade in patients with renal artery stenosis.

withdrawn and avoided in the future in order to avoid exacerbating the condition. Particular care should be taken with ACE inhibitors, NSAIDs, radiological contrast media, and aminoglycosides. The doses should be adjusted of any drugs that are renally excreted or have active metabolites that are excreted renally.

Optimisation of renal perfusion

Initial treatment should include rapid correction of fluid and electrolyte balance to maximise renal perfusion. A central line may be considered to facilitate ease of fluid infusion and monitoring of intravascular volumes. In patients where it is difficult to assess fluid balance by use of clinical examination a urinary catheter may be placed in order that fluid losses may be measured easily. However, with the recent focus on the prevention of catheter-related bacteraemia, central lines are seldom used outside specialist renal and intensive care units.

A diagnosis of acute deterioration of renal function caused by renal underperfusion implies that restoration of renal perfusion would reverse impairment by improving renal blood flow, reducing renal vasoconstriction and flushing nephrotoxins from the kidney. The use of crystalloids in the form of 0.9% sodium chloride is an appropriate choice of intravenous fluid since it replaces both water and sodium ions in a concentration approximately equal to serum. The effect of fluid replacement on urine flow and intravascular pressures should be carefully monitored. However, fluid loading with 1–1.5 L saline at <0.5 L/h is unlikely to cause harm in most patients who do not show signs of fluid overload. There is no evidence that colloids such as gelofusin or albumin provide any additional benefit for volume expansion and renal recovery over the use of 0.9% sodium chloride.

The use of inotropes such as noradrenaline and cardiac doses of dopamine should be restricted to non-renal indications.

Establishing and maintaining an adequate diuresis

Whilst loop diuretics (most commonly furosemide) may facilitate the management of fluid overload and hyperkalaemia in early or established AKI, there is no evidence that these agents are effective for the prevention of, or early recovery from, AKI. It is reasonable to use these agents whilst the urine output is maintained as this provides space for intravenous drugs and parenteral feeding including oral supplements. In experimental settings, loop diuretics decrease renal tubular cell metabolic demands and increase renal blood flow by stimulating the release of renal prostaglandins, a haemodynamic effect inhibited by NSAIDs. However, there is no demonstrable impact on clinical outcomes. Indeed, diuretic therapy should only be initiated in the context of fluid overload. If not, any diuresis might produce a negative fluid balance and precipitate or exacerbate a pre-renal state.

Doses of up to 100 mg/h of furosemide can be given by continuous intravenous infusion. Higher infusion rates may cause transient deafness. The use of continuous infusions of loop diuretics has been shown to produce a more effective diuresis with a lower incidence of side effects than seen with bolus administration. Bolus doses of loop diuretics may induce renal vasoconstriction and be theoretically detrimental to function.

The addition of small oral doses of metolazone may also be considered. Metolazone is a weak thiazide diuretic alone but produces a synergistic action with loop diuretics. In this setting, it should be used with great care as it may initiate a profound diuresis and the patient can rapidly develop intravascular depletion and worsen renal failure

Mannitol. Mannitol has historically been recommended for the treatment of AKI. The rationale for using mannitol in AKI arises from the concept that tubular debris may contribute to oliguria. There is no evidence for mannitol producing benefit in AKI over and above aggressive hydration. Indeed, mannitol can cause volume overload. Consequently, mannitol is now not recommended for patients with AKI.

Dopamine. Historically, dopamine has been recommended at low dose to improve renal blood flow and urine output. Dopamine at low dose acts as a renal vasodilator in normal kidneys, but in renal failure it is a renal vasoconstrictor even at a low dose. This translates into no demonstrable clinical benefit and it should no longer be used. Dopamine has alpha and beta adrenergic effects. Recently, fenoldapam, a pure dopaminergic D_1 agonist has been investigated in small scale clinical trials; the results have shown a trend towards benefit in recovery of renal function from AKI. However, larger trials are needed to identify if fenoldapam has a role in routine clinical practice (Kellum et al., 2008).

Drug therapy and renal auto-regulation

Intra-renal blood flow is controlled by an auto-regulatory mechanism unique to the kidney called tubuloglomerular feedback (TGF). This mechanism produces arteriolar constriction in response to an increased solute load to the distal nephrons. Glomerular filtration rate and kidney workload are thus reduced. It has been proposed that oliguria is an adaptive response to renal ischaemia and therapy designed to improve glomerular filtration rate would increase solute load to the nephrons and might increase kidney workload and worsen AKI. Clearly, reversal of a pre-renal state with fluids is a logical therapeutic aim.

Non-dialysis treatment of established acute kidney injury

Uraemia and intravascular volume overload

In renal failure, the symptoms of uraemia include nausea, vomiting and anorexia, and result principally from accumulation of toxic products of protein metabolism including urea.

Unfortunately, since uraemia causes anorexia, nausea and vomiting, many severely ill patients are unable to tolerate any kind of diet. In these patients and those who are catabolic, the use of enteral or parenteral nutrition should be considered at an early stage.

Intravascular fluid overload must be managed by restricting NaCl intake to about 1–2 g/day if the patient is not hyponatraemic and total fluid intake to less than 1 L/day plus the

volume of urine and/or loss from dialysis. Care should be taken with the so-called 'low salt' products, as these usually contain KCl, which will exacerbate hyperkalaemia.

Hyperkalaemia

This is a particular problem in AKI, not only because urinary excretion is reduced but also because intracellular potassium may be released. Rapid rises in extracellular potassium are to be expected when there is tissue damage, as in burns, crush injuries and sepsis. Acidosis also aggravates hyperkalaemia by provoking potassium leakage from healthy cells. The condition may be life-threatening causing cardiac arrhythmias and, if untreated, can result in asystolic cardiac arrest.

Dietary potassium should be restricted to less than 40 mmol/day and potassium supplements and potassium-sparing diuretics removed from the treatment schedule. Emergency treatment is necessary if the serum potassium level reaches 7.0 mmol/L (normal range 3.5–5.5 mmol/L) or if there are the progressive changes in the electrocardiogram (ECG) associated with hyperkalaemia. These include tall, peaked T waves, reduced P waves with increased QRS complexes or the 'sine wave' appearance that often presages cardiac arrest (see Chapter 18, Fig. 18.10).

Emergency treatment of hyperkalaemia consists of the following:

1. 10–30 mL (2.25–6.75 mmol) of calcium gluconate 10% intravenously over 5–10 min; this improves myocardial stability but has no effect on the serum potassium levels. The protective effect begins in minutes but is short lived (<1 h), although the dose can be repeated.
2. 50 mL of 50% glucose together with 8–12 units of soluble insulin over 10 min. Endogenous insulin, stimulated by a glucose load or administered intravenously, stimulates intracellular potassium uptake, thus removing it from the serum. The effect becomes apparent after 15–30 min, peaks after about 1 h and lasts for 2–3 h and will decrease serum potassium levels by around 1 mmol/L.
3. Nebulised salbutamol has also been used to lower potassium; however, this is not effective for all patients and does not permanently lower potassium. If used it is seen as a temporary emergency measure.

Acidosis

The inability of the kidney to excrete hydrogen ions may result in a metabolic acidosis. This may contribute to hyperkalaemia. It may be treated orally with sodium bicarbonate 1–6 g/day in divided doses (though this is not appropriate for acute metabolic acidosis seen in AKI), or 50–100 mmol of bicarbonate ions (preferably as isotonic sodium bicarbonate 1.4% or 1.26%, 250–500 mL over 15–60 min) intravenously may be used. The administration of bicarbonate in acidotic patients will also tend to reduce serum potassium concentrations. Bicarbonate will cause an increase in intracellular Na^+

through activation of the cell membrane Na^+/H^+ exchanger, which promotes increased activity of Na-K ATPase producing increased intracellular sequestration of K^+.

If calcium gluconate is used to treat hyperkalaemia, care should be taken not to mix it with the sodium bicarbonate (by giving this through the same intravenous access site) as the resulting calcium bicarbonate forms an insoluble precipitate. If elevation of serum sodium or fluid overload precludes the use of sodium bicarbonate, extreme acidosis (serum bicarbonate of less than 10 mmol/L) is best treated by dialysis.

Hypocalcaemia

Calcium malabsorption, probably secondary to disordered vitamin D metabolism, can occur in AKI. Hypocalcaemia usually remains asymptomatic, as tetany of skeletal muscles or convulsions does not normally occur until serum concentrations are as low as 1.6–1.7 mmol/L (normal 2.20–2.55 mmol/L). Should it become necessary, oral calcium supplementation with calcium carbonate is usually adequate, and although vitamin D may be used to treat the hypocalcaemia of AKI, it rarely has to be added. Effervescent calcium tablets should be avoided as they contain a high sodium or potassium load.

Hyperphosphataemia

As phosphate is normally excreted by the kidney, hyperphosphataemia can occur in AKI but rarely requires treatment. Should it become necessary to treat, phosphate-binding agents may be used to retain phosphate ions in the gut. The most commonly used agents are calcium containing such as calcium carbonate or calcium acetate and are given with food. For further information see Chapter 18.

Infection

Patients with AKI are prone to infection and septicaemia, which can ultimately cause death. Bladder catheters, central catheters and even peripheral intravenous lines should be used with care to reduce the chance of bacterial invasion. Leucocytosis is sometimes seen in AKI and does not necessarily imply infection. However, pyrexia must be immediately investigated and treated with appropriate antibiotic therapy if accompanied by toxic symptoms such as disorientation or hypotensive episodes. Samples from blood, urine and any other material such as catheter tips should be sent for culture before antibiotics are started. Antibiotic therapy should be broad spectrum until a causative organism is identified.

Other problems

Uraemic gastro-intestinal erosions

These are a recognised consequence of AKI, probably as a result of reduced mucosal cell turnover owing to high circulating levels of uraemic toxins. Proton pump inhibitors are effective and

it is unlikely that any one is more advantageous than another. However, proton pump inhibitors should be used with caution in hospitals where there are significant rates of *Clostridium difficile* diarrhoea, as they may pre-dispose to the development of this organism. H_2 antagonists are an appropriate alternative.

Nutrition

There are two major constraints concerning the nutrition of patients with AKI:

- patients may be anorexic, vomiting and too ill to eat;
- oliguria associated with renal failure limits the volume of enteral or parenteral nutrition that can be given safely.

The introduction of dialysis or haemofiltration allows fluid to be removed easily and, therefore, makes parenteral nutrition possible. Large volumes of fluid may be administered without producing fluid overload. The use of parenteral nutrition is rare but where appropriate factors to be considered include fluid balance, calorie/protein requirements, electrolyte balance/requirements, and vitamin and mineral requirements.

The basic calorie requirements are similar to those in a non-dialysed patient, although the need for protein may occasionally be increased in haemodialysis and haemofiltration because of amino acid loss. In all situations, protein is usually supplied as 12–20 g/day of an essential amino acid formulation, although individual requirements may vary.

Electrolyte-free amino acid solutions should be used in parenteral nutrition formulations for patients with AKI as they allow the addition of electrolytes as appropriate. Potassium and sodium requirements can be calculated on an individual basis depending on serum levels. There is usually no need to try to normalise serum calcium and phosphate levels as they will stabilise with the appropriate therapy, or, if necessary, with haemofiltration or dialysis. Water-soluble vitamins are removed by dialysis and haemofiltration but the standard daily doses normally included in parenteral nutrition fluids more than compensate for this loss. Magnesium and zinc supplementation may be required, not only because tissue repair often increases requirements but also because they may be lost during dialysis or haemofiltration.

It is necessary to monitor the serum urea, creatinine and electrolyte levels daily to make the appropriate alterations in the required nutritional support. The glucose concentration should also be checked daily as patients in renal failure sometimes develop insulin resistance. The plasma pH should be checked initially to determine if addition of amino acid solutions is causing or aggravating metabolic acidosis. It is also valuable to check calcium, phosphate and albumin levels regularly, and when practical, daily weighing gives a useful guide to fluid balance.

Renal replacement therapy

Renal replacement therapy is indicated in a patient with AKI when kidney function is so poor that life is at risk. However, it is desirable to introduce renal replacement therapy early in AKI, as complications and mortality are reduced if the serum urea level is kept below 35 mmol/L. Generally, replacement therapy is urgently indicated in AKI to:

1. remove uraemic toxins when severe symptoms are apparent, for example, impaired consciousness, seizures, pericarditis, rapidly developing peripheral neuropathy
2. remove fluid resistant to diuretics, for example, pulmonary oedema
3. correct electrolyte and acid–base imbalances, for example, hyperkalaemia >6.5 mmol/L or 5.5–6.5 where there are ECG changes, increasing acidosis (pH < 7.1 or serum bicarbonate <10 mmol/L) despite bicarbonate therapy, or where bicarbonate is not tolerated because of fluid overload.

Forms of renal replacement therapy

The common types of renal replacement therapy used in clinical practice are:

- haemodialysis
- haemofiltration
- haemodiafiltration
- peritoneal dialysis

Although the basic principles of these replacement therapies are similar, clearance rates, that is, the extent of solute removal, vary.

In all types of renal replacement therapy, blood is presented to a dialysis solution across some form of semi-permeable membrane that allows free movement of low molecular weight compounds. The processes by which movement of substances occur are:

- *Diffusion.* Diffusion depends upon concentration differences between blood and dialysate and molecule size. Water and low molecular weight solutes (up to a molecular weight of about 5000) move through pores in the semi-permeable membrane to establish equilibrium. Smaller molecules can be cleared from blood more effectively as they move more easily through pores in the membrane.
- *Ultrafiltration.* A pressure gradient (either +ve or −ve) across a semi-permeable membrane will produce a net directional movement of fluid from relative high to low pressure regions. The quantity of fluid dialysed is the ultrafiltration volume.
- *Convection.* Any molecule carried by ultrafiltrate may move passively with the flow by convection. Larger molecules are cleared more effectively by convection.

Haemodialysis

In haemodialysis, the form of access used in AKI is a dialysis line. This is placed in a vein (the jugular, femoral or subclavian), which has an arterial lumen through which the blood is removed from the patient and a venous lumen by which it is returned to the patient after passing through a dialyser. The terms arterial and venous lumen can be misleading as

both lumens are situated in the same vein. They are part of the same line which bifurcates and has two lumens, the longer lumen is the 'arterial' lumen and the shorter the 'venous' lumen. Heparin is added to the blood as it leaves the body to prevent the dialyser clotting. Blood is then actively pumped through the artificial kidney before being returned to the patient (Fig. 17.5). In those patients at high risk of haemorrhage, the amount of heparin used can be reduced or even avoided altogether. The dialyser consists of a cartridge comprising either a bundle of hollow tubes (hollow fibre dialyser) or a series of parallel flat plates (flat-plate dialyser) made of a synthetic semi-permeable membrane. Flat-plate dialysers are now rarely used. Dialysis fluid flows around the membrane countercurrent (opposite) to the flow of blood in order to maximise diffusion gradients. The dialysis solution is essentially a mixture of electrolytes in water with a composition approximating to extracellular fluid into which solutes diffuse. The ionic concentration of the dialysis fluid can be manipulated to control the rate and extent of electrolyte transfer. Calcium and bicarbonate concentrations can also be increased in dialysis fluid to promote diffusion into blood as replacement therapy. By manipulating the hydrostatic pressure of the dialysate and blood circuits, the extent and rate of water removal by ultrafiltration can be controlled.

Haemodialysis can be performed in either intermittent or continuous schedules. The latter regimen is preferable in the critical care situation, providing 24-h control, and minimising swings in blood volume and electrolyte composition that are found using intermittent regimens. The haemodialysis described in this section is indistinguishable from that used as maintenance therapy for many patients with end stage renal failure, the method of access in this group is often via an arterio-venous fistula (see Chapter 18).

The capital cost of haemodialysis is considerable, requires specially trained staff, and is seldom undertaken outside a renal unit. It does, however, treat renal failure rapidly and is, therefore, essential in hypercatabolic renal failure where urea is produced faster than, for example, it could be removed by

peritoneal dialysis. Haemodialysis can also be used in patients who have recently undergone abdominal surgery in whom peritoneal dialysis would be ill advised.

Haemofiltration

Haemofiltration is an alternative technique to dialysis where simplicity of use, fine fluid balance control and low cost have ensured its widespread use in the treatment of AKI.

A similar arrangement to haemodialysis is employed but dialysis fluid is not used. The hydrostatic pressure of the blood drives a filtrate, similar to interstitial fluid, across a high permeability dialyser (passes substances of molecular weight up to 30,000) by ultrafiltration. Solute clearance occurs by convection. Commercially prepared haemofiltration fluid may then be introduced into the filtered blood in quantities sufficient to maintain optimal fluid balance. As with haemodialysis, haemofiltration can be intermittent or continuous. In continuous arterio-venous haemofiltration (CAVH), blood is diverted, usually from the femoral artery, and returned to the femoral vein; this is now very seldom used. In continuous venovenous haemofiltration (CVVH), a dual lumen vascular catheter is inserted into a vein (as described above). Blood is removed from the body via the distal lumen (the one furthest from the right side of the heart) in a process assisted by a blood pump, passed through a haemofilter and returned to the body via the proximal lumen. In slow continuous ultrafiltration (SCU or SCUF), the process is performed so slowly that no fluid substitution is necessary. In addition to avoiding the expense and complexity of haemodialysis, this system enables continuous but gradual removal of fluid, thereby allowing very fine control of fluid balance in addition to electrolyte control and removal of metabolites. This control of fluid balance often facilitates the use of parenteral nutrition. Because of the advantages of haemofiltration over peritoneal dialysis and haemodialysis, continuous haemofiltration is currently the commonest type of renal replacement therapy used in patients in intensive care units.

Haemodiafiltration

Haemodiafiltration is a technique that combines the ability to clear small molecules, as in haemodialysis, with the large molecule clearance of haemofiltration. It is, however, more expensive than traditional haemodialysis, but does offer potential benefits. Whilst some studies suggest that haemodialfiltration may provide a clinical benefit compared to haemofiltration or haemodialysis, this is controversial (Rabindranath et al., 2006). However, enhanced combined control of fluid and solute removal provided by this technique is likely to be increasingly used over the next decade.

Acute peritoneal dialysis

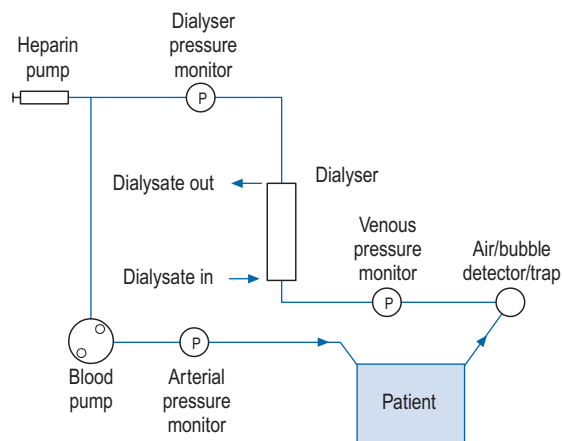
Acute peritoneal dialysis is rarely used now for AKI except in circumstances where haemodialysis is unavailable. A semi-rigid catheter is inserted into the abdominal cavity. Warmed sterile peritoneal dialysis fluid (typically 1–2 L) is


Fig. 17.5 A typical dialysis circuit representing emergency dialysis via a dialysis catheter.

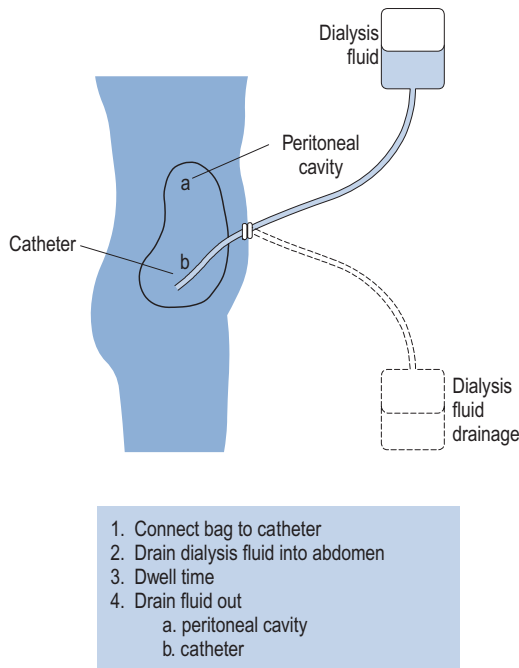
1. Connect bag to catheter
2. Drain dialysis fluid into abdomen
3. Dwell time
4. Drain fluid out
    a. peritoneal cavity
    b. catheter


Fig. 17.6 Procedure for peritoneal dialysis.

instilled into the abdomen, left for a period of about 30 min (dwell time) and then drained into a collecting bag (Fig. 17.6). This procedure may be performed manually or by semiautomatic equipment. The process may be repeated up to 20 times a day, depending on the condition of the patient.

Acute peritoneal dialysis is relatively cheap and simple, does not require specially trained staff or the facilities of a renal unit. It does, however, have the disadvantages of being uncomfortable and tiring for the patient. It is associated with a high incidence of peritonitis and permits protein loss, as albumin crosses the peritoneal membrane.

Drug dosage in renal replacement therapy

Whether a drug is significantly removed by dialysis or haemofiltration is an important clinical issue. Drugs that are not removed may well require dose reduction to avoid accumulation and minimise toxic effects. Alternatively, drug removal may be significant and require a dosage supplement to ensure an adequate therapeutic effect is maintained. In general, since haemodialysis, peritoneal dialysis and haemofiltration depend on filtration, the process of drug removal can be considered analoguous to glomerular filtration. Table 17.5 gives an indication of approximate clearances of common renal replacement therapies, which for continuous regimens provide an estimate for the creatinine clearance of the system.

Drug characteristics that favour clearance by the glomerulus are similar to those that favour clearance by dialysis or haemofiltration. These include:

- low molecular weight
- high water solubility
- low protein binding

Table 17.5 Approximate clearances of common renal replacement therapies

Renal replacement therapy	Clearance rate (mL/min)
Intermittent haemodialysis	150–200
Intermittent haemofiltration	100–150
Acute intermittent peritoneal dialysis	10–20
Continuous haemofiltration	5–15

- small volume of distribution
- low metabolic clearance

Unfortunately, a number of other factors inherent in the dialysis process affect clearance; they include:

- duration of dialysis procedure
- rate of blood flow to dialyser
- surface area and porosity of dialyser
- composition and flow rate of dialysate

For peritoneal dialysis other factors come into play and include:

- rate of peritoneal exchange
- concentration gradient between plasma and dialysate

In view of the above, it is usually possible to predict whether a drug will be removed by dialysis, but it is very difficult to quantify the process except by direct measurement, which is rarely practical. Consequently, a definitive, comprehensive guide to drug dosage in dialysis does not exist. However, limited data for specific drugs are available in the literature, while many drug manufacturers have information on the dialysability of their products and some include dosage recommendations in their summaries of product characteristics. The most practical method for treating patients undergoing dialysis is to assemble appropriate dosage guidelines for a range of drugs likely to be used in patients with renal impairment and attempt to restrict use to these.

As drug clearance by haemofiltration is more predictable than in dialysis, it is possible that standardised guidelines on drug elimination may become available. In the interim, a set of individual drug dosage guidelines similar to those described above would be useful in practice.

Factors affecting drug use

How the drug to be used is absorbed, distributed, metabolised and excreted, and whether it is intrinsically nephrotoxic are all factors that must be considered. The pharmacokinetic behaviour of many drugs may be altered in renal failure.

Absorption

Oral absorption in AKI may be reduced by vomiting or diarrhoea, although this is frequently of limited clinical significance.

Metabolism

The main hepatic pathways of drug metabolism appear unaffected in renal impairment. The kidney is also a site of metabolism in the body, but the effect of renal impairment is clinically important in only two situations. The first involves the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol (the active form of vitamin D) in the kidney, a process that is impaired in renal failure. Patients in AKI occasionally require vitamin D replacement therapy, and this should be in the form of 1α-hydroxycholecalciferol (alfacalcidol) or 1,25-dihydroxycholecalciferol (calcitriol). The latter is the drug of choice in the presence of concomitant hepatic impairment. The second situation involves the metabolism of insulin. The kidney is the major site of insulin metabolism, and the insulin requirements of diabetic patients in AKI are often reduced.

Distribution

Changes in drug distribution may be altered by fluctuations in the degree of hydration or by alterations in tissue or serum protein binding. The presence of oedema or ascites increases the volume of distribution while dehydration reduces it. In practice, these changes will only be significant if the volume of distribution of the drug is small, that is, less than 50 L. Serum protein binding may be reduced owing to either protein loss or alteration in binding caused by uraemia. For certain highly bound drugs the net result of reduced protein binding is an increase in free drug, and care is, therefore, required when interpreting serum concentrations. Most analyses measure the total serum concentration, that is, free plus bound drug. A drug level may, therefore, fall within the accepted concentration range but still result in toxicity because of the increased proportion of free drug. However, this is usually only a temporary effect. Since the unbound drug is now available for elimination, its concentration will eventually return to the original value, albeit with a lower total bound and unbound level. The total drug concentration may, therefore, fall below the therapeutic range while therapeutic effectiveness is maintained. It must be noted that the time required for the new equilibrium to be established is about four or five elimination half-lives of the drug, and this may be altered itself in renal failure. Some drugs that show reduced serum protein binding include diazepam, morphine, phenytoin, levothyroxine, theophylline and warfarin. Tissue binding may also be affected; for example, the displacement of digoxin from skeletal muscle binding sites by metabolic waste products that accumulate in renal failure result in a significant reduction in digoxin's volume of distribution.

Excretion

Alteration in renal clearance of drugs in renal impairment is the most important parameter to consider when considering dosage. Generally, a fall in renal drug clearance indicates a decline in the number of functioning nephrons. The glomerular filtration rate can be used as an estimate of the number of functioning nephrons. Thus, a 50% reduction in the glomerular filtration rate will suggest a 50% decline in renal clearance.

Renal impairment, therefore, often necessitates drug dosage adjustments. Loading doses of renally excreted drugs are often necessary in renal failure because of the prolonged elimination half-life which leads to an increased time to reach steady state. The equation for a loading dose is the same in renal disease as in normal patients, thus:

$$\text{loading dose (mg)} = \text{target concentration (mg/L)} \times \text{volume of distribution (L)}$$

The volume of distribution may be altered but generally remains unchanged.

It is possible to derive other formulae for dosage adjustment in renal impairment. One of the most useful is:

$$DR_{rf} = DR_n \times [(1 - F_{eu}) + (F_{eu} \times RF)]$$

where DR_{rf} is the dosing rate in renal failure, DR_n is the normal dosing rate, RF is the extent of renal impairment = patient's creatinine clearance (mL/min)/ideal creatinine clearance (120 mL/min) and F_{eu} is the fraction of drug normally excreted unchanged in the urine. For example, when RF = 0.2 and F_{eu} = 0.5, 60% of the normal dosing rate should be given.

An alteration in dosing rate can be achieved by either altering the dose itself or the dosage interval, or a combination of both as appropriate. Unfortunately, it is not always possible to obtain the fraction of drug excreted unchanged in the urine. In practice, it is simpler to use the guidelines for prescribing in renal impairment found in the British National Formularly. These are adequate for most cases, although the specialist may need to refer to other texts.

Nephrotoxicity

The list of potentially nephrotoxic drugs is long. Although the commonest serious forms of renal damage are interstitial nephritis and glomerulonephritis, the majority of drugs only cause damage by hypersensitivity reactions and are safe in many patients. Some drugs, however, are directly nephrotoxic, and their effects on the kidney are more predictable. Such drugs include aminoglycosides, amphotericin, colistin, the polymixins and ciclosporin. The use of any drug with recognised nephrotoxic potential should be avoided where possible. This is particularly true in patients with pre-existing renal impairement or renal failure. Figure 17.7 summarises the most important and common adverse effects of drugs on renal function, indicating the likely regions of the nephron in which damage occurs. Additional information on adverse effects can be found in Hems and Currie (2005).

Inevitably, occasions will arise when the use of potentially nephrotoxic drugs becomes necessary, and on these occasions constant monitoring of renal function is essential. In conclusion, when selecting a drug for a patient with renal failure, an agent should be chosen that approaches the ideal characteristics listed in Box 17.1.

Acute tubular necrosis
Aminoglycosides
Amphotericin B
Ciclosporin
Ciprofloxacin
Cisplatin
Methotrexate
NSAIDs
Radiocontrast media
Paracetamol (poisoning)
Rifampicin

Interstitial nephritis
Allopurinol
Azathioprine
Captopril
Cephalosporins
Cimetidine
Co-trimoxazole
Erythromycin
Isoniazid
Methyldopa
Minocycline
NSAIDs
Omeprazole
Penicillins
Phenobarbital
Phenytoin
Pyrazinamide
Quinolones
Rifampicin
Thiazides
Vancomycin

Glomerulonephritis

Membranous
Captopril
Gold salts
Heavy metals
Penicillamine
Phenytoin

Minimal change
NSAIDs

Acute nephritis
Penicillins

Renal papillary necrosis
Aspirin + phenacetin (+ other compound analgesics)
NSAIDs

Crystaluria (leading to obstruction)
Aciclovir
Methotrexate
Naftidrofuryl
Sulphonamides

Fig. 17.7 Common adverse effects of drugs on the kidney. The likely sites of damage to the nephron (stylised) are indicated.

Box 17.1 Characteristics of the ideal drug for use in a patient with renal failure

- No active metabolites
- Disposition unaffected by fluid balance changes
- Disposition unaffected by protein binding changes
- Response unaffected by altered tissue sensitivity
- Wide therapeutic margin
- Not nephrotoxic

Case studies

Case 17.1

Mrs J a 60-year-old widow, had long-standing hypertension that was unsatisfactorily controlled on a variety of agents. Her drug therapy included furosemide 40 mg once a day, amlodipine 10 mg daily and a salt restricted diet. Following a routine review of her therapy, ramipril 2.5 mg once daily was added to her treatment regimen in an attempt to improve blood pressure control.

Mrs J was recently diagnosed with gastroenteritis. A week after her diagnosis she presented to her local hospital accident and emergency unit, with ongoing diarrhoea. Her BP was found to be 100/60 mmHg and serum biochemistry revealed creatinine levels of 225 μmol/L (50–120 μmol/L, Na+ 125 mmol/L (135–145 mmol/l) and K+ 5.2 mmol/L (3.5–5.0 mmol/L).

Questions

1. What was the likely cause and underlying mechanism to this patients's problem?
2. What treatment should be given?

Answers

1. ACE inhibitors reduce angiotensin II production, thus, attenuate angiotensin II mediated vasoconstriction of the efferent arterioles that contributes to the high-pressure gradient across the glomerulus necessary for filtration. It is not usually a problem in the majority of individuals; however, in patients with pre-existing compromised renal blood flow, such as renal artery stenoses, the kidney relies more heavily on angiotensin-mediated vasoconstriction of the postglomerular arterioles to maintain renal function. Hypovolaemia caused, for example, by diuretic use and a diarrhoeal illness would tend to exacerbate this problem. Moreover, it is likely that sodium depletion would render the kidney even more dependent upon vasoconstriction of efferent arterioles through activation of the tubuloglomerular feedback system, further sensitising the kidney to the effects of ACE inhibitors.

   Mrs J might well have been suffering from incipient renal failure, but remained asymptomatic until her renal reserve diminished.
2. The inappropriate use of an ACE inhibitor should be stopped, as should the diuretic temporarily. Mrs J should be rehydrated using sodium chloride 0.9% and kidney function markers monitored in the hope that recovery will occur.
3. Investigations should be arranged to determine whether Mrs J has renal artery stenosis as a cause of her AKI after initiation of the ACE inhibitor (see Chapter 18).

Case 17.2

Mr B a known intermittent heroin and cocaine abuser, was discovered comatose in his room early in the morning. He was admitted to hospital as an emergency. An indirect history from an acquaintance indicated that Mr B had been drinking very heavily prior to the incident (probably more than a bottle of whisky in a 24-h period) and had smoked both heroin and cocaine of unknown source and purity.

On examination he was found to be dehydrated and serum biochemistry revealed the following:

		Reference range
Sodium	147 mmol/L	(135–145)
Potassium	6.1 mmol/L	(3.5–5.0)
Calcium	1.72 mmol/L	(2.20–2.55)
Phosphate	2.0 mmol/L	(0.9–1.5)
Creatinine	485 μmol/L	(50–120)
Creatinine kinase	120,000 IU/L	(<200)

Urine dipstick reacted positive for blood with no signs of red blood cells on microscopy. The urine was faintly reddish-brown in colour.

Question

What is likely to have occurred and how should it be treated?

Answer

Cocaine, heroin or alcohol abuse sometimes cause muscle damage resulting in rhabdomyolysis. The mechanism is unclear, but includes vasoconstriction, an increase in muscle activity, possibly because of seizures, self-injury, adulterants in the drug (e.g. arsenic, strychnine, amphetamine, phencyclidine, quinine) or compression (associated with long periods of inactivity). ATN may ensue from a direct nephrotoxic effect of the myoglobin released from damaged muscle cells, microprecipitation of myoglobin in renal tubules (as casts) or a reduction in medullary blood flow. The presence of myoglobin is suggested by the urine dipstick test, which reacts not only to red cells but also to free haemoglobin and myoglobin. Extremely high levels of myoglobinuria may result in urine the colour of Coca-Cola. High serum creatinine kinase levels are indicative of rhabdomyolysis together with the presence of free myoglobin in serum and urine. Serum levels of potassium and phosphate are elevated partly by the effects of incipient renal failure but also through tissue breakdown and intracellular release. Creatinine levels are often higher than expected because of muscle damage.

Treatment should involve fluid replacement with normal saline to reverse dehydration. Furosemide and other loop diuretics should be avoided as these decrease intra-tubular pH which may be a co-factor for cast precipitation. Indeed, in cases where urine pH is less than 6, administration of intravenous isotonic sodium bicarbonate may be of use. The patient's ECG should be monitored, because of the risks involved with rapid elevation in serum potassium. Timely, appropriate corrective therapy must be instigated where necessary. In 50–70% of cases with rhabdomyolysis, dialysis is required to support recovery.

Case 17.3

Mr D is a patient who has been admitted to an intensive care unit with AKI, which developed following a routine cholecystectomy. His electrolyte picture shows the following:

		Reference range
Sodium	138 mmol/L	(135–145)
Potassium	7.2 mmol/L	(3.5–5.0)
Bicarbonate	19 mmol/L	(22–31)
Urea	32.1 mmol/L	(3.0–6.5)
Creatinine	572 μmol/L	(50–120)
pH	7.28	(7.36–7.44)

The patient was connected to an ECG monitor and the resultant trace indicated absent P waves and a broad QRS complex.

Question

Explain the biochemistry and ECG abnormalities and indicate what therapeutic measures must be implemented.

Answer

Hyperkalaemia is one of the principal problems encountered in patients with renal failure. The increased levels of potassium arise from failure of the excretory pathway and also from intracellular release of potassium. Attention should also be paid to pharmacological or pharmaceutical processes that might lead to potassium elevation (e.g. inappropriate potassium supplements, ACE inhibitors, etc.). The acidosis noted in this patient, which is common in AKI, also aggravates hyperkalaemia by promoting leakage of potassium from cells. A serum potassium level greater than 7.0 mmol/L indicates that emergency treatment is required as the patient risks life-threatening ventricular arrhythmias and asystolic cardiac arrest. If ECG changes are present, as in this case, emergency treatment should be initiated when serum potassium rises above 6.5 mmol/L.

The emergency treatment should include:

1. Stabilisation of the myocardium by intravenous administration of 10–30 mL calcium gluconate 10% over 5–10 min. The effect is temporary but the dose can be repeated.
2. Intravenous administration of 10–20 units of soluble insulin with 50 mL of 50% glucose to stimulate cellular potassium uptake. The dose may be repeated. The blood glucose should be monitored for at least 6 h to avoid hypoglycaemia.
3. Acidosis may be corrected with an intravenous dose of sodium bicarbonate, preferably as an isotonic solution. Correction of acidosis stimulates cellular potassium re-uptake.
4. Intravenous salbutamol 0.5 mg in 100 mL 5% dextrose administered over 15 min has been used to stimulate the cellular Na-K ATPase pump and thus drive potassium into cells. This may cause disturbing muscle tremors at the doses required to reduce serum potassium levels.

18 Chronic kidney disease and end-stage renal disease

J. Marriott, P. Cockwell and S. Stringer

Key points

- The prevalence of chronic kidney disease (CKD) increases with age and is greater in females and some ethnic populations.
- CKD is classified according to severity from 1 to 5, where 5 is the most advanced and 1 the least.
- CKD 1–3 is common and may not cause symptoms. It may progress to end-stage renal disease but frequently remains stable for many years.
- CKD is an important risk factor for cardiovascular disease.
- As CKD becomes more advanced (stages 4 and 5), virtually all body systems are adversely affected.
- Clinical signs and symptoms of severe CKD include oedema, anaemia, hypertension, bone pain, nocturia, neurological changes and disordered muscle function.
- The aims of treatment are to reverse or arrest the process responsible for CKD, relieve symptoms and reduce cardiovascular morbidity and mortality.
- To prevent further renal damage, adequate control of blood pressure and reduction of proteinuria are essential.
- Renal anaemia is common when the glomerular filtration rate (GFR) falls below 30 mL/min but can be corrected by erythropoietin in 90–95% of cases.
- End-stage renal disease is the point at which life can only be sustained by dialysis or transplantation. This may occur soon after presentation or after several years.
- The need for dialysis therapy is increasing at about 5% per annum with attendant resource implications.
- There are two principal types of dialysis: haemodialysis and peritoneal dialysis. In both, waste products and metabolites are transferred from the patient's blood across a semi-permeable membrane to a dialysis solution.
- Renal transplantation remains the treatment of choice for end-stage renal disease. However, up to 60% of patients on dialysis programmes are not fit enough to be put on the transplant list.

Chronic kidney disease (CKD) is defined by a reduction in the glomerular filtration rate (GFR) and/or urinary abnormalities or structural abnormalities of the renal tract. The severity of CKD is classified from 1 to 5 depending upon the level of GFR (Table 18.1). It is a common condition affecting up to 10% of the population in Western societies and is more common in some ethnic minority populations and in females. The incidence increases exponentially with age such that some degree of CKD is almost inevitable in persons over 80 years of age. Social deprivation is also associated with a higher prevalence of CKD. The scale of CKD and the consequences for the health service has been appreciated only in the last few years.

Estimates for the incidence of the various grades of CKD are shown in Table 18.1 and have been derived from large American studies, although data suggests the rates in the UK are similar (UK Renal Registry, 2008). In the past, patients with CKD were often unrecognised owing to difficulties in measuring or estimating the GFR and their health needs were largely unmet. The recent development of simple methods to estimate GFR has revealed a huge population of patients with significant kidney disease. This will pose a considerable challenge to health services in the future. National guidance on the management of CKD has been published (NICE, 2008) and includes management in primary and secondary care.

CKD differs from acute kidney injury (AKI) by virtue of chronicity and a different spectrum of causes. However, AKI and CKD are not mutually exclusive; patients with AKI may not recover renal function to their baseline and may be left with residual CKD. In addition, patients with CKD may experience episodes of AKI sometimes causing reversible step-wise declines in renal function.

Renin-angiotensin-aldosterone system

The renin-angiotensin-aldosterone system (RAAS) has a critical role in the progression of CKD and an awareness of this system is important for understanding the pathophysiology of CKD and the targets for therapeutic intervention. Most of the renal effects of this system are through regulating intraglomerular pressures and salt and water balance. Renin is an enzyme which is formed and stored in the juxtaglomerular apparatus and released in response to decreased afferent intra-arterial pressures, decreased glomerular ultrafiltrate sodium levels and sympathetic nervous system activation. In patients with CKD, intra-renal pressures are often low and sympathetic overactivity is common; these factors lead to increased renin secretion. This can occur with normal or elevated systemic blood pressure.

Table 18.1 Classification of chronic kidney disease

Stage of CKD	Glomerular filtration rate	Description	Prevalence in the UK (% of population)
1	≥90 mL/min + proteinuria/haematuria or structural damage	Kidney damage with normal or increased GFR but other evidence of kidney damage	3.3
2	60–89 mL/min + proteinuria/haematuria or structural damage	Slight decrease in GFR with other evidence of kidney disease	3.0
3a 3b	45–59 mL/min 30–44 mL/min	Moderate reduction in GFR With or without evidence of other kidney disease	4.3
4	13–29 mL/min	Severe reduction in GFR	0.2
5	<15 mL/min	Kidney failure, use suffix (D) if dialysis	0.1

GFR, glomerular filtration rate.
Use suffix (P) to denote proteinuria, suffix (D) to denote dialysis and suffix (T) to denote transplantation. For example, a patient with CKD 3a and proteinuria would be described as CKD 3A p. A patient with CKD 5 on dialysis would be CKD5 d

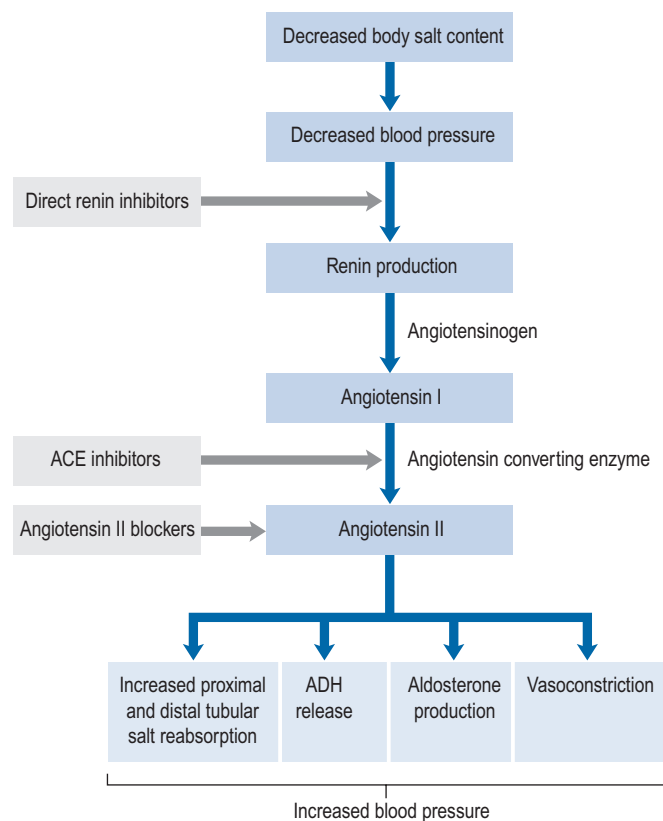
Renin promotes cleavage of the protein angiotensinogen, which is produced by the liver, to produce angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme (ACE). Angiotensin II has two major physiological effects. First, it acts on the zona glomerulosa of the adrenal cortex to promote production of the mineralocorticoid hormone aldosterone, with resultant increased distal tubular salt and water reabsorption. Furthermore, it promotes antidiuretic hormone (ADH) release, which increases proximal tubular sodium reabsorption and promotes thirst. In combination, these lead to salt and fluid retention, high intravascular volumes, hypertension and oedema. Second, it is a direct vasoconstrictor and promotes systemic and (preferential) renal hypertension. The renal effects are predominantly on the efferent glomerular arteriole. Vasoconstriction at this site is mediated by a high density of angiotensin II receptors. When these receptors are ligated by angiotensin II, there is increased intra-glomerular pressures. Whilst this leads to an overall increase in GFR in the short-term, over a longer period glomerular hypertension promotes accelerated glomerular scarring and worsening CKD. In addition to the vascular and endocrine effects of the RAAS, it is now recognised that there is a local immune modulatory role for this system. Both resident (e.g. tubular epithelial) cells and inflammatory (monocytes and macrophages) cells synthesise components of the RAAS and are themselves targeted by the system. For example, monocytes and macrophages express the angiotensin II receptor and activation through this receptor leads to an enhanced inflammatory and fibrotic phenotype of the cell. This raises the intriguing concept that some of the effects of blocking the RAAS are due to direct anti-inflammatory and anti-fibrotic effects. Figure 18.1 shows this pathway and identifies the points at which pharmacological interventions targeted for a biological effect translates into clinical outcomes.


Fig. 18.1 The renin–angiotensin–aldosterone system and targets for pharmaceutical intervention.

Measurement of renal function

The scale of CKD has only been recognised in recent years because detection is dependent upon an accurate estimation of the GFR. The GFR is defined as the volume of filtrate

produced by the glomeruli of both kidneys each minute and is a reliable indicator of renal function.

It is laborious and expensive to measure GFR by gold standard tests such as inulin or radiolabelled isotope clearance. These tests are only used when extremely accurate assessment of kidney function is required. An example of this is measurement of kidney function in a potential living kidney donor where an individual is proposing to donate a kidney to a family member or close friend.

As a consequence, a number of equations have been validated for use in the routine clinical setting. These equations provide an estimate of glomerular filtration rate (eGFR) based on the combination of serum or plasma creatinine and a number of variables which add precision to the estimation of kidney function. The commonest eGFR equation used in clinical practice is the four-variable MDRD (Modification of Diet in Renal Disease Study) equation. The biochemical variable that provides the basis of the MDRD and most other GFR equations is serum creatinine.

Serum creatinine

While serum creatinine concentration is related to renal function, it is also dependent upon the rate of production of creatinine by the patient. Creatinine is a by-product of normal muscle metabolism and is formed at a rate proportional to muscle mass (20 g muscle equates to approximately 1 mg creatinine production) and therefore is related to age, sex and ethnicity.

Creatinine is freely filtered by the glomerulus, so when muscle mass is stable any change in serum creatinine levels reflects a change in its renal clearance. Consequently, measurement of serum creatinine can be utilised to give an estimate of the kidney function. It is important to note, however, that creatinine also undergoes significant tubular secretion (~10–20%). This becomes important in advanced CKD (stages 4 and 5) and limits the value of measuring serum creatinine to determine renal function in advanced CKD.

MDRD glomerular filtration rate equation

Eight eGFR equations were validated for the MDRD study (Levey et al., 1999). These used demographic and serum variables (including serum creatinine level, age, gender, non-black ethnicity, higher serum urea levels, and lower serum albumin levels) in a series of equations. The four-variable equation (also known as the abbreviated (a)MDRD equation) has been adopted into clinical practice and incorporates age, creatinine, gender and ethnicity (Fig. 18.2).

The MDRD equation is more accurate than serum creatinine alone as an estimator of kidney function; however, it has not been validated in the elderly, those with creatinine levels within the normal range or transplant recipients. The CKD classification system is based on the aMDRD eGFR.

Other estimates of kidney function

Creatinine clearance

This is similar to the GFR as nearly all the filtered creatinine appears in the urine. It is a measurement of the volume of blood that is cleared of creatinine with time. Measurements of creatinine clearance (Cl_{Cr}) require accurate collection of 24 h urine samples with a serum creatinine sample midway through this period. This is time-consuming, inconvenient and prone to inaccuracy and as such is now rarely used in clinical practice. Figure 18.3 shows the equation for measuring creatinine clearance.

Cockroft–Gault equation

The Cockroft–Gault equation uses weight, sex and age to estimate creatinine clearance and was derived using average population data (Cockroft and Gault, 1976). The equation is shown in Fig. 18.4.

Estimates of glomerular filtration rate in paediatric patients

Estimates of GFRs in paediatric patients can be made using the Schwartz formula (Schwartz, 1985) or the Counahan–Barratt method (Counahan et al., 1976) which both rely upon inclusion of the height of the child in estimating creatinine clearance, since height correlates with muscle mass.

Urea

Urea is also used in the assessment of renal function despite a variable production rate and diurnal fluctuation in response to the protein content of the diet. Levels of urea

$$Cl_{Cr} = \frac{(U \times V)}{S}$$

where **U** is the urine creatinine concentration (µmol/L), **V** is the urine flow rate (mL/min) and **S** is the serum creatinine concentration (µmol/L)

Fig. 18.3 Creatinine clearance calculation.

$$Cl_{Cr} = \frac{F\,(140\ \text{age (years)}) \times \text{weight (kg)}}{\text{Serum creatinine (µmol/L)}}$$

where **F** = 1.04 (females) or 1.23 (males)

Fig. 18.4 The Cockroft–Gault formula.

eGFR (mL/min/1.73m²) = 186 x [serum creatinine (µmol/L)/88.4]$^{-1.154}$ x [age]$^{-0.203}$ x [0.742 if **female**] x [1.212 if **African-American**]

Fig. 18.2 Four-variable MDRD equation used to calculate eGFR.

may also be elevated by dehydration or an increase in protein catabolism such as that accompanying gastro-intestinal haemorrhage, severe infection, trauma (including surgery) and high-dose steroid therapy. Serum urea levels are, therefore, an unreliable measure of renal function, but can be used as an indicator of the patient's general condition and state of hydration. A rapid elevation of serum urea, before any rise in corresponding creatinine levels, is often a sign of an impending deterioration in renal function or a marker for pre-renal failure associated with intravascular volume depletion.

Significance of CKD

CKD is significant as it indicates the possibility of progression to end-stage renal disease, and a strong association with accelerated cardiovascular disease, similar in magnitude to that observed in diabetics. The cardiovascular risk increases with the severity of CKD but is detectable at all levels. Thus, it is important to pay particular attention to traditional cardiovascular risk factors such as smoking, cholesterol and blood pressure in patients with CKD. However, it is known from previous studies that these risk factors only contribute around 50% of the total cardiovascular disease risk and recent interest has focused on the identification of novel risk factors to explain the remainder of the risk.

It is important to make a distinction between cardiovascular disease related to macrovascular atherosclerosis and that related to microvascular changes, often found in individuals with CKD. The cardiovascular disease found in CKD is more likely to be related to small vessel disease initiated by endothelial dysfunction rather than atherosclerotic disease. In addition, patients with CKD often have associated left ventricular hypertrophy which may be related to chronic volume overload and uraemia.

Progression to more advanced stages of CKD may occur, particularly if the blood pressure is inadequately controlled and there is significant proteinuria, but this is by no means the rule and many patients with CKD remain stable for years or even decades. These patients need to be followed up with regular blood and urine tests to detect progression, if it occurs. Low risk patients, that is, those with unchanging GFR over time, with controlled blood pressure and no proteinuria may not require long-term follow up by a kidney specialist and surveillance can be carried out satisfactorily in primary care.

Patients with CKD 1–3 (Table 18.1) are frequently asymptomatic. The reduction of GFR is insufficient to cause uraemic symptoms and any minor abnormalities in the urine such as proteinuria or haematuria are usually not noticed by patients. There is a frequent association with high blood pressure which may be the cause or a consequence of renal damage. Recognition of these patients is important as it allows early modification of traditional cardiovascular risk factors. These patients should be investigated to determine if there is a treatable cause for their CKD and followed up to identify those individuals with progressive disease.

Patients with CKD stages 4 and 5 (Table 18.1) should usually be followed up in a nephrology clinic because they will require specialist management of the complications of CKD such as anaemia and bone disease, whilst many will also be undergoing preparation for renal replacement therapy.

Causes of CKD

The reduction in renal function observed in CKD results from damage to the infrastructure of the kidney in discrete areas rather than throughout the kidney. The nephron is the functional unit of the kidney and while the mechanism of damage depends on the underlying cause of renal disease, as nephrons become damaged and fail, remaining nephrons compensate for loss of function by hyperfiltration secondary to raised intra-glomerular pressure. This causes 'bystander' damage with secondary nephron loss. This vicious cycle is illustrated in Fig. 18.5. The patient remains well until so many nephrons are lost that the GFR can no longer be maintained despite activation of compensatory mechanisms. As a consequence there is a progressive decline in kidney function.

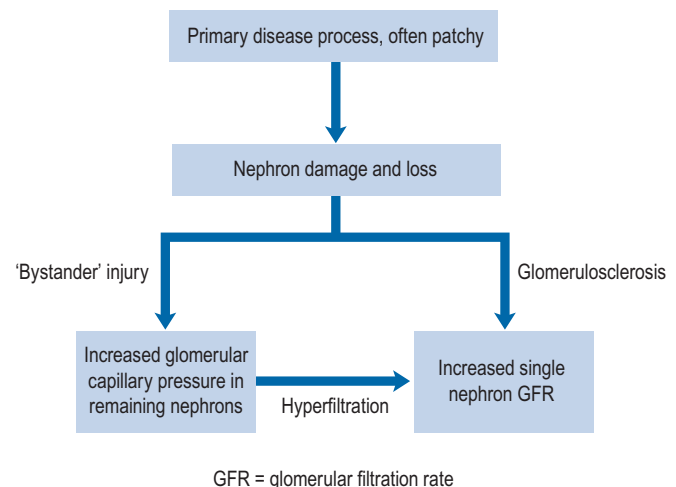
CKD arises from a variety of causes (Table 18.2), although by the time a patient has established CKD it may not be possible to identify the exact cause. However, attempting to establish the cause is useful in the identification and elimination of reversible factors, to plan for likely outcomes and treatment needs, and for appropriate counselling when a genetic basis is established. The causes of CKD listed in Table 18.2 are ordered according to prevalence. It is important to note the prevalence of these factors is different in CKD and end stage renal disease. In end stage renal disease, diseases such as adult polycystic kidney disease (APKD) are overrepresented and ischaemic/hypertensive nephropathy underrepresented. The reasons for this are that individuals with APKD are likely to survive to reach end stage renal disease while those with diabetes or ischaemic renal damage may succumb to cardiovascular disease before end stage renal disease is reached.


Fig. 18.5 Mechanism of progressive renal damage.

Table 18.2 Primary diagnosis in renal replacement therapy patients by age and gender (Renal Registry, 2008)

Primary diagnosis	% all patients	Inter-centre range (%)	% age <65	% age >65	% male:female ratio
Aetiology uncertain/ glomerulonephritis (not biopsy proven)	21.6	2.1–84.3	19.2	26.6	1.6
Glomerulonephritis (biopsy proven)	15.3	2.3–22.4	17.8	10.0	2.2
Pyelonephritis	11.9	3.2–19.4	13.6	8.3	1.1
Diabetes	13.2	2.8–26.0	12.3	15.1	1.6
Polycystic kidney	9.2	2.0–15.8	9.6	8.3	1.1
Hypertension	5.4	1.0–16.0	4.6	6.9	2.4
Renal vascular disease	3.5	0.3–16.1	1.1	8.2	2.0
Other	14.5	1.9–36.1	16.0	11.3	1.3
Not sent	5.5	0.1–46.2	5.7	5.2	1.5

Ischaemic/hypertensive renal disease

Ischaemic nephropathy has traditionally been referred to under perfusion of the kidneys caused by renal artery stenosis. This explanation has fallen from favour recently and this term is now taken to mean impairment of renal function beyond occlusion of the main renal arteries. Hypertension results in atherosclerosis which can cause occlusive renovascular disease and small vessel damage. In patients with significant large vessel occlusive disease arteriolar nephrosclerosis, interstial fibrosis and glomerular collapse may be present (Lerman and Textor, 2001). These diagnoses account for around 30% of CKD and a smaller proportion of end stage renal disease. The effective management of hypertension is crucial to reduce renal damage.

Metabolic diseases

Diabetes mellitus is the most common metabolic disease that leads to CKD, whilst the predominant lesion is glomerular and referred to as diabetic nephropathy. Diabetes accounts for around 13% of CKD (see Table 18.2) and is associated with faster renal deterioration than other pathologies: these patients are at very significant cardiovascular risk by virtue of both CKD and diabetes. Both type 1 and 2 diabetes can result in diabetic nephrophy, patients with type 1 diabetes usually present with renal complications at a younger age and may benefit from combined kidney and pancreas transplantation. Patients with diabetes may present with no proteinuria, micro albuminuria or overt proteinuria, though as the level of proteinuria increases the GFR usually declines and in many patients this represents an inexorable decline towards end stage renal disease.

Chronic glomerulonephritis

All types of chronic glomerulonephritis (GN) combined cause about 15% of cases of advanced CKD. The commonest cause of glomerulonephritis is IgA nephropathy which is characterised by deposition of polymeric IgA in the glomerulus with subsequent immune activation. Other patterns of glomerulonephritis include membranous nephropathy, where there is granular deposition of immunoglobulin on the glomerular capillary basement membrane. Systemic autoimmune diseases such as systemic lupus erythematosus can cause a variety of types of glomerulonephritis. Finally, some chronic forms of glomerulonephritis are pauci-immune, that is they have no immune deposition. This is seen in focal and segmental glomerulosclerosis.

Lower urinary tract disease

A variety of differing pathologies make up this group and together they represent 5–10% of all cases of CKD. The conditions include the following.

Reflux disease

This results from reflux of urine back up the renal tract towards the kidneys. This can result in recurrent infections and subsequent scarring.

Renal stone disease

Kidney stones are primarily formed of calcium oxalate and calcium phosphate. They can cause urinary tract obstruction and infection.

Chronic pyelonephritis

Recurrent urinary tract infection can result in renal scarring; this is often in the context of reflux disease but may occur without it.

Extrinsic renal tract obstruction

In males, the commonest cause of this is prostatic hypertrophy though there are many other causes.

Hereditary/congenital diseases

There are many inherited renal diseases and together they represent 5% of CKD cases. It is, however, important to remember that they make up a higher proportion of cases of end stage renal disease. The commoner inherited conditions are APKD and Alport's syndrome. Autosomal dominant polycystic kidney disease is an inherited condition which results in the formation of multiple cysts in both kidneys throughout life. The kidneys become enlarged and frequently fail in middle age. Alport's syndrome is a disorder of glomerular basement membranes caused by a mutation affecting type IV collagen; X-linked, autosomal dominant and autosomal recessive forms of inheritance are all seen. The clinical manifestations include progressive nephritis with haematuria, proteinuria and sensorineural deafness.

Unknown cause

It is not uncommon for the cause of CKD to be unknown and this is the case in around 30% of patients who typically present with small kidneys and unremarkable immunological investigations. When the kidneys are small it is often not possible to carry out a renal biopsy or if possible the histology often shows severe scarring with no indication of the underlying cause.

Clinical manifestations

While uraemic symptoms are rare in CKD stage 4, they become more apparent as the patient approaches end stage renal disease. The onset of symptoms is slow and insidious so that patients may not realise that they are unwell. It is not uncommon for patients to present in end stage renal disease and require immediate dialysis at their first contact with the medical profession.

End stage renal disease is characterised by the requirement of renal replacement therapy to sustain life and it is often accompanied by uraemia, anaemia, acidosis, osteodystrophy, neuropathy and is frequently accompanied by hypertension, fluid retention and susceptibility to infection (Fig. 18.6). It results from a significant reduction in the excretory, homeostatic, metabolic and endocrine functions of the kidney that occur over a period of months or years.

In the following section, the clinical features of CKD are described, along with the pathogenesis.

Urinary tract features

Both polyuria and nocturia are found in CKD though neither is universal and many patients with CKD have no urinary symptoms. Proteinuria is common in CKD and can be present

to varying degrees. Proteinuria is commonly measured using single urine samples to determine the albumin creatinine ratio (ACR). This method has almost entirely replaced the 24 h urine collection which was inconvenient and often unreliable. An ACR of 3-30 mg/mmol is described as microalbuminuria while in nephrotic-range proteinuria it is >250 mg/mmol. Haematuria may also be present and can reflect either glomerular or lower urinary tract pathology. The presence of blood and/or protein in the urine is described as an active urinary sediment. Whenever blood in the urine is detected an infection should be considered and excluded by urine microscopy for white cells and culture for organisms.

Polyuria and nocturia

Polyuria, where the patient frequently voids high volumes of urine, is often seen in CKD and results from medullary damage and the osmotic effect of a high serum urea level (>40 mmol/L). The ability to concentrate urine is also lost in CKD, which together with failure of physiological nocturnal antidiuresis, invariably results in nocturia, where the patient will be wakened two or three times a night with a full bladder.

Proteinuria

A degree of proteinuria is common in CKD and the prevalence of proteinuria increases with the severity of CKD. There are a number of precipitating factors including glomerular disease, failure of protein reabsorption in the tubules and rarely overflow of excess plasma proteins as seen in myeloma. Pronounced proteinuria (>1 g of protein in a 24-h collection, equivalent to an ACR >70 mg/mmol) usually indicates a glomerular aetiology. The presence and quantity of proteinuria are major determinants of progressive CKD.

Haematuria

Haematuria can be either macroscopic or microscopic; macroscopic haematuria is likely to result from lower urinary tract pathology (such as bladder lesions) and microscopic haematuria is most often of glomerular origin. Microscopy can identify the presence of casts which are also seen in glomerular diseases and allow the discrimination of the course of haematuria.

Hypertension and fluid overload

Most patients with CKD will have hypertension and this may be a cause or a consequence (or a combination of both) of their kidney disease. Furthermore, raised blood pressure may exacerbate renal damage and lead to accelerated deterioration of CKD.

Severe renal impairment leads to sodium retention, which in turn produces circulatory volume expansion with consequent hypertension. This form of hypertension is often termed 'salt-sensitive', as it may be exacerbated by salt intake. Lesser degrees of renal impairment reduce kidney perfusion, which activates renin production, with subsequent angiotensin-mediated vasoconstriction. Treatment of blood pressure, irrespective of choice of therapy, generally improves the course of CKD. As the GFR falls to very low levels the kidneys are unable to excrete salt and water adequately, resulting in the retention of extravascular fluid. All patients with fluid overload will by definition also have salt retention, even if this is not manifest in the serum sodium concentration.

Clinical findings

Eye damage in the form of hypertensive retinopathy may be found in those patients whose blood pressure has not been adequately controlled. This can be prevented by appropriate and timely antihypertensive therapy. Fluid retention can manifest as peripheral and pulmonary oedema and ascites. Oedema may be seen around the eyes on waking, the sacral region in supine patients and from the feet upwards in ambulatory patients. Volume-dependent hypertension occurs in about 80% of patients with CKD and becomes more prevalent as the GFR falls.

Uraemia

Many substances including urea, creatinine and water are normally excreted by the kidney and accumulate as renal function decreases. Some of the substances responsible for the toxicity of uraemia are intermediate in size between small, readily dialysed molecules and large non-dialysable proteins. These are described as 'middle molecules' and include phosphate, guanidines, phenols and organic acids. Clearly, there are a wide range of uraemic toxins but it is the blood level of urea that is often used to estimate the degree of toxin accumulation in uraemia. True symptomatic uraemia only occurs in very advanced CKD.

Clinical findings

The symptoms of uraemia include anorexia, nausea, vomiting, constipation, foul taste and skin discolouration that is presumed to be due to pigment deposition compounded by the pallor of anaemia. The characteristic complexion is often described as 'muddy', and is frequently associated with severe pruritus without an underlying rash. In extremely severe cases, crystalline urea is deposited on the skin (uraemic frost).

In uraemia, there is also an increased tendency to bleed, which can exacerbate pre-existing anaemia because of impaired platelet adhesion and modified interaction between platelets and blood vessels resulting from altered blood rheology.

Anaemia

Anaemia is a common consequence of CKD and affects most people with CKD stages 4 and 5. The fall in haemoglobin level is a slow, insidious process accompanying the decline in renal function. A normochromic, normocytic pattern is usually seen with haemoglobin levels falling to around 8 g/dL by end stage renal disease.

Several factors contribute to the pathogenesis of anaemia in CKD, including shortened red cell survival, marrow suppression by uraemic toxins and iron or folate deficiency associated with poor dietary intake or increased loss, for example, from gastro-intestinal bleeding. However, the principal cause results from damage of peritubular cells leading to inadequate secretion of erythropoietin. This hormone, which is produced mainly, although not exclusively, in the kidney, is the main regulator of red cell proliferation and differentiation in bone marrow. Hyperparathyroidism also reduces erythropoiesis by damaging bone marrow and therefore exacerbates anaemia associated with CKD. The RAAS is also involved in erythropoiesis since renin increases erythropoietin production and this explains how ACE inhibitors can cause small reductions in haemoglobin.

Clinical findings

Anaemia in CKD is a major cause of fatigue, breathlessness at rest and on exertion, lethargy and angina. Patients may also complain of feeling cold, poor concentration and reduced appetite and libido. Compensatory haemodynamic changes occur with CKD, cardiac output is increased to improve oxygen delivery to tissues, although this may result in tachycardia and palpitations. The anaemia of CKD usually responds to treatment with erythropoietin-stimulating agents (ESAs).

Bone disease (renal osteodystrophy)

Renal osteodystrophy describes the four types of bone disease associated with CKD:

- secondary hyperparathyroidism
- osteomalacia (reduced mineralisation)
- mixed renal osteodystrophy (both hyperparathyroidism and osteomalacia)
- adynamic bone disease (reduced bone formation and resorption).
Fig. 18.7　Renal and hepatic involvement in vitamin D metabolism.

Cholecalciferol, the precursor of active vitamin D, is both absorbed from the gastro-intestinal tract and produced in the skin by the action of sunlight. Production of active vitamin D, 1,25-dihydroxycholecalciferol (calcitriol), requires the hydroxylation of the colecalciferol molecule at both the 1α and the 25 position (Fig. 18.7).

Hydroxylation at the 25 position occurs in the liver, while hydroxylation of the 1α position occurs in the kidney; this latter process is impaired in renal failure. The resulting deficiency in vitamin D leads to defective mineralisation of bone and subsequent osteomalacia which is almost inevitable in those with CKD stage 3 and beyond.

The deficiency in vitamin D with the consequent reduced calcium absorption from the gut in combination with the reduced renal tubular reabsorption results in hypocalcaemia (Fig. 18.8).

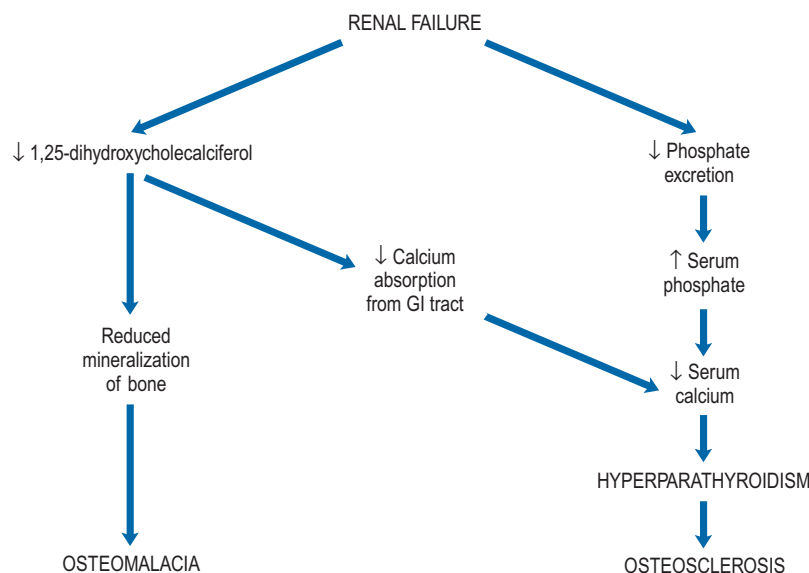
These disturbances are compounded by hyperphosphataemia caused by reduced phosphate excretion, which in turn reduces the concentration of ionised serum calcium by sequestering calcium phosphate in bone and in soft tissue. Hypocalcaemia, hyperphosphataemia and a reduction in the direct suppressive action of 1,25-dihydroxycholecalciferol on


Fig. 18.8　Disturbance of calcium and phosphate balance in chronic renal failure.

the parathyroid glands results in an increased secretion of parathyroid hormone (PTH).

Since the failing kidney is unable to respond to PTH by increasing renal calcium reabsorption, the serum PTH levels remain persistently elevated, and hyperplasia of the parathyroid glands occurs. The resulting secondary hyperparathyroidism produces a disturbance in the normal architecture of bone and this is termed osteosclerosis (hardening of the bone). A further possible consequence of secondary hyperparathyroidism produced in response to hypocalcaemia is that sufficient bone reabsorption may be caused to maintain adequate calcium levels. This, in combination with hyperphosphataemia, may result in calcium phosphate deposition and soft tissue calcification.

Clinical findings

Bone pain is the main symptom, and distinctive appearances on radiography may be observed, such as 'rugger-jersey' spine, where there are alternate bands of excessive and defective mineralisation in the vertebrae (Fig. 18.9).

Neurological changes

The most common neurological changes are non-specific and include inability to concentrate, memory impairment, irritability and stupor probably caused by uraemic toxins.
Fig. 18.9 Lateral radiograph of the spine in a patient with chronic renal failure. Characteristic endplate sclerosis (arrows) are referred to as 'rugger-jersey spine' (reproduced by kind permission of Dr M. J. Kline, Department of Diagnostic Radiology, Cleveland Clinic Foundation).

Clinical features

Fits owing to cerebral oedema or hypertension may occur. A 'glove and stocking' peripheral neuropathy can occur as can mono-neuritis multiplex.

Muscle function

Muscle symptoms are probably caused by general nutritional deficiencies and electrolyte disturbances, notably of divalent cations and especially by hypocalcaemia.

Clinical findings

Muscle cramps and restless legs are common and may be major symptoms causing distress to patients, particularly at night. Rarely a proximal myopathy of shoulder and pelvic girdle muscles may develop.

Electrolyte disturbances

Since the kidneys play such a crucial role in the maintenance of volume, extracellular fluid composition and acid–base balance, it is not surprising that disturbances of electrolyte levels are seen in CKD.

Sodium

Serum sodium levels can be relatively normal even when creatinine clearance is very low. However, patients may exhibit hypo- or hypernatraemia depending upon the condition and therapy employed (see Table 18.3).

Table 18.3 Causes and mechanism of serum sodium abnormalities in chronic kidney disease

	Mechanism	Cause/effect
Hypernatraemia	Sodium overload	Drugs, for example, antibiotic sodium salts
	Hypotonic fluid loss	Osmotic diuresis
	↓ Water intake	Sweating Unconsciousness
Hyponatraemia	Dilution by intracellular water movement	Mannitol
Hyperglycaemia	Water overload	Acute dilution by intravenous fluids, for example, 5% dextrose infusion Excessive intake Congestive cardiac failure Nephrotic syndrome

Potassium

Potassium levels can be elevated in CKD. Hyperkalaemia is a potentially dangerous condition as the first indication of elevated potassium levels may be life-threatening cardiac arrest. Potassium levels of over 7.0 mmol/L are life-threatening and should be treated as an emergency. Hyperkalaemia may be exacerbated in acidosis as potassium shifts from within cells.

ECG changes accompany any rise in serum potassium and become more pronounced as levels increase. T waves peak ('tenting'), there is a reduction in the size of P waves, an increase in the PR interval and a widening of the QRS complex. P waves eventually disappear and the QRS complex becomes even wider. Ultimately, the ECG assumes a sinusoidal appearance prior to cardiac arrest (see Fig. 18.10).

Hydrogen ions

Hydrogen ions (H^+) are a common end-product of many metabolic processes and about 40–80 mmol are normally excreted via the kidney each day. In renal failure, H^+ is retained, causing acidosis; the combination of H^+ with bicarbonate (HCO_3^-) results in the removal of some hydrogen as water, the elimination of carbon dioxide via the lungs, and a reduction in serum bicarbonate level.

A. Normal serum potassium (3.5–5.0) mmol/L
B. Serum potassium approximately 7.0 mmol/L
C. Serum potassium approximately 8.0–9.0 mmol/L
D. Serum potassium greater than 10.0 mmol/L
Fig. 18.10 Typical ECG changes in hyperkalaemia.

Diagnosis, investigations and monitoring

Although the diagnosis of CKD may be suspected because of signs and symptoms of renal disease, more often it is discovered incidentally. There are patients with CKD for whom no cause can be identified, often because they have two small kidneys which are not safe to biopsy. This appearance results from damage at some unspecified time in the past.

Family, drug and social histories are all important in elucidating the causes of renal failure, since genetics or exposure to toxins, including prescription, over-the-counter and herbal drugs, might be implicated.

Physical examination may be helpful. Signs of anaemia and skin pigmentation, excoriations owing to scratching and whitening of the skin with crystalline urea ('uraemic frost') may point to severe disease. Palpable or audible bruits over the femoral arteries are strongly associated with extensive arteriosclerosis and are commonly found in patients with renal vascular disease. Ankle oedema and a raised jugular venous pressure suggest fluid retention and in severe CKD a fishy smell on the breath known as 'uraemic foetor' is characteristic. In some patients, the kidneys may be palpable. Large irregular kidneys are indicative of polycystic disease, whereas smooth, tender enlarged kidneys are likely to be infected or obstructed. However, in the large majority of CKD the kidneys are small and are impalpable. A palpable bladder suggests outflow tract obstruction which is often due to prostatic hypertrophy in men.

Functional assessment of the kidney may be performed by testing serum and urine. The serum creatinine level is a more reliable indicator of renal function than the serum urea level though both are normally measured. Hyperkalaemia, acidosis with a correspondingly low serum bicarbonate level, hypocalcaemia and hyperphosphataemia are frequently present and can help to differentiate a new presentation of CKD from AKI.

Urine should be examined visually and microscopically and urinalysis performed for assessment of urinary sediment and a spot urine assessment of the ACR. The patient may report a change in urine colour, which might result from blood staining by whole cells or haemoglobin, drugs or metabolic breakdown products. Urine may also appear milky after connection with lymphatics, cloudy following infection, contain solid material such as stones, crystals, casts, or froth excessively in proteinuria.

Dipstick tests enable simple, rapid estimation of a wide range of urinary parameters including pH, specific gravity, leucocytes, nitrites, glucose, blood and protein. Positive results should, however, be quantified by more specific methods.

Structural assessments of the kidney may be performed using a number of imaging procedures, including:

- ultrasonography
- intravenous urography (IVU)
- plain abdominal radiography
- computed tomography (CT), magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA).

Ultrasonography

This method produces two dimensional images using sound waves and is used as the first-line investigational tool in many hospitals. The technique is harmless, non-invasive, quick, inexpensive, enables measurements to be made and produces images in real time. The latter feature allows accurate and safe positioning of biopsy needles. Ultrasonography is particularly useful in the differentiation of renal tumours from cysts and in the assessment of renal tract obstruction. Doppler ultrasonography is a development that enables measurement of flow rate and direction of the intra- and extrarenal blood supply.

Intravenous urography

IVU is now used very infrequently because it uses high doses of radiation and contrast media, newer modalities such as CT scanning can provide more information. Timed serial radiographs are taken of the kidneys and the full length of the urinary tract following an intravenous injection of an iodine-based contrast medium that is filtered and excreted by the kidney. IVU will show the following:

- the presence, length and position of the kidneys; in CKD the kidneys generally shrink in proportion to nephron loss, the exception being the enlarged kidneys seen in polycystic disease
- the presence or absence of renal scarring and the shape of the calices and renal pelvis; renal cortical scarring and caliceal distortion indicate chronic pyelonephritis
- obstruction to the ureters, for example, by a stone, tumour or retroperitoneal fibrosis; these require surgical intervention
- the shape of the bladder and the presence of residual urine; enlargement and a post-micturition residue suggest urethral obstruction such as prostatic hypertrophy.

Nuclear medicine investigations

There are two commonly used nuclear medicine investigations, the first uses mercapto acetyl tri-glycerine (MAG3). This is used for assessment of renal perfusion and the identification of outflow obstruction. The other is a dimercapto succinic acid (DMSA) scan, the purpose of which is to ascertain the percentage that each kidney contributes to overall function.

The similar techniques of CT and MRI provide excellent structural information about the kidneys and urinary tract. They use less radiation (none in the case of MRI) and less contrast media than an IVU, although the machinery required is more expensive than that needed for traditional imaging methods. CT is particularly useful in the investigation of kidney stones, where it has superseded the IVU. MRA can also give information about renal blood supply; however, in recent years, concerns have arisen about the use of gadolinium as a contrast agent used in MRA. This has been associated with nephrogenic systemic fibrosis which results in death in a proportion of patients; those with CKD stages 4 and 5 are at highest risk
Fig. 18.11 Stylised reciprocal creatinine plots. (A) Linear, uniform progression in the decline in renal function. (B) Sudden decline in renal function (arrow).

of developing this condition. While the use of gadolinium is not contraindicated in this group, it must be used with great care and protocols will vary from unit to unit.

Renal biopsy

If imaging techniques fail to give a cause for the reduction in renal function, a renal biopsy may be performed, although in advanced disease extensive scarring of the renal tissue may obscure the original (primary) diagnosis. Also, the small shrunken kidneys often seen in CKD are difficult to biopsy and may subsequently bleed. Most clinicians do not biopsy in this setting. In patients whose GFR is below 30 mL/min, injection of vasopressin (ADH) might minimise bleeding following renal biopsy, although evidence for this is limited and use is not widespread.

Graphical plots of glomerular filtration rate

All patients with CKD should have their serum biochemistry and haematology monitored regularly to detect any of the sequelae of the disease. In some patients with CKD, the decline in renal function progresses at a constant rate and may be monitored by plotting the estimated GFR against time (Fig. 18.11). The intercept with the x-axis indicates the time at which renal function will fall to zero and can be used to predict when the GFR will reach approximately 10 mL/min, that is, the level at which renal replacement therapy should be initiated (Fig. 18.11A). If an abrupt decline in the slope of the reciprocal plot is noted (Fig. 18.11B), this indicates a worsening of the condition or the presence of an additional renal insult. The cause should be detected and remedied if possible. It is, however, increasingly recognised that most patients with CKD do not sustain a predictable decline. Many stabilise or follow a path of episodes of accelerated decline followed by months or years of stability. These observations are of great interest and are an increasing focus of clinical research.

Prognosis

When the GFR has declined to about 20 mL/min, a continuing deterioration in renal function to end stage renal disease is common even when the initial cause of the kidney damage has been

removed and appropriate treatment instigated. The mechanisms for the decline in renal function include uncontrolled hypertension, proteinuria and damage resulting from hyperfiltration through the remaining intact nephrons. Serial GFR measurements should be monitored in conjunction with the patient's clinical condition to ensure the detection of the most appropriate point at which to commence renal replacement therapy. When a patient reaches an eGFR of 20 mL/min, plans should be in place for choice of renal replacement modality, transplantation or conservative management and where appropriate ongoing management of anaemia and bone disease.

Treatment

The aims of the treatment of CKD can be summarised as follows:

- Reverse or arrest the process causing the renal damage (this may not be possible)
- Avoid conditions that might worsen renal failure (Box 18.1)
- Treat the secondary complications of CKD (renal anaemia and bone disease)
- Relieve symptoms
- Implement regular dialysis treatment and/or transplantation at the most appropriate time.

Reversal or arrest of primary disease

By definition, CKD rarely has a readily reversible component, in contrast to acute renal failure. However, it is sometimes possible to identify a disease specific factor that is contributing to declining renal function and remove it. A postrenal lesion such as a ureter obstructed by a stone or a ureteric tumour may be successfully treated surgically. Glomerulonephritis may respond to immunosuppressants and/or steroids. Clearly, when drug-induced renal disease is suspected the offending agent should be stopped. These factors predominantly cause acute renal failure but they can cause acute on chronic failure and their reversal may prevent further deterioration.

Hypertension

Optimum control of blood pressure is one of the most important therapeutic measures since there is a vicious cycle of events whereby hypertension causes damage to the intrarenal vasculature resulting in thickening and hyalinisation of the

---

Box 18.1 Factors that might exacerbate established chronic renal failure

Hypotension
Hypertension
Nephrotoxins including drugs
Renal artery disease
Obstruction, for example, prostatic hypertrophy

---

walls of arterioles and small vessels. This damage effectively reduces renal perfusion, contributing to stimulation of the RAAS. Arteriolar vasoconstriction, sodium and water retention result, which in turn exacerbates the hypertension.

Antihypertensive therapy with certain agents might produce a transient reduction in GFR over the first 3 months of treatment as the systemic and glomerular blood pressure drop; this is mainly seen with ACE inhibitors/angiotensin receptor blockers (ARBs). However, it is possible to ultimately halt or slow the decline in many cases.

The drugs used to treat hypertension in renal disease are generally the same as those used in other forms of hypertension, although allowance must be made for the effect of renal failure on drug disposition (NICE, 2008).

Calcium channel blockers

For patients without proteinuria, calcium channel blockers (CCBs) are the agents of choice. They produce vasodilatation principally by reducing Ca^{2+} influx into vascular muscle cells. CCBs also appear to promote sodium excretion in hypertension associated with fluid overload. The mechanism is unclear but may relate to the finding that high sodium levels can cause vasoconstriction by interfering with calcium transport.

Both verapamil and diltiazem (non-dihydropyridine CCBs) block conduction across the atrioventricular node and should not be used in conjunction with β-blockers. They are also negative cardiac inotropes. By contrast, dihydropyridines such as nifedipine and amlodipine produce less cardiac depression and differentially dilate afferent arterioles in the kidney. In theory, dihydropyridines can, therefore, cause intraglomerular hypertension and glomerular damage despite decreased systemic hypertension, the relevance of this to the history of CKD is uncertain.

CCBs can produce headache, facial flushing and oedema. The latter can be confused with the symptoms of volume overload but is resistant to diuretics. The mechanism via which these effects occur is related to a change in pre-capillary hydrostatic pressure, which forces fluid into the interstitial compartment. The oedema is not related to salt or water retention; hence, the lack of response to diuretic therapy.

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers

The role of ACE inhibitors in hypertensive patients with renal insufficiency is complicated, the current evidence base supports the principle that all diabetic patients with micro/macroalbuminuria and CKD should be treated with ACE inhibitors or ARBs regardless of blood pressure. There is also evidence that in non-diabetic patients with proteinuria, the use of these drugs can reduce proteinuria and thus reduce progression of CKD. ACE inhibitors reduce circulating angiotensin II and ARBs block binding to the angiotensin II receptor, which results in vasodilatation and reduced sodium retention.

These agents can produce a reduction in GFR by preventing the angiotensin II mediated vasoconstriction of the

efferent glomerular arteriole. This contributes to the high-pressure gradient across the glomerulus, which is responsible for filtration and intra-glomerular hypertension. This problem may only be important in patients with renal vascular disease, particularly those with functionally significant renal artery stenoses where they should be avoided.

ACE inhibitors and ARBs preferentially protect the glomerulus over and above their effect as systemic hypertensive agents, through decreasing efferent glomerular arteriolar vasoconstriction and therefore intra-glomerular hypertension and hyperfiltration. Whilst the evidence for use of these drugs in patients with diabetic renal disease and proteinuric non-diabetic CKD is clear, care must be exercised in the following settings:

- Patients who sustain an early decline (in the first 7–10 days after ACE inhibitors/ARBs commencement) in kidney function. The drug should be stopped and potential renal artery stenosis investigated.
- Patients with non-proteinuric, non-diabetic CKD. These agents are overused in this setting. There is no evidence that they provide a real renal benefit over other anti-hypertensive drugs.
- Patients with an accelerated decline in kidney function in the months to years after commencement of ACE inhibitors/ARBs. This is increasingly described and may reflect a resetting of the intra-renal perfusion to a level that potentiates chronic renal ischaemia present in most cases of CKD irrespective of cause.
- Patients with an intercurrent acute illness, particularly those admitted to hospital. Hypotension or infection will put patients at an increased risk of AKI.

For long-term management, it is usually preferable to use an agent with a duration of action that permits once-daily dosing. There is little to choose clinically between the ACE inhibitors currently on the market; however, consideration should be given to the cost benefits of choosing an agent that does not require dose adjustment in renal failure.

It has been reported that ACE inhibitors may reduce thirst, which may be useful in those patients who have a tendency to fluid overload as a result of excessive drinking. ACE inhibitors are potassium sparing and therefore serum potassium should be monitored carefully. A low-potassium diet may be necessary.

ARBs have properties similar to ACE inhibitors with the advantage that, since they do not inhibit the breakdown of kinins such as bradykinin, they do not cause the dry cough associated with the ACE inhibitors. There is interest in the potential use of dual blockade of the RAAS using ACE inhibitors and ARBs to produce more complete blockade of angiotensin II. However, evidence to date has shown no added benefit and some evidence of adverse renal outcomes.

The observation that patients treated with ACE inhibitors initially have lower circulating angiotensin II but then experienced a rise in angiotensin II, known as the escape phenomenon, led to the expectation that dual blockade with ACE inhibitors and ARBs would resolve this. This has not been the case in practice and other solutions to this problem have been sought. Renin is the rate-limiting enzyme of the RAAS, and it has been suggested that interruption at this stage should provide complete RAAS blockade. The direct renin inhibitors (DRIs) are a new class of antihypertensive and the early evidence suggests a greater benefit when combined with an ARB than when used as monotherapy.

Diuretics

Diuretics are of use in patients with salt and volume overload, which is usually indicated by the presence of oedema. This type of hypertension may be particularly difficult to treat. The choice of agent is generally limited to a loop diuretic. Potassium sparing diuretics are usually contraindicated owing to the risks of developing hyperkalaemia, and thiazides become ineffective as renal failure progresses. In combination with ACE inhibitors, spironolactone can significantly reduce proteinuria; however, the combination of these agents clearly raises the risk of significant hyperkalaemia and care must be taken (Bianchi et al., 2005). The combination should be avoided when the eGFR falls to <30 mL/min.

As loop diuretics need to be filtered to exert an action, progressively higher doses are required as CKD worsens. Doses of more than 250 mg/day of furosemide may be required in advanced renal failure. Patients who do not respond to oral loop diuretic therapy alone may benefit from concomitant administration of metolazone, which acts synergistically to produce a profound diuresis. Alternatively, the loop diuretic may be given intravenously. Care must be taken to avoid hypovolaemia (by monitoring body weight) and electrolyte disturbances such as hypokalaemia and hyponatraemia.

Thiazide diuretics, with the notable exception of metolazone, are ineffective at a low GFR and may accumulate, causing an increased incidence of side effects.

β-Blockers

β-Blockers are commonly used in the treatment of hypertension in CKD. They exhibit a range of actions including a reduction of renin production. Consequently, β-blockers have a particular role in the rational therapy of hypertension without fluid overload. However, β-blockers can reduce cardiac output, cause peripheral vasoconstriction and exacerbate peripheral vascular disease.

It is advisable to use the more cardioselective β-blockers atenolol or metoprolol. Atenolol is excreted renally and consequently should require dosage adjustment in renal failure. In practice, however, atenolol is effective and tolerated well by renal patients at standard doses. However, metoprolol is theoretically a better choice since it is cleared by the liver and needs no dosage adjustment, although small initial doses are advised in renal failure since there may be increased sensitivity to its hypotensive effects.

Selective α1-blockers

These vasodilators produce a variety of actions that may be of benefit in hypertension associated with CKD. Sympathetic adrenergic activity can lead to sodium retention. Selective

α_1-blockers have also been shown to produce improvements in insulin sensitivity, adverse lipid profiles and obstruction caused by hypertrophy of the prostate, all of which might be associated with some forms of CKD. These agents are used less commonly since there is some evidence that, in comparison to other antihypertensives, use is associated with adverse cardiovascular outcomes, especially the development of heart failure.

Vasodilators

The vasodilators hydralazine and minoxidil have been used to treat hypertension in CKD with varying degrees of success but are usually only used when other measures inadequately control blood pressure. The sensitivity of patients to these drugs is often increased in renal failure, so, if used, therapy should be initiated with small doses. These agents cause direct peripheral vasodilation with resultant reflex tachycardia, which may require suppression by co-prescription of a β-blocker.

Centrally acting drugs

Methyldopa and clonidine are not commonly used as antihypertensives in CKD because of their adverse side effect profiles. If they are used in renal failure, initial doses should be small because of increased sensitivity to their effects.

Spironolactone

The potassium sparing diuretic spironolactone is an aldosterone receptor antagonist, and it is through this effect that it reduces proteinuria. Studies have suggested that it may be additionally effective in combination with either an ACE inhibitor or an ARB but not as triple therapy. Care needs to be taken to avoid hyperkalaemia in patients on these regimens.

Statins

Statins are known to have beneficial effects on endothelial function, improving renal perfusion while reducing abnormal permeability to plasma proteins. However, statins are not indicated for delaying the progression of CKD but are currently used for conventional indications only in such patients.

Management of symptoms associated with CKD

Gastro-intestinal symptoms

Nausea and vomiting may persist after starting a low-protein diet. Metoclopramide is useful to treat this, but sometimes accumulation of the drug and its metabolites may occur, leading to extrapyramidal side effects. Patients should be started on a low dose, which should then be increased slowly. Prochlorperazine or cyclizine may also be useful. The 5-HT$_3$ antagonists such as ondansetron have also been shown to be effective. The anaemic patient often becomes less nauseated when treated with an erythropoiesis stimulating agent.

Constipation is a common problem in patients with renal disease, partly as a result of fluid restriction and anorexia and partly as a consequence of drug therapy with agents such as phosphate binders. It is particularly important that patients managed with peritoneal dialysis do not become constipated, as this can reduce the efficacy of dialysis. Conventional laxative therapy may be used, such as bulk-forming laxatives or increased dietary fibre for less severe constipation. Alternatively, a stimulant such as senna with enemas or glycerine suppositories may be used for severe constipation. Higher doses of senna, typically 2–4 tablets at night, may be required. It should be noted that certain brands of laxatives that contain ispaghula husk may also contain significant quantities of potassium, and should be avoided in renal failure because of the risk of hyperkalaemia. Sterculia preparations are an effective alternative.

Pruritus

Itching associated with renal failure can be extremely severe, distressing and difficult to treat. It can also be disfiguring as a result of over-enthusiastic scratching. The exact mechanism responsible for the itching is not clear and several possibilities have been suggested including: xerosis (dry skin), skin micro-precipitation of divalent ions, elevated PTH levels and increased dermal mast cell activity. Generally, however, no underlying cause is found and it is likely that a multifactorial process is responsible.

Sometimes correction of serum phosphate or calcium levels improves the condition, as does parathyroidectomy. Conventionally, oral antihistamines are used to treat pruritus; however, topical versions should not be used owing to the risk of allergy. Non-sedating antihistamines such as loratidine are generally less effective than sedating antihistamines such as chlorphenamine or alimemazine which may be useful, particularly at night. Topical crotamiton lotion and creams may also be useful in some patients. Other non-drug therapies include either warming or cooling the skin using baths, three times weekly, UVB phototherapy and modified electrical acupuncture.

Dietary modifications for uraemic symptoms

Although urea is only one of the toxins encountered in uraemia, many patients experience a symptomatic improvement when dietary protein intake is reduced, presumably through a reduction in the output of nitrogenous waste. There is some evidence that, as well as reducing the symptoms of uraemia, protein restriction slows the progression of CKD, but this remains controversial. Protein-restricted diets have been used extensively in the past but they are unpalatable and the benefits marginal, so they are used infrequently in modern medical practice.

Dietary modifications in CKD

Low protein diets have already been discussed. Other dietary modifications include sodium and fluid restriction to reduce the risk of fluid overload, potassium restriction to reduce the risk of hyperkalaemia and vitamin supplementation. The dietary restrictions for patients with CKD can be arduous and difficult to follow.

Fluid retention

Oedema may occur as a result of sodium retention and the resultant associated water retention. Patients with CKD may also have hypoalbuminaemia following renal protein loss, and this can result in an osmotic extravasation of fluid and its retention in tissues. By end stage renal disease pulmonary and peripheral oedema is best controlled with dialysis but diuretics can be useful. The daily fluid intake should be restricted to between one and three litres, depending upon the volume of urine produced by the patient (if any). It is important to note that the fluid allowance must include fluids ingested in any form, including sauces, medicines and fruits, in addition to drinks. The fluid restriction is very difficult to maintain. Sucking ice cubes may relieve an unpleasantly dry mouth, but patients should be encouraged not to swallow the melted water.

Sodium restriction. Sodium intake can be reduced to a satisfactory level of 80 mmol/day by avoiding convenience foods and snacks or the addition of salt to food at the table. This is usually tolerable to patients. It is important to be aware of the contribution of sodium-containing medication, including some antibiotics, soluble or effervescent preparations, magnesium trisilicate mixture, Gaviscon, sodium bicarbonate and the plasma expanders hetastarch and gelatin.

Potassium restriction. Hyperkalaemia often occurs in CKD and may cause life-threatening cardiac arrhythmias. If untreated, asystolic cardiac arrest and death may result. Patients are often put on a potassium-restricted diet by avoiding potassium-rich foods such as fruit and fruit drinks, vegetables, chocolate, beer, instant coffee and ice cream. Many medicines have a high potassium content, for example, potassium citrate mixture, some antibiotics and ispaghula husk sachets. The use of these drugs is less of a problem in dialysed patients. Emergency treatment is necessary if the serum potassium level is above 7.0 mmol/L or if there are ECG changes. The most effective treatment is dialysis but if this is not available other measures may be tried (see Chapter 17).

The rationale and necessity for a renal diet and fluid restriction can be difficult for a patient to understand and adherence may be a problem. Consequently, the involvement of a specialist renal dietician can be valuable in optimising dietary therapies.

Anaemia

The normochromic, normocytic anaemia of CKD does not respond to iron or folic acid unless there is a coexisting deficiency. Traditionally, the only treatment available was to give red blood cell transfusions, but this is time-consuming, expensive, an infection risk, may lead to fluid and iron overload and promotes antibody formation, which may give problems if transplantation is subsequently attempted. The introduction of ESAs, initially as recombinant human erythropoietins (epoetin alfa and beta) have transformed the management of renal anaemia. Epoetin alfa and beta were thought to be indistinguishable in practical terms, as well as being immunologically and biologically indistinguishable from physiological erythropoietin. However, it has now been recognised that epoetins can be associated with the production of anti-erythropoietin antibodies leading to a severe anaemia which is unresponsive to exogenous epoetin. This is known as pure red cell aplasia (PRCA) and is more commonly associated with epoetin alfa when given by the subcutaneous route. The subcutaneous route is preferred as it provides equally effective clinical results while using similar or smaller doses (up to 30% less) when given three times a week. Most patients report a dramatically improved quality of life after starting epoetin therapy.

Darbepoetin alfa is a novel erythropoiesis-stimulating protein (NESP) that is a recombinant hyperglycosylated analogue of epoetin which stimulates red blood cell production by the same mechanism as the endogenous hormone. The terminal half-life in man is three times longer than that of epoetin and consequently requires a once weekly or alternate weekly dosing schedule. Recently, a longer acting ESA has been introduced (methoxy polyethylene glycol-epoetin beta, pegzerepoetin alfa). This is a continuous erythropoietin receptor activator (CERA), which can be used in a once monthly dosing schedule.

Iron and folate deficiencies must be corrected before therapy is initiated, while patients receiving epoetin generally require concurrent iron supplements because of increased marrow requirements. Supplemental iron is often given intravenously owing to bioavailability problems with oral forms. Maintaining iron stores ensures the effect of epoetin is optimised for minimum cost, as with insufficient iron stores a patient will not respond to treatment with epoetin.

Epoetin therapy should aim to achieve a slow rise in the haemoglobin concentration to avoid cardiovascular side effects associated with a rapidly increasing red cell mass, such as hypertension, increased blood viscosity/volume, seizures and clotting of vascular accesses. Blood pressure should be closely monitored.

An initial subcutaneous or intravenous epoetin dose of 50 units/kg body-weight three times weekly, increased as necessary in steps of 25 units/kg every 4 weeks, should be given to produce a haemoglobin increase of not more than 2 g/dL per month. The target haemoglobin concentration is commonly 10.5–12.5 g/dL with most aiming for a target around 11.5 g/dL. Once this has been reached, a maintenance dose of epoetin in the region of 33–100 units/kg three times a week or 50–150 units/kg twice weekly should maintain this level.

There have been several studies of ESAs which have shown an increased risk of cardiovascular morbidity and overall mortality in people treated to a target >12.5 g/dL (Phrommintikul

et al., 2007). This has lead to more conservative dosing strategies and prompt discontinuation or reduction of dose in patients with Hb >12.5 g/dL.

Correcting anaemia usually helps control the symptoms of lethargy and myopathy, and often greatly reduces nausea. Improved appetite on epoetin therapy can, however, increase potassium intake, and may necessitate dietary control.

Acidosis

Since the kidney is the main route for excreting H^+ ions, CKD may result in a metabolic acidosis. This will cause a reduction in serum bicarbonate that may be treated readily with oral doses of sodium bicarbonate of 1–6 g/day. As the dose of bicarbonate is not critical, it is easy to experiment with different dosage forms and strengths to suit individual patients. If acidosis is severe and persistent then dialysis may be required. Correction of acidosis may slow the decline in renal function.

Neurological problems

Neurological changes are generally caused by uraemic toxins and improve on the treatment of uraemia by dialysis or diet. Muscle cramps are common and are often treated with quinine sulphate. Restless legs may respond to low doses of clonazepam or co-careldopa.

Osteodystrophy

The osteodystrophy of renal failure is due to three factors: hyperphosphataemia, vitamin D deficiency and hyperparathyroidism.

Hyperphosphataemia

The management of hyperphosphataemia depends initially upon restricting dietary phosphate. This can be difficult to achieve effectively, even with the aid of a specialist dietician, because phosphate is found in many palatable foods such as dairy products, eggs, chocolate and nuts. Phosphate-binding agents can be used to reduce the absorption of orally ingested phosphate in the gut, by forming insoluble, non-absorbable complexes when taken a few minutes before or with meals. Traditionally, phosphate-binders were usually salts of a di- or trivalent metallic ion, such as aluminium, calcium or occasionally magnesium. Whilst calcium containing phosphate binders remain in widespread use, sevelemar and lanthanum-based binders are increasingly used.

Calcium acetate is widely used as a phosphate binder. The capacity of calcium acetate and calcium carbonate to control serum phosphate appears similar. However, phosphate control is achieved using between half and a quarter of the dose of elemental calcium when calcium acetate is used. Whether this translates to a decreased likelihood of producing unwanted hypercalcaemia with calcium acetate therapy is as yet unclear.

Calcium carbonate has been used as a phosphate binder. Unfortunately, it is less effective as a phosphate binder than aluminium, and sometimes requires doses of up to 10 g daily. Calcium carbonate has advantages, however, in that correction of concurrent hypocalcaemia can be achieved.

Sevelamer, a hydrophilic but insoluble polymeric compound is used increasingly as a phosphate binder. Sevelamer binds phosphate with an efficacy similar to calcium acetate but with no risk of hypercalcaemia. Mean levels of total and low-density cholesterol are also reduced with sevelamer use. This compound does not appear to present any risk of toxicity but may cause bowel obstruction and is relatively expensive when compared to other phosphate binders.

Lanthanum, like sevelamer, is a non-calcium containing phosphate binder; there is therefore no resultant risk of hypercalcaemia but there are gastro-intestinal side effects and the drug is significantly more expensive than the alternatives. While both of the non-calcium containing phosphate binders available have been shown to reduce phosphate levels and keep calcium within acceptable levels, no improvements in cardiovascular endpoints have been demonstrated to date.

Historically, aluminium hydroxide was widely used as a phosphate binder owing to the avid binding capacity of aluminium ions. However, a small amount of aluminium may be absorbed by patients with CKD owing to poor clearance of this ion, which can produce toxic effects including encephalopathy, osteomalacia, proximal myopathy and anaemia. Dialysis dementia was a disease observed among haemodialysis patients associated with aluminium deposition in the brain and exacerbated by aluminium in the water supply and the use of aluminium cooking pans. Desferrioxamine (4–6 g in 500 mL of saline 0.9% per week) has been used to treat this condition by removing aluminium from tissues by chelation. The tendency of aluminium to cause constipation is an added disadvantage. Therefore, aluminium as a phosphate binder in CKD should be used with caution.

Vitamin D deficiency and hyperparathyroidism

Vitamin D deficiency may be treated with the synthetic vitamin D analogues 1α-hydroxycholecalciferol (alfacalcidol) at 0.25–1 μcg/day or 1,25-dihydroxycholecalciferol (calcitriol) at 1–2 μcg/day. The serum calcium level should be monitored, and the dose of alfacalcidol or calcitriol adjusted accordingly. Hyperphosphataemia should be controlled before starting vitamin D therapy since the resulting increase in the serum calcium concentration may result in soft tissue calcification.

A new agent, paricalcitol, has recently been suggested for use in patients who either do not respond to alfacalcidol or who need doses of alfacalcidol that are impractical because of hypercalcaemia. Paricalcitol is a synthetic, biologically active vitamin D analogue that selectively upregulates the vitamin D receptor in the parathyroid glands reducing PTH synthesis and secretion. It also upregulates the calcium sensing receptor in the parathyroids and reduces PTH by inhibiting parathyroid proliferation, PTH synthesis and secretion without affecting calcium or phosphorus levels.

The rise in 1,25-dihydroxycholecalciferol and calcium levels that result from starting vitamin D therapy usually suppresses the production of PTH by the parathyroids. If vitamin D therapy does not correct PTH levels then parathyroidectomy, to remove part or most of the parathyroid glands, may be needed. This surgical procedure was once commonly performed on CKD patients, but is now less frequent owing to effective vitamin D supplementation.

Cinacalcet is a calcimimetic which increases the sensitivity of calcium sensing receptors to extracellular calcium ion, this results in reduced PTH production. The benefit of this treatment is the suppression of PTH without resultant hypercalcaemia. It is recommended (NICE, 2007) for use as an alternative to parathyroidectomy for patients who are not fit enough to undergo this procedure. Common therapeutic problems in chronic renal failure are summarised in Table 18.4.

Renal transplantation

Renal transplantation has transformed the outlook for many patients with end stage renal disease. The clinical outcomes of renal transplantation are now excellent. One-year patient and graft survival is 98% and 90–95%, respectively, and most patients who receive a transplant will never need to return to dialysis treatment. A renal transplant performed today in the developed world will continue to function, on average, in excess of 15 years. However, an important consider-

ation is that renal transplantation is the treatment of choice for patients with end stage renal disease who are fit to receive a renal transplant; this recognises that many patients in end stage renal disease are frail and elderly and/or have a number of co-existing medical problems such that they are not fit to undergo a major operation (implantation of the kidney) or to tolerate the immunosuppressive drugs that are required to prevent the transplant rejecting. This means that at any given time the majority of patients are not actually on a national waiting list for a renal transplant.

For those patients who are fit enough to receive a renal transplant and are successfully transplanted, there is a profound survival benefit compared to remaining on dialysis treatment. The average transplant recipient lives two or three times as long as a matched dialysis patients who does not receive a renal transplant but remains on dialysis treatment. In addition, a transplant patient is less likely to be hospitalised and has a better quality of life than a dialysis patient. The secondary complications of CKD such as anaemia and bone disease resolve in many patients who are successfully transplanted. Furthermore, there are major health economic benefits to renal transplantation compared to dialysis. Transplantation is a far less expensive treatment than dialysis, particularly after the first year, when the large majority of the costs are limited to payment for the immunosuppressive drugs.

One of the major challenges for renal transplantation is the identification of a sufficient number of donor kidneys to fulfil demand. This is reflected in the increasing number

Table 18.4 Common therapeutic problems in chronic renal failure

Problem	Comment
Drug choice	Care with choice/dose of all drugs. Care to avoid renotoxic agents pre-dialysis to preserve function. Beware herbal therapies as some contain immune system boosters (reverse immunosuppressant effects) and some are nephrotoxic
Drug excretion	CKD will lead to accumulation of drugs and their active metabolites if they are normally excreted by the kidney
Dietary restrictions	Restrictions on patient often severe. Fluid allowance includes foods with high water content, for example, gravy, custard, and fruit
Hypertension	Frequently requires complex multiple drug regimens. CCBs can cause oedema that might be confused with fluid overload
Analgesia	Side-effects are increased. Initiate with low doses and gradually increase. Avoid pethidine as metabolites accumulate. Avoid NSAIDs unless specialist advice available
Anaemia	Epoetin requires sufficient iron stores to be effective. Absorption from oral iron supplements may be poor and i.v. iron supplementation might be required. Care required to make sure that epoetin use does not produce hypertension
Immunosuppression	Use of live vaccines should be avoided (BCG, MMR, mumps, oral polio, oral typhoid, smallpox, yellow fever)
Pruritis (itching)	Can be severe. Treat with chlorphenamine; less sedating antihistamines often less effective. Some relief with topical agents, for example, crotamiton
Restless legs	Involuntary jerks can prevent sleep. Clonazepam 0.5–1 mg at night may help

of people who are waiting for a kidney; in the UK the average time on the waiting list before transplantation is around 3 years. Kidneys donated for the national waiting list are harvested from deceased donors. At the time of donation, donors are classified as dead as a consequence of either brain stem or cardiac death; these are also called heart beating and non-heart beating donors, respectively.

The numbers of deceased donors as a proportion of those on the waiting list for a kidney transplant have fallen. Therefore, living donor transplantation has become increasingly common. In addition to part addressing the scarcity of donor organs, patients who receive kidney transplants from living donors have better outcomes than patients who receive deceased donor kidneys. This is due to a number of factors, including the quality of the organs, because living donors undergo a detailed health screening and if there is any indication that they have significant medical problems they are excluded from donation.

One of the major factors responsible for excellent outcomes for kidney transplant recipients is the use of immunosuppressive drugs to control the response the immune system of the recipient mounts against the donor kidney. This is called an alloresponse. Alloimmunity refers to an immune response against tissue derived from an individual of the same species as the recipient of the tissue.

The major disadvantage of all immunosuppressive agents is their relative non-specificity, in that they cause a general depression of the immune system. This exposes the patient to an increased risk of malignancy and infection, which is an important cause of morbidity and mortality.

Immunosuppressants

The major pharmacological groups of immunosuppressive agents are summarised in Table 18.5.

Transplant recipients receive a high load of immunosuppression at the time of transplantation; this is known as induction immunosuppression. Induction immunosuppression is to protect the transplant from the high immunological risk that is present in the first few weeks after surgery. In the months following the transplant, the immunosuppression load is then incrementally reduced. Most patients will reach long-term low dose maintenance immunosuppression sometime between 6 and 12 months after the transplant. However, whilst the transplant remains in the recipient it continues to represent an immunological risk; whilst overt,

Table 18.5 Mechanism of action of immunosuppressants commonly used following renal transplantation

Drug	Mechanism	Comment
Steroids	Bind to steroid receptors and inhibit gene transcription and function of T-cells, macrophages and neutrophils	Prophylaxis against and reversal of rejection
Ciclosporin	Forms complex with intracellular protein cyclophilin → inhibits calcineurin. Ultimately inhibits interleukin-2 synthesis and T-cell activation	Long-term maintenance therapy against rejection
Tacrolimus	Forms complex with an intracellular protein → inhibits calcineurin	Long-term maintenance therapy against rejection. Rescue therapy in severe or refractory rejection
Sirolimus	Inhibits interleukin-2 cell signalling → blocks T-cell cycling and inhibits B-cells	Usually used in combination with ciclosporin ± steroids
Mycophenolate	Inhibits inosine monophosphate dehydrogenase → reduces nucleic acid synthesis → inhibits T- and B-cell function	Usually used in combination with ciclosporin/tacrolimus ± steroids
Azathioprine	Incorporated as a purine in DNA → inhibits lymphocyte and neutrophil proliferation	Usually used in combination with ciclosporin/tacrolimus ± steroids
Muromonab (OKT3, mouse monoclonal anti-CD3)	Binds to CD3 complex → blocks, inactivates or kills T-cell. Short $t_{1/2}$	Prophylaxis against rejection. Reversal of severe rejection
Polyclonal horse/rabbit antithymocyte or antilymphocyte globulin (ATG, ALG)	Antibodies against lymphocyte proteins → alter T- and B-cell activity	Prophylaxis against rejection. Reversal of severe rejection
Humanised or chimaeric anti-CD25 (basiliximab and daclizumab)	Monoclonal antibodies that bind CD25 in interleukin-2 complex → prevent T-cell proliferation	Prophylaxis against acute rejection in combination with ciclosporin and steroids

late rejection is uncommon, it can occur at any time if the patient stops taking their immunosuppressants. For a transplant to last many years, sustained day on day adherence with treatment is essential.

The commonest combination used at induction is the calcineurin inhibitor (CNI) tacrolimus, the anti-proliferative agent mycophenolate mofetil (MMF) and corticosteroids. Most patients also receive antibody induction. The antibody that is most commonly used is a monoclonal anti-CD25 antibody for people at low or medium immunological risk and anti-T-cell polyclonal antibodies (thymoglobulin or ATG) for people at high immunological risk. Patients at high immunological risk include: those who have lost a previous transplant because of rejection; the presence of preformed circulating anti-HLA antibodies at the time of transplantation (sensitisation); and major HLA mismatches (particularly at HLA-DR) between donor and recipient. Guidelines for the use of immunosuppressive therapy in kidney transplant patients have been issued (NICE, 2004). More recent international consensus guidelines recommend use of newer agents such as MMF and emphasise the use of tacrolimus (rather than ciclosporin) as the CNI of choice. Tacrolimus is associated with less acute rejection than ciclosporin and may be associated with better graft function at one year and less graft loss (Knoll and Bell, 1999). However, there is no overwhelming evidence as yet that patients who receive tacrolimus as a CNI from induction have a survival benefit compared to patients who receive ciclosporin. It should be noted that generic/proprietary formulations of some drugs (e.g. tacrolimus and ciclosporin) are not interchangeable.

Calcineurin inhibitors (ciclosporin and tacrolimus)

The discovery and development of ciclosporin and latterly tacrolimus has led to a step improvement in one-year renal transplant survival from 50–70% to 85–95%.

In T-cells that have been exposed to T-cell receptor (TCR) ligation (signal 1) and co-stimulation (signal 2), there is activation of intra-cytoplasmic signalling pathways that include mobilisation of a molecule called calcineurin. Calcineurin contributes to the activation of a molecule called nuclear factor of activated T-cells (NFAT). This factor then migrates to the nucleus and initiates transcription of IL-2 and other pro-inflammatory cytokines which are involved in driving an activated T-cell into a proliferative phase, so that it makes multiple copies of itself. Ciclosporin and tacrolimus affect calcineurin through blocking binding proteins (cyclophilin and tacrolimus-binding protein, respectively) that are important for calcineurin activity.

The action of CNIs is partially selective in that they predominantly target T-cells and have no direct effect on B cells; as a consequence, CNIs are associated with infections seen in people with deficiencies in the cellular limb of the immune response. These are predominantly intracellular infections such as viral, fungal, protozoal and mycobacterial infections.

Both ciclosporin and tacrolimus are critical dose drugs. That is, there is a narrow therapeutic window between underdosing and toxicity. Both drugs, therefore, require monitoring

by serum levels. Trough levels are usually taken 12 h after the previous dose and immediately before the next dose.

Ciclosporin

Ciclosporin causes a wide range of side effects, including nephrotoxicity, hypertension, fine muscle tremor, gingival hyperplasia, nausea and hirsutism. Hyperkalaemia, hyperuricaemia, hypomagnesaemia and hypercholestraemia may also occur. Nephrotoxicity is a particularly serious side effect and occasionally necessitates the withdrawal of ciclosporin. There is tremendous inter- and intra-patient variation in absorption of ciclosporin. Blood level monitoring is required to achieve maximum protection against rejection and minimise the risk of side effects. The range regarded as acceptable varies between centres, but is commonly around 100–200 ng/mL in the first 6 months after transplantation and 80–150 ng/mL from 6 months onwards.

Ciclosporin interacts with a number of drugs that either lead to a reduction in ciclosporin levels, increase the risk of rejection or cause an elevation in ciclosporin levels leading to increased toxicity. Some drugs enhance the nephrotoxicity of ciclosporin (Box 18.2).

Ciclosporin should not be administered with grapefruit juice, which should also be avoided for at least an hour pre-dose, as this can result in marked increases in blood concentrations. This effect appears to be due to inhibition of enzyme systems in the gut wall resulting in transiently reduced ciclosporin metabolism.

Tacrolimus

Tacrolimus is not chemically related to ciclosporin, but acts by a similar mechanism. The side effect profile is similar to that of ciclosporin with some subtle differences. Disturbances of glucose metabolism leading to impaired glucose tolerance and new onset diabetes after transplantation (NODAT) occurs in around 10–15% of patients who receive tacrolimus, this is twice as common as the incidence seen in patients who receive ciclosporin. In contrast, hirsutism is less of a problem in patients who receive tacrolimus than those who receive ciclosporin. In patients who are commenced on ciclosporin and then develop an episode of acute rejection, conversion to tacrolimus lowers the risk of recurrent rejection. Tacrolimus is an easier drug to use than ciclosporin. Careful monitoring is required with a target level of 8–15 ng/mL in the first weeks following transplantation which is usually decreased in patients who follow an uncomplicated course to 5–8 ng/mL from 6 months.

Box 18.2 Examples of drug interactions involving ciclosporin

- Reduce ciclosporin serum levels (hepatic enzyme inducers): phenytoin, phenobarbital, rifampicin, isoniazid
- Increase ciclosporin serum levels (hepatic enzyme inhibitors): diltiazem, erythromycin, corticosteroids, ketoconazole
- Enhance ciclosporin nephrotoxicity: aminoglycosides, amphotericin, co-trimoxazole, melphalan

Steroids

Prednisolone is the oral agent commonly used for immunosuppression after renal transplantation, while high-dose intravenous methylprednisolone is given as a single dose at induction with further use limited for cases of acute rejection. The maintenance dose of prednisolone to minimise adrenal suppression is around 0.1 mg/kg/day given as a single dose in the morning. The use of steroid therapy often leads to complications, particularly if high doses are given for long periods. In addition to a cushingoid state, the use of steroids may cause gastro-intestinal bleeding, hypertension, dyslipidaemia, diabetes, osteoporosis and mental disturbances. Patients who are temporarily unable to take oral prednisolone should be given an equivalent dose of hydrocortisone intravenously.

In the past decade, there has been an increasing use of steroid avoidance regimens. This term is misleading as patients still receive steroids, but use is restricted to the first week of transplantation. Currently, there is no long-term evidence to show this approach provides equivalence to a continuous steroid dosing regimen, but one-year outcomes are comparable. If steroids are subsequently withdrawn months after the transplant, then outcomes with steroid avoidance regimens are worse.

Azathioprine

Azathioprine is derived from 6-mercaptopurine and is, therefore, an antimetabolite which reduces DNA and RNA synthesis-producing immunosuppression.

Azathioprine is given orally in a dose of up to 2 mg/kg/day. There is no advantage in giving it in divided doses. Since azathioprine interferes with nucleic acid synthesis, it may be mutagenic, and pharmacy and nursing staff should avoid handling the tablets. Azathioprine has a significant drug interaction with allopurinol, causing fatal marrow suppression and this combination should be avoided.

Mycophenolate mofetil (MMF)

MMF is a pro-drug of mycophenolic acid. It inhibits the enzyme inosine monophosphate dehydrogenase needed for guanosine synthesis which leads to reduced B-cell and T-cell proliferation. However, other rapidly dividing cells are less affected, as guanosine is produced in other cells. Consequently, mycophenolate has a more selective mode of action than azathioprine.

The drug is given in combination with tacrolimus at a dose of 1 g twice a day which can subsequently be reduced after 6 weeks to 750 mg twice a day. A dose of 1.5 g twice a day is prescribed when used in combination with ciclosporin because the ciclosporin interferes with enterohepatic recirculation of mycophenolate metabolites with consequent lower exposure at a similar dose.

Compared to azathioprine, MMF reduces the risk of acute rejection episodes and improves long-term graft survival. However, it is a more potent immunosuppressant than azathioprine and is associated with a significant increased risk of opportunistic infections.

Sirolimus (rapamycin)

Sirolimus is a macrolide antibiotic that binds to the FKBP-25 cellular receptor. This complex initiates a sequence that produces modulation of regulatory kinases that ultimately interfere with the proliferative effects of IL-2 on lymphocytes. The progression of T-cells from the G1 to S phase is blocked, so inhibiting cell division and therefore cell proliferation.

Adverse effects include hyperkalemia, hypomagnesemia, hyperlipidemia, hypertriglyceridemia, leukopenia, anemia, imp-aired wound healing, and joint pain. Currently, the role of sirolimus in renal transplantation has not been clearly defined. In combination with CNIs, it produces additive nephrotoxicity; when used with MMF it increases the risk of marrow suppression and mucosal side effects. Most experts currently limit the use of sirolimus to patients who have declining kidney function as a consequence of CNIs, but where graft function is still maintained to a GFR of >40 mL/min without significant proteinuria.

Monoclonal antibodies

The humanised or chimeric anti-CD25 monoclonal antibodies basiliximab and daclizumab are clinically similar and bind to CD25 in the IL-2 complex of activated T-lymphocytes. This renders all T-cells resistant to IL-2 and therefore prevents T-cell proliferation. They are used as prophylaxis against acute rejection in combination with CNIs and steroids (NICE, 2004). Daclizumab is currently not available in the UK.

Polyclonal antibodies

These were the first antibodies used as immunosuppressants and contain antibodies with a number of different antigen-combining sites. Polyclonal antibodies are used peri-operatively as prophylaxis against rejection and in some cases to reverse episodes of severe rejection. The main preparations are antithymocyte globulin (ATG) or antilymphocyte globulin (ALG).

ATG is produced from rabbit or equine serum immunised with human T-cells. It contains antibodies to human T-cells, which on injection will attach to, neutralise and eliminate most T-cells, thereby weakening the immune response. ALG is similar to ATG, is of equine origin, but is not specific to T-cells as it also acts on B-cells.

It is not certain how polyclonal antibodies act to inhibit T-cell mediated immune responses but depletion of circulating T-cells, modulation of cell surface receptor molecules, induction of energy and apoptosis of activated T-cells have all been proposed.

The main drawback to the use of anti-T-cell sera is the relatively high incidence of side effects, notably anaphylactic reactions including hypotension, fever and urticaria. These reactions are more frequently observed with the first dose and may require supportive therapy with steroids and antihistamines. Severe reactions may necessitate stopping treatment. Steroids and antihistamines may be given prophylactically to prevent or minimise allergic reactions. Pyrexia often occurs on the first day of treatment but usually subsides without requiring treatment. Tolerance testing by administration of a test dose is advisable,

particularly in patients such as asthmatics who commonly experience allergic reactions. In the event of adverse reactions, ALG and ATG can be substituted for each other.

Other precautions

Transplant patients are given prophylactic antibiotic therapy for varying periods postoperatively owing to the risks of infection associated with immunosuppression. Treatment with co-trimoxazole to prevent *Pneumocystis carinii*, isoniazid and pyridoxine in high-risk patients to prevent tuberculosis, valganciclovir to prevent cytomegalovirus, and nystatin or amphotericin to prevent oral candidiasis are commonly used. Vaccination with live organisms (e.g. BCG, MMR, oral poliomyelitis, oral typhoid) must be avoided in the immunosuppressed patient.

Implementation of regular dialysis treatment

End stage renal failure is the point at which the patient will die without the institution of renal replacement by dialysis or transplantation.

The principle of dialysis is simple. The patient's blood and a dialysis solution are positioned on opposing sides of a semi-permeable membrane across which exchange of metabolites occurs. The two main types of dialysis used in CKD are haemodialysis and peritoneal dialysis. Neither has been shown to be superior to the other in any particular group of patients and so the personal preference of the patient is important when selecting dialysis modality. Haemodialysis and acute peritoneal dialysis are discussed in Chapter 17.

As patients with end stage renal failure may require dialysis treatment for many years, adaptations to the process of peritoneal dialysis have been made that enable the patient to follow a lifestyle as near normal as possible. Continuous ambulatory peritoneal dialysis (CAPD) involves a flexible non-irritant silicone rubber catheter (Tenckhoff catheter) that is surgically inserted into the abdominal cavity. Dacron cuffs on the body of the catheter become infiltrated with scar tissue during the healing process, causing the catheter to be firmly anchored in place. Such catheters may remain viable for many years. During the dialysis process thereafter, a bag typically containing 2.5 L of warmed dialysate and a drainage bag are connected to the catheter using aseptic techniques. Used dialysate is drained from the abdomen under gravity into the drainage bag, fresh dialysate is run into the peritoneal cavity and the giving set is disconnected. The patient continues his or her activities until the next exchange some hours later. The procedure is repeated regularly so that dialysate is kept in the abdomen 24 h a day. This is usually achieved by repeating the process four times a day with an average dwell time of 6–8 h. A number of different dialysis solutions are available of which the majority are glucose based.

Another form of peritoneal dialysis is known as automated peritoneal dialysis (APD) in which exchanges are carried out overnight while the patient sleeps. Dialysis fluid is exchanged – three to five times over a 10-h period with volumes of 1.5–3 L each time. During the day time the patient usually has a dwell of fluid within the abdominal cavity.

Since peritoneal dialysis is continuous and corrects fluid and electrolyte levels constantly, dietary and fluid restrictions are less stringent. Blood loss is also avoided, making the technique safer in anaemic patients. Unfortunately, peritoneal dialysis is not an efficient process; it only just manages to facilitate excretion of the substances required and, as albumin crosses the peritoneal membrane, up to 10 g of protein a day may be lost in the dialysate. It is also uncomfortable and tiring for the patient, and is contraindicated in patients who have recently undergone abdominal surgery.

Peritonitis is the most frequently encountered complication of peritoneal dialysis. Its diagnosis usually depends on a combination of abdominal pain, cloudy dialysate or positive microbiological culture. Empirical antibiotic therapy should, therefore, be commenced as soon as peritonitis is clinically diagnosed. Gram-positive cocci (particularly *Staphylococcus aureus*) and Enterobacteriaceae are the causative organisms in the majority of cases, while infection with Gram-negative species and *Pseudomonas* species are well recognised. Fungal infections are also seen, albeit less commonly.

Most centres have their own local protocol for antibiotic treatment of peritonitis. In one example, levofloxacin, a quinolone with good Gram-negative activity is given orally, in combination with vancomycin, which has excellent activity against Gram-positive bacteria, is administered via the intraperitoneal route. As in all situations, the antibiotic regimen should be adjusted appropriately after the results of microbiological culture and sensitivity have been obtained.

Haemodialysis is particularly suitable for patients producing large amounts of metabolites, such as those with high nutritional demands or a large muscle mass, where these substances are produced faster than peritoneal dialysis can remove them. It also provides a back-up for those patients in whom peritoneal dialysis has failed.

The various techniques of haemofiltration, a technique related to haemodialysis, are also discussed in detail in Chapter 17.

Case studies

Case 18.1

Mr D, a 19-year-old undergraduate student, visited his university health centre complaining of a 3-month history of fatigue, weakness, nausea and vomiting that he had attributed to 'examination stress'. His previous medical history indicated an ongoing history of bed wetting from an early age. Laboratory results from a routine blood screen showed the following:

		Reference range
Sodium	137 mmol/L	(135–145)
Potassium	4.8 mmol/L	(3.5–5.0)
Phosphate	2.5 mmol/L	(0.9–1.5)
Calcium	1.6 mmol/L	(2.20–2.55)
Urea	52 mmol/L	(3.0–6.5)
Creatinine	620 μmol/L	(50–120)
Haemoglobin	7.5 g/dL	(13.5–18.0)

Subsequent referral to a specialist hospital centre established a diagnosis of chronic renal failure secondary to reflux nephropathy.

Question

Explain the signs and symptoms experienced by Mr D and the likely course of his disease?

Answer

Mr D is suffering from the signs and symptoms of uraemia resulting from chronic renal failure. Mechanical reflux damage to his kidneys has compromised renal function and resulted in an accumulation of toxins, including urea and creatinine that, in turn, have contributed to his nausea, vomiting and general malaise. His biochemical results indicate other features typical of uraemic syndrome associated with chronic renal failure. The low haemoglobin is indicative of reduced erythropoetin production following progressive kidney damage. Renal osteodystrophy is also present, as inadequate vitamin D production and the raised serum phosphate have contributed to the hypocalaemia.

This patient is likely to have remained symptom free for a period of years despite progressively worsening renal function. The kidneys operate with a substantial functional reserve under normal conditions. Patients generally remain asymptomatic as their renal reserve diminishes. Eventually there is a failure in the ability of the damaged kidney to compensate and symptoms appear late in the condition.

Case 18.2

Mr K, a 43-year-old male with established CKD, had been maintained for 3 years on continuous ambulatory peritoneal dialysis. He was admitted to hospital for cadaveric renal transplantation. On examination he was found to have slight ankle oedema. He weighed 60 kg and his blood pressure was 135/90 mmHg and pulse rate 77 min^{-1}. He was administered the following immunosuppressants preoperatively: an anti-CD25 antibody, tacrolimus, mycophenolate and prednisolone.

Question

How should the immunosuppressants be administered to Mr K and how should immunosuppression be managed postoperatively?

Answer

Anti-CD25 antibodies and high-dose methylprednisolone are given intravenously at the time of the operation. Typically, tacrolimus at 200–300 µcg/kg/day as two split doses, it is important to note that there are two preparations of tacrolimus, a once daily dose and a divided dose preparation. The once daily preparation is called Advagraf® and the twice daily preparation is Prograf®, the preparations are not interchangeable and as a result they must be prescribed by brand name, changes between preparations must only be made by a transplant specialist. MMF at 1 g twice a day and prednisolone at 10 mg twice a day are given as oral doses to continue in the days and weeks following transplantation. These are commenced within 12 h of the operation. In living kidney donation where the transplant operation is planned, patients are preloaded for several days before the transplant. Intravenous tacrolimus is available, but should only be used in exceptional circumstances, usually when the gut is not working and all drugs and nutrition need to be given by the parenteral route.

Early dose adjustments in tacrolimus following transplantation are common and directed by drug levels. These are checked daily for the first week following transplantation; by 6 months they will be checked on alternate weeks. In the long-term, the median dose of tacrolimus is around 2 mg twice a day and the dose of MMF can be reduced to 500–750 mg twice a day in the large majority of patients. The dose of prednisolone is titrated down so that by 3 months it is 5–10 mg/day. Acute rejection episodes, diagnosed on a renal biopsy performed for a decline in graft function are treated with high-dose steroids. For antibody mediated (severe) rejection, plasma exchange and intravenous immunoglobulin are used.

Case 18.3

Mr A is a patient with CKD secondary to chronic interstitial nephritis. He complains of chronic fatigue, lethargy and breathlessness on exertion, palpitations and poor concentration. His recent haematological results were found to be:

		Reference range
Haemoglobin	5.6 g/dL	(13.5–17.5)
Red cell count	2.92 × 10^9 L^{-1}	(4.5–6.5 × 10^9 L^{-1})
Haematocrit	0.208	(0.40–0.54)
Serum ferritin	88.0 µcg/L	(15–300)

Question

Explain Mr A's symptoms and haematological results and outline the optimal treatment.

Answer

Mr A's symptoms are most likely to result from a normochromic, normocytic anaemia caused by renal failure. Levels of erythropoetin produced by the kidney are reduced in renal failure. Production of erythropoetin from extrarenal sites, for example, liver, are not sufficient to maintain erythropoesis, which is also inhibited by uraemic toxins and hyperparathyroidism. The anaemia associated with renal failure is further compounded by a reduction in red cell survival through low-grade haemolysis, bleeding from the gastro-intestinal tract and blood loss through dialysis, aluminum toxicity which interferes with haem synthesis, and iron deficiency, usually through poor dietary intake.

Therapy with epoetin is the treatment of choice. However, iron and folate deficiencies should be corrected if epoetin therapy is to be successful. Iron demands are generally raised during epoetin treatment and iron status should be regularly monitored. If serum ferritin falls below 100 µcg/L then iron supplementation should be started. Often intravenous iron is required to provide an adequate supply, despite the dangers associated with administration of iron by this route.

Hypertension 19

A. G. Dyker

Key points

- Hypertension can be defined as a condition in which blood pressure is elevated to an extent where benefit is obtained from blood pressure lowering. There is no clear-cut blood pressure threshold separating normal from hypertensive individuals. The risk of complications is related to the levels that blood pressure is elevated.
- The World Health Organization has identified hypertension as one of the most important preventable causes of premature morbidity and mortality.
- Hypertension should not be seen as a risk factor in isolation and decisions on management should not focus on blood pressure alone but on total cardiovascular risk.
- The complications of hypertension include stroke, myocardial infarction, heart failure, renal failure and dissecting aortic aneurysm.
- Modest reductions in blood pressure result in substantial reductions in the relative risks of these complications.
- For correct diagnosis, careful measurement of blood pressure is necessary on several occasions using well-maintained and validated equipment.
- Non-pharmacological interventions are important and include weight reduction, avoidance of excessive salt and alcohol, increased intake of fruit and vegetables and regular aerobic exercise. Other cardiovascular risk factors such as smoking, dyslipidaemia and diabetes should be addressed.
- A large selection of antihypertensive drugs is available. It is important to use drugs that minimise patient side effects.
- The most appropriate choice of initial drug therapy depends on the age and racial origin of the patient, as well as the presence of other medical conditions. For younger white patients, an ACE inhibitor is recommended as first-line treatment. For older patients and black people, a calcium channel blocker or thiazide diuretic is an appropriate initial choice.
- Many people need combinations of drugs to achieve adequate blood pressure control. Medication should be convenient to take and adverse effects should be avoided.

Hypertension (high blood pressure) is an important risk factor for the future development of cardiovascular disease. It can be defined as a condition where blood pressure is elevated to an extent that clinical benefit is obtained from blood pressure lowering. Blood pressure measurement includes systolic and diastolic components, and both are important in determining an individual's cardiovascular risk.

Blood pressure is continuously distributed in the population and there is no clear cut-off point between hypertensive and normotensive subjects, although a figure of systolic/diastolic blood pressure of 140/90 mmHg is considered the upper limit of 'normal'. Such values that are used as treatment thresholds or targets are, however, largely arbitrary. Treatment decisions in milder hypertensive subjects should now be made on the basis of patients' overall future risk of vascular disease. There is, however, considerable evidence from clinical trials to demonstrate that treatment of subjects with blood pressures above the threshold currently used in clinical practice results in important clinical benefits. Hypertension is largely a condition of older individuals. While diastolic pressure peaks at age 50, systolic pressure continues to increase with advancing age, making isolated systolic hypertension a common feature of old age. Generally, the risk of cardiovascular disease doubles for every 20/10 mmHg rise in blood pressure.

The cardiovascular complications associated with hypertension are shown in Box 19.1. The most common and important of these are stroke and myocardial infarction. An increase of 5 mmHg in usual diastolic blood pressure is associated with a 35–40% increased risk of stroke. There is a similar but less steep association for coronary heart disease risk. The risk of heart failure is increased six-fold in hypertensive subjects. Meta-analysis of clinical trials has indicated that these risks are reversible with relatively modest reductions in blood pressure of 10/6 mmHg associated with a 38% reduction in stroke and 16% reduction in coronary events (Collins et al., 1990), while a 5 mmHg reduction in blood pressure is associated with a 25% reduction in risk of renal failure.

The absolute benefits of blood pressure lowering achieved as a result of these relative risk reductions depend on the underlying level of risk in an individual. High-risk subjects

Box 19.1 Complications of hypertension

- Myocardial infarction
- Stroke
  - Cerebral/brainstem infarction
  - Cerebral haemorrhage
  - Lacunar syndromes
  - Multi-infarct disease
- Hypertensive encephalopathy/malignant hypertension
- Dissecting aortic aneurysm
- Hypertensive nephrosclerosis
- Peripheral vascular disease

295

gain more benefit in terms of events saved per year of therapy. Absolute risk is highest in those who already have evidence of cardiovascular disease, such as previous myocardial infarction, transient ischaemic attack or stroke, or who have other evidence of cardiovascular dysfunction such as electrocardiogram (ECG) or echocardiograph abnormality. Risk is also increased in the elderly and in people with diabetes or renal failure and is further enhanced by other risk factors such as smoking, dyslipidaemia, obesity and sedentary lifestyle. In those under the age of 75, men are at greater risk than women. Cardiovascular risk in an individual who has no current cardiovascular disease can be estimated from coronary risk prediction charts (Joint British Societies, 2005; see Chapter 24).

Epidemiology

Between 10% and 25% of the population are expected to benefit from drug treatment of hypertension; the exact figure depending on the cut-off value for blood pressure and the age group considered for active treatment.

In 90–95% of cases of hypertension, there is no underlying medical illness to cause high blood pressure. This is termed 'essential' hypertension, so named because at one time it was erroneously believed to be an 'essential' compensation mechanism to maintain adequate circulation. The precise aetiology of essential hypertension is currently unknown. Genetic factors clearly play a part as the condition clusters in families, with hypertension being twice as common in subjects who have a hypertensive parent. Genetic factors account for about one-third of the blood pressure variation between individuals, although no single gene appears to be responsible except in some rare conditions such as polycystic kidney disease and other metabolic conditions such as Liddle's syndrome (Beevers et al., 2001). The remaining 5–10% of cases are secondary to some other disease process (Box 19.2).

Box 19.2 Causes of hypertension

Primary hypertension (90–95%)
- Essential hypertension

Secondary hypertension (5–10%)
- Renal diseases
- Endocrine diseases
  – *Steroid excess*: hyperaldosteronism (Conn's syndrome); hyperglucocorticoidism (Cushing's syndrome)
  – *Growth hormone excess*: acromegaly
  – *Catecholamine excess*: phaeochromocytoma
  – *Others*: pre-eclampsia
- Vascular causes
  – *Renal artery stenosis*: fibromuscular hyperplasia; renal artery atheroma; coarctation of the aorta
- Drugs
  – Sympathomimetic amines
  – Oestrogens (e.g. combined oral contraceptive pills)
  – Ciclosporin
  – Erythropoietin
  – NSAIDs
  – Steroids

Hypertension is more common in black people of African Caribbean origin, who are also at particular risk of stroke and renal failure. Hypertension is exacerbated by other factors, for example, high salt or alcohol intake or obesity.

Regulation of blood pressure

The mean blood pressure is the product of cardiac output and total peripheral resistance. In most hypertensive individuals, cardiac output is not increased and high blood pressure arises as a result of increased total peripheral resistance caused by constriction of small arterioles.

Control of blood pressure is important in evolutionary terms and a number of homeostatic reflexes have evolved to provide blood pressure homeostasis. Minute-to-minute changes in blood pressure are regulated by the baroreceptor reflex, while the renin–angiotensin–aldosterone system is important for longer term salt, water and blood pressure control. Long-term increases in shear stress can cause vascular remodelling of the endothelium which lead to the formation of a procoagulant rather than anticoagulant surface. At the same time, systems that lead to vascular relaxation, for example nitric oxide, are overcome by increased sensitivity to vasoconstricter substances such as endothelin which predispose to vascular disease and further increases in peripheral resistance which lead to a vicious cycle increasing blood pressure further due to the increase in vascular resistance. Other substances with a role in controlling blood pressure include atrial natriuretic peptide, bradykinin and antidiuretic hormone. Some new therapies seek to treat high blood pressure by modifying responses to these substances, for example, the endothelin antagonist darusentan.

Clinical presentation

Hypertension is often an incidental finding when subjects present for screening or with unrelated conditions. Severe cases may present with headache, visual disturbances or evidence of target organ damage (stroke, ischaemic heart disease or renal failure). In the UK, all patients under 80 years of age should have their blood pressure checked at least every 5 years, with an annual review for those with high normal values in the range 135–139 mmHg systolic or 85–89 mmHg diastolic.

Malignant (accelerated) hypertension

Malignant or accelerated hypertension is an uncommon condition characterised by greatly elevated blood pressure (usually >220/120 mmHg) associated with evidence of ongoing small vessel damage. Fundoscopy may reveal papilloedema, haemorrhages and/or exudates, while renal damage can manifest as haematuria, proteinuria and impaired renal function. The condition may be associated with hypertensive encephalopathy, which is caused by small vessel changes in the cerebral circulation associated with cerebral oedema. The clinical features are confusion, headache, visual loss, seizures and coma. Brain imaging (particularly MRI) usually demonstrates extensive

white matter changes. Malignant hypertension is a medical emergency that requires hospital admission and rapid control of blood pressure over 12–24 h towards normal levels.

Management of hypertension

In the UK, the management of hypertension is guided by consensus guidelines produced by the British Hypertension Society (BHS) and the National Institute for Health and Clinical Excellence (NICE). In 2004, there were significant differences between NICE and BHS guidance but these were addressed in the form of modified joint guidance issued in 2006 which specifically addressed the areas of controversy (National Collaborating Centre for Chronic Conditions: Hypertension, 2006). The European Society of Hypertension also published a task force discussion document in January 2009 and formal guidance in 2007 (Mancia et al., 2009).

Diagnosis of hypertension

In the UK, it is recommended that all adults have their blood pressure measured every 5 years. Those with high normal (130–139 mmHg systolic or 85–89 mmHg diastolic) or previous high readings should have annual measurement.

Blood pressure should be measured using a well-maintained sphygmomanometer of validated accuracy. Blood pressure should initially be measured in both arms and the arm with the highest value used for subsequent readings. The subject should be relaxed and, at least at the first presentation, blood pressure should be measured in both the sitting and the standing positions. An appropriate sized cuff should be used since one that is too small will result in an overestimation of the patient's blood pressure. The arm should be supported level with the heart and it is important that the patient does not hold their arm out since isometric exercise increases blood pressure. Blood pressure is measured using the Korotkov sounds which appear (the first phase) and disappear (the fifth phase) over the brachial artery as pressure in the cuff is released. Cuff deflation should occur at approximately 2 mmHg/s to allow accurate measurement of the systolic and diastolic blood pressures. The fourth Korotkov phase (muffling of sound) has previously been used for diastolic blood pressure measurement but is not currently recommended unless Korotkov V cannot be defined. Having established that the blood pressure is increased, the measurement should be repeated several times over several weeks, unless the initial measurement is at dangerously high levels, in which case several measurements should be made during the same clinic attendance.

Home or ambulatory blood pressure measurements

Some people develop excessive and unrepresentative blood pressure rises when attending the doctor's surgery, so-called 'white coat' hypertension. These patients can be diagnosed if they use a blood pressure machine themselves at home or by 24-h ambulatory blood pressure monitoring. Home blood pressure measurement is inexpensive but it is important to have a machine of validated accuracy that the patient can use properly. Ambulatory blood pressure monitoring over 24 h is also useful for patients who have unusual variability in blood pressure, resistant hypertension or symptoms suggesting hypotension. Home or ambulatory blood pressure measurements are usually lower than clinic recordings, on average by 12/7 mmHg.

Assessment of the hypertensive patient

Secondary causes

It is important to take a careful history checking for features that might suggest a possible secondary cause of hypertension. Examples would be symptoms of renal disease, for example, haematuria, polyuria, etc., or the paroxysmal symptoms that suggest the rare diagnosis of phaeochromocytoma and include headache, postural dizziness, syncope. A careful physical examination should be performed for abdominal bruits, which suggest possible renal artery stenosis, radiofemoral delay which suggest coarctation of the aorta and palpable kidneys which suggest polycysctic kidney disease. Laboratory analysis should include a full blood count, electrolytes, urea, creatinine and urinalysis. In some patients, further investigations may be appropriate, for example, ultrasound of the abdomen or isotope renogram where renal disease is suspected. A renin–angiotensin ratio is a useful screening test to investigate for possible hyperaldosteronism while serum metanephrine and urinary catecholamines may detect underlying phaeochromocytoma.

A low serum potassium may alert to the presence of hyperaldosteronism but it should be remembered that renin levels are suppressed by β-blockers and aldosterone by angiotensin converting enzyme inhibitors and receptor antagonists. A very high aldosterone/renin ratio may suggest Conn's syndrome or primary hyperaldosteronism. This is usually caused by a benign adenoma or simple hyperplasia within the zona glomerulosa of the adrenal gland, the presence of which may be demonstrated by CT or MRI scanning. The tumours may be surgically resected, but where there is a suggestion of hyperaldosteronism and no obvious tumour on imaging, patients may still respond to spironolactone, an aldosterone antagonist, while remaining relatively resistant to other antihypertensives.

Contributing factors

The patient should also be assessed for possible contributory factors to hypertension such as obesity, excess alcohol or salt intake and lack of exercise. Occasionally, hypertension may be provoked by the use of drugs (see Box 19.2), including over-the-counter medicines used as cold and flu remedies. Other risk factors should also be documented and addressed, for example, smoking, diabetes and hyperlipidaemia. It is important to establish whether there is a family history of cardiovascular disease.

Evidence of end-organ damage

The patient should also be examined carefully for evidence of end-organ damage from hypertension. This should include examination of the optic fundi to detect retinal changes.

An ECG should be performed to detect left ventricular hypertrophy or subclinical ischaemic heart disease. It is advisable to check the renal function and test the urine for signs of microalbuminutria which may be an indicator of a higher risk of future end-stage renal disease and overall vascular risk.

Determination of cardiovascular risk

An accurate assessment of cardiovascular disease risk is essential before recommending appropriate management in hypertension. Patients with documented atheromatous vascular disease, for example, previous myocardial infarction or stroke, angina or peripheral vascular disease are at high risk of recurrent events. Those with type 2 diabetes over 40 years of age are also at high risk and can be regarded as 'coronary equivalents', that is, with risks similar to non-diabetic patients with previous myocardial infarction. For non-diabetic patients without vascular disease it is necessary to estimate cardiovascular risk (see Chapter 24). A 10-year cardiovascular disease risk of 20% (equivalent to a 15% coronary heart disease risk) is regarded as an appropriate threshold for antihypertensive therapy in patients with moderate hypertension, as well as for lipid-lowering therapy. Treatment decisions based on these tables will favour treatment in elderly subjects. While a younger patient may be at lower absolute risk over 10 years and may not meet the criteria for blood pressure and lipid treatment, they may be at higher lifetime and longer term risk of premature death and vascular disease and, thus, still merit risk factor intervention.

Other factors to consider include microalbuminuria which increases cardiovascular risk by a factor of 2–3 and the combination of reduced GFR and microalbuminuria may increase risk by as much as six-fold (Cirillo et al 2008; Sehestedt et al., 2009).

Treatment

Non-pharmacological approaches

Non-pharmacological management of hypertension is important, although the effects are often disappointing. Patients with mild hypertension in the range 140–159/90–100 mmHg can be assessed for levels of risk while offered lifestyle advice. General health education is important to allow patients to make informed choices about management. In order to maximise potential benefit, patients should receive clear and unambiguous advice, including written information they can digest in their own time. Written advice for patients can be downloaded from the BHS website (http://www.bhsoc.org/).

In patients who are overweight, weight loss results in reduction in blood pressure of about 2.5/1.5 mmHg/kg. The DASH diet (Dietary Approaches to Stop Hypertension) was evaluated in a clinical trial and found to lower blood pressure significantly (4.5/2.7 mmHg) compared with a typical US diet. This diet emphasises fruit, vegetables, and low-fat dairy produce in addition to fish, low-fat poultry and whole grains while minimising red meat, confectionary and sweetened drinks (Appel et al., 1997). Subjects should reduce their salt intake, for example, by not adding salt to food on the plate. A daily sodium intake of <100 mmol (i.e. 6 g sodium chloride or 2.4 g elemental sodium) should be the aim. There is a significant amount of hidden salt in processed meat, ready meals, cheese and even bread. A dietary assessment may be required to accurately quantify a patient's salt intake and advise on how reductions might be made.

Most subjects will need to control their intake of calories and saturated fat. Regular aerobic exercise, at a level appropriate to the individual subject, at least 3 times a week for at least 30 min derives maximum benefit. This results in improved physical fitness as well as a reduction in blood pressure. Alcohol intake should be restricted to two (females) or three (males) units per day. Although smoking does not affect blood pressure, it increases cardiovascular risk and patients should quit or, if this is not possible, reduce their cigarette consumption.

Unless hypertension is severe, it is appropriate to observe the subject over several months while instituting non-pharmacological interventions. However, if there is a more urgent need for drug treatment, non-pharmacological interventions should occur in parallel.

Drug treatment

Treatment thresholds

Treatment thresholds are summarised in Table 19.1. Lifestyle advice should be provided to all patients with any degree of hypertension. Patients with severe hypertension (>220/120 mmHg confirmed on several readings on the same occasion) should be treated immediately and some guidance suggests that dual therapy should be commenced immediately in patients with blood pressure >20 mmHg above their target as monotherapy is unlikely to be fully effective (Mancia et al., 2007). Patients with blood pressures in the range 160–220/100–120 mmHg should be monitored over several weeks and treated if blood pressure remains in this range. The period of observation before starting treatment depends on the severity of the hypertension and the presence or absence of end-organ damage (see Table 19.1). Patients whose blood pressure is in the range 140–159/90–99 mmHg should be observed annually unless they have evidence of target organ damage, cardiovascular complications, diabetes or a calculated cardiovascular risk >20% over 10 years, in which case drug treatment should be offered. Patients with blood pressure in the range 135–139/85–89 mmHg should be reassessed annually, while those with blood pressure lower than this can be rechecked every 5 years.

Target blood pressures

Within the Hypertension Optimal Treatment (HOT) study (Hansson et al., 1998), patients were allocated diastolic target blood pressures of <90, 85, 80 mmHg. The study struggled to stratify patients effectively into these treatment groups but analysis suggested that the optimum target blood pressure was <140/85 mmHg with little benefit in lowering to lower levels of 120/70 mmHg but also little evidence of harm.

Table 19.1 Threshold blood pressures for intervention

Initial blood pressure		Management
Systolic (mmHg)	Diastolic (mmHg)	
Malignant hypertension		Admit and treat immediately
>220	>120	Repeat several times at the same attendance and treat immediately if blood pressure persists in this range
180–219	110–119	Confirm over 1–2 weeks and treat if blood pressure remains in this range
160–179	100–109	Repeat over 3–4 weeks (end-organ damage present) or 2–12 weeks (no end-organ damage), institute non-pharmacological measures and treat if blood pressure persists in this range
140–159	90–99	Repeat over several weeks. Institute non-pharmacological measures. Treat if remains in this range and patient has target organ damage, cardiovascular complications or an estimated 10-year cardiovascular risk >20%. Otherwise reassess annually
135–139	85–89	Reassess annually
<135	<85	Reassess in 5 years

The UK Prospective Diabetes Study Group (1998a,b) suggested 'tight' blood pressure control was better than less tight in patients with non-insulin-dependent diabetes. The targets in the UK Prospective Diabetes Study were 'tight' <150/85 mmHg and 'less tight' <180/105 mmHg but the actually achieved blood pressures were lower, for example, 154/87 mmHg versus 144/82 mmHg. Recommendations in diabetics have, therefore, suggested treating to a target of 140/80 mmHg or less, although few studies have successfully lowered blood pressure to these levels.

A more recent study (Cardio-Sis) randomised non-diabetic subjects with systolic blood pressure >150 mmHg to target systolic blood pressure of <140 or <130 mmHg (Verdecchia et al., 2009). The primary end-point was left ventricular hypertrophy though the secondary end-point of a composite cardiovascular end-point was reduced (as well as the primary end-point) in the 130-mmHg group, with no increase in adverse events. This, however, is not robust enough evidence to recommend a reduction in blood pressure target levels and would require a larger study of hard clinical end-points to confirm these findings.

Achievement of target blood pressures is incorporated as a quality indicator for the General Medical Services Contract for primary care doctors in the UK. Diabetic patients are an exception and benefit from more aggressive blood pressure reduction. Target blood pressures for diabetic and non-diabetic subjects are summarised in Table 19.2. It should be emphasised that the audit standard will not be achieved in all patients.

Antihypertensive drug classes

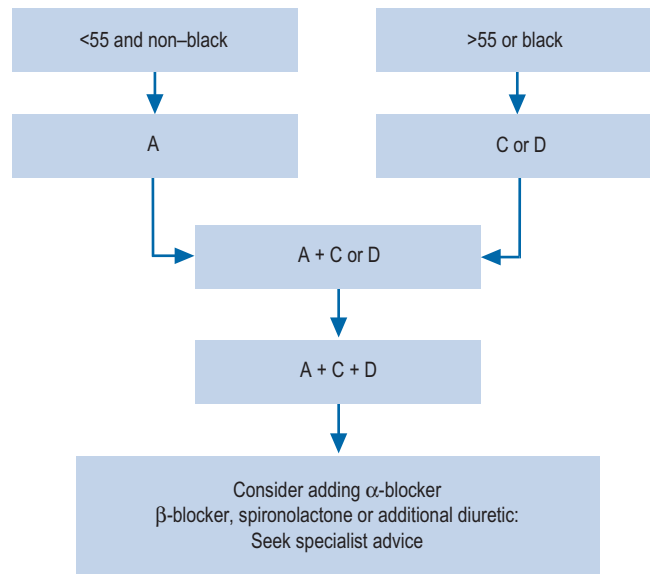
β-Adrenoreceptor antagonists

The mode of action of β-adrenoreceptor antagonists in hypertension is uncertain. β-Adrenoreceptor blockade reduces cardiac output in the short term and during exercise. They also reduce renin secretion by antagonising β-receptors in the juxtaglomerular apparatus. Central actions may also be important for

Table 19.2 Target clinic blood pressures according to British Hypertension Society guidelines 2004 (Williams et al., 2004)

	Clinic blood pressure	
	No diabetes (mmHg)	Diabetes (mmHg)
Optimal treated blood pressure	<140/85	<130/80
Audit standard	<150/90	<140/80

some agents. Non-selective β-blockers may give rise to adverse effects as a result of antagonism of β_2-adrenoceptors, that is, asthma and worsened intermittent claudication. However, the so-called 'cardioselective' (β_1-selective) β-blockers are not entirely free of these adverse effects. Patients who develop very marked bradycardia and tiredness may tolerate a drug with partial agonist activity such as pindolol.

β-Adrenoreceptor antagonists also have substantial clinical trial evidence of benefit over placebo in hypertension, and are relatively inexpensive. However, their use is declining and they have been relegated to fourth-line therapy in the UK according to NICE guidance (Fig. 19.1). This recommendation largely stems from the evidence that they may be less effective at preventing stroke in conjunction with their diabetogenic effects. The Losartan For Endpoint reduction in hypertension (LIFE) study compared an atenolol/thiazide-based regime with a losartan-based regime and demonstrated equivalent levels of blood pressure reduction but with a small excess incidence of stroke in the atenolol arm (Dahlöf et al., 2002). In the Anglo Scandinavian Cardiac Outcomes Trial (ASCOT) study, the risk of diabetes was 2.5% higher in the atenolol arm compared with the amlodipine arm with similar increased risk of diabetes found within the atenolol arm of the LIFE study (Dahlöf et al., 2005). A Cochrane review


A = ACE inhibitor; C = calcium channel blocker; D = diuretic

Fig. 19.1 Algorithm for drug sequencing in hypertension.

warned of the excess risk in developing diabetes in patients prescribed combinations of thiazide diuretics and β-blockers. This would equate to one new case per 500 treated (Mason et al., 2004). The combination of thiazide and a β-blocker should, therefore, be avoided if possible, particularly in those who are at risk of developing diabetes (e.g. obese, strong family history of diabetes, South Asian origin).

To complicate matters, however, a long-term 20-year follow-up study of the UKPDS study found similar cardiovascular outcomes between patients on β-blockers and ACE inhibitors with a reduction in all causes of mortality which actually favoured β-blockers (Holman et al., 2008). β-Blockers do remain most suitable for younger hypertensives who have another indication for β-blockade, such as coronary heart disease. β-Blockers are also effective in suppressing atrial fibrillation and this may be one group of patients where first-line therapy with β-blockers is still merited.

It can be safely assumed that the place for β-blockers for patients with hypertension is likely to remain controversial.

Diuretics

There is substantial clinical trial evidence that benefit is obtained from the use of thiazide, for example, bendroflumethiazide, hydrochlorothiazide, or thiazide-like, for example, chlortalidone, indapamide, diuretics in hypertension; these drugs are both inexpensive and well tolerated by most patients. Their diuretic action is achieved by blockade of distal renal tubular sodium reabsorption. Initially, they reduce blood pressure by reducing circulating blood volume but in the longer term they reduce total peripheral resistance, suggesting a direct vasodilatory action.

Although generally well tolerated, thiazide and thiazide-like diuretics may cause hypokalaemia, small increases in LDL-cholesterol and triglyceride, and gout associated with impaired urate excretion. Erectile dysfunction is also common.

Most blood pressure lowering occurs with very low doses of thiazide diuretics. Increasing the dose substantially increases the risk of metabolic disturbance without causing further blood pressure reduction. For bendroflumethiazide it is rarely (if ever) appropriate to use doses greater than 2.5 mg/day and a dose of 1.25 mg daily is often effective. Most studies of diuretics have also incorporated β-blockers and this combination can have adverse metabolic consequences which may lead to new onset diabetes. Within the Anti-hypertensive and Lipid Lowering treatment to prevent Heart Attack Trial (ALLHAT), the absolute risk of developing diabetes was 3.5% higher in the chlortalidone group than the lisinopril group (ALLHAT Collaborative Research Group, 2002).

As with the β-blocker saga it remains an issue of contention as to whether this diabetic tendency is clinically significant. There was no reduction in efficacy associated with thiazide use in ALLHAT and indeed there were less heart failure outcomes in the diuretic-treated patients compared with those receiving calcium channel blockers or ACE inhibitors.

Loop diuretics are no more effective at lowering blood pressure than thiazides unless renal function is significantly impaired or the patient is receiving agents that inhibit the renin–angiotensin system. They are also a suitable choice if heart failure is present.

Spironolactone, an aldosterone antagonist, is not suitable for first-line therapy but is an increasingly important treatment option for patients with resistant hypertension. Where hyperaldosteronism is suspected, spironolactone may prove to be effective. Spironolactone is a potassium sparing diuretic and should be used with caution especially if used in combination with ACE inhibitors or angiotensin receptor blockers

(ARBs), and should almost always be avoided with other potassium sparing diuretics, for example, amiloride.

Renin-angiotensin-aldosterone antagonists

ACE inhibitors block the conversion of angiotensin I to angiotensin II, while ARBs block the action of angiotensin II at the angiotensin II type 2_1 receptor. Since angiotensin II is a vasoconstrictor and stimulates the release of aldosterone, antagonism results in vasodilation and potassium retention as well as inhibition of salt and water retention. ACE inhibitors also block kininase production and, thus, prevent the breakdown of bradykinin. This appears to be important in the aetiology of ACE inhibitor induced cough, which is a troublesome side effect in 10–20% of users. ARBs do not inhibit kininase and are an appropriate choice for patients who are intolerant of ACE inhibitors because of cough. ACE inhibitors are also associated with a significant incidence of angioedema, which can in severe cases cause dangerous swelling of the pharyngolargyngeal area leading to stridor, threatening the patient's airway. This adverse reaction is commoner in black subjects.

Calcium channel blockers

These agents block slow calcium channels in the peripheral blood vessels and/or the heart. The dihydropyridine group work almost exclusively on L-type calcium channels in the peripheral arterioles and reduce blood pressure by reducing total peripheral resistance. In contrast, the effect of verapamil and diltiazem are primarily on the heart, reducing heart rate and cardiac output. Long-acting dihydropyridines are preferred because they are more convenient for patients and avoid the large fluctuations in plasma drug concentrations that may be associated with adverse effects.

Although effective for lowering blood pressure and preventing cardiovascular events, adverse effects are common, for example, oedema and flushing. Gum hypertrophy may occur with dihydropyridines and constipation with verapamil. Concerns have previously been raised by observational studies (Psaty et al., 1995) and meta-analysis (Furberg et al., 1995) that there may be an increased risk of coronary heart disease in recipients of dihydropyridine calcium channel blockers. However, randomised clinical trials have not confirmed these observations (Gong et al., 1996, Staessen et al., 1997) and have indicated that dihydropyridines are of similar efficacy to thiazide diuretics in preventing cardiovascular events (Brown et al., 2000).

α-Adrenoreceptor blockers

Drugs of this class antagonise α-adrenoceptors in the blood vessel wall and, thus, prevent noradrenaline (norepinephrine)-induced vasoconstriction. As a result, they reduce total peripheral resistance and blood pressure. Prazosin was originally used but had the disadvantage of being short-acting and causing first-dose hypotension. Newer agents such as doxazosin and terazosin have a longer duration of action. There are concerns about the first-line use of β-blockers since the

ALLHAT study has indicated that doxazosin is more often associated with heart failure and stroke than thiazide diuretics (ALLHAT Collaborative Research Group, 2000). However, they are an appropriate choice as add-in therapy for patients inadequately controlled using other agents. They can frequently cause postural hypotension but may alleviate symptoms in men with prostatic hyperterophy.

Centrally acting agents

Methyldopa and moxonidine inhibit sympathetic outflow from the brain, resulting in a reduction in total peripheral resistance. Methyldopa is not widely used because it has pronounced central adverse effects, including tiredness and depression. It continues to be used in pregnancy, since it does not cause fetal abnormalities. It is also occasionally used in patients with resistant hypertension. Moxonidine is a newer agent that blocks central imidazoline and α_2-adrenoceptors found within the medulla oblongata of the brain. It can cause side effects of dry mouth, headache, fatigue and dizziness, although it appears to have fewer central adverse effects than methyldopa. Other centrally acting agents such as clonidine and reserpine are almost never used in modern practice because of their pronounced adverse effects.

Other agents

Several other drugs are available for use for people with more resistant hypertension. Minoxidil is a powerful antihypertensive drug but its use is associated with severe peripheral oedema and reflex tachycardia. It should be restricted to patients with severe hypertension who are also taking β-blockers and diuretics. It causes pronounced hirsutism and is not a suitable treatment for women. Hydralazine can be used as add-on therapy for patients with resistant hypertension but is not well tolerated as it is a profound vasodilator and may occasionally be associated with drug-induced systemic lupus erythematosus. Sodium nitroprusside is a direct-acting arterial and venous dilator that is administered as an intravenous infusion for treating hypertensive emergencies and for the acute control of blood pressure during anaesthesia. Hypertension has previously been treated with ganglion blockers such as guanethidine but these drugs are now of historical interest only.

Recent additions to the licensed armory of antihypertensive agents include the renin antagonist aliskiren. There is evidence that this agent may have a similar blood pressure lowering effect to other agents and may be safely added to other inhibitors of the renin–angiotensin–aldosterone system to provide a greater level of inhibition (O'Brien et al., 2007). Due to its cost and a relative lack of experience in its use, it can only be suggested as an add-on therapy where other more established treatment options have failed to control blood pressure. It is generally well tolerated but may cause diarrhoea at higher doses.

The endothelin antagonist darusentan is undergoing clinical trials in resistant hypertension. Early studies show it may be effective in resistant cases but may be associated with a high incidence of fluid retention (Weber et al., 2009).

Drug selection

Drugs should be chosen on the basis of efficacy, safety, convenience to the patient and cost. For assessing efficacy, it is essential to use evidence from large-scale clinical trials that demonstrate measurable effects on hard end-points like incidence of stroke and other cardiovascular events or death. Smaller scale studies looking at the effects of drugs on blood pressure and surrogate markers such as left ventricular hypertrophy or carotid artery stenosis may generate a hypothesis of a future treatment strategy but should be used to change current strategies. When considering safety, it is important to recognise that these drugs will be taken in the long term and there are advantages to using drugs which have long-established safety records. It is also important to recognise the importance of symptomatic adverse effects since these may reduce adherence. Patients should feel as well during treatment of their blood pressure as they did before drug treatment was instituted. Patient convenience is another important factor and use of once-daily preparations will result in better adherence than more frequent regimens. Since the hypertensive population is very large it is necessary to be conscious of the cost of individual preparations. Combinations of low doses of antihypertensive drugs are often better tolerated than single drugs taken in high dose. The choice of drugs available for treating hypertension is shown in Table 19.3, and common therapeutic problems are noted.

Clinical trial evidence

Initial evidence of benefit in placebo-controlled clinical trials came from studies that primarily involved thiazide diuretics or β-blockers. However, there is increasing evidence of clinical benefit from newer drug classes including ACE inhibitors and calcium channel blockers.

The Blood Pressure Lowering Treatment Trialists Collaboration (2000) carried out a meta-analysis of old against new treatments. They concluded that newer treatments were no more effective than older therapies. Since this study was done several landmark comparative clinical trials have been published.

The Captopril Prevention Project (CAPPP) demonstrated that captopril was as effective as diuretics or β-blockers for preventing cardiovascular morbidity (Hansson et al., 1999a). However, captopril was associated with a 25% higher stroke risk, perhaps because it did not reduce blood pressure as effectively as conventional therapy in this particular study.

The LIFE study demonstrated that losartan was more effective at preventing vascular events, especially stroke, than atenolol in just over 9000 hypertensive patients with left ventricular hypertrophy, although reductions in blood pressure were similar. Losartan was also better tolerated (Dahlöf et al., 2002).

The ALLHAT study (ALLHAT Collaborative Research Group, 2002) involved over 40,000 older, high-risk hypertensive patients with the aim of determining whether the occurrence of fatal coronary heart disease or non-fatal myocardial infarction was lower in those treated with newer agents (amlodipine, lisinopril or doxazosin) compared with a thiazide-like diuretic (chlortalidone). The doxazosin arm was discontinued early because of a higher rate of events, especially heart failure, compared with the diuretic. For the remaining three drugs there was no difference in occurrence of the primary end-point. Chlortalidone was more effective than amlodipine and lisinopril in lowering blood pressure and preventing heart failure and was also marginally more effective than lisinopril in preventing stroke.

The second Australian National Blood Pressure Study Group (Wing et al., 2003) compared enalapril with hydrochlorthiazide in just over 6000 hypertensive subjects recruited in primary care. The primary end-point was any cardiovascular event or death from any cause. In this relatively small study, there was a trend in favour of the ACE inhibitor which was of borderline statistical significance.

The VALUE study (Julius et al., 2004) compared amlodipine and valsartan in high-risk hypertensive subjects. No differences in the primary composite cardiac end-point were observed, although non-fatal myocardial infarction was less common with amlodipine, which also lowered blood pressure to a greater extent. Conversely, onset of diabetes was less common with valsartan.

The ASCOT study (Dahlöf et al., 2005) compared a modern treatment regimen based on amlodipine and perindopril with a traditional regimen based on atenolol and bendroflumethiazide. The study involved over 20,000 high-risk hypertensives. The amlodipine-based therapy was associated with better blood pressure reduction and reductions in the occurrence of cardiovascular events, total mortality and diabetes, although the primary composite end-point was not significantly affected. It is uncertain how much of the benefit can be attributed to the better blood pressure control achieved in the amlodipine-based arm and how specific these findings are to the drug doses and sequencing specified in the trial protocol for each arm of the study.

These various trials have provided results that are conflicting, in part because of differences in trial design and quality. However, there is increasing evidence that β-blockers may be less effective at preventing cardiovascular end-points, as suggested by LIFE and ASCOT studies. In a meta-analysis (Lindholm et al., 2005), β-blockers were less effective than other antihypertensives at preventing stroke, although no significant differences were observed in effects on myocardial infarction or death. There is no consistent evidence that thiazides or thiazide-like drugs are less effective than newer agents in preventing cardiovascular events.

Recommendations for drug sequencing

In the UK, the BHS and NICE issued joint guidelines in 2006 on the order in which drugs should be used (National Collaborating Centre for Chronic Conditions, 2006). This replaced previous guidelines which differed between the two reflecting the ongoing controversy regarding the role of β-blockers. These recommend an initial choice of an

Table 19.3 Summary of antihypertensive drugs and common therapeutic problems

Class	Examples	Major adverse effects	Comment
Diuretics	Thiazides: bendroflumethiazide	Hypokalaemia Gout Glucose intolerance Hyperlipidaemia	Cheap, effective. Efficacy proven in clinical trials Concerns about long-term metabolic effects More appropriate in older patients
	Loops: furosemide K sparing: spironolactone	Impotence Uraemia Dehydration Hyperkalaemia Gynaecomastia	Especially for patients with cardiac failure Especially for resistant hypertension
β-Blockers	Atenolol Propranolol Metoprolol	Tiredness Reduced exercise tolerance Bradycardia	Cheap Adverse effects common Possibly less effective in preventing cardiovascular events
	Labetalol Celiprolol	Cold peripheries Claudication Wheezing Cardiac failure Impotence	Especially for patients with ischaemic heart disease
Calcium antagonists: dihydropyridine	Nifedipine	Flushing	Not well tolerated (especially early in treatment). Recent trials confirm reductions in stroke and myocardial infarction
	Amlodipine	Oedema Postural hypotension Headache	Similar efficacy to thiazides Especially for elderly patients and those with ischaemic heart disease or diabetes
Calcium antagonists: rate limiting	Verapamil	Bradycardia/heart block	Well tolerated. Suitable for patients with ischaemic heart disease who are unable to tolerate β-blockers
	Diltiazem	Constipation (verapamil only)	Caution needed when used in combination with β-blockers
ACE inhibitors	Captopril Enalapril Lisinopril Perindopril Ramipril	Cough Rash, taste disturbance Renal failure Angioedema	More expensive. Cough very common Appropriate for use in younger patients and those with cardiac failure or diabetes
α-Blockers	Prazosin Doxazosin	Oedema Postural hypotension	More expensive. Adverse effects common. No evidence to date of long-term efficacy. Less effective than thiazides at preventing heart failure and combined cardiovascular outcomes (ALLHAT study)
	Terazosin		Second line
Angiotensin receptor blockers	Losartan Valsartan	Renal failure Oedema	More expensive Especially for patients in whom ACE inhibitor indicated but not tolerated due to cough
	Irbesartan	Headache	More effective in preventing vascular events than atenolol in patients with LVH
Centrally acting vasodilators	Methyldopa	Tiredness	Poorly tolerated. Only used in severe hypertension or hypertension of pregnancy
	Moxonidine	Depression	Third line
Direct-acting vasodilators	Diazoxide Minoxidil Nitroprusside	Oedema Postural hypotension Headache	Poorly tolerated. Only used in severe hypertension

ACE inhibitor or ARB (A) as first-line therapy in younger (<55 years) non-black patients. The rationale for this is that these patients often have hypertension associated with high concentrations of renin. It is, therefore, logical to treat these patients with drugs that antagonise the renin–angiotensin system.

For patients >55 and black patients, who tend to have hypertension associated with low renin concentrations, calcium channel blockers (C) or thiazide diuretics (D) are advocated as first-line options. If initial drug therapy fails to control blood pressure, A and D or C is suggested. Subsequently, a combination of A plus C plus D may be used. After this, further therapies, for example, β-blocker, α-blocker, spironolactone, etc., could be added as necessary to achieve adequate control (Fig. 19.1). β-Blockers may be used in those patients with a high sympathetic drive, in pregnant women where labetolol has a good safety record or where other agents are not tolerated.

European guidance (Box 19.3) has eschewed a formal ranking of treatments and instead suggested a table of drugs and indications where they might be most appropriately indicated (Mancia et al., 2007).

Box 19.3 Conditions favouring use of particular antihypertensive agents (modified from Mancia et al., 2007)

Thiazide diuretics
- Systolic hypertension in the elderly
- Heart failure
- Black patients

ACE inhibitors
- Heart failure
- Left ventricular dysfynction
- Post-myocardial infarction
- Diabetic nephropathy
- Left ventricular hypertrophy
- Proteinuria

β-Blockers
- Angina
- Post-myocardial infarction
- Heart failure (stable)
- Atrial fibrillation
- Pregnancy

Calcium channel blockers (dihydropyridines)
- Systolic hypertension in the elderly
- Angina
- Pregnancy
- Black patients

Calcium channel blockers (verapamil/diltiazem)
- Angina
- Atrial fibrillation

Loop diuretics
- Renal impairment
- Heart failure

Aldosterone antagonists
- Heart failure
- Post-myocardial infarction
- Conn's syndrome

Special patient groups

Race

People of African Caribbean origin have an increased prevalence of hypertension and left ventricular hypertrophy and are at high risk of stroke and renal failure. They obtain particular benefit from reduced salt intake and are also sensitive to diuretic and calcium channel blockers, while β-blockers appear less effective, at least when used as monotherapy. African Caribbean people have reduced plasma renin activity and, as a result, ACE inhibitors and ARBs are also less effective. This was illustrated in the ALLHAT study where stroke and coronary events were more common in black patients randomised to lisinopril compared to those receiving chlortalidone.

British Asians also have an increased prevalence of hypertension, diabetes and insulin resistance and a particularly high risk of coronary heart disease and stroke. There is currently no evidence of a difference in drug response when compared with white Europeans. However, combinations of β-blockers and thiazides should be avoided when possible because of the higher risk of diabetes.

Elderly

The elderly have a high prevalence of hypertension, with over 70% having blood pressures greater than 140/90 mmHg. They are also at high absolute risk of cardiovascular events. Therefore, the absolute benefits of blood pressure treatment are particularly large in this group. Antihypertensive therapy may also reduce the risk of heart failure and dementia. The Study of Cognition and Prognosis in the Elderly (SCOPE) study (Lithell et al., 2003) was designed to investigate the effects of candesartan on the occurrence of cognitive decline or dementia but revealed no benefit, probably because of the lack of difference in blood pressure between the two arms of the study

The elderly are at particular risk of certain adverse effects of treatment such as postural hypotension and it is important that both sitting and standing blood pressure are monitored. Nevertheless, the benefits of therapy are so great that treatment should be offered at any age unless the patient is very frail or their life expectancy is very short. Isolated systolic hypertension (systolic >160 mm Hg, diastolic <90 mmHg) is common in the elderly and there is irrefutable evidence that drug treatment is beneficial in this group (SHEP Co-operative Research Group, 1991, Staessen et al., 1997). The elderly have more variable blood pressure and larger numbers of measurements may be required to confirm hypertension.

Calcium channel blockers and low-dose thiazide diuretics are safe and effective treatments for elderly hypertensive people and their use is endorsed by large-scale clinical trials. β-Blockers are less effective at reducing blood pressure and preventing clinical end-points. The Swedish Trial in Old Patients with hypertension-2 (STOP-2) compared the effects of conventional (β-blocker or thiazide) and newer drugs (ACE inhibitors or calcium channel blockers) on cardiovascular morbidity in older subjects and did not detect significant differences (Hansson et al., 1999b).

In the Hypertension in the Very Elderly Trial (HYVET), 4000 patients with a mean age of 84, blood pressure 160–199 mmHg systolic at entry were treated to a target of systolic 150 mmHg for 1.8 years with indapamide (a thiazide-like diuretic) and if required the ACE inhibitor perindopril. There was a 30% reduction in fatal and non-fatal stroke, 21% reduction in death from all causes, and fewer adverse events in the actively treated group (Beckett, 2008).

The elderly certainly benefit from treatment of hypertension but the threshold and target for treatment has not been fully elucidated. Most studies in the elderly recruited patients with relatively high baseline targets (>160–190 mmHg systolic) achieving blood pressure on treatment of between 150 and 170 mmHg and only one achieved target blood pressure lower than 140 mmHg and in this study outcome was poorer in the treated group (JATOS Study Group, 2008). There may be little benefit in striving for strict systolic targets beyond 150 mmHg in these patients, particularly if control is being achieved to the detriment of overall patient well-being.

Diabetes

In type 1 diabetes, the presence of hypertension often indicates the presence of diabetic nephropathy. In this group, blood pressure reduction and ACE inhibition slow the rate of decline in renal function. To achieve adequate blood pressure control, combinations of drugs will be needed. Thiazides, β-blockers, calcium channel blockers and α-blockers are all suitable as add-on treatments to ACE inhibitors which should be first-line therapy. Target blood pressure should be <130/80 mmHg or <125/75 mmHg if there is diabetic nephropathy. The evidence supporting this recommendation is, however, limited and obtaining such levels of control in diabetics often impossible.

In type 2 (non-insulin dependent) diabetes, hypertension is particularly common, affecting 70% of people in this group. It is strongly associated with obesity and insulin resistance and control of blood pressure is more important for preventing complications than tight glycaemic control. There is no evidence that one group of drugs is more or less effective than any other. The ADVANCE trial treated diabetics with indapamide and perindopril in addition to prestudy antihypertensive agents. The active group was found to have a further reduction in blood pressure and a significant reduction in adverse renal outcomes (21%) (Patel et al., 2007). It remains a subject of debate whether ACE inhibitors and ARBs have specific renoprotective benefits over and above their effects on blood pressure.

Renal disease

In patients with chronic renal impairment, good blood pressure control slows the progression of renal dysfunction. ACE inhibition reduces the incidence of end-stage renal failure but it is not clear if this is a specific effect or non-specific action as a result of blood pressure lowering. ACE inhibitors also reduce 24-h protein loss and should be used in patients with 24-h protein excretion of >3 g or rapidly progressive renal dysfunction. ACE inhibitors may worsen renal impairment in patients with renal vascular disease and careful monitoring of electrolytes and creatinine is mandatory. Salt restriction is particularly important in managing hypertension in renal disease. Thiazide diuretics are ineffective in patients with significant renal dysfunction and loop diuretics should be used when a diuretic is needed.

A further note of caution regarding overtreatment of blood pressure to overaggressive targets comes from the ONTARGET study which randomised patients with vascular disease or high-risk diabetics to high-dose ramipril, telmisartan (ARB) or both. Many patients were already taking polypharmacy for hypertension and blood pressures at entry were approximately 142/82 mmHg in all groups. Treatment reduced blood pressure by 6.4/4.3 mmHg in the ramipril group, 7.4/5.0 mmHg in the telmisartan group and 9.8/6.3 mmHg in the combination group. This would give the combination group a post-treatment blood pressure of 132/76 mmHg. This combination group was associated with adverse renal outcomes, for example, renal failure and high potassium with no improvement in other cardiovascular outcomes (Yusuf et al., 2008a).

Stroke

Hypertension is the most important risk factor for stroke in patients with or without previous stroke. There is increasing evidence that in those with a previous stroke, blood pressure reduction reduces the risk of stroke recurrence as well as other cardiovascular events. The PROGRESS study, while clearly demonstrating a benefit of lowering blood pressure in patients with cerebrovascular disease, only demonstrated benefit in those whose blood pressure was >140 mmHg on entry or who were already on antihypertensives. The size of benefit was proportional to the size of the blood pressure reduction. The combination of perindopril and indapamide lowered systolic blood pressure by 12.3 mmHg and stroke incidence by an impressive 43%, while perindopril alone was associated with a small drop in systolic blood pressure and no reduction in stroke risk (PROGRESS Collaborative Group, 2001). On treatment, blood pressure in the actively treated group was 132 mmHg systolic which has led some to suggest a target of 130 mmHg for such patients but this is based on post hoc analysis and has not been recommended in formal guidance.

The PROFESS study randomised patients with cerebrovascular disease to telmistartan or placebo and obtained systolic blood pressure of 136 in the active group versus 140 mmHg in the placebo group with no difference in the vascular outcomes between the two groups. This may have been due to the relatively small difference in blood pressure between the two groups (Yusuf et al., 2008b).

The question 'what to do with blood pressure in the setting of acute stroke?' has remained an evidence-free zone until fairly recently. Blood pressure naturally rises then falls in the days and hours following acute stroke and some have

argued that elevated levels are necessary to maintain brain circulation due to the failure of cerebral autoregulatory mechanisms around the time of stroke. The theory that lowering blood pressure could reduce cerebral perfusion due to a lack of the usual autoregulatory mechanisms is counterweighted by the potential for further damage due to cerebral oedema. The Control Hypertension and Hypotension Immediately Poststroke Study (CHHIPS) randomised acute stroke patients to placebo, lisinopril (sublingual) or intravenous bolus of labetolol and evaluated the incidence of neurological deterioration. There was no adverse outcome in any actively treated group despite reductions in blood pressure (21 vs. 11 mmHg for systolic blood pressure; Potter et al., 2009) This was a relatively small study and larger confirmatory studies are required before firm recommendations for patient management should be made.

In patients with intracerebral haemorrhage, acute reduction of blood pressure has also been demonstrated to be feasible and probably safe with reduced haematoma growth in the actively treated group (Anderson et al., 2008).

Pregnancy

An increased blood pressure before 20 weeks gestation usually indicates pre-existing chronic hypertension that may not have been previously diagnosed. As in all younger hypertensive patients, a careful assessment is needed to exclude possible secondary causes, although radiological and radionuclide investigations should usually be deferred until after pregnancy. Hypertension diagnosed after 20 weeks gestation may also indicate chronic hypertension, which may have been masked during early pregnancy by the fall in blood pressure that occurs at that time. Patients with elevated blood pressure in pregnancy are at increased risk of pre-eclampsia and intrauterine growth retardation. They need frequent checks of their blood pressure, urinalysis and fetal growth. Pre-eclampsia is diagnosed when the blood pressure increases by 30/15 mmHg from measurements obtained in early pregnancy or if the diastolic blood pressure exceeds 110 mmHg and proteinuria is present. There is consensus that blood pressure should be treated with drugs if it exceeds 150–160/100–110 mmHg, although some clinicians use a lower threshold, for example, 140/90 mmHg. Methyldopa is the most suitable drug choice for use in pregnancy because of its long-term safety record. Calcium channel blockers, hydralazine and labetalol are also used. β-Blockers, particularly atenolol, are used less often as they are associated with intrauterine growth retardation. Although diuretics reduce the incidence of pre-eclampsia they are little used in pregnancy because of concerns about decreasing maternal blood volume. ACE inhibitors and ARBs are contraindicated, as they are associated with oligohydramnios, renal failure and intrauterine death.

Meta-analysis of trials suggests that antihypertensive drugs reduce risk of progression to severe hypertension and reduce hospital admissions, although excessive blood pressure reduction may reduce fetal growth.

Oral contraceptives

Use of combined oral contraceptives results, on average, in an increase of 5/3 mmHg in blood pressure. However, severe hypertension can occur in a small proportion of recipients months or years into treatment. Progesterone-only preparations do not cause hypertension so often but are less effective for contraception, especially in younger women. Combined oral contraceptives are not absolutely contraindicated in hypertension unless other risk factors for cardiovascular disease, such as smoking, are present.

Hormone replacement therapy

There is little evidence that hormone replacement therapy is associated with an increase in blood pressure and women with hypertension should not be denied access to these agents if there is an appropriate indication. However, hormone replacement therapy itself does not reduce and may increase the risk of cardiovascular events. Large increases in blood pressure have occasionally been reported in individuals and it is important to monitor blood pressure during the first few weeks of therapy and 6-monthly thereafter. In women with resistant hypertension, during treatment with hormone replacement therapy, the effectiveness of discontinuing hormone replacement should be assessed.

A list of the indications and contraindications to the various antihypertensive agents can be found in Table 19.4.

Ancillary drug treatment

Aspirin

The use of aspirin reduces cardiovascular events at the expense of an increase in gastro-intestinal complications. Its use should be restricted to patients who have no contraindications and either:

- have evidence of established vascular disease or
- have no evident cardiovascular disease but who are over 50 years of age and have either evidence of target organ damage or a 10-year cardiovascular disease risk of >20%.

Blood pressure should be controlled (<150/90 mmHg) before aspirin is instituted.

Lipid-lowering therapy

There is increasing evidence from clinical trials of the benefit of lipid-lowering drug treatment in patients with hypertension. For example, in the ASCOT study lipid-lowering arm (ASCOT-LLA), treatment with atorvastatin 10 mg was associated with substantial reductions in coronary heart disease and stroke, in spite of the fact that those with total cholesterols initially higher than 6.5 mmol/L were excluded from the study (Sever et al., 2003). Lipid-lowering therapy, usually with a statin, should be prescribed to patients under 80 years of age with a total cholesterol >3.5 mmol/L who either have pre-existing vascular disease or a 10-year cardiovascular risk of >20%.

Table 19.4 Use of antihypertensive drugs adapted from British Hypertension Society guidelines

Class	Indications	Contraindications
Diuretics	Elderly ISH Heart failure Secondary stroke prevention	Gout
β-Blockers	Myocardial infarction Angina (Heart failure)	Asthma/chronic obstructive pulmonary disease Heart block (Heart failure) (Dyslipidaemia) (Peripheral vascular disease) (Diabetes, except with coronary heart disease)
Calcium antagonists: dihydropyridine	Elderly isolated systolic hypertension (Elderly) (Angina)	
Calcium antagonists (rate limiting)	Angina (Myocardial infarction)	Combination with β-blocker (Heart block) (Heart failure)
ACE inhibitors	Heart failure Left ventricular (LV) dysfunction Type 1 diabetic nephropathy Secondary stroke prevention (Chronic renal disease) (Type 2 diabetic nephropathy) (Proteinuric renal disease)	Pregnancy Renovascular disease (Renal impairment) (Peripheral vascular disease)
α-Blockers	Benign prostatic hypertrophy (Dyslipidaemia)	Urinary incontinence (Postural hypotension) (Heart failure)
Angiotensin receptor blockers	ACE inhibitor intolerance Type 2 diabetic nephropathy Hypertension with LVH Heart failure in ACE inhibitor-intolerant subjects Post-MI (LV dysfunction post-MI) (Intolerance of other antihypertensive drugs) (Proteinuric renal disease) (Chronic renal failure) (Heart failure)	As ACE inhibitors
Centrally acting vasodilators	Pregnancy (methyldopa only) Resistant hypertension unresponsive to first-line therapy	
Direct-acting vasodilators	Resistant hypertension, unresponsive to first-line therapy	

Note: Strong indications and contraindications are shown. Text in parentheses indicates weak/possible indications or contraindications.

Case studies

Case 19.1

A 55-year-old woman of African Caribbean origin is found to have consistently elevated blood pressure over several weeks, her lowest reading being 155/98 mmHg. She is overweight and has diabetes, and is being treated with metformin. Her renal function and urinalysis are both normal.

Questions

1. Should drug therapy be initiated for her hypertension?
2. If her hypertension was treated with drugs, which agents offer particular advantages, and which should be avoided?

Answers

1. Provided her blood pressure has been measured accurately over several weeks, it should be treated, since her diabetes is an important additional risk factor. It is important to ensure that an appropriately sized blood pressure cuff is being used, in view of her obesity. Non-pharmacological interventions should also take place in parallel. Restriction of salt intake may be particularly helpful in people of African Caribbean race and weight reduction would benefit her hypertension and diabetes.
2. ACE inhibitors are an attractive choice for diabetic patients who have nephropathy. However, there is no evidence of nephropathy in this patient and ACE inhibitors are less effective antihypertensives in people of African Caribbean origin. β-Blockers reduce hypoglycaemic awareness; this is not a contraindication in this case since metformin does not cause hypoglycaemia. However, β-blockers are also less effective in those of African Caribbean descent. Diuretics work well in African Caribbean patients with hypertension, but may worsen glucose tolerance and may not, therefore, be the most appropriate first choice. Calcium channel blockers do not have adverse metabolic effects and are effective in people of this origin and would, therefore, be an appropriate choice. Tight blood pressure control is important and several agents may be required, including diuretics, ACE inhibitors, β-blockers and α-blockers.

Case 19.2

Mr PT, a 35-year-old man, is overweight and has a blood pressure of 178/114 mmHg. He smokes 25 cigarettes daily and drinks 28 units of alcohol per week. He has a sedentary occupation. He eats excessive quantities of saturated fat and salt.

Questions

1. How should this patient be managed?
2. What pharmacological treatment for blood pressure would be appropriate if non-pharmacological treatment was unsuccessful?
   Mr PT subsequently stopped smoking and lost some weight but remained hypertensive. He was treated with atenolol 50 mg daily.
   His blood pressure fell to 136/84 mmHg but he developed tiredness and bradycardia and complained of erectile impotence.
3. What are the treatment options for Mr PT?

Answers

1. Since he is a young man, his absolute risk of cardiovascular events is low, at least for the time being. However, he has several additional risk factors that need to be addressed, including his sedentary lifestyle and his smoking. Non-pharmacological methods have the potential of reducing his blood pressure considerably, including reduction in weight and salt intake. Measurement of plasma cholesterol may help him modify his diet, although he is unlikely to qualify for lipid-lowering therapy in view of his young age.
2. If drug treatment was appropriate, initial treatment with an ACE inhibitor would be consistent with current guidance, in view of his age. This is likely to be more effective for blood pressure lowering than a calcium channel blocker or diuretic. β-Blockers have been recommended as an option in younger patients but are now considered less suitable as initial therapy. Other drugs could be added or substituted if he was intolerant to initial therapy or it did not reduce his blood pressure to target levels.
3. It is possible that he would feel less tired using a β-blocker with intrinsic sympathomimetic activity (e.g. pindolol) but this is by no means guaranteed. The effects on his sexual function are unpredictable. It would probably be better to change him to a

drug of a different class such as an ACE inhibitor.
A calcium channel blocker or thiazide diuretic (although these also commonly cause impotence) may be added if necessary.

Case 19.3

A 24-year-old woman with a family history of hypertension is prescribed an oral contraceptive. Six months after starting this, she is noted to have a blood pressure of 148/96 mmHg.

Question

How should this patient be managed?

Answer

If her blood pressure is consistently raised she may have either essential hypertension or hypertension induced by the oral contraceptive, or a combination. Her blood pressure may fall if her oral contraceptive is discontinued. She will, however, need advice on adequate contraceptive methods. A progesterone-only preparation would be one possibility. She would need careful counselling about the methods available and how successful they are. If her blood pressure remained elevated after discontinuing her oral contraception, she is likely to have underlying hypertension. This may be essential in nature, in view of the family history; however, because of her age she should undergo some investigations to exclude possible secondary causes of hypertension. She is at low risk of complications and there is no urgency to consider drug treatment. If there is a strong wish to use combined oral contraception, it would be important to control other risk factors as far as possible and to consider drug treatment for her hypertension.

Case 19.4

A 73-year-old lady has a long-standing history of hypertension and intolerance to antihypertensive drugs. Bendroflumethiazide was associated with acute attacks of gout, she developed breathlessness and wheezing while taking atenolol, nifedipine caused flushing and headache, and doxazosin was associated with intolerable postural hypotension. Four weeks earlier she had been started on enalapril but was now complaining of a dry persistent cough. Her blood chemistry has remained normal.

Questions

1. Is the patient's cough likely to be an adverse effect of enalapril?
2. What other options are available for controlling her blood pressure?

Answers

1. Yes it is. A dry cough is a common adverse effect of ACE inhibitors. It affects approximately 10–20% of recipients and is more common in women. Some patients are able to tolerate the symptom but in many the drug has to be discontinued.
2. Angiotensin receptor blockers can be used in patients intolerant of ACE inhibitors due to cough. They are unlikely to produce this symptom since they do not inhibit the metabolism of pulmonary bradykinin. Centrally acting agents such as methyldopa or moxonidine could also be considered. However, these are not well tolerated and side effects are quite likely in this patient. A non-dihydropyridine calcium channel blocker such as verapamil is another alternative. Measurement of plasma uric acid could also be considered followed by prophylactic treatment with allopurinol before introducing a diuretic. Alternatively, a trial of spironolactone or the renin antagonist aliskiren could be considered.

Case 19.5

A 23-year-old woman has a normal blood pressure (118/82 mmHg) when reviewed at 8 weeks of pregnancy. In the 24th week of pregnancy, she is reviewed by her midwife and found to have a blood pressure of 148/96 mmHg. Urinalysis is normal.

Questions

1. What is the likely diagnosis?
2. What complications does the patient's high blood pressure place her at increased risk of?
3. Should she receive drug treatment? If so, with which drug? If not, how should she be managed?

Answers

1. She may have gestation-induced hypertension or chronic hypertension that had previously been masked by the fall in blood pressure that happens in early pregnancy.
2. She is at increased risk of pre-eclampsia and intrauterine growth retardation.
3. There are differences of opinion between specialists as to whether blood pressure should be treated at this level during pregnancy. In favour of treatment is the substantial rise over the earlier blood pressure recording. Some specialists would not treat unless the blood pressure was >170/110 mmHg or other complications were present. If she were treated, methyldopa would be a suitable choice. In any event, she needs close monitoring of her blood pressure, urinalysis and fetal growth.

Case 19.6

An elderly patient comes to the pharmacy with a prescription for the following medications: salbutamol inhaler 200 μcg as required, beclometasone inhaler 200 μcg twice daily, bendroflumethiazide 2.5 mg daily, modified release diltiazem 180 mg once daily and atenolol 50 mg daily. The atenolol was being started by the patient's primary care doctor, apparently because of inadequate blood pressure control.

Question

What action should the pharmacist take?

Answer

There are two reasons to be concerned about the addition of atenolol to this patient's drug regimen. First, there is a potentially hazardous interaction with diltiazem which may result in severe bradycardia or heart block. Second, the patient is receiving treatment for obstructive airways disease and this may be worsened by the atenolol. Third, there is increasing evidence to demonstrate the combination of a thiazide and a β-blocker increases the risk of developing diabetes. The prescription should be discussed with the prescriber.

Case 19.7

A patient is admitted to hospital with a stroke. A CT scan of the brain shows a cerebral infarct. The patient's blood pressure is 178/102 mmHg and remains at this level over the first 6 h after admission to the ward.

Question

Should antihypertensive medication be prescribed?

Answer

There is no good evidence that antihypertensive drug treatment is beneficial in the early stages of acute stroke and there is a risk that lowering blood pressure may compromise cerebral perfusion further. However, in the longer term, blood pressure reduction is valuable for preventing further strokes and other cardiovascular events. It would be appropriate to monitor the blood pressure and start treatment after a few days if it remains persistently elevated. A thiazide diuretic and/or ACE inhibitor are commonly used under these circumstances, following the demonstration of benefit in the PROGRESS study (PROGRESS Collaborative Group, 2001).

Case 19.8

A 67-year-old man has been treated for hypertension with atenolol 50 mg daily for several years. He feels well and his blood pressure is controlled. He has read an article in the paper that suggests atenolol is not considered the most suitable drug for treating high blood pressure and enquires about changing his prescription.

Question

Should an alteration to his treatment be recommended?

Answer

There is increasing evidence that β-blockers, including atenolol, may be less effective at preventing cardiovascular events, especially stroke, than other drugs and are associated with a higher risk of development of diabetes, especially if used in combination with thiazide diuretics. They are also less effective at reducing blood pressure in older people. However, if his blood pressure is well controlled and the treatment suits him there is no strong reason to change his medication unless he is at particular risk of diabetes.

Case 19.9

A 58-year-old male patient is noted to have high blood pressure by his primary care doctor. There is no evidence of end-organ damage and he has no other cardiovascular risk factors. The blood pressure remains greater than 160/100 mmHg each time it is checked in the surgery over several weeks, in spite of salt and alcohol reduction. The patient buys a wrist blood pressure monitor in a pharmacy and takes several readings at home. These are all below 130/75 mmHg.

Question

What advice should he be given about the need for drug treatment?

Answer

He may have 'white coat' hypertension. Since this is associated with a lower risk than sustained hypertension he may not need drug treatment. However, before making this judgement it is important to check that his machine is accurate. This can be done by comparing readings with a validated machine, or by checking to see if the make of blood pressure monitor has been verified as accurate by the British Hypertension Study.

20 Coronary heart disease

D. McRobbie

Key points

- Coronary heart disease (CHD) is common, often fatal and frequently preventable.
- High dietary fat, smoking and sedentary lifestyle are risk factors for CHD and require modification if present.
- Hypertension, hypercholesterolaemia and diabetes mellitus, obesity and personal stress are also risk factors and require optimal management.
- Stable angina should be managed with nitrates for pain relief and β-blockers, unless contraindicated, for long-term prophylaxis. Where β-blockers are inappropriate, the use of calcium channel blockers and/or nitrates may be considered.
- Acute coronary syndromes arise from unstable atheromatous plaques and may be classified as to whether there is ST elevation myocardial infarction (STEMI) or non-ST elevation myocardial infarction (NSTEMI).
- ST elevation on the ECG indicates an occluded coronary artery and is used to determine treatment with fibrinolysis or primary angioplasty.
- Patients with NSTEMI may have experienced myocardial damage, are at increased risk of death and may benefit from a glycoprotein IIb/IIIa inhibitor.

Coronary heart disease (CHD), sometimes described as coronary artery disease (CAD) or ischaemic heart disease (IHD), is a condition in which the vascular supply to the heart is impeded by atheroma, thrombosis or spasm of coronary arteries. This may impair the supply of oxygenated blood to cardiac tissue sufficiently to cause myocardial ischaemia which, if severe or prolonged, may cause the death of cardiac muscle cells. Similarities in the development of atheromatous plaques in other vasculature, in particular the carotid arteries, with the resultant cerebral ischaemia has resulted in the term cardiovascular disease (CVD) being adopted to incorporate CHD, cerebrovascular disease and peripheral vascular disease.

Myocardial ischaemia occurs when the oxygen demand exceeds myocardial oxygen supply. The resultant ischaemic myocardium releases adenosine, the main mediator of chest pain, by stimulating the A1 receptors located on the cardiac nerve endings. Myocardial ischaemia may be 'silent' if the duration is of insufficient length, the afferent cardiac nerves are damaged (as with diabetics) or there is inhibition of the pain at the spinal or supraspinal level.

Factors increasing myocardial oxygen demand often precipitate ischaemic episodes and are commonly associated with increased work rate (heart rate) and increased work load (force of contractility). Less commonly, myocardial ischaemia can also arise if oxygen demand is abnormally increased, as may occur in patients with thyrotoxicosis or severe ventricular hypertrophy due to hypertension. Myocardial oxygen supply is dependant on the luminal cross-sectional area of the coronary artery and coronary arteriolar tone. Atheromatous plaques decrease the lumen diameter and, when extensive, reduce the ability of the coronary artery to dilate in response to increased myocardial oxygen demand. Ischaemia may also occur when the oxygen-carrying capacity of blood is impaired, as in iron-deficiency anaemia, or when the circulatory volume is depleted.

CHD kills over 6.5 million people worldwide each year.

Epidemiology

Almost 200,000 people die from CVD in the UK each year with CHD accounting for almost a half of these. About 30% of premature deaths (below 75 years old) in men and 22% of premature deaths in women result from CVD.

The epidemiology of CHD has been studied extensively and risk factors for developing CHD are now well described. Absence of established risk factors does not guarantee freedom from CHD for any individual, and some individuals with several major risk factors seem perversely healthy. Nonetheless, there is evidence that in developed countries, education and publicity about the major risk factors have led to changes in social habits, particularly with respect to a reduction in smoking and fat consumption, and this has contributed to a decrease in the incidence of CHD.

The UK has seen a steady decline in deaths from CHD of about 4.5% per annum since the late 1970s. A recent study indicated that both reductions in major risk factors and improvements in treatment have contributed to this reduction (Unal et al., 2004). While impressive, this rate of decline has not been as great as in other countries like Australia and Finland. In Eastern European countries, the death rates from CHD have increased significantly during the same period.

The improvement in deaths from CHD has been chiefly among those with higher incomes; however, the less prosperous social classes continue to have almost unchanged levels of CHD. Better treatment has also contributed to a decrease

in cardiac mortality, although CHD still accounted for some 94,000 deaths in 2006 in the UK, including 70% of sudden natural deaths, 22% of male deaths and 16% of female deaths. In most developed countries, CHD is the leading cause of adult death but in the UK the poor outcome of lung cancer treatments makes cancer marginally the leading cause. In the UK, in comparison with Caucasians, people of South Asian descent have a 45–50% higher death rate from CHD, and Caribbeans and West Africans have a 35–50% lower rate.

Prevalence

About 3.5% of UK adults have symptomatic CHD. One-third of men aged 50–59 years of age have evidence of CHD, and this proportion increases with age. In the UK, there are about 1.3 million people who have survived a myocardial infarction and about 2 million who have, or have had, angina and this equates to about 5% of men and 3% of women. Approximately 260,000 people suffer a myocardial infarction in any year, of whom 40–50% die.

Mortality increases with age and is probably not due to a particular age-related factor but to the cumulative effect of risk factors that lead to atheroma and thrombosis and hence to CAD. In the USA, age-related death rates for CHD have fallen by 25% over a decade, but the total number of CHD deaths has fallen by only 10% because the population is ageing. Similarly, in the UK the death rates are falling but the numbers living with CHD are increasing.

Women appear less susceptible to CHD than men, although they seem to lose this protection after menopause, presumably because of hormonal changes. Race has not proved to be a clear risk factor since the prevalence of CHD seems to depend much more strongly on location and lifestyle than on ethnic origin or place of birth. It has been shown that lower social or economic class is associated with increased obesity, poor cholesterol indicators, higher blood pressure and higher C-reactive protein (CRP) measurements, an indicator of inflammatory activity.

Risk factors

Traditionally, the main potentially modifiable risk factors for CHD have been considered to be hypertension, cigarette smoking, raised serum cholesterol and diabetes. More recently psychological stress and abdominal obesity have gained increased prominence (Box 20.1). Patients with a combination of all these risk factors are at risk of suffering a myocardial infarction some 500 times greater than individuals without any of the risk factors. Stopping smoking, moderating alcohol intake, regular exercise and consumption of fresh fruit and vegetables were associated independently and additively with reduction in the risk of having a myocardial infarction.

Diabetes mellitus is a positive risk factor for CHD in developed countries with high levels of CHD, but it is not a risk factor in countries with little CHD. Insulin resistance, as defined by high fasting insulin concentrations, is an independent risk factor for CHD in men. In the UK, the mortality rates from CHD are up to five times higher for people with diabetes, while the risk of stroke is up to three times higher.

Box 20.1 Factors that increase or decrease the risk of developing CHD

Factors that increase the risk of CHD
Cigarette smoking
Raised serum cholesterol
Hypertension
Diabetes
Abdominal obesity
Increased personal stress

Factors that decrease the risk of CHD
Regular consumption of fresh fruit and vegetables
Regular exercise
Moderate alcohol consumption
Modification of factors that increase the risk of CHD

While unusual physical exertion is associated with an increased risk of infarction, an active lifestyle that includes regular, moderate exercise is beneficial, although the optimum level has not been determined and its beneficial effect appears to be readily overwhelmed by the presence of other risk factors. A family history of CHD is a positive risk factor, independent of diet and other risk factors. Hostility, anxiety or depression are associated with increased CHD and death, especially after myocardial infarction when mortality is doubled by anxiety and quadrupled by depression.

Epidemiological studies have shown associations between CHD and prior infections with several common micro-organisms, including *Chlamydia pneumoniae* and *Helicobacter pylori*, but a causal connection has not been shown. The influence of fetal and infant growth conditions, and their interaction with social conditions in childhood and adult life, has been debated strongly for decades but it is clear that lower socio-economic status and thinness in very early life are linked to higher incidences of CHD.

Aetiology

The vast majority of CHD occurs in patients with atherosclerosis of the coronary arteries (see Fig. 20.1) that starts before adulthood. The cause of spontaneous artherosclerosis is unclear, although it is thought that in the presence of hypercholesterolaemia, a non-denuding form of injury occurs to the endothelial lining of coronary arteries and other vessels. This injury is followed by subendothelial migration of monocytes and the accumulation of fatty streaks containing lipid-rich macrophages and T-cells. Almost all adults, and 50% of children aged 11–14 years, have fatty streaks in their coronary arteries. Thereafter, there is migration and proliferation of smooth muscle cells into the intima with further lipid deposition. The smooth muscle cells, together with fibroblasts, synthesise and secrete collagen, proteoglycans, elastin and glycoproteins that make up a fibrous cap surrounding cells and necrotic tissue, together called a plaque. The presence of atherosclerotic plaques results in narrowing of vessels and a reduction in blood flow and a decrease in the ability of the
Fig. 20.1 Main coronary arteries.

coronary vasculature to dilate and this may become manifest as angina. Associated with the plaque rupture is a loss of endothelium. This can serve as a stimulus for the formation of a thrombus and result in more acute manifestations of CHD, including unstable angina (UA) and myocardial infarction. Plaque rupture caused by physical stresses or plaque erosion may precipitate an acute reaction. Other pathological processes are probably involved, including endothelial dysfunction which alters the fibrin–fibrinolysis balance and the vasoconstriction–vasodilation balance. There is interest in the role of statins and angiotensin-converting enzyme (ACE) inhibitors in modifying endothelial function.

There is also great interest in the role of inflammation, especially in acute episodes. At postmortem, many plaques are found to contain inflammatory cells and inflammatory damage is found at the sites of plaque rupture.

Measurement of acute phase inflammatory reactions, such as fibrinogen and CRP, has a predictive association with coronary events. High-sensitivity CRP assays have been used in populations without acute illness to stratify individuals into high-, medium- and low-risk groups. In patients with other risk factors, however, CRP adds little prognostic information. CRP is produced by atheroma, in addition to the major producer which is the liver, and is an inflammatory agent as well as a marker of inflammation. Evidence is emerging that drug therapy which reduces CRP in otherwise healthy individuals reduces the incidence of major cardiac events (Ridker, 2008).

Oxidative stress which involves the uncontrolled production of reactive oxygen species (ROS) or a reduction in anti-oxidant species has been linked in the laboratory to several aspects of cardiovascular pathogenesis including endothelial malfunction, lipid metabolism, atheroma formation and plaque rupture, but the clinical importance is unclear. The use of antioxidants has been disappointingly unsuccessful but there is interest in peroxisome proliferator-activated receptor (PPAR) agonists that modify ROS production; some of these are already in use for treating diabetes and are associated with favourable changes in many metabolic markers for CVD. Other agents that reduce ROS production include statins and drugs that reduce angiotensin production.

Modification of risk factors

Common to all stages of CHD treatment is the need to reduce risk factors (Table 20.1). The patient needs to appreciate the value of the proposed strategy and to be committed to a plan for changing their lifestyle and habits, which may not be easy to achieve after years of smoking or eating a particular diet. Preventing CHD is important but neither instant nor spectacular. It may require many sessions of counseling over several years to initiate and maintain healthy habits. It may also involve persuasion of patients to continue taking medication

Table 20.1 Effect of interventions on risk of myocardial infarction

Intervention	Control	Benefit of intervention
Stopping smoking for ≥5 years	Current smokers	50–70% lower risk
Reducing serum cholesterol		2% lower risk for each 1% reduction in cholesterol
Treatment of hypertension		2–3% lower risk for each 1 mmHg decrease in diastolic pressure
Active lifestyle	Sedentary lifestyle	45% lower risk
Mild to moderate alcohol consumption (approx. 1 unit/day)	Total abstainers	25–45% lower risk
Low-dose aspirin	Non-users	33% lower risk in men
Postmenopausal oestrogen replacement	Non-users	44% lower risk

The quality of data associated with these interventions varies greatly and figures may not apply to all patient groups.

for asymptomatic disorders such as hypertension or hyperlipidaemia. The general public, with government as its agent, need to agree that a reduction in the incidence of CHD is worth some general changes in lifestyle or liberty, for example, such as prohibiting the freedom to smoke in public. National campaigns to encourage healthy eating or exercise are expensive, as is the long-term medical treatment of hypertension or hyperlipidaemia, and such strategies must have the backing of governments to succeed. It has been argued that community-wide campaigns on cholesterol reduction have had measurable benefits in Finland, the USA and elsewhere, at least in high-risk, well-educated and affluent groups. It follows that the next challenge is to extend that success to poorer, ethnically diverse groups and to those portions of the population with mild-to-moderate risk.

For every individual there is a need to act against the causative factors of CHD. Thus, attempts should be made to control hypertension, heart failure, arrhythmias, dyslipidaemia, obesity, diabetes mellitus, thyroid disease, anaemia and cardiac valve disorders. Apart from medication, these will require careful attention to diet and exercise and will necessitate smoking cessation. Cardiac rehabilitation classes and exercise programmes improve many risk factors including obesity, lipid indices, insulin resistance, psychological state and lifestyle. They also impact on morbidity and mortality.

Epidemiological studies have suggested that antioxidants and hormone replacement therapy may be of benefit in preventing and treating coronary disease. Unfortunately, randomised clinical trials of vitamin E or hormone replacement therapy suggest that these agents are not of benefit and may indeed result in higher rates of cardiovascular events.

Clinical syndromes

The primary clinical manifestation of CHD is chest pain. Chest pain arising from stable coronary atheromatous disease leads to stable angina and normally arises when narrowing of the coronary artery lumen exceeds 50% of the original luminal diameter. Stable angina is characterised by chest pain and breathlessness on exertion; symptoms are relieved promptly by rest.

A stable coronary atheromatous plaque may become unstable as a result of either plaque erosion or rupture. Exposure of the subendothelial lipid and collagen stimulates the formation of thrombus which causes sudden narrowing of the vessel. The spectrum of clinical outcomes that result are grouped together under the term acute coronary syndrome (ACS) and characterised by chest pain of increasing severity either on minimal exertion or, more commonly, at rest. These patients are at high risk of myocardial infarction and death and require prompt hospitalisation. Many aspects of the treatment of stable angina and ACS are similar but there is a much greater urgency and intensity in the management of ACS.

Stable angina

Stable angina is a clinical syndrome characterised by discomfort in the chest, jaw, shoulder, back, or arms, typically elicited by exertion or emotional stress and relieved by rest or nitroglycerin. Characteristically, the discomfort (it is often not described by the patient as a pain) occurs after a predictable level of exertion, classically when climbing hills or stairs, and resolves within a few minutes on resting. Unfortunately, the clinical manifestations of angina are very variable. Many patients mistake the discomfort for indigestion. Some patients, particularly diabetics and the elderly, may not experience pain at all but present with breathlessness or fatigue; this is termed silent ischaemia.

Further investigations are needed to confirm the diagnosis and assess the need for intervention. The resting electrocardiogram (ECG) is normal in more than half of patients with angina. However, an abnormal ECG substantially increases the probability of coronary disease; in particular, it may show signs of previous myocardial infarction. Non-invasive testing is helpful. Exercise testing is useful both in confirming the diagnosis and in giving a guide to prognosis. Alternatives such as myocardial scintigraphy (isotope scanning) and stress echocardiography (ultrasound) provide similar information.

Coronary angiography is regarded as the gold standard for the assessment of CAD and involves the passage of a catheter through the arterial circulation and the injection of radio-opaque contrast media into the coronary arteries. The X-ray images obtained permit confirmation of the diagnosis, aid assessment of prognosis and guide therapy, particularly with regard to suitability for angioplasty and coronary artery bypass grafting.

Non-invasive techniques, including magnetic resonance imaging (MRI) and multi-slice CT scanning, are being developed and tested as alternatives to angiography.

Treatment of stable angina is based on two principles:

- Improve prognosis by preventing myocardial infarction and death.
- Relieve or prevent symptoms.

Pharmacological therapy can be considered a viable alternative to invasive strategies, providing similar results without the complications associated with percutaneous coronary intervention (PCI). An algorithm for addressing both these principles is outlined in Fig. 20.2. In addition, diabetes, hypertension and dyslipidaemia in patients with stable angina should be well controlled. Smoking cessation, without or with pharmacological support, and weight loss should be attempted.

Antithrombotic drugs

One of the major complications arising from atheromatous plaque is thrombus formation. This causes an increase in plaque size and may result in myocardial infarction. Antiplatelet agents, in particular aspirin, are effective in preventing platelet activation and thus thrombus formation. Aspirin is of proven benefit in all forms of established CHD, although the risk–benefit ratio in people at risk of CHD is less clear.

Aspirin. Aspirin acts via irreversible inhibition of platelet COX-1 and thus thromboxane production, which is normally complete with chronic dosing of 75 mg/day. This antiplatelet action is apparent within an hour of taking a dose of 300 mg. The effect on platelets lasts for the lifetime of the platelet.

Stable angina for medical management

Immediate short-term relief

Short-acting subligual or buccal nitrate, pm

Aspirin 75–150 mg od → Contraindication (e.g. aspirin allergic) → Clopidogrel 75 mg od

Treatment aimed at improving prognosis

Statin
Titrate dose to reach target serum cholesterol → Intolerant or contraindication → Interchange statins or ezetimibe with lower dose statin or replace with alternative lipid-lowering agent

ACE inhibitor in proven CVD

β blocker post MI
β blocker no prior MI → Intolerant (e.g. fatigue) or contraindication

Symptoms not controlled after dose optimization

Calcium antagonist or long-acting nitrate or K-channel opener or I_f inhibitor

Treatment aimed at relief of symptoms

Add calcium antagonist or long-acting nitrate → Intolerant

Symptoms not controlled after dose optimization

Symptoms not controlled after dose optimization

Either substitute alternative subclass of calcium antagonist or long-acting nitrate

Combination of nitrate and calcium antagonist or K-channel opener

Consider suitability for revascularization ← Symptoms not controlled on two drugs after dose optimization

Fig. 20.2 Algorithm for the medical management of stable angina (Fox et al., 2006).

The optimal maintenance dose seems to be 75–150 mg day with lower doses having limited cardiac risk protection and higher doses increasing the risk of gastro-intestinal side effects. Dyspepsia is relatively common in patients taking aspirin and patients should be advised to take the medicine with or immediately after food. Enteric-coated preparations are no safer, and patients with ongoing symptoms of dyspepsia may require concomitant acid suppression with a proton pump inhibitor or switching to clopidogrel. Adverse reactions to aspirin include allergy, including bronchospasm. The benefits and risk of using aspirin in patients with asthma or a previous history of gastro-intestinal bleeding need to be carefully considered.

Clopidogrel. Clopidogrel inhibits ADP activation of platelets and is useful as an alternative to aspirin in patients who are allergic or cannot tolerate aspirin. Data from one major trial (CAPRIE Steering Committee, 1996) indicate that clopidogrel is at least as effective as aspirin in patients with stable coronary disease. The usual dose is 300 mg once, then 75 mg daily. Although less likely to cause gastric erosion and ulceration, gastro-intestinal bleeding is still a major complication of clopidogrel therapy. There is evidence that the combination of a proton pump inhibitor and aspirin is as effective as using clopidogrel alone in patients with a history of upper gastro-intestinal bleeding.

COX-2 inhibitors. The analgesic and anti-inflammatory action of non-steroidal anti-inflammatory drugs (NSAIDs) is believed to depend mainly on their inhibition of COX-2, and the unwanted gastro-intestinal effects of NSAIDs on their inhibition of COX-1. COX-2 inhibition reduces the production of prostacyclin, which has vasodilatory and platelet-inhibiting effects. Studies have raised concern about the cardiovascular safety of NSAIDs. Initially, the concern was focussed on the selective cyclo-oxygenase-2 inhibitors and a link to an increased cardiovascular risk. Recently, evidence has shown the more traditional non-selective NSAIDs increase

cardiovascular risk in both patients with established CVD and in the healthy population (Fosbol et al., 2010). NSAIDs with high COX-2 specificity increase the risk of myocardial infarction and should be avoided where possible in patients with stable angina.

ACE inhibitors

ACE inhibitors are established treatments for hypertension and heart failure, and have proven beneficial post myocardial infarction. In addition to the vasodilation caused by inhibiting the production of angiotensin II, ACE inhibitors have anti-inflammatory, antithrombotic and antiproliferative properties. Some of these effects are mediated by actions on vascular endothelium and might be expected to be of benefit in all patients with CAD. ACE inhibitors also reduce the production of ROS.

The use of ACE inhibitors in patients without myocardial infarction or left ventricular damage is based on two trials: the HOPE study (Yusuf et al., 2000) which studied ramipril and the EUROPA (2003) study which used perindopril. These trials also identified an incidental delay in the onset of diabetes mellitus in susceptible individuals which may be of long-term benefit to them. The HOPE study, a secondary prevention trial, investigated the effect of an ACE inhibitor on patients over 55 years old who had known atherosclerotic disease or diabetes plus one other cardiovascular risk factor. The use of ramipril decreased the combined endpoint of stroke, myocardial infarction or cardiovascular death by approximately 22%. The benefits were independent of blood pressure reduction. This has major implications for the management of CHD patients, both for the decision to treat all and the choice of treatment. At present the use of ACE inhibitors in patients with coronary disease, but without myocardial infarction, has general acceptance and is recommended in European guidelines.

Statins

Studies have repeatedly demonstrated the benefit of reducing cholesterol, especially low-density lipoprotein-cholesterol (LDL-C), in patients with CHD.

Earlier studies focused on patients with 'elevated' cholesterol, but all patients with coronary risk factors benefit from reduction of their serum cholesterol level. It is now clear that there is no 'safe' level of cholesterol for patients with CAD and that there is a continuum of risk down to very low cholesterol levels. Levels of LDL-C of <2 mmol/L and total cholesterol <4 mmol/L are recommended for patients with established CVD (NICE, 2008). Statins should be prescribed alongside lifestyle advice for both primary prevention of CVD and in those with established CVD (see Chapter 24 for more detail).

In addition to cholesterol-lowering properties, statins also have antithrombotic, anti-inflammatory and antiproliferative properties. They are also important in restoring normal endothelial function and inhibit the production of ROS in the vessel wall. There is some evidence that patients with elevated levels of CRP have better outcomes with statin therapy even if cholesterol levels are not raised. Most patients with stable angina will be on statins for their cholesterol-lowering effects. It is important, however, to recognise that these drugs may have beneficial effects independent of cholesterol lowering and this makes them valuable even in patients with 'normal' cholesterol levels.

Symptom relief and prevention

In stable angina, much of the drug treatment is directed towards decreasing the workload of the heart and, to a lesser extent, improving coronary blood supply; this provides symptomatic relief and improves prognosis. Therapy to decrease workload is targeted at both decreasing afterload and controlling heart rate. Recent evidence suggests a prognostic benefit when the resting heart rate is controlled below 70 beats/min. Drug treatment is initiated in a stepwise fashion according to symptom relief and side effects. A number of patients will require a number of anti-anginal medicine to control their angina symptoms.

β-Blockers

Various studies have demonstrated the beneficial effect of β-blockers in angina and they are now considered first-line agents. β-Blockers reduce mortality both in patients who have suffered a previous myocardial infarction and in those with heart failure. They reduce myocardial oxygen demand by blocking β-adrenergic receptors, thereby decreasing the heart rate and force of left ventricular contraction and lowering blood pressure. The decreased heart rate not only reduces the energy demand on the heart but also permits better perfusion of the subendocardium by the coronary circulation. β-Blockers may also reduce energy-demanding supraventricular or atrial arrhythmias and counteract the cardiac effects of hyperthyroidism or phaeochromocytoma.

β-Blockers are particularly useful in exertional angina. Patients treated optimally should have a resting heart rate of around 60 beats/min. Although many patients may dislike the side effects of β-blockers, they should be urged to continue wherever reasonable. β-Blockers should be used with caution in patients with diabetes as the production of insulin is under adrenergic system control and thus their concomitant use may worsen glucose control. β-Blockers can also mask the symptoms of hypoglycaemia and patients in whom the combination is considered of value should be warned of this; however, most clinicians now believe that the benefits of taking β-blockers, even in diabetics, outweigh the risks and they are frequently prescribed.

While β-blockers are widely used, their tendency to cause bronchospasm and peripheral vascular spasm means that they are contraindicated in patients with asthma, and used with caution in chronic obstructive airways diseases and peripheral vascular disease as well as in acute heart failure and bradycardia.

Cardioselective agents such as atenolol, bisoprolol and metoprolol are preferred because of their reduced tendency to cause

bronchoconstriction, but no β-blocker is completely specific for the heart. Agents with low lipophilicity, for example, atenolol, penetrate the central nervous system (CNS) to a lesser extent than others, for example, propranolol, metoprolol, and do not so readily cause the nightmares, hallucinations and depression that are sometimes found with lipophilic agents, which should not be used in patients with psychiatric disorders. CNS-mediated fatigue or lethargy is found in some patients with all β-blockers, although it must be distinguished from that of myocardial suppression. β-Blockers should not be stopped abruptly for fear of precipitating angina through rebound receptor hypersensitivity. They are contraindicated in the rare Prinzmetal's angina where coronary spasm is a major factor.

All β-blockers tend to reduce renal blood flow, but this is only important in renal impairment. Drugs eliminated by the kidney (Table 20.2) may need to be given at lower doses in the renally impaired or in the elderly, who are particularly susceptible to the CNS-mediated lassitude. Drugs eliminated by the liver have a number of theoretical interactions with other agents that affect liver blood flow or metabolic rate, but these are rarely of clinical significance since the dose should be titrated to the effect. Likewise, although there is theoretical support for the use of agents with high intrinsic sympathomimetic activity (ISA) to reduce the incidence or severity of drug-induced heart failure, there is no β-blocker that is free from this problem, and clinical trials of drugs with ISA have generally failed to show any extra benefit.

Calcium channel blockers

Calcium channel blockers (CCBs) act on a variety of smooth muscle and cardiac tissues and there are a large number of agents which have differing specificities for different body tissues.

Table 20.2 Properties and pharmacokinetics of β-blockers

	Blockade	Lipophilicity	ISA	Oral absorption	Elimination
Acebutolol	β_1 (some β_2)	+	+	90%[a]	Active metabolite ($t_{1/2}$ 11–13 h, renal)
					Gut 50%, $t_{1/2}$ 3–4 h
Atenolol	β_1	–	–	50%	Renal $t_{1/2}$ 5–7 h
Betaxolol	β_1	+	–	100%	Hepatic + renal $t_{1/2}$ 15 h
Bisoprolol	β_1	+	–	90%	Hepatic + renal $t_{1/2}$ 10–12 h
Carteolol	$\beta_1\beta_2$	–	++	80%	Hepatic + renal $t_{1/2}$ 3–7 h
Carvedilol	$\beta_1\beta_2\alpha_1$	+	–	80%[a]	Hepatic + renal $t_{1/2}$ 4–8 h
Celiprolol	$\beta_1\alpha_2$	–	β_2+	30–70%	Renal + gut $t_{1/2}$ 5–6 h
Esmolol	β_1	–	–	i.v.	Blood enzymes $t_{1/2}$ 9 min
Labetalol	$\beta_1\beta_2\alpha_1$	–	–	100%[a]	Hepatic $t_{1/2}$ 6–8 h
Metoprolol	β_1	+	–	95%[a]	Hepatic $t_{1/2}$ 3–4 h
Nadolol	$\beta_1\beta_2$	–	–	30%	Renal $t_{1/2}$ 16–18 h
Nebivolol	β_1	+	–	12–96%[b]	Hepatic $t_{1/2}$ 8–27 h[b]
Oxprenolol	$\beta_1\beta_2$	+	++	90%[a]	Hepatic + $t_{1/2}$ 1–2 h
Pindolol	$\beta_1\beta_2$	+	+++	90%	Hepatic + renal $t_{1/2}$ 3–4 h
Propranolol	$\beta_1\beta_2$	+	–	90%[a]	Hepatic $t_{1/2}$ 3–6 h
Sotalol	$\beta_1\beta_2$	–	–	70%	Renal $t_{1/2}$ 15–17 h
Timolol	$\beta_1\beta_2$	+	–	90%[a]	Hepatic + renal $t_{1/2}$ 3–4 h

All figures are approximate and subject to interpatient variability. Therapeutic ranges are not well defined.
ISA, intrinsic sympathomimetic activity; $t_{1/2}$, elimination half-life.
[a]Extensive first-pass metabolism may result in a significant decrease in bioavailability.
[b]Genetically determined groups of slow and fast metabolisers have been identified.

While short-acting dihydropyridine CCBs have been implicated in the exacerbation of angina due to the phenomenon of 'coronary steal', longer acting dihydropyridines, for example, amlodipine and felodipine or longer acting formulations, for example, nifedipine LA, have demonstrated symptom-relieving potential similar to β-blockers. Dihydropyridines have no effect on the conducting tissues and are effective arterial dilators, decreasing afterload and improving coronary perfusion but also causing flushing, headaches and reflex tachycardia. This may be overcome by combination with a β-blocker. The use of dihydropyridines in angina is based on efficacy in trials that have used surrogate markers such as exercise tolerance rather than mortality as the endpoint.

CCBs with myocardial rate control as well as vasodilatory properties, for example, diltiazem, and those with predominantly rate-controlling effects, for example, verapamil, have also been shown to improve symptom control, reduce the frequency of anginal attacks and increase exercise tolerance. They should be avoided in patients with compromised left ventricular function and conduction abnormalities. Verapamil and diltiazem are suitable for rate control patients in whom β-blockers are contraindicated on grounds of respiratory or peripheral vascular disease. They should be used with caution in patients already receiving β-blockers, as bradycardia and heart block have been reported with this combination.

CCBs have a particular role in the management of Prinzmetal's (variant) angina which is thought to be due to coronary artery spasm.

Nitrates

Organic nitrates are valuable in angina because they dilate veins and thereby decrease preload, dilate arteries to a lesser extent thereby decreasing afterload, and promote flow in collateral coronary vessels, diverting blood from the epicardium to the endocardium. They are available in many forms but all relax vascular smooth muscle by releasing nitric oxide, which was formerly known as endothelium-derived relaxing factor, which acts via cyclic GMP. The production of nitric oxide from nitrates is probably mediated by intracellular thiols, and it has been observed that when tolerance to the action of nitrates occurs, a thiol donor (such as *N*-acetylcysteine) may partially restore the effectiveness of the nitrate. Antioxidants such as vitamin C have also been used. While clinical trials have not established any mortality gain from the use of oral nitrate preparations, their role in providing symptom relief is well established.

Tolerance is one of the main limitations to the use of nitrates. This develops rapidly, and a 'nitrate-free' period of a few hours in each 24-h period is beneficial in maintaining the effectiveness of treatment. The nitrate-free period should coincide with the period of lowest risk, and this is usually night time, but not early morning, which is a high-risk period for infarction. Many patients receiving short-acting nitrates two or three times a day would do well to have their doses between 7 a.m. and 6 p.m. (say, 8 a.m. and 2 p.m. for isosorbide mononitrate), but this is generally not practised in UA where there is no low-risk period and where continuous dosing is used, with increasing doses if tolerance develops.

There are many nitrate preparations available, including intravenous infusions, conventional or slow-release tablets and capsules, transdermal patches, sublingual tablets and sprays and adhesive buccal tablets. Slow-release preparations and transdermal patches are expensive, do not generally offer such flexible dosing regimens as short-acting tablets. Sustained release tablets do not release the drug over the whole 24-h period producing a 'nitrate free period', whereas patches need to be removed for a few hours each day. Buccal tablets are expensive and offer no real therapeutic advantage in regular therapy. Like sublingual sprays and tablets, however, they have a rapid onset of action and the drug bypasses the liver, which has an extensive first-pass metabolic effect on oral nitrates. The sublingual preparations, whether sprays or suckable or chewable tablets, are used for the prevention or relief of acute attacks of pain but may elicit the two principal side effects of nitrates: hypotension with dizziness and fainting, and a throbbing headache. To minimise these effects, patients should be advised to sit down, rather than lie or stand, when taking short-acting nitrates, and to spit out or swallow the tablet once the angina is relieved. Sublingual glyceryl trinitrate (GTN) tablets have a very short shelf-life on exposure to air, need to be stored carefully and replaced frequently. As a consequence they are now little used. All nitrates may induce tachycardia.

Three main nitrates are used: GTN (mainly for sublingual, buccal, transdermal and intravenous routes), isosorbide dinitrate and isosorbide mononitrate. All are effective if given in appropriate doses at suitable dose intervals (Table 20.3). Since isosorbide dinitrate is metabolised to the mononitrate, there is a preference for using the more predictable mononitrate, but this is not a significant clinical factor. A more relevant feature may be that whereas the dinitrate is usually given three or four times a day, the mononitrate is given once or twice a day. Slow-release preparations exist for both drugs.

Nicorandil

Nicorandil is a compound that exhibits the properties of a nitrate but which also activates ATP-dependent potassium channels. The IONA Study Group (2002) compared nicorandil with placebo as 'add-on' treatment in 5126 high-risk patients with stable angina. The main benefit for patients in the nicorandil group was a reduction in unplanned admission to hospital with chest pain. The study did not tell us when to add nicorandil to combinations of antianginals such as β-blockers, CCBs and long-acting nitrates. There is a theoretical benefit from these agents in their action to promote ischaemic preconditioning. This phenomenon is seen when myocardial tissue is exposed to a period of ischaemia prior to sustained coronary artery occlusion. Prior exposure to ischaemia renders the myocardial tissue more resistant to permanent damage. This mechanism is mimicked by the action of nicorandil.

Table 20.3 Properties of commonly used nitrates

Drug	Speed of onset	Duration of action	Notes
Glyceryl trinitrate (GTN)			
Intravenous	Immediate	Duration of infusion	
Transdermal	30 min	Designed to release drug steadily for 24 h	Tolerance develops if applied continuously
SR tablets and capsules	Slow	8–12 h	
Sublingual tablets	Rapid (1–4 min)	<30 min	Inactivated if swallowed
			Less effective if dry mouth
Spray	Rapid (1–4 min)	<30 min	
Buccal tablets	Rapid (1–4 min)	4–8 h	Nearly as rapid in onset as sublingual tablets
Isosorbide dinitrate			
SR tablets	Similar to GTN		
Intravenous	Similar to GTN		
Sublingual	Slightly slower than GTN	As for GTN	
Chewable tablets	2–5 min	2–4 h	Less prone to cause headaches than sublingual tablets
Oral tablets	30–40 min	4–8 h	
Isosorbide mononitrate			
Oral tablets	30–40 min	6–12 h	
SR tablets or capsules	Slow	12–24 h	Some brands claim a nitrate-free period if given once daily

SR, sustained-release.

Ivabradine

Ivabridine represents a class of antianginal agents which block the I_f current. I_f is a mixed Na^+–K^+ inward current activated by hyperpolarisation and modulated by the autonomic nervous system. This regulates pacemaker activity in the sinoatrial node and controls heart rate. Inhibition, therefore, reduces heart rate without affecting the force of contraction. Ivabridine is similar in efficacy to atenolol and CCBs and may be of particular use in patients in whom β-blockers are contraindicated. The most frequent adverse drug reactions are dose-dependent transient visual symptoms that manifest as transient enhanced brightness commonly associated with abrupt changes in light intensity. They may be related to the action of ivabradine at hyperpolarisation-activated, cyclic nucleotide-gated cation current channels present in the retina. Visual symptoms may resolve spontaneously during therapy or after drug discontinuation.

Ranolazine

Ranolazine, a selective inhibitor of late sodium influx, attenuates the abnormalities of ventricular repolarisation and contractility associated with ischaemia. It has been shown to increase exercise tolerance, reduce anginal episodes and reduce the use of GTN. Side effects include dizziness, constipation, nausea, and the potential for prolongation of the QTc interval. Ranolazine seems to be a safe addition to current traditional drugs for chronic stable angina, especially in aggressive multidrug regimens.

Acute coronary syndrome

Definition and cause

The group of conditions referred to as ACS often present with similar symptoms of chest pain which is not, or only partially, relieved by GTN. These conditions include acute myocardial infarction (AMI), UA and non-ST-elevation myocardial infarction (NSTEMI). AMI with persistent ST segment elevation on the ECG usually develops Q waves, indicating transmural infarction. UA and NSTEMI present without persistent ST segment elevation and are managed differently, although a similar early diagnostic and therapeutic approach is employed. All patients with ACS should be admitted to hospital for evaluation, risk stratification and treatment. The spectrum of ACS is described in Fig. 20.3.

ACS arises from the rupture of an unstable atheromatous plaque. This exposes the cholesterol-rich plaque in the intima to the blood, initiating platelet activation and eventual thrombus formation. The volume of the eventual thrombus and the time the vessel is occluded determine the degree of myocardial necrosis that occurs. The major difference in approach to these patients arises from whether the coronary artery involved is felt to be occluded or open.

Patients with an occluded coronary artery suffer myocardial damage, the extent of which is determined by the duration and site of the occlusion. The primary strategy for these patients is the restoration of coronary flow with either a fibrinolystic agent or primary angioplasty. If the coronary artery is patent, however, then fibrinolysis is unnecessary and probably harmful, although

Admission	**Chest pain**		
Working diagnosis	Suspicion of acute coronary syndrome		
ECG	Persistent ST elevation	ST/T abnormalities	Normal or undetermined ECG
Biochemistry		Troponin positive	Troponin 2 x negative
Risk stratification		High risk	Low risk
Diagnosis	STEMI	NSTEMI	Unstable angina
Treatment	Reperfusion	Invasive	Non-invasive

STEMI = ST elevation myocardial infarction
NSTEMI = non ST elevation myocardial infarction

Fig. 20.3 The spectrum of acute coronary syndrome (Thygesen et al., 2007).

angioplasty may still be appropriate. When the vessel is open, for both groups, patient management focuses on the unstable coronary plaque and is, therefore, fundamentally similar.

Troponins (troponin I or troponin T) are cardiac muscle proteins which are released following myocardial cell damage and are highly sensitive and specific for myocardial infarction. They are useful in diagnosing patients with ACS and for predicting response to drug therapy; they are now key to the management of these patients and have replaced cardiac enzymes such as creatinine kinase (CK), aspartate transaminase (AST) and lactate dehydrogenase (LDH).

Diagnostic criteria for AMI have changed to incorporate the increasing availability of new diagnostic techniques with traditional symptoms and ECG changes. The following criteria for AMI, agreed by the European Society of Cardiology, rely on the rise of cardiac biomarkers (preferably troponin) with at least one value above the 99th percentile of the upper reference limit (URL) together with evidence of myocardial ischaemia with at least one of the following symptoms of ischaemia:

- ECG changes indicative of new ischaemia: new ST changes (STEMI or new left bundle branch block (LBBB))
- Development of pathological Q waves in the ECG
- Image evidence of new loss of viable myocardium or new regional wall motion abnormality.

Mortality rates of patients with presumed myocardial infarction or ACS in the first month is approximately 50% and of these deaths about half occur within the first 2 h. The

prognosis of an individual who has suffered a STEMI and receives hospital treatment has improved following the widespread use of thrombolytic therapy and primary percutaneous intervention

The most dangerous time after a myocardial infarction is the first few hours when ventricular fibrillation (VF) is most likely to occur.

Patients without persistent ST elevation on the ECG may still have experienced myocardial damage due to temporary occlusion of the vessel or emboli from the plaque-related thrombus blocking smaller distal vessels and will have raised levels of troponin. These patients have had a NSTEMI. Patients without ST elevation and without a rise in troponin or cardiac enzymes are defined as having UA. The long-term prognosis in NSTEMI is similar to that of STEMI. The early adverse event rate is lower but these patients are more likely to suffer death, recurrent myocardial infarction or recurrent ischaemia after hospital discharge than patients with STEMI. More emphasis is now placed on improving the treatment of patients with NSTEMI than was previously the case.

The Global Registry of Acute Coronary Events (GRACE; available at http://www.outcomes-umassmed.org/GRACE/) is an international registry which has enrolled patients with ACS (UA, NSTEMI and STEMI) since 1999. The registry indicates a similar incidence of UA, NSTEMI and STEMI.

The classification of ACS based on ECG findings and measurement of troponin is shown in Fig. 20.4.

Treatment of ST elevation myocardial infarction

Treatment of STEMI may be divided into three categories:

- provide immediate care to alleviate pain, prevent deterioration and improve cardiac function;
- manage complications, notably heart failure and arrhythmias;
- prevent further infarction or death (secondary prophylaxis).

The management of heart failure and arrhythmias are covered more extensively in Chapters 21 and 22, respectively, and will not be discussed here. The remaining therapeutic aims are to relieve pain, return patency to the coronary arteries, minimise infarct size, provide prophylaxis to arrhythmias and institute secondary prevention.

Immediate care to alleviate pain, prevent deterioration and improve cardiac function

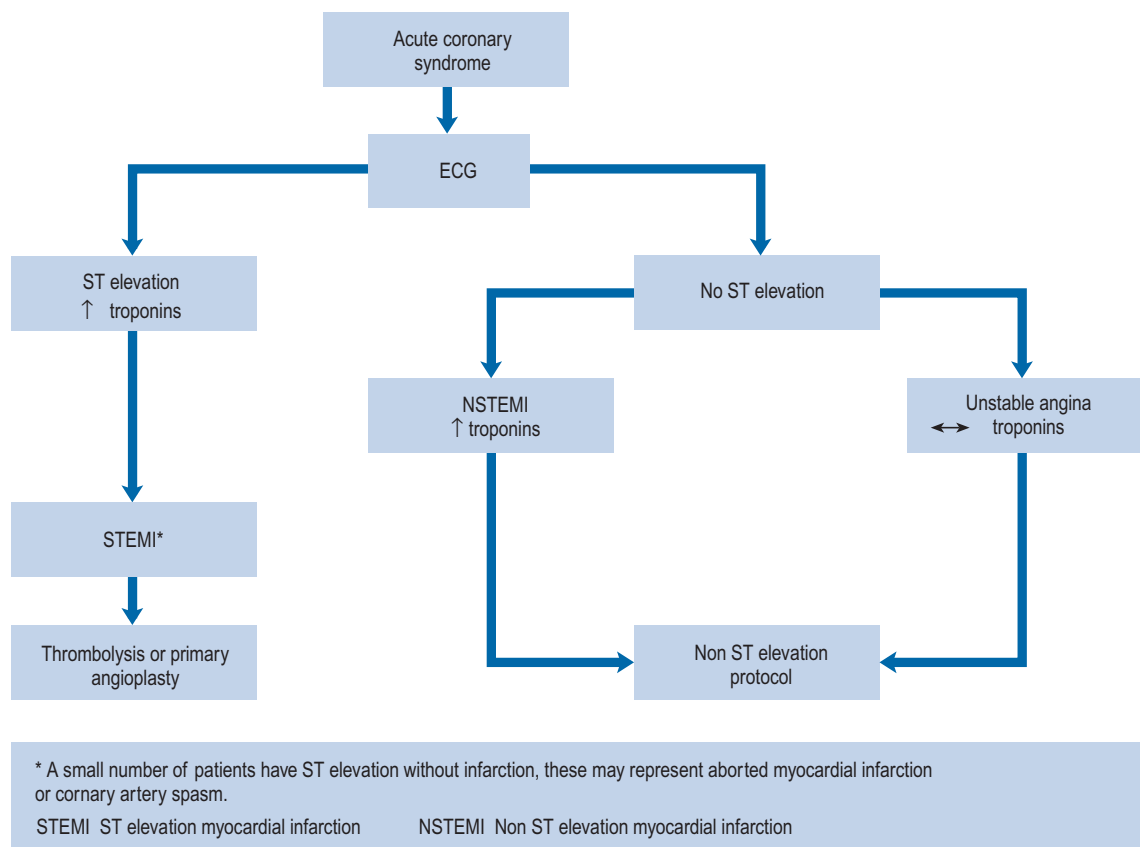
Pain relief. Patients with suspected STEMI should receive sublingual GTN under the tongue, oxygen administered and intravenous access established immediately. If sublingual GTN fails to relieve the chest pain, intravenous morphine may be administered together with an antiemetic such as prochlorperazine or metoclopramide. There is no benefit in leaving a patient in pain while the diagnosis is considered. Pain is associated with sympathetic activation, which causes vasoconstriction, increases the workload of the heart and can exacerbate the underlying condition.


Fig. 20.4 Classification of ACS based on ECG and measurement of troponins.

Antiplatelet therapy. An aspirin tablet chewed as soon as possible after the infarct and followed by a daily dose for at least 1 month has been shown to reduce mortality and morbidity. Follow-up studies have demonstrated additional benefit in continuing to take daily aspirin, probably for life. The reduction in mortality is additional to that obtained from thrombolytic therapy (Table 20.4). Clopidogrel, given in addition to aspirin, can further improve coronary artery blood flow but the additional absolute reduction in mortality is small, at approximately 0.4% (Sabatine et al., 2005). In suspected heart attack patients in the UK, both aspirin and clopidogrel may be administered by the ambulance crew.

Restoring coronary flow and myocardial tissue perfusion

In patients with STEMI, early restoration of coronary artery patency results in an improved outcome; this may occur spontaneously in some patients but frequently only after substantial myocardial damage has occurred. Clinical trial data indicate that hospital mortality at 1 month has been reduced from 16% to 4–6% with the widespread use of coronary interventions, fibrinolytic agents and secondary prevention. In practice, available data suggest a higher mortality than that recorded in clinical trials.

The timing of treatment is vital, since myocardial damage after onset of an acute ischaemic episode is progressive and there are pathological data to suggest it is irreversible beyond 6 h. Clinical data from large studies of fibrinolysis have shown that the sooner treatment is started after the onset of pain, the better. All trials show that rapid treatment is important and this has a greater effect than the choice of drug; several studies indicate that giving fibrinolytics an average of 30–60 min earlier can save 15 lives per 1000 treated. Hospitals need to maintain fast-track systems to ensure maximum benefit, although there is still some worthwhile benefit up to 12 h after infarction.

Treatment within 1 h has been found to be particularly advantageous, although difficult to achieve, for logistical reasons, in anyone who has an infarct outside hospital. Prioritisation of ambulances to emergency calls for chest pain and appropriately equipped paramedics or primary care doctors administering fibrinolytics out of hospital have all helped reduce delay in fibrinolysis administration. Increased numbers of and direct access to hospitals offering primary angioplasty sites has further reduced the time to myocardial tissue reperfusion. Current reperfusion strategies are outlined in Fig. 20.5.

Table 20.4 Vascular deaths at 35 days in the ISIS-2 study (1990)

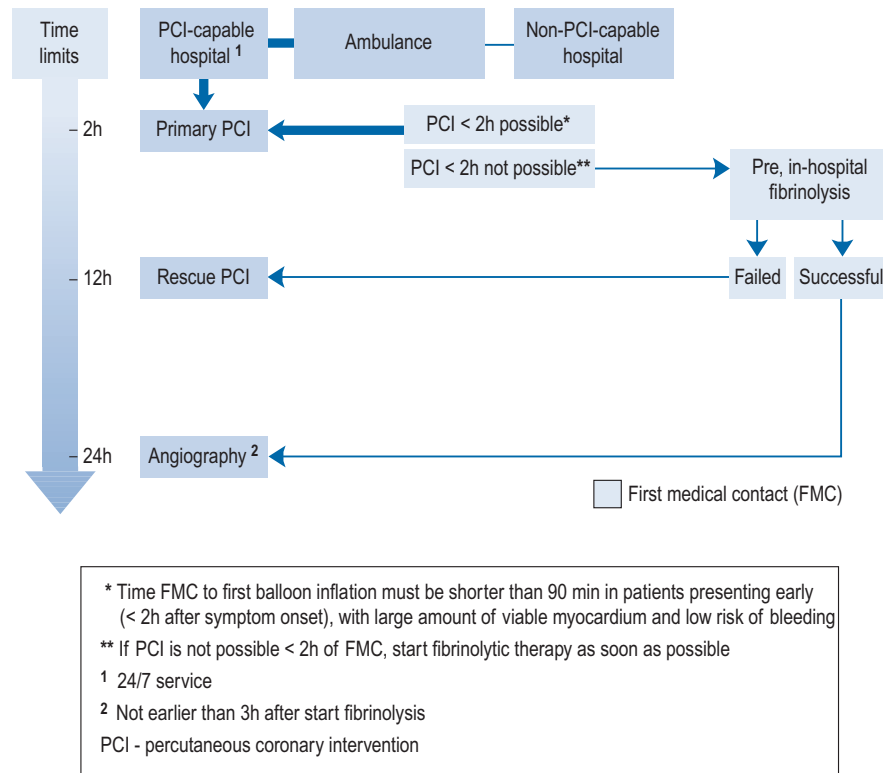
Placebo	13.2%
Aspirin	10.7%
Streptokinase	10.4%
Aspirin + streptokinase	8.0%


Fig. 20.5 Reperfusion strategies. The thick arrow (dark blue) indicate the preferred strategy (Van de Werf, 2008).

Fibrinolytics. Fibrinolytic agents (Table 20.5) have transformed the management of these patients by substantially improving coronary artery patency rates which has translated into a 25% relative reduction in mortality. The risk of haemorrhagic stroke (around 1%) and a failure to adequately reperfuse the affected myocardium in approximately 50% of cases have remained despite advances in fibrinolytics.

Percutaneous coronary intervention. The introduction of primary PCI (angioplasty and/or stent insertion without prior or concomitant fibrinolytic therapy) has demonstrated superiority to fibrinolysis when it can be performed expeditiously by an experienced team in a hospital with an established 24 h a day interventional programme. In this context, primary angioplasty is better than fibrinolysis at reducing the overall short-term death, non-fatal reinfarction and stroke. The target for time from first medical contact to first balloon inflation should be less than 2 h. If the delay to angioplasty is likely to be longer than 2 h, facilitated PCI can be undertaken.

Facilitated PCI involves use of a fibrinolytic to achieve reperfusion prior to a planned PCI. This approach allows the clinical team to bridge an anticipated delay in undertaking a PCI.

Rescue PCI is performed on coronary arteries which remain occluded despite attempts at fibrinolysis. It has better outcomes than repeated fibrinolytic therapy or conservative management.

PCIs encompass various invasive procedures to improve myocardial blood delivery by opening up the blood vessels. PCIs open stenosed coronary vessels and are less invasive than coronary bypass surgery, where the coronary vessels are replaced.

A percutaneous (through the skin) transluminal (through the lumen of the blood vessels) coronary (into the heart) angioplasty (surgery or repair of the blood vessels) (PTCA) was first carried out on a conscious patient in 1977. Now over 2 million people a year undergo PCIs. The procedure is less invasive than coronary artery bypass graft (CABG) surgery.

PCI involves the passing of a catheter via the femoral or radial artery and aorta into the coronary vasculature under

Table 20.5 Fibrinolytic agents (thrombolytics)

	Fibrin specificity	Elimination	Half-life (min)	Dosing	Antigenic	Mode of action
Streptokinase		Hepatic	18–23	1 h infusion	Yes	Activator complex
Alteplase	++	Hepatic	3–8	Bolus + 90 min infusion	No	Direct
Reteplase	+	Renal	15–18	Two boluses	No	Direct
Tenecteplase	+++	Hepatic	20–28	One bolus	No	Direct

radio-contrast guidance. Inflation of a balloon at the end of the catheter in the area of the atheromatous plaques opens the lumen of the artery. For patients undergoing PCI there is a small risk of death, myocardial infarction and long-term restenosis. This is reduced by insertion of a coronary artery stent and the use of pre- and peri-procedural antiplatelet therapy. Over the last 10 years the proportion of patients undergoing PCI and stent insertion has accounted for >95% of all PCI procedures.

Antiplatelet and anticoagulant therapy. After stent insertion there is a short-term risk of thrombus formation until the endothelial lining of the blood vessel has been re-established. The combination of clopidogrel (600 mg initiated pre-procedure and 75 mg daily thereafter) and aspirin has been shown to reduce the risk of myocardial infarction and need for reperfusion therapy and decrease the length of hospital stay.

Patients undergoing primary PCI should receive aspirin and clopidogrel as early as possible. Antiplatelet naïve patients should receive 300 mg of aspirin and 600 mg of clopidogrel. In the UK and elsewhere in Europe, these are administered by paramedics. Prasugrel has less metabolic activation steps and has a faster and more reliable onset of antiplatelet action. In combination with aspirin, it is recommended (NICE, 2009) for preventing atherothrombotic events in individuals undergoing PCI only when:

- immediate primary PCI for STEMI is necessary;
- stent thrombosis has occurred during clopidogrel treatment; and
- the individual has diabetes mellitus.

Heparin is routinely administered during the PCI procedure and is titrated to maintain an activated clotting time (ACT) of 250–350 s. Glycoprotein IIb/IIIa receptor antagonists, particularly abciximab, have been shown to reduce mortality if used during the procedure. These are used in combination with heparin, and a lower ACT (200–250 s) is targeted to reduce bleeding complications. Bivalirudin, a direct thrombin inhibitor, has demonstrated less bleeding compared to abciximab and may be useful in those at risk of increased bleeding.

Much of the evidence for the use of glycoprotein IIb/IIIa receptor antagonists was accumulated before high-dose clopidogrel or more potent antiplatelets were in routine practice. Current recommendations are that in the setting of dual-antiplatelet therapy with unfractionated heparin or bivalirudin as the anticoagulant, glycoprotein IIb/IIIa receptor antagonists can be useful at the time of primary PCI but cannot be recommended as routine therapy.

Intracoronary administration of vasodilators such as adenosine, verapamil, nicorandil, papaverine, and nitroprusside during and after primary PCI has been shown to improve flow in the infarct-related coronary artery and myocardial perfusion, and/or to reduce infarct size, but large prospective randomised trials with hard clinical outcomes are missing.

Fibrinolytics. Fibrinolytic agents fall into two categories: fibrin specific (alteplase, tenecteplase and reteplase) and fibrin non-specific (streptokinase). There are theoretical advantages for the fibrin-specific agents which are superior in terms of achieving coronary artery patency in angiographic studies. Angiographic patency has been shown to correlate well with outcome in thrombolytic trials but it has been difficult to prove that this benefit translates into an improvement in mortality. Studies have demonstrated considerable benefit from fibrinolytics given soon after the onset of pain but little difference between streptokinase and the more expensive tissue plasminogen activator (alteplase) in reducing mortality. Fast injection of fibrin-specific agents is better than slower infusion of streptokinase, especially in younger patients with anterior infarcts. Tenecteplase and reteplase have the advantage that they can be administered by bolus injection, which facilitates pre-hospital administration and reduces errors.

Patients receiving alteplase also receive a 5000 unit heparin bolus followed by a 48-h infusion adjusted to maintain the activated partial thromboplastin time (APTT) in the therapeutic range. Intravenous enoxaparin followed by subcutaneous injections may be an alternative. Heparin has not been compared to placebo in trials of tenecteplase or reteplase but it is standard practice to use heparin with these agents. Heparin has no advantage in addition to streptokinase, which has a longer lasting and less specific fibrinolytic action.

A low dose of fondaparinux, a synthetic, indirect anti-Xa agent, has been found to be superior to placebo or heparin in preventing death and reinfarction in patients who received fibrinolytic therapy (OASIS-6 Trial Group, 2006).

Bivalirudin, a direct thrombin inhibitor, reduces reinfarction rates compared to heparin when given with streptokinase but has not been studied with fibrin-specific agents. This combination resulted in a non-significant increase in non-cerebral bleeding complications (HERO-2 Trial Investigators, 2001).

Trials using various dosing combinations of glycoprotein IIb/IIIa inhibitors with newer fibrinolytic agents have not found a regimen that increases overall survival (Menon et al., 2004).

All fibrinolytics cause haemorrhage, which may present as a stroke or a gastro-intestinal bleed, and there is an increased risk with regimens that use intravenous heparin. Recent strokes, bleeds, pregnancy and surgery are contraindications to fibrinolysis. Streptokinase induces cross-reacting antibodies which reduce its potency and may cause an anaphylactoid response. Patients with exposure to streptokinase, or with a history of rheumatic fever or recent streptococcal infection, should not receive the drug. The use of hydrocortisone to reduce allergic responses has fallen out of favour, but patients should be carefully observed for hypotension during the administration of streptokinase.

Old age is no longer considered to be a contraindication to fibrinolysis. Although the risks are greater, the benefit is also greater, but the doses of alteplase and tenecteplase need to be adjusted for body weight.

All the major trials have used specific ECG criteria for entry, usually ST elevation in adjacent leads or LBBB, and eliminated patients with major contraindications to fibrinolysis (Box 20.2). Confusion often arises about the term 'relative contraindication'. For example, systolic hypertension is common in AMI, so most protocols recommend lowering the blood pressure with either a β-blocker or intravenous nitrates before commencing fibrinolysis. An increasing number of

Box 20.2 Contraindications to fibrinolysis (Van de Werf, 2008)

Absolute contraindications
- Haemorrhagic stroke of unknown origin at any time
- Ischaemic stroke in preceding 6 months
- CNS damage or neoplasms
- Recent major trauma/surgery/head injury (within preceding 3 weeks)
- Gastro-intestinal bleed within the last month
- Known bleeding disorder
- Non-compressible punctures
- Aortic dissection

Relative contraindications
- Transient ischaemic attack in preceding 6 months
- Oral anticoagulant therapy
- Pregnancy or within 1 week postpartum
- Advanced liver disease
- Active peptic ulcer
- Infective endocarditis
- Traumatic resuscitation
- Refractory hypertension (systolic blood pressure >180 mmHg)

patients are on warfarin and this again is regarded as a relative contraindication to fibrinolysis; thresholds for the use of fibrinolysis in patients on warfarin vary from an INR of 2–2.4. The use of fibrinolytic therapy in patients with relative contraindications should take into account the site of the myocardial infarction and the likely size of the infarction. For example, in patients with a large anterior myocardial infarction the benefits of fibrinolysis may outweigh risk. In patients where there is a serious concern regarding bleeding following fibrinolysis, primary angioplasty should be considered.

Management of complications

Heart failure. Heart failure during the acute phase of STEMI is associated with a poor short- and long-term prognosis. It should be managed with oxygen, intravenous furosemide and nitrates. More severe failure or cardiogenic shock (tissue hypoperfusion resulting from cardiac failure with symptoms of hypotension, peripheral vasoconstriction and diminished pulses, decreased urine output and decreased mental status) should be treated with inotropes and/or inter-aortic balloon pumps to maintain the systolic blood pressure above 90 mmHg. Invasive monitoring may be required.

Arrhythmias. Life-threatening arrhythmias such as ventricular tachycardia, sustained VF or atrio-ventricular block occur in about one fifth of patients presenting with a STEMI, although this is decreasing due to early reperfusion therapy. β-Blockers have been the subject of many studies because of their anti-arrhythmic potential and because they permit increased subendocardial perfusion. In studies undertaken prior to the widespread use of fibrinolytics, the early administration of an intravenous β-blocker was shown to limit infarct size and reduce mortality from early cardiac events. A post hoc analysis of the use of atenolol in the GUSTO-I trial and a systematic review (Freemantle et al., 1999) did not support the routine, early intravenous use of β-blockers and, therefore, oral β-blockers are started within 24 h of the event. If a

β-blocker is contraindicated because of respiratory or vascular disorders, verapamil may be used, since it has been shown to reduce late mortality and reinfarction in patients without heart failure, although it shows no benefit when given immediately after an infarct. Diltiazem is less effective but may be used as an alternative. This is clearly not a class effect; other echannel blockers have produced different results and nifedipine increases mortality in patients following a myocardial infarction.

Initially, magnesium infusions looked promising when given early after infarction. However, in large trials (ISIS-4), no reductions in mortality were found making the routine use of magnesium inappropriate. Magnesium infusions are used, however, to correct low serum magnesium levels if cardiac arrhythmias are present.

Sinus bradycardia and heart block may also occur after a myocardial infarction and patients may require temporary or permanent pacemaker insertion.

Blood glucose. Patients with a myocardial infarction are often found to have high serum and urinary glucose levels, usually described as a stress response. The CREATE-ECLA trial (Mehta et al., 2005) studied more than 20,000 patients and showed a neutral effect of insulin on mortality, cardiac arrest and cardiogenic shock. Current guidelines do not support the routine use of insulin in STEMI in patients not previously known to be diabetic.

Up to 20% of patients who have a myocardial infarction have diabetes. Moreover, diabetic patients are known to do poorly after infarction, with almost double the mortality rate of non-diabetics. In these patients, an intensive insulin regimen, both during admission and for 3 months after, was found to save lives (Malmberg, 1997). However, the follow-up study (Malmberg et al., 2005) did not show any mortality benefit from intensive insulin therapy compared to standard therapy. In patients with diabetes, it appears reasonable, however, to continue to control blood glucose levels within the normal range immediately post-infarct.

Prevention of further infarction or death (secondary prophylaxis)

Lipid-lowering agents. Reduction of cholesterol through diet and use of lipid-lowering agents are effective at reducing subsequent mortality and morbidity in patients with established CAD. Patients with established CHD should be treated to ensure LDL-C is less than 2 mmol/L and total cholesterol less than 4 mmol/L (see Chapter 24). In patients with AMI or high-risk NSTEMI, there was a reduction in the combination end point of death, myocardial infarction, or documented UA requiring hospitalisation, revascularisation or stroke when patients were treated with high intensity statin (atorvastatin 80 mg) compared to standard statin therapy (Cannon et al., 2004). A meta-analysis of studies (Josan et al., 2008) reaffirmed the benefit of high intensity statin therapy especially in those patients with ACSs. An additional finding of particular interest was that the results were significant for the high intensity treatment arms despite approximately half of patients not achieving LDL-C of less than 2 mmol/L.

β-Blockers. Long-term use of a β-blocker has been shown in several studies to decrease mortality in patients in whom there is no contraindication. β-Blockade should be avoided in individuals with heart block, bradycardia, asthma, obstructive airways disease or peripheral vascular disease. One large cohort study compared low and high doses of β-blockers with no therapy and found benefit in all treated patients with similar survival rates but a lower heart failure rate in the low-dose group (Rochon et al., 2000).

Angiotensin-converting enzyme inhibitors. ACE inhibitors have been tried in various doses and durations and have proved beneficial in reducing the incidence of heart failure and mortality. In all but the earliest trials, patients were given an ACE inhibitor for 4–6 weeks and treatment continued in patients with signs or symptoms of heart failure or left ventricular dysfunction. The HOPE study (Yusuf et al., 2000) found that ramipril improved survival in all groups of patients with CHD and this has led clinicians to continue ACE inhibitors in all patients with a myocardial infarction over the age of 55 and in younger patients with evidence of left ventricular dysfunction. Contraindications to their use include hypotension and intractable cough.

There is considerable interest in focusing on the possible benefits of combining ACE inhibition with angiotensin II receptor blockers. Angiotensin blockade alone does not cause the accumulation of bradykinins that may be part of the benefit of using ACE inhibitors. Clinical trials (OPTIMAAL Study Group, 2002; VALIANT Investigators, 2003) have failed to find a benefit over ACE inhibition. Nonetheless, angiotensin receptor blockers are probably suitable in patients who cannot tolerate an ACE inhibitor. The relative benefits of ACE inhibitors and other treatments are shown in Table 20.6.

Eplerenone. In patients with heart failure, post-AMI, an improvement in survival and decreased cardiovascular mortality and hospitalisation was seen in those taking the aldosterone antagonist eplerenone (EPHESUS Trial; Pitt et al., 2003). Serious hyperkalemia occurred more frequently in the eplerenone arm and monitoring of serum potassium is warranted when used in practice.

Antidepressants. Anxiety is almost inevitable and a quarter of patients who have suffered a myocardial infarction subsequently experience marked depression. Post-myocardial infarction depression is associated with poor medication compliance, a lower quality-of-life score and a four-fold increase in mortality (Januzzi et al., 2000). Antidepressant treatments have not been subjected to formal trials but it seems reasonable to try to reduce the depression. There is concern about the potential for older antidepressants, such as tricyclic antidepressants, to increase the QT interval and cause arrhythmias. Newer antidepressants are less prone to cause these arrhythmias and selective seretonin receptor inhibitors (SSRIs) are preferred.

Rehabilitation programmes, which include some measure of social interaction, physical activity and education, are also of proven benefit. Although psychological stress clearly worsens outcomes, stress reduction interventions have not been tested and proven to work independently of other measures.

Nitrates. Studies on nitrates in myocardial infarction were mostly completed before fibrinolysis was widely used.

Table 20.6 Relative benefits of treating 1000 patients for myocardial infarction (MI)

Intervention	Events prevented
Intravenous β-adrenoceptor blocker	6 deaths
ACE inhibitor	6 deaths
Aspirin	20–25 deaths
Streptokinase (in hospital)	20–25 deaths
Alteplase (in hospital)	35 deaths
Streptokinase (before hospital)	35–40 deaths
Fibrinolysis 4½–1 h earlier	15 deaths
Long-term aspirin	16 deaths/MI/strokes
Long-term β-blockade	18 deaths/MI
Long-term ACE inhibitor	21–45 deaths/MI
10% reduction in serum cholesterol	7 deaths/MI
Stopping smoking	27 deaths

Adapted from McMurray and Rankin (1994).

Nitrates improve collateral blood flow and aid reperfusion, thus limiting infarct size and preserving functional tissue. ISIS-4 (1993) and GISSI-3 (1994) demonstrated that nitrates did not confer a survival advantage in patients receiving fibrinolysis. Sublingual nitrates may be given for immediate pain relief, and the use of intravenous or buccal nitrates can be considered in patients whose infarction pain does not resolve rapidly or who develop ventricular failure.

Anticoagulants and antiplatelets. Anticoagulation with warfarin is not generally recommended following a myocardial infarction, despite promising results in trials that have practiced exceptionally good anticoagulant monitoring. This is partly because of the success of antiplatelet therapy with aspirin. Aspirin does not have the same need for expensive and time-consuming follow-up and monitoring as warfarin, and is associated with fewer drug interactions. Clopidogrel has been shown to be beneficial, in addition to aspirin, in patients who have had a myocardial infarction (COMMIT, 2005). As the number of patients who receive a stent increases, the combination of aspirin and clopidogrel for a year or longer is now more frequent. Routine use of dipyridamole and sulfinpyrazone is not recommended after a myocardial infarction.

Treatment of non-ST elevation acute coronary syndromes

ACS without ST elevation is classified as either UA or NSTEMI. UA is defined as angina that occurs at rest or with minimal exertion, or new (within 1 month) onset of severe

angina or worsening of previously stable angina. NSTEMI (or non-Q wave MI) is the more severe manifestation of ACS.

There are about 115,000 new patients diagnosed each year with UA or NSTEMI in England and Wales. Despite the use of standard therapy the rate of adverse outcomes such as death, non-fatal MI or refractory angina requiring revascularisation, remains at 5–7% at 7 days and about 15–30% at 30 days; 5–14% of patient with UA or NSTEMI die within the first year of diagnosis.

There are extensive data for angioplasty following NSTEMI where patients frequently have significant residual coronary artery narrowing despite treatment with antiplatelet agents, heparin and glycoprotein IIb/IIIa antagonists.

Patients with NSTEMI may either be treated with an interventional strategy, where all patients undergo angiography and PCI following admission, or conservatively where they undergo angiography and intervention only if they remain unstable or have a positive exercise test. Initial trials of early intervention did not demonstrate any benefit but with the advent of advanced angioplasty techniques using stents and adjuvant drug therapies including clopidogrel and glycoprotein IIb/IIIa antagonists, there appears to be a clear advantage for an interventional strategy in high-risk patients (Fox et al., 2005).

Patients presenting with UA/NSTEMI can be classified into three categories depending on their risk of death or likelihood of developing an AMI. High-risk patients (those with ST segment changes during chest pain, chest pain within 48 h, troponin T-positive patients and those presenting already on intensive anti-anginal therapy) can be effectively managed with aggressive medical and interventional therapy. This results in fewer individuals progressing to AMI.

Various pharmacological agents such as antithrombin and antiplatelet drugs, and coronary revascularisation (particularly PCI) have been shown to improve the outcome of patients with UA or NSTEMI. These interventions are known to be associated with some treatment hazards, particularly bleeding complications. The risks must be balanced against potential treatment benefits for each individual patient. This balance is influenced by the patient's estimated risk of an adverse cardiovascular outcome as a consequence of the ACS. The absolute magnitude of benefit from an intervention is generally greatest in those at highest risk. A confounding issue is that treatment hazards, such as bleeding complications, are often also greatest in those at highest risk of an ischaemic event.

Measures of risk can be derived from the clinical assessment of a patient and the use of a formal risk scoring system, such as the GRACE, PURSUIT, PREDICT or TIMI scores. Scores based on clinical trial data generally exclude patients who are at high risk of an adverse cardiovascular outcome such as the elderly, or those with renal or heart failure, and as a consequence the evidence for clinical and cost-effectiveness of therapeutic interventions is confined to patients at lower to intermediate levels of risk. Risk score based on registry data, for example, GRACE, may provide a more realistic estimation of risk (Tables 20.7 and 20.8).

In patients with NSTEMI, the immediate administration of 300 mg aspirin can reduce mortality or subsequent myocardial infarction by 50%. Risk stratification according to a recognised tool should be used to guide the subsequent choice of pharmacological and/or surgical intervention. The exclusion of STEMI and confirmation of NSTEMI is important as the use of fibrinolysis in NSTEMI confers no benefit, and merely increases the risk of bleeding. In patients with NSTEMI, the preferred treatment normally involves a combination of antiplatelet agents to reduce the formation of a thrombus.

Antiplatelet and anticoagulant drugs

The current range of antiplatelet and anticoagulant drugs available for the reduction of thrombotic events in ACS leads to the potential for a large number of combinations. In all cases, the benefit of reducing thrombotic events must be balanced against the potential for an increased risk of bleeding.

In the early 1990s, unfractionated heparin, when combined with aspirin showed a reduction in death and subsequent myocardial infarction compared with aspirin alone. The use of the low molecular weight heparin (LMWH), enoxaparin, subsequently demonstrated superiority over unfractionated heparin, with both usually continued for 48 h, or until chest pain resolved or discharge. Both groups of drugs were tested in the era before PCI became part of routine practice.

The CURE study (2001) showed that clopidogrel, given as a loading dose of 300 mg followed by 75 mg daily in combination with aspirin and heparin, reduced the combined end point of death, myocardial infarction and revascularisation in all patients with NSTEMI. Clopidogrel needs to be continued for 12 months but should be stopped 5–7 days before any major surgery to reduce the risk of bleeding.

As PCI has become more routine as part of the management of high-risk NSTEMI patients, more aggressive antiplatelet treatment has been required to reduce both peri-procedural and post-procedural thromboembolic complications.

Expression of glycoprotein IIb/IIIa is one of the final steps in the platelet aggregation cascade. Inhibiting these receptors has been a strategy prior to, and during, PCI for some time. Glycoprotein IIb/IIIa inhibitors bind to the IIb/IIIa receptors on platelets (Fig. 20.6) and prevent cross-linking of platelets by fibrinogen. There are three classes of these agents: murine-human chimeric antibodies, for example, abciximab; synthetic peptides, for example, eptifibatide; and non-peptide synthetics, for example, tirofiban. Oral agents are ineffective and the murine-human chimeric antibodies appear to be effective only in the context of PCI.

In high-risk patients undergoing PCI and receiving background heparin, triple antiplatelet therapy (aspirin, clopidogrel and a glycoprotein IIb/IIIa inhibitors) has been shown to be superior to standard dose dual-antiplatelet therapy (aspirin and clopidogrel) particularly in troponin positive individuals (Kastrati et al., 2006). However, much of this evidence was generated before the introduction of higher doses of clopidogrel or more potent oral antiplatelet agents.

There is no clear benefit to giving glycoprotein IIb/IIIa inhibitors more than 4 h before PCI (upstream) compared to waiting until immediately before or during the procedure (deferred) (Stone et al., 2007).

Currently, all patients with a likely or definite diagnosis of NSTEMI should receive a loading dose of aspirin 300 mg (see Fig. 20.7). Patients undergoing PCI intervention should

have a higher loading dose of 600 mg of clopidogrel or 60 mg of prasugrel, unless contraindicated, to reduce events during and after PCI. Clopidogrel is often given as 300 mg on admission and a further 300 mg when the decision to intervene is made. Prasugrel, with its faster time to maximum effect, has demonstrated some benefit but routine use is not recommended (NICE, 2009). Patients who are not planned for intervention should receive a lower loading dose of clopidogrel 300 mg.

All patients should receive heparin, bivalirudin or fondaparinux. Unfractionated heparin is preferred for patients with compromised renal function. Fondaparinux, a synthetic pentasaccharide factor Xa inhibitor which has predictable and sustained anticoagulation with fixed dose, once-a-day subcutaneous administration, causes less bleeding than enoxaparin, an LMWH. Concerns over catheter related thrombus mean it should not be considered if patients are planned for PCI within 24 h of chest pain. Bivalirudin is a

Table 20.8 GRACE prediction nomogram for all cause mortality during in-hospital stay and up to 6 months post discharge

Risk category (tertiles)	GRACE risk score	In-hospital death (%)
Low	<109	<1
Intermediate	109–140	1–3
High	>140	>3
Risk category (tertiles)	GRACE risk score	Post-discharge to 6 months
Low	<89	<3
Intermediate	89–118	3–8
High	>118	>8

synthetic analogue of hirudin that binds reversibly to thrombin and inhibits clot-bound thrombin and may be considered an alternative.

The decision to use glycoprotein IIb/IIIa inhibitors is dependant on the centre and operator and whether the planned intervention for the patient is to be surgical or pharmacological. The introduction of higher loading doses of clopidogrel and more potent oral agents, as well as an increased focus on the bleeding risks associated with combination therapy, has reduced the use of these agents in many centres.

Recommendation of an anticoagulant regimen has become more complicated by a number of new choices suggested by contemporary trials, some of which do not provide adequate comparative information for common practice settings.

Anti-ischaemic drugs

The use of both β-blockers and nitrates in the management of patients with NSTEMI is based on studies of their use in stable angina and AMI. Their use is, however, well established and based on a firm pathophysiological and pharmacological rationale.

Statins

High intensity statins have been shown to benefit patients when given early in ACS. They are usually started on admission if the diagnosis of CAD is definite, independent of the patient's cholesterol level. Treatment should aim to achieve total cholesterol of <4 mmol/L and an LDL-C of <2 mmol/L.

Glycoprotein IIb/IIIa receptor antagonist

Patient care

Patients with CHD range from those who have investigational evidence of CHD but no symptoms to those who have major pain and exercise limitation. All need encouragement in adhering to preventive measures including diet, exercise and smoking cessation. Patients need to be able to discuss concerns about their health.

Exercise must be tailored according to the patient's threshold for angina. In general, although some patients are too cavalier, most are likely to err on the cautious side and may need to be encouraged to do more. Many centres now run cardiac rehabilitation classes to encourage patients to exercise and adopt a suitable lifestyle.

There are simple treatments and important lifestyle changes that can reduce cardiovascular risk and slow or even reverse progression of established coronary disease. The most important of these to address is smoking cessation. The risk of CHD is two to four times higher in heavy smokers (those who smoke at least 20 cigarettes/day) than in those who do not smoke. Other reports estimate the age-adjusted risk for smokers of more than 25 cigarettes/day is five to 21 times that of non-smokers. Smokers should be encouraged to quit. Within months of stopping smoking, CHD risk begins to decline. Within 5 years of smoking cessation the risk decreases to approximately the level found in people who have never smoked, regardless of the amount smoked, duration of the habit and the age at cessation. The use of nicotine replacement therapy almost doubles a smokers' chance of successfully stopping smoking (18% vs. 11%). All patients who smoke should be offered advice on cessation and encouraged to attend specialist smokers' clinics to further improve their chance of quitting.

Patient beliefs about medicines and medication-taking behaviour (and therefore adherence) are also important determinants of outcome and are influenced by many factors. These can largely be divided into beliefs about the importance of the medicine and concerns about the medicine's harmful effects. In order to assure the patient's concordance with medication regimens, it is necessary to address each individual patient's beliefs and concerns. One approach to counselling patients with CHD may be to divide the medication prescribed into those used to reduce risk of heart attacks and death, and those for symptom control. Key points to be discussed will relate to side effects and what to do if they occur, the need to continue medication until told otherwise and to ensure they do not run out of medication. Patients should be encouraged to identify their concerns and these should be addressed as openly and honestly as possible.

Patients also need up-to-date advice when faced with difficult choices regarding medical treatment, angiographic procedures or surgery. Patients have good reason to be anxious at times but some patients restrict their activities unnecessarily out of fear of angina and infarction.

Some of the common therapeutic problems encountered in the management of CHD are described in Table 20.9.

Table 20.9 Common therapeutic problems in coronary heart disease

Problem	Comment
Used incorrectly, nitrates may cause hypotensive episodes or collapse	Advise to sit down when using nitrate sprays or sublingual tablets
A daily nitrate-free period is required to maintain efficacy of nitrates	Avoid long-acting preparations and prescribe asymmetrically (e.g. 8 a.m. and 2 p.m.)
NSAIDs are associated with renal failure when given with ACE inhibitors	Warn patients to use paracetamol as their analgesic of choice
Speed is essential when patients need fibrinolytic drugs after infarction	Arrange emergency admission to hospital where fast-track systems should exist
Aspirin may cause gastro-intestinal bleeding	Advise on taking with food and water. Consider use of prophylactic agents in high-risk patients
β-Blockers are often considered unpleasant to take	Encourage patient to use regularly. Change the time of day. Consider a vasodilator if cold extremities are a problem. Consider verapamil or diltiazem
β-Blockers are contraindicated in respiratory and peripheral vascular disease	Consider verapamil or diltiazem. Pay strict attention to other treatments and removal of precipitating factors
Patients often receive multiple drugs for prophylaxis and for treatment of co-existing disorders	Use once-daily preparations, dosing aids and intensive social and educational support. Avoid all unnecessary drugs
ACE inhibitors are contraindicated in pregnancy, especially the first trimester	Advise women of child-bearing years to avoid conception or seek specialist advice first

Case studies

Case 20.1

A 55-year-old man presents to his primary care doctor complaining of tightness in his chest when he digs the garden. It eases when he has a rest. On investigation he has a raised serum glucose concentration and is considered to be a newly diagnosed non-insulin-dependent type II diabetic.

Question

What cardiovascular investigations and treatments should this patient receive?

Answer

The patient's blood pressure and ECG should be checked and he should be examined for signs of hypertensive or diabetic target organ damage, including albuminuria. His serum lipid profile should be measured.

He should receive GTN spray or sublingual tablets for the chest symptoms that are almost certainly angina. He should take aspirin daily and a statin if his lipid profile is abnormal. Some prescribers would give a statin in almost all diabetic, CHD patients and likewise an ACE inhibitor. Certainly, any hypertension should be treated aggressively so that the diastolic pressure is less than 80 mmHg. A β-blocker may also be useful to control blood pressure and prevent further episodes of angina, but many prescribers would wait until there was evidence of failure of the other therapies. In view of his relatively young age, a referral to a cardiologist for possible angiography would be considered. Dietary advice and help to stop smoking, if needed, would be given. Diabetic treatments should be given (see Chapter 44).

Case 20.2

The following patients are admitted for treatment of myocardial infarction:
1. **an asthmatic**
2. **a man previously treated for infarction**
3. **a patient with rheumatoid arthritis.**

Question

What contraindications, or possible contraindications, are there to standard treatments in the above patients?

Answers

1. An asthmatic should not receive a β-blocker without careful consideration and supervision because of the risk of bronchoconstriction; there is also a small risk of bronchoconstriction with aspirin.
2. A previous infarct may have been treated with streptokinase and a repeat dose should be avoided. Tissue plasminogen activator should be used instead.
3. Fibrinolytics are contraindicated if there is a serious risk of bleeding. A patient with rheumatoid arthritis may be receiving NSAIDs or steroids and enquiries must be made into any history of gastro-intestinal bleeding. NSAIDs would also not be prescribed with ACE inhibitors because of the risk of impaired renal function. Aspirin is not contraindicated with NSAIDs, and may be useful, but will increase the risk of gastro-intestinal bleeding.

Case 20.3

A patient with rheumatoid disease, treated with naproxen, has CHD.

Question

Is there any benefit or harm in adding aspirin to his treatment?

Answer

Aspirin is more beneficial than any other non-steroidal anti-inflammatory agent in modifying platelet activity and reducing mortality and morbidity in CHD. There is an increased risk of gastro-intestinal bleeding if two agents are given but at low doses of aspirin this should not be a major consideration. There is some evidence, however, that some NSAIDs interfere with the action of aspirin by blocking access to the active site on the COX-1 enzyme. Such agents should be avoided. Diclofenac does not block the receptor and ibuprofen has a short action and is acceptable if given 2 h after the daily dose of aspirin.

Chronic heart failure 21

S. A. Hudson, J. McAnaw and T. Dreischulte

Key points

- Heart failure is a common condition that affects the quality of life causing fatigue, breathlessness and oedema. It often has a poor prognosis.
- Heart failure is a maladaptive condition with haemodynamic and neurohormonal disturbances. Increased understanding of its pathophysiology and the strength of the evidence base allow a rational approach to therapeutic management.
- The aims of drug treatment are to control symptoms and to improve survival. By slowing disease progression the aim is to maintain quality of life.
- Diuretics are used for symptomatic management of heart failure, and are combined with other agents in the treatment of systolic dysfunction.
- Angiotensin converting enzyme (ACE) inhibitors and β-blockers are first-line agents in asymptomatic and symptomatic patients with systolic dysfunction.
- Angiotensin II receptor blockers (ARBs) are an alternative choice in patients intolerant of or resistant to ACE inhibitor therapy. Where use of an ARB is inappropriate, the combination of hydralazine and nitrate may still have a place.
- Aldosterone antagonists have been shown to improve morbidity and mortality when used as adjunctive therapy in patients with heart failure due to systolic dysfunction.
- Digoxin may still have a role in improving symptoms and reducing the rate of hospitalisation for patients with heart failure in sinus rhythm, but has not been demonstrated to affect mortality.
- Heart failure is a condition in which integration of pharmaceutical care within multidisciplinary models of patient care can improve clinical outcomes for patients and contribute to the continuity of care.

Chronic heart failure results from deficiency in the heart's function as a pump, where the delivery of blood, and therefore oxygen and nutrients, becomes inadequate for the needs of the tissues. Chronic heart failure is a complex condition associated with a number of symptoms arising from defects in left ventricular filling and/or emptying, of which shortness of breath (exertional dyspnoea, orthopnoea and paroxysmal nocturnal dyspnoea), fatigue and ankle swelling are the most common. The symptoms of heart failure are due to inadequate tissue perfusion, venous congestion and disturbed water and electrolyte balance. Impairment of renal function, and the associated water retention, adds to the burden placed on the heart. In chronic heart failure, the physiological mechanisms that aim to maintain adequate tissue perfusion become counterproductive and contribute to the progressive nature of the condition.

Treatment is aimed at improving left ventricular function, controlling the secondary effects that lead to the occurrence of symptoms, and delaying disease progression. Drug therapy is indicated in all patients with heart failure to control symptoms (where present), improve quality of life and prolong survival. Patients with heart failure usually have their functional status assessed and categorised using the New York Heart Association (NYHA) classification system shown in Table 21.1.

Epidemiology

Chronic heart failure is a common condition with a prevalence ranging from 0.3% to 2% in the population at large, 3–5% in the population over 65 years old, and between 8% and 16% of those aged over 75 years. Heart failure accounts for 5% of adult medical admissions to hospital. There is a loss of cardiac reserve with age, and heart failure may often complicate the presence of other conditions in the elderly. More than 10% of patients with heart failure also have atrial fibrillation as a contributory factor. This combination presents a risk of thrombo-embolic complications, notably stroke; the risk is 2% in patients in sinus rhythm, but may exceed 10% a year in patients with atrial fibrillation who are not anticoagulated and have attendant risk factors.

Table 21.1 New York Heart Association (NYHA) classification of functional status of the patient with heart failure	
I	No symptoms with ordinary physical activity (such as walking or climbing stairs)
II	Slight limitation with dyspnoea on moderate to severe exertion (climbing stairs or walking uphill)
III	Marked limitation of activity, less than ordinary activity causes dyspnoea (restricting walking distance and limiting climbing to one flight of stairs)
IV	Severe disability, dyspnoea at rest (unable to carry on physical activity without discomfort)

Heart failure is a progressive condition with complex possible causes, and mortality varies according to aetiology and severity. The variable prognosis is represented by a median survival of about 5 years after diagnosis. The prognosis can be predicted according to the severity of the disease, with an overall annual mortality rate for patients with chronic heart failure estimated at 10%. Main causes of death are progressive pump failure, sudden cardiac death and recurrent myocardial infarction.

Aetiology

Heart failure may be a consequence of myocardial infarction, but as a chronic condition it is often gradual in onset with symptoms arising insidiously and without any specific cause over a number of years. The common underlying aetiologies in patients with heart failure are coronary artery disease and hypertension. The appropriate management of these predisposing conditions is also an important consideration in controlling heart failure in the community. Identifiable causes of heart failure include aortic stenosis, cardiomyopathy, mechanical defects such as cardiac valvular dysfunction, hyperthyroidism and severe anaemia. Conditions that place increased demands on the heart can create a shortfall in cardiac output and lead to intermittent exacerbation of symptoms. Symptoms of heart failure may occur as a consequence of hyperthyroidism, where the tissues place a greater metabolic demand, or severe anaemia, where there is an increased circulatory demand on the heart. Cardiac output may also be compromised by bradycardia or tachycardia, or by a sustained arrhythmia such as that experienced by patients in atrial fibrillation.

Atrial fibrillation often accompanies hyperthyroidism and mitral valve disease, where a rapid and irregular ventricular response can compromise cardiac efficiency. Improved management of the underlying causes, where appropriate, may alleviate the symptoms of heart failure, whereas the presence of mechanical defects may require the surgical insertion of prosthetic valve(s). While around 50% of patients with heart failure have significant left ventricular systolic dysfunction, the other half is comprised of patients who have either a normal or insignificantly reduced left ventricular ejection fraction (EF), although there is no consensus on the threshold for compromised EF and assessment of each patient relies mainly on clinical symptoms. These patients are referred to as having heart failure with preserved left ventricular ejection fraction (HFPEF). However, most of the available evidence from clinical trials regarding the pharmacological treatment of heart failure to date relates to those patients with heart failure due to left ventricular systolic dysfunction. Clinical symptomatic description of chronic heart failure is mild, moderate, or severe heart failure. 'Mild' is used for patients who are mobile with no important limitations of dyspnoea or fatigue, 'severe' for patients who are markedly symptomatic in terms of exercise intolerance and 'moderate' for those with restrictions in between. Trials tend to formalise these categories into NYHA Categories I–IV (Table 21.1).

Pathophysiology

In health, cardiac output at rest is approximately 5 L/min with a mean heart rate of 70 beats per minute and stroke volume of 70 mL. Since the filled ventricle has a normal volume of 130 mL, the fraction ejected is over 50% of the ventricular contents, with the remaining (residual) volume being approximately 60 mL. In left ventricular systolic dysfunction, the EF is reduced to below 45%, and symptoms are common when the fraction is below 35%, although some patients with a low EF can remain asymptomatic. When the EF falls below 10%, patients have the added risk of thrombus formation within the left ventricle and in most cases anticoagulation with warfarin is indicated.

Left ventricular systolic dysfunction can result from cardiac injury, such as myocardial infarction, or by exposure of the heart muscle to mechanical stress such as long-standing hypertension. This may result in defects in systolic contraction, diastolic relaxation, or both. Systolic dysfunction arises from impaired contractility, and is reflected in a low EF and cardiac dilation. Diastolic dysfunction arises from impairment of the filling process. Diastolic filling is affected by the rate of venous return, and normal filling requires active diastolic expansion of the ventricular volume. The tension on the ventricular wall at the end of diastole is called the preload, and is related to the volume of blood available to be pumped. That tension contributes to the degree of stretch on the myocardium. In diastolic dysfunction, there is impaired relaxation or reduced compliance of the left ventricle during diastole and, therefore, less additional blood is accommodated. In pure diastolic dysfunction, the EF can be normal but cardiac dilation is absent. Sustained diastolic dysfunction, which is a feature in a minority of patients with heart failure, may lead to systolic dysfunction associated with disease progression and left ventricular remodelling (structural changes and/or deterioration).

During systolic contraction, the tension on the ventricular wall is determined by the degree of resistance to outflow at the exit valve and that within the arterial tree, that is, the systemic vascular resistance. Arterial hypertension, aortic narrowing and disorders of the aortic valve increase the afterload on the heart by increasing the resistance against which the contraction of the ventricle must work. The result is an increased residual volume and consequently an increased preload as the ventricle overfills, and produces greater tension on the ventricular wall. In the normal heart, a compensatory increase in performance occurs as the stretched myocardium responds through an increased elastic recoil. In the failing heart, this property of cardiac muscle recoiling under stretch is diminished, with the consequence that the heart dilates abnormally to accommodate the increased ventricular load. With continued dilation of the heart the elastic recoil property can become much reduced. Failure of the heart to handle the increasing ventricular load leads to pulmonary and systemic venous congestion. At the same time, the increased tension on the ventricular wall in heart failure raises myocardial oxygen requirements, which increases the risk of an episode of myocardial ischaemia or arrhythmias.

The failing heart may show cardiac enlargement due to dilation, which is reversible with successful treatment. An irreversible increase in cardiac muscle mass, cardiac hypertrophy,

occurs with progression of heart failure and is a consequence of long-standing hypertension. While hypertrophy may initially alleviate heart failure, the increased mass is pathologically significant because it ultimately increases the demands on the heart and oxygen consumption.

A reflex sympathetic discharge caused by the diminished tissue perfusion in heart failure exposes the heart to catecholamines where positive inotropic and chronotropic effects help to sustain cardiac output and produce a tachycardia. Arterial constriction diverts blood to the organs from the skin and gastro-intestinal tract but overall raises systemic vascular resistance and increases the afterload on the heart.

Reduced renal perfusion due to heart failure leads to increased renin release from the glomerulus in the kidney. Circulating renin raises blood pressure through the formation of angiotensin I and angiotensin II, a potent vasoconstrictor, and renin also prompts adrenal aldosterone release. Aldosterone retains salt and water at the distal renal tubule and so expands blood volume and increases preload. Arginine vasopressin released from the posterior pituitary in response to hypoperfusion adds to the systemic vasoconstriction and has an antidiuretic effect by retaining water at the renal collecting duct.

These secondary effects become increasingly detrimental to cardiac function as heart failure progresses, since the vasoconstriction adds to the afterload and the expanded blood volume adds to the preload. The expanded blood volume promotes the atrial myocytes to release a natural vasodilator, atrial natriuretic peptide (ANP), to attenuate the increased preload.

The compensatory mechanisms for the maintenance of the circulation eventually become overwhelmed and are ultimately highly counterproductive, leading to the emergence and progression of clinical signs and symptoms of heart failure. The long-term consequences are that the myocardium of the failing heart undergoes biochemical and histological changes that lead to remodelling of the left ventricle which further complicates disease progression. In those patients where the condition is severe and has progressed to an end stage, heart transplantation may be the only remaining treatment option.

Clinical manifestations

The reduced cardiac output, impaired oxygenation and diminished blood supply to muscles cause fatigue. Shortness of breath occurs on exertion (dyspnoea) or on lying (orthopnoea). When the patient lies down, the postural change causes abdominal pressure on the diaphragm which redistributes oedema to the lungs, leading to breathlessness. At night the pulmonary symptoms give rise to cough and an increase in urine production prompts micturition (nocturia), which adds to the sleep disturbance. The patient can be inclined to waken at night as gradual accumulation of fluid in the lungs may eventually provoke regular attacks of gasping (paroxysmal nocturnal dyspnoea). Characteristically the patient describes the need to sit or stand up to seek fresh air, and often describes a need to be propped up by three or more pillows to remedy the sleep disturbances that are due to fluid accumulation.

Table 21.2 Clinical manifestations of heart failure

Venous (congestion)	Cardiac (cardiomegaly)	Arterial (peripheral hypoperfusion)
Dyspnoea	Dilation	Fatigue
Oedema	Tachycardia	Pallor
Hypoxia	Regurgitation	Renal impairment
Hepatomegaly	Cardiomyopathy	Confusion
Raised venous pressure	Ischaemia, arrhythmia	Circulatory failure

Patients with heart failure may appear pale and their hands cold and sweaty. Reduced blood supply to the brain and kidney can cause confusion and contribute to renal failure, respectively. Hepatomegaly occurs from congestion of the gastro-intestinal tract, which is accompanied by abdominal distension, anorexia, nausea and abdominal pain. Oedema affects the lungs, ankles and abdomen. Signs of oedema in the lungs include crepitations heard at the lung bases. In acute heart failure, symptoms of pulmonary oedema are prominent and may be life-threatening. The sputum may be frothy and tinged red from the leakage of fluid and blood from the capillaries. Severe dyspnoea may be complicated by cyanosis and shock. Table 21.2 presents the clinical manifestations of heart failure.

Investigations

Patients with chronic heart failure are diagnosed and monitored on the basis of signs and symptoms from physical examination, history and an exercise tolerance test. On physical examination of the patient, a lateral and downward displacement of the apex beat can be identified as evidence of cardiac enlargement. Additional third and/or fourth heart sounds are typical of heart failure and arise from valvular dysfunction. Venous congestion can be demonstrated in the jugular vein of the upright reclining patient by an elevated jugular venous pressure (JVP), which reflects the central venous pressure. The JVP is measured by noting the visible distension above the sternum and may be accentuated in heart failure by the application of abdominal compression in the reclining patient. Confirmation of heart failure, however, should not be based on symptom assessment alone.

Echocardiography is important when investigating patients with a suspected diagnosis of heart failure. An echocardiogram allows visualisation of the heart in real time and will identify whether heart failure is due to systolic dysfunction, diastolic dysfunction or heart valve defects. With the provision of direct access echocardiography services to doctors in primary care, an increasing number of patients can now be quickly referred to confirm or exclude heart failure due to left ventricular systolic dysfunction or other structural abnormalities. Some reports suggest that between 50% and 75% of

Table 21.3 Investigations performed to confirm a diagnosis of heart failure

Investigation	Comment
Blood test	The following assessments are usually performed: • Blood gas analysis to assess respiratory gas exchange • Serum creatinine and urea to assess renal function • Serum alanine- and aspartate-aminotransferase plus other liver function tests • Full blood count to investigate possibility of anaemia • Thyroid function tests to investigate possibility of thyrotoxicosis • Serum BNP or NT pro-BNP to indicate likelihood of a diagnosis of heart failure (screening test) • Fasting blood glucose to investigate possibility of diabetes mellitus
12-lead electrocardiogram	A normal ECG usually excludes the presence of left ventricular systolic dysfunction. An abnormal ECG will require further investigation
Chest radiograph	A chest radiograph (X-ray) is performed to look for an enlarged cardiac shadow and consolidation in the lungs
Echocardiography	An echocardiogram is used to confirm the diagnosis of heart failure and any underlying causes, for example, valvular heart disease

patients referred to direct access clinics may have normal left ventricular function, which has important implications for the selection of appropriate drug treatment. Table 21.3 shows a number of investigations that are routinely performed in the assessment of heart failure symptoms. The use of serum natriuretic peptide measurement in the diagnosis of patients with heart failure is currently limited by the lack of defined cut-off values and, therefore, measurements are only considered in combination with ECG/chest X-ray data prior to echocardiography.

Treatment of heart failure

Until the 1980s, pharmacotherapy was driven by the aim to control symptoms, when diuretics and digoxin were the mainstay of treatment. While relieving the symptoms of heart failure remains decisive in improving a patient's quality of life, a better understanding of the underlying pathophysiology has led to major advances in the pharmacological treatment of heart failure. With the introduction of angiotensin converting enzyme (ACE) inhibitors, β-blockers, angiotensin II receptor blockers (ARBs) and aldosterone antagonists, delaying disease progression and ultimately improving survival have become realistic goals of therapy. An outline of the site of action of the various drugs is schematically presented in Fig. 21.1.

In heart failure patients with co-morbid conditions known to contribute to heart failure, such as hyperthyroidism, anaemia, atrial fibrillation and valvular heart disease, attention must be given to ensuring these underlying contributing factors are well controlled. Patients with atrial fibrillation may be candidates for electrocardioversion. Tachycardia from atrial fibrillation usually requires control of the ventricular rate through suppression of atrioventricular node conduction. In patients with heart failure, the use of digoxin and/or β-blockers is recommended in such circumstances. In these patients, the use of either anticoagulant or antiplatelet agents is necessary and should be based on an assessment of stroke risk.

In patients with heart failure and preserved EF, diuretics are commonly used for symptom control and there is some limited evidence to suggest that ACE inhibitors can reduce hospitalisation. However, the use of all other agents of proven benefit in treating heart failure due to left ventricular systolic dysfunction are currently not supported by an evidence base.

There is consensus that all patients with left ventricular systolic dysfunction should be treated with both an ACE inhibitor and a β-blocker in the absence of intolerance or contraindications. The evidence base for treatment clearly shows that use of an ACE inhibitor (or angiotensin receptor blocker) and β-blocker therapy in patients with heart failure due to left ventricular systolic dysfunction leads to an improvement in symptoms and reduction in mortality. There is some evidence to suggest that either agent can be initiated first, as both appear to be just as effective and well tolerated (CARMEN 2004, CIBIS III, 2005). Beneficial effects on morbidity and mortality have also been shown for the use of ARBs, aldosterone antagonists and hydralazine/nitrate combinations when used in the treatment of chronic heart failure. Digoxin has been shown to improve morbidity and reduce the number of hospital admissions in patients with heart failure, although its effect on mortality has not been demonstrated. Table 21.4 describes the treatment of acute heart failure in the hospital setting, while Fig. 21.2 highlights the possible treatment options for patients with chronic heart failure due to left ventricular systolic dysfunction.

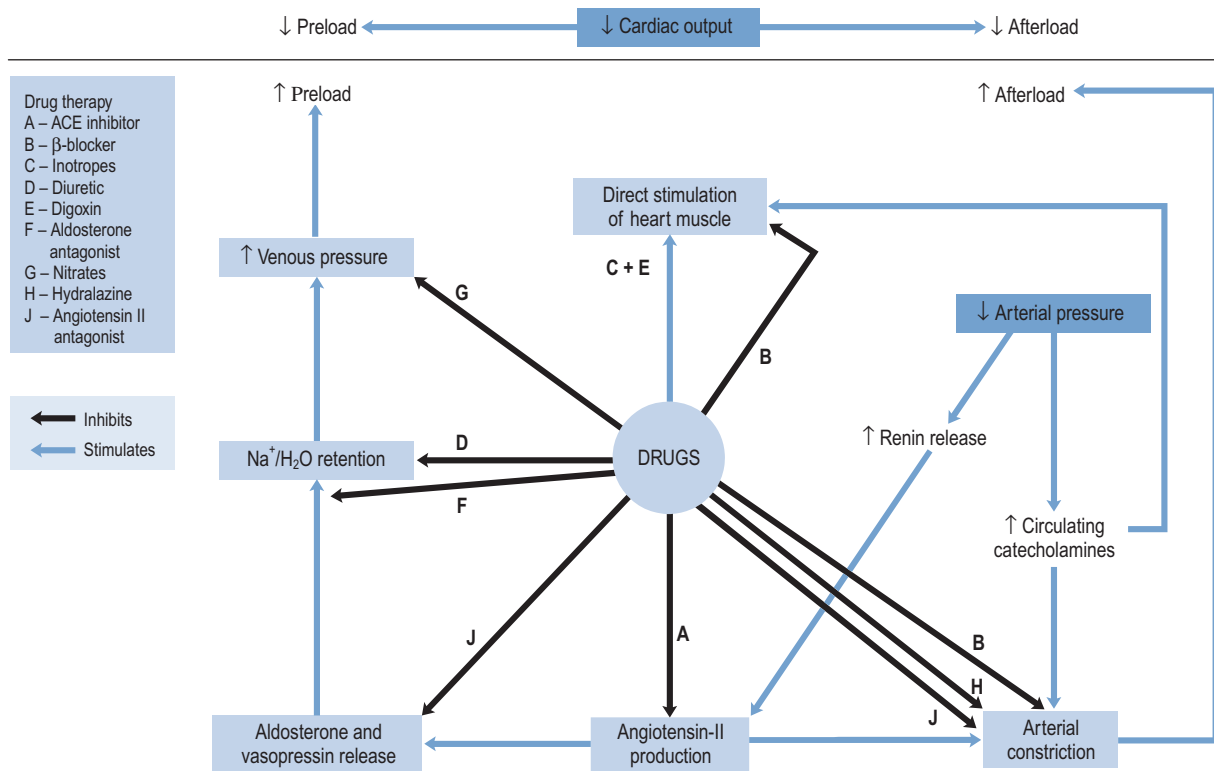
The selection of adjunctive therapy beyond the use of ACE inhibitor and β-blocker therapy is largely dependent on the nature of the patient and the preference of the heart failure specialist involved in the patient's care. It is accepted that there is a limit as to how many agents any one patient can tolerate; therefore, the selection of drug therapy will probably be tailored to each individual patient, meaning that treatment plans will vary.


Fig. 21.1 Schematic representation of drug action in heart failure.

Table 21.4 Treatment of acute heart failure due to left ventricular systolic dysfunction in patients requiring hospitalisation

Problem	Drug therapy indicated
Anxiety	Use of intravenous opiates to reduce anxiety and reduce preload through venodilation
Breathlessness	High-flow oxygen (60–100%) may be required in conjunction with i.v. furosemide as either direct injection or 24-h infusion (5–10 mg/h). Venodilation with i.v. GTN is also effective at doses titrated every 10–20 min against systolic BP ≤ 110 mmHg
Arrhythmia	Digoxin useful in control of atrial fibrillation. Amiodarone is the drug of choice in ventricular arrhythmias
Expansion of blood volume following blood transfusion	An elevation in preload, such as can occur acutely by expansion of blood volume after a transfusion, can exacerbate the degree of systolic dysfunction. Therefore, it is necessary to continue or increase diuretic dosage during this time

Diuretics

In chronic heart failure, diuretics are used to relieve pulmonary and peripheral oedema by increasing sodium and chloride excretion through blockade of sodium re-absorption in the renal tubule. Normally, in the proximal tubule, about 70% of sodium is reabsorbed along with water. In mild heart failure, either a thiazide or more often a loop diuretic is chosen depending on the severity of the symptoms experienced by the patient and the degree of diuresis required. Thiazides are described as 'low-ceiling agents' because maximum diuresis occurs at low doses, and they act mainly on the cortical diluting segment (the point of merger of the ascending limb with the distal renal tubule) at which 5–10% of sodium is normally removed. Although thiazides have some action at this site, they fail to produce a marked diuresis since a compensatory increase in sodium re-absorption occurs in the loop of Henle, and consequently thiazides are ineffective in patients with moderate-to-severe renal impairment (eGFR <30 mL/min) or persisting symptoms. Additionally, doses above the equivalent of bendroflumethiazide 5 mg have an increased risk of adverse metabolic effects with no additional symptomatic benefit. Thiazides are, therefore, now rarely used as sole diuretic therapy and are reserved for cases where the degree of fluid retention is very mild, renal function is not compromised or as an adjunct to loop diuretics (see below).

Functional status of patient (NYHA)		Drug therapy indicated
Asymptomatic	I	In absence of contraindication or intolerance • ACE inhibitor (use Angiotensin II receptor blocker if not tolerated) • β-blocker In early post-MI patient with diabetes mellitus • Eplerenone*
Symptomatic	II–IV	As above, with addition of • Diuretic Where patient still symptomatic despite optimization of above therapy, consider addition of the following agents on specialist advice** • Candesartan • Digoxin (if patient in sinus rhythm) • Spironolactone (in moderate to severe heart failure) • Eplerenone* (if patient post-MI or spironolactone-intolerant) • Hydralazine/ISDN (beneficial in African-American patients)

* Therapy should be introduced within a month after acute MI
** Use of adjunctive therapy must be guided by a heart failure specialist/cardiologist, as there are certain combinations that require very close monitoring or complete avoidance according to current clinical evidence.

Fig. 21.2 Outline of treatment options for patients with chronic heart failure due to left ventricular systolic dysfunction.

Loop diuretics are indicated in the majority of symptomatic patients and most patients will be prescribed one of either furosemide, bumetanide or torasemide in preference to a thiazide. These agents are known as 'high-ceiling agents' because their blockade of sodium re-absorption in the loop of Henle continues with increased dose. They have a shorter duration of action (average 4–6h) compared to thiazides (average 12–24h), and produce less hypokalaemia. In high doses, however, their intensity of action may produce hypovolaemia with risk of postural hypotension, worsening of symptoms and renal failure. In practice, high doses of furosemide (up to 500 mg/day) may be required to control oedema in patients with poor renal function. In the acute situation, doses of loop diuretics are titrated to produce a weight loss of 0.5–1 kg per day.

In longer term use, patients with heart failure frequently develop some resistance to the effects of loop diuretic due to a compensatory rebound in sodium retention. In this situation, a combination of thiazide and loop diuretics has been shown to have a synergistic effect, even in patients with reduced renal function. In the UK, metolazone is also used as an adjunct to augment the effects of loop diuretics. The potentially profound diuresis produced by such a combination poses serious risks, such as dehydration and hypotension, and patients who are prescribed metolazone in addition to an existing loop diuretic must be carefully monitored. In practice, patients with oedema treated with loop diuretics may best be treated using a degree of self-management. Some patients are instructed to make upward adjustment of loop diuretic dose or to add metolazone therapy on particular days, for example, when they self-record a gain of 2 kg or more in their body weight over a short period of time.

Diuretics also have a mild vasodilator effect that helps improve cardiac function and the intravenous use of loop diuretics reduces preload acutely by locally relieving pulmonary congestion before the onset of the diuretic effect. Effective diuretic therapy is demonstrated by normalisation of filling pressure. Therefore, continued elevation of the JVP suggests a need for more diuretic unless otherwise contraindicated. Intravenous furosemide must be administered at a rate not exceeding 4 mg/min to patients with renal failure, since it can cause ototoxicity when administered more rapidly.

Details of diuretic therapy used in left ventricular systolic dysfunction are summarised in Table 21.5.

ACE inhibitors

ACE inhibitors are indicated as first-line treatment for all grades of heart failure due to left ventricular systolic dysfunction, including those patients who are asymptomatic. These agents exert their effects by reducing both the preload and afterload on the heart, thereby increasing cardiac output.

ACE inhibitors act upon the renin–angiotensin–aldosterone system, and they reduce afterload by reducing the formation of angiotensin II, a potent vasoconstrictor in the arterial system. These drugs also have an indirect effect on sodium and water retention by inhibiting the release of aldosterone and vasopressin, thereby reducing venous congestion and preload. The increase in cardiac output leads to an improvement in renal perfusion, which further helps to alleviate oedema. ACE

Table 21.5 Diuretics and aldosterone antagonists used in the treatment of heart failure

Class and agent	Onset and duration of effect		Comment
Thiazide and related Bendroflumethiazide Metolazone	**Oral** Onset 1–2 h Duration 12–18 h Onset 1–2 h Duration 12–24 h		Thiazides are effective in the treatment of sodium and water retention, although there is generally a loss of action in renal failure (GFR <25 mL/min). Metolazone has an intense action when added to a loop diuretic and is effective at low GFR
Loop Furosemide Bumetanide Torasemide	**Oral** Onset 0.5–1 h Duration 4–6 h As above Onset <1 h Duration <8 h	**Parenteral** Onset 5 min Duration 2 h As above Onset 10 min Duration <8 h	Loop diuretics are preferred in the treatment of sodium and water retention where renal dysfunction is evident or more severe grades of heart failure present. Agents can be given orally or by infusion, and all are effective at low GFR
Aldosterone antagonist Spironolactone	**Oral** Onset 7 h Duration 24 h		Can enhance diuretic effect of loop and/or thiazide. Due to slow onset of action needs 2–3 days before maximum diuretic effect reached. Spironolactone can improve survival when given as an adjunct to ACE inhibitor and diuretic therapy at a recommended dose of 25 mg daily (initial dose of 25 mg daily or on alternate days)
Aldosterone antagonist Eplerenone	**Oral** Half-life 3–5 h		In early post-MI patients with symptomatic heart failure (or asymptomatic patients with diabetes mellitus), eplerenone 50 mg daily improved survival when added to optimal therapy (initial dose of 25 mg daily)

inhibitors also potentiate the vasodilator bradykinin and may intervene locally on ACE in cardiac and renal tissues.

ACE inhibitors are generally well tolerated by most patients and have been shown to improve the quality of life and survival in patients with mild-to-severe systolic dysfunction (CONSENSUS, 1987; CONSENSUS II, 1992; SOLVD-P, 1992; SOLVD-T, 1991; V-HeFT II, 1991), including those patients who have experienced a myocardial infarction (AIRE), 1993; SAVE, 1992; TRACE, 1995). When an ACE inhibitor is prescribed, it is important to ensure that the dose is started low and increased gradually, paying close attention to renal function and electrolyte balance. The dose should be titrated to achieve the target dose that has been associated with long-term benefits shown in clinical trials or (if not possible) the maximum tolerable dose. There is some evidence to suggest that high doses of ACE inhibitor are more effective than low doses in relation to reduction in mortality, although it is uncertain whether this is a general class effect (ATLAS, 1999). In clinical practice, it is possible that some patients may be treated with ACE inhibitors at doses below those used in clinical trials. As a consequence, actual outcomes in heart failure treatment may not be as good as expected from the trial findings.

The introduction of an ACE inhibitor may produce hypotension, which is most pronounced after the first dose and is sometimes severe. Patients at risk include those already on high doses of loop diuretics, where the diuretics cannot be stopped or reduced beforehand, and patients who may have a low-circulating fluid volume (due to dehydration) and an activated renin–angiotensin system. Hypotension can also occur where the ACE inhibitor has been initiated at too high a dose or where the dose has been increased too quickly after initiation. In the primary care setting, treatment must be started with a low dose which is usually administered at bedtime. In patients at particular risk of hypotension, a test dose of the shorter-acting agent captopril can be given to assess suitability for treatment before commencing long-term treatment with a preferred ACE inhibitor. Once it has been established that the ACE inhibitor can be initiated safely, the preferred option would be to switch to a longer acting agent with once- or twice-daily dosing, starting with a low dose which would be gradually titrated upwards to the recommended target (Table 21.6). Monitoring of fluid balance, blood biochemistry and blood pressure are essential safety checks during initiation and titration of ACE inhibitor therapy.

One of the most common adverse effects seen with ACE inhibitors is a dry cough and this is reported in at least 10% of patients. However, since a cough can occur naturally in patients with heart failure it is sometimes difficult to determine the true cause. ACE inhibitor therapy can also compromise renal function, although in patients in whom there is a reduction in renal perfusion due to worsening heart failure or hypovolaemia,

Table 21.6 Vasodilators used in the treatment of heart failure

	Dose	Frequency	Half-life (h)	Comment
ACE inhibitor				
Captopril	Target: 50–100 mg Start: 6.25 mg	Three times daily	8	First-dose hypotension may occur. May worsen renal failure. Adjust dose in renal failure. Hyperkalaemia, cough, taste disturbance and hypersensitivity may occur particularly with captopril
Enalapril	Target: 10–20 mg Start: 2.5 mg	Twice daily	11	
Lisinopril	Target: 20–35 mg Start: 2.5–5 mg	Once daily	12	ACE inhibitors have been shown to improve survival, with starting and target dose for those agents used in clinical trials highlighted
Ramipril	Target: 10 mg Start: 2.5 mg	Once daily (or divided dose)	13–17	
Trandolapril	Target: 4 mg Start: 0.5 mg	Once daily	16–24	
Cilazapril		Once daily	9	
Fosinopril		Once daily	11–14	
Perindopril		Once daily	25	
Quinapril		Once daily	–	
β-Blocker				
Carvedilol	Target: 25–50 mg Start: 3.125 mg	Twice daily	6–10	May initially exacerbate symptoms but if initiated at low dose and slowly titrated can improve long-term survival, even in elderly patients with heart failure
Bisoprolol	Target: 10 mg Start: 1.25 mg	Once daily	10–12	Metoprolol succinate is currently not licensed for use in the UK
Metoprolol (succinate) CR/XL formulation	Target: 200 mg Start: 12.5–25 mg	Once daily	3–7	
Nebivolol	Target: 10 mg Start: 1.25 mg	Once daily	10	Half-life of nebivolol can be 3–5 times longer in slow metabolisers
Nitrates				
Glyceryl trinitrate			1–4 min	Isosorbide dinitrate metabolised to isosorbide mononitrate. High doses needed. Tolerance can be prevented by nitrate-free period of >8 h. Protective effect against cardiac ischaemia. GTN given intravenously for sustained effect in acute/severe heart failure but limited by tolerance
Isosorbide dinitrate			1	
Isosorbide mononitrate			5	
Nitroprusside			2 min	Light sensitive. Acts on veins and arteries. Cyanide accumulation and acidosis limit treatment duration
Angiotensin II receptor blocker				
Losartan			6–9	Comparable effectiveness to ACE inhibitor in patients with ACE inhibitor intolerance, although similar effect on renal function and blood pressure. Recent evidence suggests improved survival when ARB used as adjunctive therapy. However, increased potential for deterioration in renal function and/or hyperkalaemia
Candesartan	Target: 32 mg Start: 4–8 mg	Once daily	9	
Valsartan	Target: 160 mg Start: 40 mg	Twice daily	9	
Hydralazine			2–3	Hydralazine has a direct action on arteries. Tolerance occurs. May cause drug-induced lupus and sodium retention

renal dysfunction can also occur. Therefore, there are a number of instances where ACE inhibitor intolerance can be misdiagnosed in practice. Where ACE inhibitor intolerance is suspected, patients can usually be successfully rechallenged with an ACE inhibitor once their heart failure is more stable, although careful monitoring of the patient should be undertaken during initiation and subsequent dose titration. If the increase in the patient's serum creatinine is >100% from baseline, the ACE inhibitor should be stopped, intolerance confirmed and specialist advice sought. Where the increase from baseline is 50–100%, the ACE inhibitor dose should be halved and serum creatinine concentration rechecked after 1–2 weeks. If renal function is stable and no cough or other adverse effects are reported, therapy should be continued. Where the problem persists, an alternative treatment option might be required, for example, ARB (similar benefits on morbidity and mortality, but there is a possibility of similar adverse effects on blood pressure and renal function) or hydralazine–nitrate combination.

ACE inhibitors are potentially hazardous in patients with pre-existing renal disease, as blockade of the renin-angiotensin system may lead to reversible deterioration of renal function. In particular, ACE inhibitors are contraindicated in patients with bilateral renal artery stenosis, in whom the renin-angiotensin system is highly activated to maintain renal perfusion. Since most ACE inhibitors or their active metabolites rely on elimination via the kidney, the risk of other forms of dose-related toxicity is also increased in the presence of renal failure. Fosinopril, which is partially excreted by metabolism, may be the preferred agent in patients with renal failure. ACE inhibitors are also contraindicated in patients with severe aortic stenosis because their use can result in a markedly reduced cardiac output due to decreased filling pressure within the left ventricle. Table 21.6 summarises the activity and use of ACE inhibitors.

Angiotensin II receptor blockers

Although comparisons of ACE inhibitors and ARBs have shown similar benefits on morbidity and heart failure mortality, only ACE inhibitors have been shown to have positive effects on all cause mortality. ARBs should, therefore, not be used instead of ACE inhibitors, unless the patient experiences intolerable side effects.

The use of ARBs as an adjunct to ACE inhibitor and β-blocker therapy has been associated with significant reductions in cardiovascular events and hospitalisation rate (CHARM Added, 2003). Although this finding is encouraging, the impact on mortality alone remains inconsistent and there is no clear consensus on when to use an ARB as adjunctive therapy. In studies involving patients unable to tolerate an ACE inhibitor, ARBs have been shown to be comparable to ACE inhibitors in reducing the risk of cardiovascular death and rate of hospitalisation, and in the control of symptoms in heart failure patients (CHARM Alternative, 2003; Val-HeFT, 2002). Therefore, ARBs are recommended for use as an alternative to ACE inhibitor therapy where intolerance has been confirmed. It is important to note that in patients who have renal failure secondary to ACE inhibitors, switching to an ARB is of no theoretical or practical benefit, as similar adverse effects are likely.

A recent meta-analysis has raised concerns about a possible increase of cancer in people taking ARBs (Sipahi et al., 2010). Although the implications of this are unclear it adds weight to the recommendation that ACE inhibitors, not ARBs, should be the first-line agent when selecting a drug to act on the renin-angiotensin system.

β-Blockers

Formerly, β-blockers have been contraindicated in patients with heart failure. However, the sympathetic neurohormonal overactivity that occurs in response to the failing heart has been identified as a decisive factor in the progression of ventricular dysfunction. Consequently, β-blockers have been tested in a number of clinical trials. There is now substantial evidence that β-blockers reduce mortality among patients with mild-to-moderate symptomatic heart failure (ANZ Carvedilol, 1997; CAPRICORN, 2001; CIBIS II, 1999; MERIT-HF, 1999; US Carvedilol, 1996) and those with severe heart failure

(COPERNICUS, 2001). This beneficial effect also extends to the elderly heart failure population (SENIORS, 2005).

The use of β-blockers is, therefore, recommended for all patients with heart failure due to left ventricular systolic dysfunction, irrespective of age and the degree of dysfunction. However, due to their negative inotropic effects, β-blockers should only be initiated when the patient's condition is stable. There is insufficient evidence for a class effect to be assumed illustrated by the fact that in one trial, metoprolol tartrate was found to be inferior to carvedilol (COMET, 2003). Currently, nebivolol, bisoprolol and carvedilol are the only licensed β-blockers for the treatment of heart failure in the UK.

It is likely that patients will experience a worsening of symptoms during initiation of therapy and, therefore, patients are started on very low doses of β-blocker (e.g. carvedilol 3.125 mg daily) with careful titration occurring over a number of weeks or months with careful monitoring. The goal is to titrate the dose towards those used in clinical trials that have been associated with morbidity and mortality benefits (carvedilol 25–50 mg daily). Table 21.6 summarises the activity and use of β-blockers in heart failure.

Despite the demonstrated benefits, there is ongoing concern that certain subgroups of patients with heart failure continue to be undertreated with β-blockers. These groups include patients with chronic obstructive pulmonary disease (COPD), peripheral vascular disease, diabetes mellitus, erectile dysfunction and older adults. With the exception of patients with reversible pulmonary disease, who have typically been excluded from β-blocker trials (CIBIS II, 1999; MERIT-HF, 1999), there is now sufficient evidence to justify the use of β-blockers licensed for heart failure in these patients. In addition, a systematic review of trials on cardio-selective β-blockers found no clinically significant adverse respiratory effects in patients with reversible COPD, although it would be prudent to use these agents in such patients with caution and with appropriate monitoring in place (Salpeter S. et al., 2005).

Aldosterone antagonists

The use of aldosterone antagonists as an adjunct to standard treatment has been shown to have an effect on morbidity and mortality in patients with heart failure. Spironolactone has been shown to reduce mortality and hospitalisation rates in patients with moderate-to-severe heart failure (RALES, 1999). The use of eplerenone has also been shown to be associated with similar benefits in early post-MI patients with symptomatic heart failure or early post-MI diabetic patients with asymptomatic heart failure (EPHESUS, 2003, EMPHASIS-HF, 2010).

Aldosterone can cause sodium and water retention, sympathetic activation and parasympathetic inhibition, all of which are associated with harmful effects in the patient with heart failure. Aldosterone antagonists counteract these effects by directly antagonising the activity of aldosterone, providing a more complete blockade of the renin–angiotensin–aldosterone system when used in conjunction with an ACE inhibitor. Although the combination of spironolactone (at a dose of 50 mg daily or more) and an ACE inhibitor is associated with an increased risk of developing hyperkalaemia, the use of a 25-mg daily dose has been shown to have little effect

on serum potassium and provides a significant reduction in mortality. The use of spironolactone is, however, contraindicated in those patients with a serum potassium >5.5 mmol/L or serum creatinine >200 μmol/L. With eplerenone, similar contraindications exist and, therefore, close monitoring of blood biochemistry and renal function must be undertaken for use of either agent. The activity and use of spironolactone and eplerenone are summarised in Table 21.5.

Currently, there is no evidence available regarding the effectiveness and safety of combining an ACE inhibitor, ARB and an aldosterone antagonist, and therefore it is recommended that this combination is avoided until more information about this particular combination becomes available.

Digoxin

Although digoxin has an established role in the control of atrial fibrillation, its place in the treatment of heart failure is still the subject of debate. There is evidence to show that when digoxin has been used to treat heart failure in patients in sinus rhythm, as an adjunct to ACE inhibitor and diuretic therapy, then worsening of symptoms occurs on withdrawal of digoxin (PROVED, 1993; RADIANCE, 1993). While the use of digoxin in heart failure in patients in sinus rhythm has no measurable impact on mortality, it reduces the number of hospital admissions (DIG, 1997). Consequently, digoxin is currently recommended for use as add-on therapy at low doses in patients with moderate-to-severe heart failure who remain symptomatic despite adequate doses of ACE inhibitor, β-blocker and diuretic treatment. Due to the lack of effect on mortality, it is unlikely that digoxin would be considered before the other adjunctive therapies available.

Digoxin is a positive inotropic agent and acts by increasing the availability of calcium within the myocardial cell through an inhibition of sodium extrusion, thereby increasing sodium–calcium exchange and leading to enhanced contractility of cardiac muscle. Digoxin increases cardiac output in patients with co-existing atrial fibrillation by suppressing atrioventricular conduction and controlling the ventricular rate. In patients with atrial fibrillation, the serum digoxin concentration usually needs to be at the higher end of the reference range (0.8–2 μcg/L) or beyond to control the arrhythmia. However, a high serum digoxin concentration is not necessarily required to achieve an inotropic effect in patients in sinus rhythm. Digoxin is also associated with both vagal stimulation and a reduction in sympathetic nerve activity, and these may play important roles in the symptomatic benefits experienced by those patients in sinus rhythm receiving lower doses. In practice, the dose prescribed will be judged appropriate by the clinical response expressed as relief of symptoms and control of ventricular rate. Routine monitoring of serum digoxin concentrations in the pharmaceutical care of the patient is not recommended, other than to confirm or exclude digoxin toxicity or investigate issues around patient compliance.

Digoxin treatment is potentially hazardous due to its low therapeutic index and so all patients receiving this drug should be regularly reviewed to exclude clinical signs or symptoms of adverse effects. Digoxin may cause bradycardia and lead to potentially fatal cardiac arrhythmias. Other symptoms associated with digoxin toxicity include nausea, vomiting, confusion and visual disturbances. Digoxin toxicity is more pronounced in the presence of metabolic or electrolyte disturbances and in patients with cardiac ischaemia. Those patients who develop hypokalaemia, hypomagnesaemia, hypercalcaemia, alkalosis, hypothyroidism or hypoxia are at particular risk of toxicity. Treatment may be required to restore serum potassium, and in emergency situations intravenous digoxin-specific antibody fragments can be used to treat life-threatening digoxin toxicity. Table 21.7 summarises the activity and use of digoxin.

Table 21.7 Inotropic agents used in the treatment of heart failure

Class and agent	Pharmacological half-life	Comment
Cardiac glycosides		
Digoxin	39 h	In renal failure, half-life of digoxin is prolonged. Dosage individualisation required. Serum drug concentration monitoring used to confirm or exclude toxicity or effectiveness. Dose of digitoxin unaffected by renal failure. CNS, visual and GI symptoms linked to digoxin toxicity. No benefit in terms of mortality, but use associated with improved symptoms and reduced hospitalisation for heart failure. Beneficial in AF, although risk of arrhythmias with high doses. If given i.v. must be administered slowly (20 min) to avoid cardiac ischaemia
Digitoxin	5–8 days	
Phosphodiesterase inhibitors		
Enoximone	4.2 h	Used only in severe heart failure as adjunctive therapy. Associated with arrhythmias and increased mortality with chronic use
Milrinone	2.4 h	
Sympathomimetics		
Dobutamine	2 min	Continuous intravenous use only. Require close monitoring in critical care setting
Dopamine	2 min	
Dopexamine	6–7 min	
Isoprenaline	>1 min	

Nitrates/hydralazine

Nitrates exert their effects in heart failure predominantly on the venous system where they cause venodilation, thereby reducing the symptoms of pulmonary congestion. The preferred use of nitrates is in combination with an arterial vasodilator such as hydralazine, which reduces the afterload, to achieve a balanced effect on the venous and arterial circulation. The combined effects of these two drugs lead to an increase in cardiac output, and there is evidence to show the combination is effective and associated with a reduction in mortality in patients with heart failure (V-HeFT I, 1986). Although the combination can improve survival, the reduction in mortality is much smaller than that seen with ACE inhibitors (V-HeFT II, 1991), especially in the white population. The combination has been shown to reduce mortality, heart failure hospitalisation rates and quality of life in patients of African descent, when added as an adjunct to optimum medical therapy (A-HeFT, 2004) and this benefit is sustained (A-HeFT, 2007).

The evidence supports the use of hydralazine 300 mg daily with isosorbide dinitrate (ISDN) 160 mg daily (although in practice an equivalent dose of isosorbide mononitrate, ISMN, is often used). Since the emergence of ACE inhibitors, with their superior effects on morbidity and mortality, the combination has mainly been reserved for patients unable to tolerate, or with a contraindication to, ACE inhibitor therapy.

Organic nitrate vasodilators work by interacting with sulphydryl groups found in the vascular tissue. Nitric oxide is released from the nitrate compound and this in turn activates soluble guanylate cyclase in vascular smooth muscle, leading to the vasodilatory effect. Plasma nitric oxide concentrations are not clearly related to pharmacological effects because of their indirect action on the vasculature. Depletion of tissue sulphydryl groupings can occur during continued treatment with nitrates, and is partly responsible for the development of tolerance in patients with sustained exposure to high nitrate doses. Restoration of sulphydryl groupings occurs within hours of treatment being interrupted; therefore, nitrate tolerance can be prevented by the use of an asymmetrical dosing regimen to ensure that the patient experiences a daily nitrate-free period of more than 8 h.

In the acute setting, glyceryl trinitrate (GTN) is frequently administered intravenously, along with a loop diuretic, to patients with heart failure to relieve pulmonary congestion. When using this route of administration, it is important that a Teflon-coated catheter is used to avoid adsorption of the GTN onto the intravenous line.

ISDN can be given orally and is completely absorbed; however, only 25% of a given dose appears as ISDN in serum with 60% of an oral dose being rapidly converted to ISMN. ISMN is longer acting and, therefore, most of the accumulated effects of a dose of ISDN are attributable to the 5-isosorbide mononitrate metabolite. Consequently, a 20-mg dose of ISDN is approximately equivalent to a 10-mg dose of ISMN. In practice, nitrate preparations are usually given orally in the form of ISMN, and intravenously in the form of GTN (see Table 21.6).

Hydralazine has a direct action on arteriolar smooth muscle to produce arterial vasodilation. Its use is associated with the risk of causing drug-induced systemic lupus erythematosus (SLE). SLE is an uncommon multisystem connective tissue disorder that is more likely to occur in patients classified as slow acetylators of hydralazine, which accounts for almost half the UK population.

Inotropic agents

The use of inotropic agents (except digoxin) is almost exclusively limited to hospital practice, where acute heart failure may require the use of one or more inotropic agents, particularly the sympathomimetic agents dobutamine and dopamine, in an intravenous continuous infusion. These agents have inotrope-vasodilator effects which differ according to their action on α, β_1, β_2 and dopamine receptors (β_1-agonists increase cardiac contractility, β_2-agonists produce arterial vasodilation, dopamine agonists enhance renal perfusion). With dopamine, low doses (0–2 µcg/kg/min) have a predominant effect on dopamine receptors within the kidneys to improve urine output, intermediate doses (2–5 µcg/kg/min) affect β_1-receptors, producing an inotropic effect, and high doses (10 µcg/kg/min) have a predominant action on α-adrenoreceptors. Dobutamine has a predominantly inotropic and vasodilator action due to the action of the (+) isomer selectively on β-adrenoreceptors (see Table 21.7). Tolerance to sympathomimetic inotropic agents may develop on prolonged administration, particularly in patients with underlying ischaemia, and is also associated with a risk of precipitating arrhythmias.

Noradrenaline (norepinephrine) is an α-adrenoreceptor agonist where its vasoconstrictor action limits its usefulness in severely hypotensive patients such as those in septic shock. Adrenaline (epinephrine) has β_1, β_2 and α-adrenoreceptor agonist effects and is used in patients with low vascular resistance. However, it is more arrhythmogenic than dobutamine and should be used with caution.

Phosphodiesterase inhibitors are rarely used in clinical practice as a consequence of trials showing an increased risk of mortality (PROMISE, 1991).

Other agents

Direct-acting vasodilators such as sodium nitroprusside are rarely used except in the acute setting when they are given by continuous infusion. Vasodilation occurs as a result of the catalysis of nitroprusside in vascular smooth muscle cells to produce nitric oxide. The fact that nitric oxide production in this instance is via a different route when compared to the catalysis of GTN (where there is a need for sulphydryl groups) may explain why there is little tolerance seen with nitroprusside. In patients with impaired renal function thiocyanate, a metabolic product of nitroprusside can accumulate over several days, causing nausea, anorexia, fatigue and psychosis.

Patients with coronary heart disease may be candidates for calcium-blocking antianginal vasodilators. However, some of these agents can exacerbate co-existing heart failure, since their negative inotropic effects offset the potentially beneficial arterial vasodilation. Amlodipine and felodipine have a more selective action on vascular tissue and, therefore, a less pronounced

effect on cardiac contractility than other calcium antagonists and should be the agents of choice where appropriate.

In hospitalised patients in whom compromised respiratory function remains despite medical management of heart failure, the treatment options include mechanical ventilation, continuous positive airway pressure ventilation and the use of intra-aortic balloon pumping.

Guidelines

Several groups have produced evidence-based consensus clinical guidelines for the management of chronic heart failure. The focus of the various guidelines tends to be on chronic medication use (National Institute for Health and Clinical Excellence, 2010; American College of Cardiology/American Heart Association Task Force on Practice Guidelines, 2009; European Society of Cardiology, 2008; Scottish Intercollegiate Guidelines Network, 2007). All guidelines confirm that ACE inhibitors and β-blockers should be given to all patients with all grades of heart failure, whether symptomatic or asymptomatic, in the absence of contraindication or intolerance.

In ACE inhibitor-intolerant patients, the preferred alternative is an ARB. However, it should be remembered that where ACE inhibitor intolerance is due to renal dysfunction, hypotension or hyperkalaemia, similar effects could be expected with an ARB. If an ARB is an unsuitable alternative, the use of hydralazine/nitrate combination or digoxin could be considered, although the latter combination of agents has no effect on mortality. For patients with symptomatic heart failure, a loop diuretic is usually recommended to treat oedema and control symptoms. In heart failure patients who are still symptomatic despite being on optimum therapy (ACE inhibitor, β-blocker with/without a diuretic), the use of adjunctive therapies is recommended which can include ARB, aldosterone antagonists, hydralazine/nitrate combination and digoxin where the patient is still in sinus rhythm.

There is also debate as to whether diastolic dysfunction is a true diagnosis. The cause of 'apparent' heart failure symptoms can in many cases be attributed to another disease/condition such as respiratory disease, obesity or ischaemic heart disease. However, there may also be some patients in whom the cause of heart failure symptoms remains uncertain. Therefore, specific recommendations for the drug treatment of diastolic heart failure are still lacking.

Patient care

Heart failure remains poorly understood by the general public, amongst whom only 3% were able to identify the condition when presented with a list of typical symptoms. Patients with heart failure are often elderly and often include patients with co-morbidity such as coronary heart disease and hypertension. Other complications include renal impairment, polypharmacy and variable adherence to prescribed medication regimens. Where renal function is compromised, careful attention to dosage selection is required for drugs excreted largely unchanged in the urine. Patients with heart failure are

at particular risk of fluid or electrolyte imbalance, adverse effects and drug interactions. Consequently, careful monitoring is indicated to help detect problems associated with sub-optimal drug therapy, unwanted drug effects and poor patient adherence.

A number of therapeutic problems may be encountered by the patient with heart failure. Notably, heart failure often complicates other serious illness, and is a common cause of hospital admission. In addition to monitoring clinical signs and symptoms in the acute setting, there should be monitoring of fluid and electrolyte balance, assessment of renal and hepatic function, and performance of chest radiograph, electrocardiograph and haemodynamic measurements where appropriate.

Patient education and self-monitoring

The patient must be in a position to understand the need for treatment and the benefits and risks offered by prescribed medication before concordance with a treatment plan can be reached. Appropriate patient education is necessary to encourage an understanding of their condition, inform patients of the extent of their condition and how prescribed drug treatment will work and affect their daily lives. It is also important to encourage them to be an active participant in their care where appropriate. Specific advice should be given to reinforce the timing of doses and how each medication should be taken. Patients also need to be advised of potentially troublesome symptoms that may occur with the medication, and whether such effects are avoidable, self-limiting or a cause for concern.

Patients should be made aware that diuretics will increase urine production, and that doses are usually timed for the morning to avoid inconvenience during the rest of the day or overnight. However, there are cases where patients are advised that they can alter the timing of the dose(s) if required to suit their lifestyle or social commitments, with the agreement of their doctor. There are also some patients who use a flexible diuretic dosing regimen, where they can take an extra dose of diuretic in response to worsening signs or symptoms as part of an agreed self-management protocol. To use such a regimen, the patient has to monitor and record their weight on a daily basis, and have clear instructions to take an extra dose of diuretic when a notable increase in weight is detected as a result of fluid retention, and when to seek medical attention. It is also important for patients to be aware of signs and symptoms of drug toxicity with medicines such as digoxin, for example anorexia, diarrhoea, nausea and vomiting, and be aware of the action to be taken should these symptoms occur.

Timing of doses is also important. If a nitrate regimen is being used, then patients must be made aware that the last dose of the nitrate should be taken mid to late afternoon to ensure that a nitrate-free period occurs overnight, thus, reducing the risk of nitrate tolerance. However, patients with prominent nocturnal symptoms require separate consideration. Where β-blockers are introduced, it is important that the patient is aware of the need for gradual dose titration due to the risk of the medication aggravating heart failure symptoms. Certain medicines for

the treatment of minor ailments that are available for purchase over the counter without a prescription can aggravate heart failure, such as ibuprofen, antihistamines and effervescent formulations. It is important that patients know what action to take if their symptoms become progressively worse, and whom to contact when necessary for advice. Table 21.8 provides a general patient education and self-monitoring checklist, highlighting the typical areas where advice should be given.

Monitoring effectiveness of drug treatment

Therapeutic effectiveness is confirmed by assessing the patient for improvements in reported symptoms such as shortness of breath and oedema, and for noticeable changes in exercise tolerance. Oedema is often visible and remarked upon by patients, especially in the feet (ankles) and hands (wrists and fingers). Increased oedema may be reflected by an increase in the patient's body weight, and can be more easily assessed if the patient routinely records their weight and reviews this on a daily basis. Questions about tolerance to exercise are also use-

ful in identifying patients who may be experiencing difficulties with their condition or where the treatment plan is suboptimal. Onset or deterioration of symptoms is often slow and patients are more inclined to adapt their lifestyle gradually by moderating daily activities to compensate. This should be borne in mind whenever a patient assessment is undertaken.

Identifying the symptoms of poor heart failure control can be complicated by many factors, such as the presence of conditions like arthritis and parkinsonism which can also affect a patient's mobility. Poor control of respiratory disease, presenting as an increased shortness of breath or exacerbation of other respiratory symptoms, can also be mistaken for loss of control of heart failure. Therefore, consideration of these and other factors is necessary in the interpretation of presenting symptoms, as a deterioration in symptoms may not be solely due to worsening heart failure or ineffective heart failure medication.

Dietary factors can lead to loss of symptom control, where failure to restrict sodium intake may contribute to an ongoing problem of fluid retention. Simple dietary advice to avoid processed foods and not to add salt to food should be reinforced.

Table 21.8 Patient education and self-monitoring in the treatment of heart failure

Topic	Advice	Comment
Diuretics	• Will cause diuresis • Timing of dose • Flexible dosing (where indicated)	Monitor for incontinence, muscle weakness, confusion, dizziness, gout, unusual gain in weight within very short time-period (few days). Use of diary to record and monitor daily weight can help identify when to take an agreed extra dose of diuretic. Patient also able to adjust time of dose to suit lifestyle where necessary
ACE inhibitors	• Improve symptoms • Avoid standing rapidly	Monitor for hypotension, dizziness, cough, taste disturbance, sore throat, rashes, tingling in hands, joint pain
β-Blockers	• Symptoms worsen initially • Gradual increase in dose	Monitor for hypotension, dizziness, headache, fatigue, gastro-intestinal disturbances, bradycardia
Cardiac glycosides	• Report toxic symptoms	Monitor for signs or symptoms of toxicity, such as anorexia, nausea, visual disturbances, diarrhoea, confusion, social withdrawal
Nitrates	• Timing of dose • Postural hypotension • Avoid standing rapidly	Monitor for headache, hypotension, dizziness, flushing (face or neck), gastro-intestinal upset. Ensure asymmetrical dosing pattern for nitrates to provide nitrate-free period and reduce risk of tolerance developing
Potassium salts	• Administration of dose (soluble + non-soluble)	Monitor for gastro-intestinal disturbances, swallowing difficulty, diarrhoea, tiredness, limb weakness. Ensure patient knows how to take their medication safely, for example, swallow whole immediately after food, or soluble forms to be taken with appropriate amount of water/fruit juice and allow fizzing to stop
Purchased medicines	• Choice of medicines	Ensure patient is aware of need to seek advice when purchasing medicines for minor ailments. Ask pharmacist to confirm suitability when selecting
Understanding the condition	• What heart failure is • Impact on lifestyle • Treatment goals	Ensure patient understands their condition, treatment goals and complications that may impact on their quality of life. Important to motivate the patient with respect to lifestyle modification and achievement of agreed treatment goals relative to the degree of heart failure present (asymptomatic, mild, moderate or severe symptoms)
Health issues	• Diet; sodium intake • Alcohol intake • Smoking • Exercise • Other risk factors	Issues related to diet, alcohol consumption, smoking habit, regular gentle exercise (walking). Other associated risk factors, for example, hypertension, ischaemic heart disease, need to be addressed where appropriate

According to some manufacturers, the absorption of ACE inhibitors, for example, captopril, perindopril, may be slowed by food or antacids and, therefore, patients should be advised to take the dose before food in the morning to ensure maximum effect.

Patients with heart failure may often receive suboptimal drug treatment, due to the fact that they are not prescribed first-line therapy, such as ACE inhibitors and β-blockers, and the dosage is below the recommended target dose. All patients at risk of suboptimal treatment need to be routinely identified, and this will require the involvement of health care professionals in the monitoring of symptoms and the individualisation of each patient's therapeutic plan.

In an effort to systematically identify whether a patient's therapeutic plan adheres to the current evidence base for treatment, and whether any changes might be required to optimise therapy, the audit tool shown in Box 21.1 could be used in routine practice. The tool has been derived from published consensus-based clinical guidelines, and could underpin a more comprehensive medication review.

Monitoring safety of drug treatment

A number of issues around the safe use of medication must be considered, especially in those patients with co-morbidity and/or a high number of prescribed medicines. In these patients there is an increased risk of drug–drug and drug–disease interactions (Tables 21.9-21.11). It is important to be aware of clinically important interactions and to investigate potentially problematic combinations, as well as to regularly assess the patient for any signs or symptoms of drug therapy problems. Monitoring for problems such as negative inotropic effects, excessive blood pressure reduction, and salt and fluid retention should be undertaken and, where appropriate, laboratory measurement of serum drug concentration (digoxin) or physiological markers (potassium, creatinine) should be performed to confirm or exclude adverse effects. Patients started on an ACE inhibitor should have renal function and serum electrolytes checked at 1 and 3 months after starting therapy, and 6 monthly once a maintenance dose is reached.

Potential problems with diuretic therapy

The use of diuretic therapy for sodium and water retention is common in the treatment of heart failure, although there can be a number of problems for the patient to contend with. Elderly patients in particular are at risk from the unwanted effects of diuretics. The increase in urine volume can worsen incontinence or precipitate urinary retention in the presence of an enlarged prostate, while overuse can lead to a loss of

Table 21.9 Monitoring the effectiveness of drug treatment in patients with heart failure

Consider	Monitor for	Comment
Clinical markers	• Poor symptom control • Achievement of agreed treatment goals	Signs or symptoms of undertreatment or advancing disease need to be addressed (dyspnoea, breathlessness and/or fatigue). The aim is for good symptom control and either maintenance or improvement in quality of life. Persisting symptoms or hospitalisation may indicate a revision of drug therapy or the addition of other agents where appropriate
Interactions	• Drug–drug interactions	Some interactions may result in reduced effectiveness and require dosage adjustment or change in choice of drug
Compliance	• Formulation acceptability • Dose timing and interval • Unusual time interval between requests for prescription medication	Poor adherence can result from drug being ineffective (over- or under-use), experience of side effects, a complicated drug regimen or patient behaviour (intentional non-adherence or forgetfulness). Reasons need to be identified and addressed where possible, for example, adjusting frequency and timing of doses, review choice of formulation, education. Initiation of devices to improve compliance should be considered where appropriate
Evidence-based prescribing	• Implementation of evidence-based guidelines • Audit of prescribed treatment for heart failure	The drug of choice for a particular patient may not reflect the evidence base for treatment for patients with heart failure. It is important to ensure evidence-based treatments are considered for every patient, and choices of medication confirmed or changed where appropriate. Audit of guideline recommendations to help confirm that treatment plans are optimal can be systematically applied to help assess appropriateness of treatment (see Box 21.1)
Multidisciplinary working	• Input from other health care professionals	It is important to be aware of what care has already been provided to minimise the risk of giving conflicting advice to the patient or duplicating work already done. It may also allow reinforcement of key information. There is an increasing evidence base for the benefits of multidisciplinary models of care for chronic heart failure patients

Box 21.1 Criteria for the assessment of drug treatment in a patient with chronic heart failure (Scottish Intercollegiate Guidelines Network, 2007)

Need for drug therapy (all patients)
1. Is an ACE inhibitor prescribed?
2. If intolerant to ACE inhibitor, is an ARB prescribed?
3. If intolerant to an ACE inhibitor and ARB, is H/ISDN prescribed?
4. Is a β-blocker prescribed?
5. Has patient received pneumococcal vaccination?
6. Has patient received influenza vaccination?

Need for drug therapy (as appropriate)
7. If symptomatic on optimised doses of ACE inhibitor and BB, is an aldosterone antagonist or candesartan prescribed?
8. If symptomatic on optimised therapy with ACE inhibitor I, BB and ARB/aldosterone antagonist, is digoxin prescribed?
9. If post-MI, is an antiplatelet and statin prescribed?
10. In AF, is thrombo-embolic prophylaxis prescribed?

Need for dose titration
11. If an ACE inhibitor I is prescribed, target dose achieved?
12. If an ARB is prescribed, target dose achieved?
13. If a BB is prescribed, target dose achieved?
14. If warfarin prescribed, is dose titrated to INR?

Medication safety
15. Aggravating drugs avoided (if possible):
    (a) NSAIDs
    (b) Tricyclic antidepressants
    (c) Some antihistamines (e.g. diphenhydramine)
    (d) Dihydropyridine calcium channel blockers (except amlodipine or felodipine)
    (e) Diltiazem, verapamil
    (f) Glitazone anti-diabetics
    (g) Minoxidil
    (h) Itraconazole and other azole antifungals
    (i) Macrolide antibiotics
    (j) Corticosteroids
    (k) Tadalafil
    (l) Lithium

ACE inhibitor, angiotensin converting enzyme inhibitor; AF, atrial fibrillation; ARB, angiotensin receptor blocker; BB, β-blocker; H, hydralazine; INR, international normalised ratio; MI, myocardial Infarction.

control of heart failure and worsening of symptoms. Rapid diuresis with a loop diuretic leading to more than a 1-kg loss in body weight per day may exacerbate heart failure due to an acute reduction in blood volume, hypotension and diminished renal perfusion, with a consequent increase in renin release. Prolonged and excessive doses of diuretics can also contribute to symptoms of fatigue as a consequence of electrolyte disturbance and dehydration. The adverse biochemical effects of excessive diuresis include uraemia, hypokalaemia and alkalosis. Diuretic-induced glucose intolerance may affect diabetic control in type 2 diabetes, but more commonly diuretics reveal glucose intolerance in patients who are not diagnosed as being diabetic. Diuretics also increase serum urate leading to hyperuricaemia, although this may not require a change in drug therapy if symptoms of gout are absent (estimated incidence of 2%).

Hyponatraemia may occur with diuretics, and is usually due to water retention rather than sodium loss. Severe hyponatraemia (serum sodium concentration of less than 115 mmol/L) causes confusion and drowsiness. It commonly arises when potassium-sparing agents are used in diuretic combinations.

Diuretics may also lead to hypokalaemia as a result of urinary sodium increasing the rate of K^+/Na^+ exchange in the distal tubule. Serum potassium concentrations below 3.0 mmol/L occur in less than 5% of patients receiving diuretics. The occurrence of hypokalaemia is hazardous for patients receiving digoxin and also for those with ischaemic heart disease or conduction disorders. It is more commonly found with thiazide diuretics than loop agents, and is more likely to occur when diuretics are used for heart failure than for hypertension. This is probably due to the fact that higher doses are used and there is an associated activation of the renin–angiotensin system. Patients with a serum potassium level of less than 3.5 mmol/L require treatment with potassium supplements or the addition of a potassium-sparing diuretic. The use of a potassium-sparing diuretic is considered to be more effective at preventing hypokalaemia than using potassium supplements. Prevention of hypokalaemia requires at least 25 mmol of potassium, while treatment requires 60–120 mmol of potassium daily. Since proprietary diuretic-potassium combination products usually contain less than 12 mmol in each dose, their use is often inappropriate.

Potassium supplements are poorly tolerated at the high doses often needed to treat hypokalaemia, and a liquid formulation is more preferable to a solid form. This is mainly due to the fact that solid forms can produce local high concentrations of potassium salts in the gastro-intestinal tract, with the risk of damage to the tract in patients with swallowing difficulties or delayed gastro-intestinal transit. In patients with deteriorating renal function or renal failure, the use of potassium supplements or potassium-sparing diuretics might cause hyperkalaemia, and therefore careful monitoring of these agents is essential.

Potential problems with ACE inhibitor and ARB therapy

ACE inhibitors are the cornerstone of the treatment of heart failure, but there are also risks associated with their use. ARBs, which also act on the renin–angiotensin–aldosterone system, pose similar risks to those recognised for ACE inhibitors. Both agents can predispose patients to hyperkalaemia through a reduction in circulating aldosterone; therefore, potassium supplements or potassium-retaining agents should be used with care when co-prescribed, and careful monitoring of serum potassium should be mandatory. Although potassium retention can be a problem with ACE inhibitors and ARBs, it can also be an advantage by helping to counteract the potassium loss that can result from the use of diuretic therapy. However, since this effect on potassium cannot be predicted, laboratory monitoring is still necessary to confirm that serum potassium concentration remains within safe limits.

The use of an aldosterone antagonist as adjunctive therapy with an ACE inhibitor (or ARB if the patient is ACE inhibitor intolerant) can be safely undertaken with minimal effects on the serum potassium concentration, provided that recommended target doses for the aldosterone antagonist are not

Table 21.10 Common drug–drug interactions with prescribed heart failure medication

Drug	Interacts with	Result of interaction
Diuretic	NSAIDs	Decreased effect of diuretic and increased risk of renal impairment
	Carbamazepine	Increased risk of hyponatraemia
	Lithium	Excretion of lithium impaired (thiazides worse than loop diuretics)
ACE inhibitor or ARB	NSAIDs	Antagonism of hypotensive effect. Increased risk of renal impairment
	Ciclosporin	Increased risk of hyperkalaemia
	Lithium	Excretion of lithium impaired
	Diuretics	Enhanced hypotensive effect. Increased risk of hyperkalaemia with potassium-sparing drugs
Digoxin	Amiodarone	Increased digoxin level (need to halve maintenance dose of digoxin)
	Propafenone	Increased digoxin level (need to halve maintenance dose of digoxin)
	Quinidine	Increased digoxin level (need to halve maintenance dose of digoxin)
	Verapamil	Increased risk of AV block
	Diuretics	Increased risk of hypokalaemia and therefore toxicity
	Amphotericin	Increased cardiac toxicity if hypokalaemia present
Nitrates	Sildenafil	Increased hypotensive effect
	Heparin	Increased excretion of heparin
Spironolactone	Digoxin	Spironolactone may interfere with measurement of digoxin serum levels, resulting in inaccurate interpretation
β-Blocker	Amiodarone	Increased risk of bradycardia
	Diltiazem	Increased risk of AV block and bradycardia
	Verapamil	Increased risk of hypotension, heart failure and asystole

Table 21.11 Common drug–disease interactions with prescribed heart failure medication

Drug	Concurrent disease	Potential outcome
Diuretic	Prostatism	Urinary retention/incontinence
	Hyperuricaemia	Exacerbation of gout
	Liver cirrhosis	Encephalopathy
ACE inhibitor	Renal artery stenosis	Renal failure
	Severe aortic stenosis	Exacerbation of heart failure
	Renal impairment	Renal failure
	Hypotension	Hypotension and cardiogenic shock
β-Blocker	Asthma	Bronchoconstriction/ respiratory arrest
	Bradyarrhythmias	Exacerbation of heart failure
	Hypotension	Further hypotension and cardiogenic shock
Digoxin	Bradyarrhythmias	Exacerbation of heart failure
	Renal impairment	Exacerbation of heart failure and digoxin toxicity leading to cardiac arrhythmias

exceeded (see Table 21.5). Although this is usually the case, laboratory monitoring of potassium is mandatory to ensure patient safety. Heparin therapy has also been shown to increase the risk of hyperkalaemia when used alongside ACE inhibitor or ARB therapy, and therefore a similar approach to monitoring should be taken when co-prescribed.

When initiating ACE inhibitor or ARB therapy, volume depletion due to prior use of a diuretic increases the risk of a large drop in blood pressure occurring following the first dose. As a consequence, diuretic treatment is usually withheld during the initiation phase of therapy in an effort to minimise this effect.

A dry cough, which may be accompanied by a voice change, occurs in about 10% of patients receiving an ACE inhibitor. It is more common in women and is associated with a raised level of kinins. Rashes, loss or disturbances of taste, mouth ulcers and proteinuria may also occur with ACE inhibitor therapy, particularly with captopril. These unwanted effects tend to be more common in patients with connective tissue disorders.

A number of ACE inhibitors are administered as pro-drugs, so close monitoring is advised in patients with liver dysfunction, as this could reduce the benefits associated with their use. Most ACE inhibitors are dependent on the kidney for excretion, and require careful dosage titration in patients with existing renal dysfunction. Differences in the pharmacokinetic characteristics do not fully explain the differences in duration of action seen with the ACE inhibitors, as this is also related to ACE binding affinity. Throughout treatment the dose must be individualised to obtain maximum benefit in relation to symptom relief and survival, with minimum side effects. When the experience of adverse effects requires a review of therapeutic alternatives, ARBs can be considered as an alternative treatment option. Although the side effect profile of ARB therapy is very similar to that of ACE inhibitors, it is not identical.

Potential problems with β-blocker therapy

Until recently, the use of β-blockers was contraindicated in patients with heart failure due to negative inotropic and chronotropic effects. However, β-blockers have clearly been shown to be safe and effective in patients with heart failure and should be used in all patients in the absence of contraindications or intolerance. Initiation of treatment and titration of dose must be done under close supervision, with very small dose increments used to minimise transient worsening of heart failure symptoms. Titration of the dose to target is normally performed over a number of weeks or months, and close patient monitoring is required to ensure safety is not compromised. The maximum tolerable dose for a patient may be below the target dose and may limit further dose titration. Monitoring for excessive bradycardia or rapid deterioration of symptoms is necessary to ensure patient safety, while also monitoring the patient's prescribed dose to ensure that dosage increments are gradual and the patient is not subjected to an overall worsening of symptoms.

Potential problems with digoxin therapy

Although digoxin has been shown to reduce hospitalisation rates for patients with heart failure, its use is associated with a range of adverse effects including non-specific signs and symptoms of toxicity such as nausea, anorexia, tiredness, weakness, diarrhoea, confusion and visual disturbances. Digoxin also has the potential to cause fatal arrhythmias. It slows atrioventricular conduction and produces bradycardia, but it may also cause various ventricular and supraventricular arrhythmias. Digoxin toxicity typically causes conduction disturbances with enhanced automaticity leading to premature ventricular contractions. Patients at particular risk are those with myocardial ischaemia, hypoxia, acidosis or renal failure.

The appropriateness of digoxin dosage should be guided by assessment of the patient's renal function (from serum creatinine and creatinine clearance determinations) and from the patient's pulse rate. Renal function may also be affected by drug therapy or loss of control of heart failure; therefore, any medicine which affects in digoxin clearance will have an impact on the serum digoxin concentration. The possibility of a high serum digoxin concentration should also be considered in any patient whose health deteriorates or who shows signs and symptoms of potential digoxin toxicity.

Potential problems with other cardiovascular drugs

There are a number of other cardiovascular drugs that may be prescribed for patients with diseases or conditions other than heart failure, with some agents capable of worsening or aggravating symptoms. Patients with coronary artery disease may be candidates for calcium-blocking antianginal vasodilators. However, some of these agents, for example, diltiazem and verapamil, can exacerbate co-existing heart failure, since their negative inotropic effects offset the potentially beneficial arterial vasodilation. Second-generation dihydropyridines such as amlodipine and felodipine have a preferential action on the vasculature. They have less pronounced effects on cardiac contractility than other calcium antagonists, and this makes them the agents of choice where a limitation of the heart rate is not required.

Symptoms of fainting or dizziness on standing may indicate a need to review diuretic or vasodilator therapy. Patients should be reassured about mild postural effects and given advice to avoid standing from their chair too quickly. The patient and the health care team need to confirm the safety of the patient's treatment plan regularly, and be vigilant for any signs or symptoms suggesting otherwise.

A summary of monitoring activity required to ensure the safety of drug use is outlined in Table 21.12.

Table 21.12 Monitoring the safety of drug treatment in patients with heart failure

Consider	Monitor	Comment
Clinical markers	Side effects Toxicity Adverse drug reactions	There is a need to monitor for signs/symptoms of overtreatment with prescribed medication, such as diuretics (dehydration) and digoxin (nausea and vomiting). Look for signs of patient intolerance, allergy, serious adverse effects or troublesome side effects. Document unexpected adverse drug reactions if reported
Laboratory markers	Changes in organ function Biochemical changes Haematological changes Suspected digoxin toxicity	Renal function assessment and implications for drug choice and dosage individualisation required, especially in the elderly and for initiation or titration of ACE inhibitor therapy (creatinine, potassium, urea). Hypokalaemia can lead to digoxin toxicity, and serum drug concentration measurement may be performed to confirm or exclude toxicity. Haematological side effects with some drugs have been reported, for example, ACE inhibitors, therefore, laboratory checks may be required in response to clinical signs/symptoms presented
Interactions	Drug–drug interactions Drug–disease interactions	Some interactions may result in harm to the patient
Co-morbidity	Drug selection for concomitant conditions	The presence of heart failure may influence treatment choice for co-existing diseases or conditions, for example, coronary artery disease, thyroid disease, respiratory disease. Where possible, ensure drugs known to worsen heart failure are avoided or used with caution, for example, non-steroidal anti-inflammatory agents or corticosteroids in rheumatoid arthritis

Potential problems with non-cardiovascular agents

A number of agents should be avoided or used with caution in patients with heart failure because of their known negative inotropic or pro-arrhythmic effects that may aggravate symptoms of heart failure (see Box 21.1). In particular, the use of non-steroidal anti-inflammatory drugs (NSAIDs) should be actively discouraged where possible. Not only do NSAIDs cause fluid retention and put patients at increased risk of bleeding, especially if they are already taking antiplatelets or anticoagulants, there is also an increased risk of acute renal failure, particularly in those on long-term use and in the elderly. Recent articles have described the synergistic/cumulative adverse renal effects of combinations of ACE inhibitors or ARBs with diuretics and NSAIDs, which are particularly common in patients with heart failure.

Case studies

Case 21.1

Mr GF, a 57-year-old, suffered a myocardial infarction 12 months ago and at the time was also found to have left ventricular systolic dysfunction on echocardiography. He is currently asymptomatic (NYHA I). At your request, he has agreed to see you for a medication review regarding his drug therapy. He has a history of type 2 diabetes mellitus (8 years) and his current prescription includes enalapril 10 mg twice daily, gliclazide 80 mg twice daily, bisoprolol 5 mg daily, aspirin 75 mg daily, and a glyceryl trinitrate spray to use when required.

Question

1. Is the current treatment plan for heart failure optimal?

Answer

1. Mr GF has echocardiographic evidence of left ventricular systolic dysfunction, but has no signs or symptoms of heart failure at present. Therefore, the absence of diuretic therapy is expected, although enquiry into the presence/absence of symptoms would form part of any review and would be included in the patient monitoring.

   He is prescribed an ACE inhibitor at the recommended target dose (enalapril 10–20 mg twice daily) and treatment with this agent is optimal at present. There is scope for a further increase in dose should the need arise. When we consider β-blocker therapy, the current dose of bisoprolol (5 mg daily) is below the recommended target and should, therefore, be titrated to a dose of 10 mg daily or maximum tolerable dose. This titration should be implemented gradually over a period of weeks or months with close monitoring of blood pressure and heart rate. Regular assessment of the patient for side effects or signs and symptoms of heart failure should also be undertaken, as each incremental rise in β-blocker dose may be accompanied by a worsening (or in this case, appearance) of heart failure symptoms. When considering other potential changes to the treatment plan for heart failure, there may have been an opportunity for the introduction of eplerenone at the time of his myocardial infarction provided this was done within 14 days of the event. However, given that the myocardial infarction was 12 months ago, the use of eplerenone would not be indicated based on the current evidence.

With Mr GF's history of myocardial infarction and type 2 diabetes mellitus, his cardiovascular risk is high and he should, therefore, also be prescribed lipid-lowering therapy (regardless of his serum cholesterol measurement), for example, a statin.

Case 21.2

Mrs JM, 66 years old, presents with a new prescription for candesartan 4 mg daily. On checking her medication record she has been prescribed lisinopril 20 mg daily, bisoprolol 10 mg daily and furosemide 40 mg daily for the last 6 months to treat her heart failure. Her blood pressure was measured 2 weeks ago and was 128/78 mmHg.

Question

1. How do you respond to the new prescription?

Answer

1. It is unclear from the information given whether candesartan is prescribed as an adjunct to ACE inhibitor therapy (provided the dose has been optimised) or as an alternative to ACE inhibitor due to intolerance. If being used as an adjunct, it is also unclear whether the patient also has an intolerance to aldosterone antagonists. Therefore, it is important to confirm the intended use of candesartan in this case through speaking to the patient and/or prescriber. If candesartan is being used as an alternative to either the ACE inhibitor or aldosterone antagonist, it is important to establish the reason for intolerance and ensure the therapeutic choice is appropriate for the patient. Patients are usually found to be intolerant of ACE inhibitors for three main reasons: dry cough, hypotension or compromised renal function. As heart failure can produce symptoms of a dry cough, it can sometimes be difficult to ascertain whether the ACE inhibitor or the heart failure is responsible. Dry cough occurs secondary to the inhibition of bradykinin metabolism and is generally identified shortly after initiation of an ACE inhibitor or after a dose increase; therefore, inquiry into the timing of symptoms attributed to ACE inhibitor intolerance is important. If the reason is due to persistent dry cough, an ARB would be a suitable alternative. However, if the ACE inhibitor intolerance is related to hypotension or renal dysfunction, it is likely an ARB would induce similar adverse effects and, therefore, other alternatives may need to be discussed with a heart failure specialist. In patient's intolerant of an aldosterone antagonist, the main reasons tend to be related to hyperkalaemia or unacceptable side effects such as gynaecomastia in men, gastro-intestinal intolerance and renal dysfunction.

   If candesartan is being used as adjunctive therapy, which is supported by the current evidence base for treatment, careful introduction and titration of dose must be undertaken due to the increased risk of hypotension, renal dysfunction and hyperkalaemia (ACE inhibitors and ARBs are both potassium conserving). The addition of candesartan would normally be under the guidance of a heart failure specialist, and should be initiated at a low dose and gradually titrated up to the target (32 mg daily) or maximum tolerable dose. It is important to note that dose increases during the titration period should be at least 2 weeks apart. Although Mrs JM has a normal blood pressure measurement at present, it is unclear whether renal function or blood biochemistry has previously been checked and it is important that this is confirmed prior to starting candesartan. The monitoring plan for Mrs JM should include regular checks of blood pressure, serum creatinine (and estimation of renal function), serum potassium and clinical assessment for any signs/symptoms of adverse effects/intolerance. This should be done

7–14 days after initiation and final dose titration. As the addition of candesartan should improve heart failure symptom control, regular patient monitoring will allow an assessment of the effectiveness of therapy.

Case 21.3

Mr HS, 72 years old, is admitted to hospital with increasing shortness of breath at rest. He has a previous medical history of severe left ventricular systolic dysfunction, confirmed by echocardiography, and angina. Before admission he had been taking the following medication: lisinopril 10 mg daily, furosemide 80 mg each morning and 40 mg at 2 pm, digoxin 62.5 µcg each morning, ISMN SR 60 mg daily, glyceryl trinitrate spray 1–2 doses as required, aspirin 75 mg dispersible each morning. His chest X-ray shows severe pulmonary oedema, his blood pressure is 110/70 mmHg and serum urea and electrolytes are within normal range. During the admission, carvedilol 3.125 mg twice daily is started.

Questions

1. What therapeutic options would you choose to treat the acute symptoms presented by Mr HS at the beginning of his admission?
2. Was the addition of bisoprolol appropriate for this patient?
3. What other drug treatment options might be considered for this patient in the longer term?

Answers

1. The administration of furosemide by the intravenous route is necessary as there is decreased absorption of oral furosemide secondary to gastro-intestinal oedema in acute heart failure. The administration of i.v. furosemide allows rapid serum levels to be achieved which has the benefit of producing venodilation (reducing the preload) which helps improve symptoms long before there is diuresis. Only after the oedema has resolved should the patient revert back to oral administration of diuretics. At this time, the dosage can be adjusted to maintain an appropriate fluid balance. Where diuresis is inadequate with an oral loop diuretic alone, the addition of a thiazide diuretic such as bendroflumethiazide or metolazone should be considered. Metolazone should be given initially at low dose of 2.5 mg daily, or less often if required, to avoid rapid diuresis leading to hypotension and/or renal failure.
2. Although there is good evidence to show that β-blocker therapy is safe and effective for patients with NYHA stage IV heart failure, it is not currently recommended that it should be initiated in patients with acute symptoms of heart failure. Where β-blocker therapy is indicated, initiation should occur when the patient's heart failure has been stable for at least 2 weeks and started at a very low dose on specialist advice (i.e. carvedilol 3.125 mg twice daily). The dose should be titrated gradually over a period of months towards the recommended target dose where appropriate, provided the patient tolerates each increment. In Mr HS's case, however, there is evidence to suggest that β-blocker use at discharge can be done safely in patients with heart failure, with positive effects on survival for both heart failure and coronary heart disease.
3. There is also scope to increase the dose of lisinopril to 20–35 mg daily provided the patient can tolerate the higher dose, as this is associated with greater benefits on morbidity and mortality. Based on his systolic blood pressure and assuming satisfactory renal function, there is no reason why this option cannot be explored and it would be reasonable to delay any titration of dosage until the symptoms become more stable. This is important since the use of large doses of loop diuretics in acutely ill patients

may predispose to ACE inhibitor-induced renal impairment. An aldosterone antagonist (or angiotensin receptor blocker if patient tolerance poor) could be added to Mr HS's existing drug therapy. If the patient is poorly controlled on optimised doses of ACE inhibitor and β-blocker. Either addition would show benefits on morbidity and mortality if added to the existing treatment plan. The decision to initiate the angiotensin receptor blocker would usually lie with a heart failure specialist based on the individual patient. As Mr HS approaches end-stage heart failure, there may be a need to focus solely on symptom relief.

Case 21.4

Mrs FM, a 70-year-old with chronic asthma and mild heart failure, has been prescribed naproxen 250 mg three times daily. On inspection of her medication record, it is discovered that she is also receiving:

Furosemide 40 mg each morning
Ramipril 5 mg in the morning
Prednisolone 5 mg daily
Salbutamol inhaler two puffs four times daily when required
Salmeterol 50 µcg inhaler one puff twice daily
Beclometasone 250 µcg inhaler two puffs twice daily
Omeprazole 10 mg daily

When asked her about symptom control she told that she is still breathless at night which, in addition to her painful knee, is keeping her awake.

Questions

1. Do you think Mrs FM should be taking naproxen?
2. What other aspects of this patient's medication regimen could be improved?
3. What is the likely effect of the prescribed therapy on serum potassium concentrations?

Answers

1. NSAIDs such as naproxen can exacerbate asthma and heart failure by inducing bronchospasm and by causing fluid retention, respectively. They can also lead to upper gastro-intestinal problems, particularly when co-prescribed with oral steroids. It would be worth checking what has been tried already. If the painful knee is responsive to a simple analgesic such as paracetamol, this would be the preferred option. Alternatively, if an NSAID is necessary and tolerated, the use of ibuprofen in low dosage would be slightly less likely to have an effect on respiratory and renal function, although it may still aggravate symptoms of heart failure. Further investigation into the persistence of respiratory symptoms is required as it is unclear whether the patient's breathlessness is due to an exacerbation of her asthma or a worsening of her heart failure, and therefore the interpretation of this symptom is difficult.
2. The clinical nature of the breathlessness is not easy to determine, and therefore makes the solution to this case uncertain at this stage. A number of issues, which also include confirming both diagnoses, should be considered. It is important to establish whether the patient is receiving maximum benefit from inhaled treatment. Inhaler technique must be checked and improved if necessary and the dose of beclometasone optimised. A regular regimen of salbutamol is not advisable since it may impair control of asthma by masking the onset of exacerbations. A review of the need for an oral steroid should be undertaken, and any reduction in the use of an oral steroid must be done gradually to avoid exacerbation of the asthma and ensure that the patient does not experience adrenal insufficiency.

Reduction of the oral steroid dose may benefit the heart failure. Although the prednisolone dose is low its impact on treated heart failure is probably low but nevertheless should be taken into account in the review of its use.

When considering the treatment of heart failure, application of the criteria set identified the following were not met in Mrs FMs treatment:

- **Not achieved target dose of ACE inhibitor**
- **Not prescribed any aldosterone antagonist**
- **Not prescribed candesartan**
- **Potentially aggravating drug prescribed (NSAID, naproxen)**

There is scope to increase the dose of ramipril to 5 mg twice daily if tolerated, which is the target dose in heart failure patients. However, as β-blocker is contraindicated in this patient, consideration may be given to an adjunctive therapy such as an aldosterone antagonist, for example spironolactone. If the patient was known to be intolerant of an aldosterone antagonist, an ARB, for example candesartan, could be added instead. The decision around which agent to select first may come down to personal choice if symptoms are moderate. An increase in the dose of furosemide could also be considered provided the breathlessness is due to heart failure.

3. Mrs FM is receiving a number of medications with the potential to affect serum potassium. Diuretics, oral and inhaled steroids (high dose) and β-agonists can reduce potassium, while ACE inhibitors can increase potassium. It is impossible to predict the extent to which each agent will affect potassium, especially with inhaled treatments as the dose normally needs to be high before there is any significant systemic absorption. Determination of serum potassium is necessary and if it remains low under the current treatment plan, or is at risk of being altered due to changes in drug dosage such as an increase in ramipril to 5 mg twice daily, then close observation will be required.

Case 21.5

Mr CH, a 78-year-old, regularly visits your pharmacy for his medication and has moderately symptomatic heart failure (NYHA III). During a recent review with his primary care doctor, Mr CH described worsening of his heart failure symptoms. His doctor has said he could take an extra dose of furosemide 40 mg if required, but Mr CH would need to be referred back to the hospital cardiology consultant before changing any other medication. He is currently prescribed ramipril 5 mg daily, nebivolol 2.5 mg daily and furosemide 40 mg daily. His blood pressure has been measured as 103/62 mmHg (heart rate 54 bpm) and he has an estimated creatinine clearance of 20 mL/min.

Questions

1. What is the rationale behind the decision to refer Mr CH to the cardiology consultant?
2. What other drug treatment options might be considered?

Answers

1. Mr CH is prescribed both ACE inhibitor and β-blocker therapy in accordance with the evidence base for treatment. As Mr CH has symptomatic heart failure (NYHA III), he is also prescribed furosemide in response to signs and symptoms of fluid retention. When Mr CH reports deterioration in the control of his heart failure symptoms, the prescriber must consider what treatment options are available for Mr CH and make any necessary changes.

   Neither the ACE inhibitor nor β-blocker is prescribed at the recommended target dose (see Table 21.6); therefore, there is scope to titrate the dose of either agent to the target dose which should result in improvement of symptoms and a reduced need for diuretic therapy. However, there may be reluctance to increase the dose of ACE inhibitor possibly due to the fact that Mr CH has a relatively low blood pressure and compromised renal function (estimated creatinine clearance 20 mL/min). However, it is unclear whether Mr CH is receiving maximally tolerated doses and whether his apparent hypotension is indeed symptomatic. Similarly, there may be reluctance to increase the dose of β-blocker due to a low blood pressure and heart rate (54 bpm). As both options may adversely affect the patient, the doctor has decided to treat the symptoms with additional diuretic when required as a short-term solution prior to Mr CH's appointment with the cardiology consultant. Advice should be sought from a heart failure specialist where a patient may be poorly tolerant of ACE inhibitor or β-blocker, or where there is a risk of hypotension or renal failure in susceptible individuals. In Mr CH's case, specialist supervision is required for optimisation of therapy.

2. It is unlikely that there will be much scope to add further medication, and optimising either ACE inhibitor or β-blocker therapy will be limited due to their effects on blood pressure and/or renal function. Mr CH may be a likely candidate for cardiac resynchronisation therapy (CRT) and should probably be assessed for this. An ECG would confirm his eligibility for therapy if his QRS duration was >120 ms, and would be likely to improve his symptoms and survival. It may also help increase his blood pressure and renal function to a point where further optimisation of ACE inhibitor and β-blocker dose might be possible.

22 Arrhythmias

S. Sporton and S. Antoniou

Key points

- Arrhythmias are common and should be treated only if they cause symptoms or threaten haemodynamic failure.
- An understanding of the ionic basis of the cardiac action potential is important because drugs used in the treatment of cardiac arrhthymias act by altering the function of the trans-membrane ion channels.
- The heart is designed to work most efficiently in sinus rhythm. Any arrhythmia compromises cardiac function.
- Non-pharmacological treatments for arrhythmias are becoming more common.
- Atrial fibrillation is the most common arrhythmia and is associated with an increased risk of thromboembolic stroke. All patients with atrial fibrillation should undergo assessment of their stroke risk.
- Antiarrhythmic drugs are grouped by the Vaughan–Williams classification based on their ability to block the movement of specific ions across the myocardial cell membrane.
- All antiarrhythmic drugs are also proarrhythmic in some circumstances.
- While drug treatment has been the mainstay of arrhythmia treatment, it is often of limited efficacy and may be associated with significant toxicity.
- ß-Blockers and amiodarone are the most commonly used antiarrhythmic drugs.

Normal cardiac electrophysiology

The normal cardiac rhythm, sinus rhythm, is characterised by contraction of first the atria and then the ventricles (systole) followed by relaxation (diastole) during which the heart refills with blood before the next cardiac cycle begins. This orderly sequence of contraction and relaxation is regulated by the heart's electrical activity. Heart muscle cells (myocytes) are electrically active and capable of generating action potentials, which initiate contraction of the myocyte through a process known as excitation–contraction coupling. Adjacent myocytes form electrical connections through protein channels called gap junctions. An action potential in one myocyte causes current flow between itself and adjacent myocytes which in turn generate their own action potentials and in this way an 'activation wavefront' spreads though the myocardium, resulting in a wave of contraction.

Cardiac action potential

An understanding of the ionic basis of the cardiac action potential is important because drugs used in the treatment of cardiac arrhythmias act by altering the function of trans-membrane ion channels. Inherited abnormalities of ion channel function ('channelopathies') are an important cause of sudden cardiac death due to arrhythmia and are increasingly implicated in the pathogenesis of other arrhythmias including atrial fibrillation (AF).

The phospholipid membrane of cardiac myocytes is spanned by numerous proteins known as ion channels, whose permeability to specific ions varies during the cardiac cycle resulting in a resting (diastolic) membrane potential, diastolic depolarisation in cells with pacemaker activity, and action potentials.

The resting membrane potential of –60 to –90 mV occurs because the intracellular potassium (K^+) concentration is much higher than the extracellular K^+ concentration as a result of a transmembrane pump known as Na^+–K^+–ATPase, which pumps K^+ ions into the cell in exchange for sodium (Na^+) ions. K^+ ions diffuse out of the cell through selective K^+ channels (the inward rectifier current or I_{K1}) unaccompanied by anions, resulting in a net loss of charge and thus a negative resting, diastolic or phase 4, transmembrane potential (Fig. 22.1A).

Certain specialised myocytes form the cardiac conduction system and these cells have pacemaker activity, that is, they are capable of generating their own action potentials due to gradual depolarisation of the transmembrane potential during diastole (phase 4), referred to as the pacemaker potential (Fig. 22.1B). The pacemaker potential occurs as a result of (i) a gradual reduction in an outward K^+ current called the delayed rectifier (I_K) current, (ii) increasing dominance of an inward current of Na^+ and some Ca^{2+} ions known as I_f (f stands for 'funny') and (iii) an inward calcium current I_{Ca} through voltage-gated calcium channels. As a result of the pacemaker potential, the transmembrane potential gradually becomes less negative until a threshold potential is reached at which an action potential is triggered. The rate of depolarisation of the pacemaker potential, and hence the heart rate, is influenced by the autonomic nervous system. Sympathetic nervous system activation and circulating catecholamines increase the heart rate by binding to ß₁-adrenoreceptors leading to an increase in intracellular cyclic AMP, which results in changes to the permeability of the various ion channels
Fig. 22.1 The cardiac action potential. (A) An action potential from ventricular myocardium. During diastole (phase 4), the resting transmembrane potential is constant at –90 mV. The upstroke (phase 0) of the action potential is due to the rapid influx of Na$^+$ ions. The early phase of repolarisation (phase 1) is due to efflux of K$^+$ ions, followed by a plateau phase (phase 2) at about 0 mV during which influx of Ca^{2+} ions is balanced by efflux of K$^+$ ions. Towards the end of diastole, influx of Ca^{2+} ions diminishes and efflux of K$^+$ ions increases, resulting in repolarisation (phase 3) back to the negative resting membrane potential. (B) An action potential from the sinus node. During diastole (phase 4), there is progressive depolarisation towards a threshold potential at which an action potential is triggered. The upstroke (phase 0) of the action potential is less steep than in ventricular myocardial cells because the sinus node cells lack 'fast' Na$^+$ channels and so depolarisation is dependent upon influx of Ca^{2+} ions.

responsible for the pacemaker current. Parasympathetic nervous system activation, mediated by muscarinic cholinergic receptors, has the opposite effect.

The rapid depolarisation of the cardiac action potential (Fig. 22.1A, phase 0) occurs because of a rapid increase in the permeability of the cell membrane to Na$^+$ ions, which enter rapidly through 'fast' Na$^+$ channels in a current known as I_{Na}. The I_{Na} current is brief as the 'fast' Na$^+$ channels inactivate rapidly. The early phase of repolarisation (phase 1) is due to closure of the fast Na$^+$ channels, an outward K$^+$ current

known as I_{to} (to – transient outward) and a further K$^+$ current known as the ultra-rapid component of the delayed rectifier current or I_{Kur}. The plateau phase (phase 2) of the cardiac action potential occurs because the inward movement of Ca^{2+} ions (I_{Ca}) is balanced by the outward movement of K$^+$ ions. Repolarisation (phase 3) occurs as I_{Ca} diminishes and two further components of the delayed rectifier (I_K) current known as the rapid (I_{Kr}) and slow (I_{Ks}) components predominate, with an important contribution from I_{K1}.

There is considerable variation in the expression of transmembrane ion channels in different parts of the heart, with corresponding variation in the morphology of the action potential. The most marked example is that myocytes in the sinus and AV nodes contain few Na$^+$ channels. The upstroke of the action potential in these cells is due, predominantly, to the influx of Ca^{2+} ions and, therefore, is considerably slower than the upstroke in other myocytes (Fig. 22.1B). The variation in ion channel expression throughout the heart is essential for normal cardiac function, helps to explain the pathophysiology of many inherited and acquired diseases complicated by cardiac arrhythmia and accounts for the relative selectivity of antiarrhythmic and other drugs for certain parts of the heart.

Refractoriness

The action potential of cardiac myocytes differs from that seen in nerve cells by the presence of a plateau phase during which the myocyte is electrically inexcitable and refractory, that is, incapable of generating another action potential. It is only towards the end of repolarisation (phase 3) that the myocyte regains excitability. The time interval between the onset of the action potential and the regaining of electrical excitability is known as the refractory period. Under most circumstance the refractory period of a cardiac myocyte corresponds closely to the duration of the cardiac action potential and, therefore, drugs that prolong action potential duration (APD) prolong the refractory period.

Normal cardiac conduction

During normal sinus rhythm (Fig. 22.2), an activation wavefront begins in the sinus node, a group of cells with pacemaker activity on the upper free wall of the right atrium. The rate of diastolic depolarisation and hence the rate of discharge of the sinus node is increased by sympathetic nerve stimulation, circulating catecholamines or sympathomimetic drugs mediated by ß$_1$-adrenoreceptors on the cell membranes of the sinus node myocytes. Parasympathetic (vagus) nerve stimulation exerts the opposite effect, mediated by muscarinic cholinergic receptors.

An activation wavefront spreads across the atrial myocardium, leading to atrial contraction and generating the P wave on the surface electrocardiogram (ECG; Fig. 22.3). The last part of the atria to be activated is the atrioventricular (AV) node, the electrical and structural properties of which result in a slow conduction velocity, allowing atrial emptying to be completed before ventricular contraction begins
Fig. 22.2 The normal cardiac conduction system. During sinus rhythm, an activation wavefront spreads from the sinus (sinoatrial – SA) node across the atrial myocardium before entering the atrioventricular node. The activation wavefront then enters the bundle of His, which penetrates the annulus fibrosus and forms the only electrical connection between the atria and ventricles. The bundle of His divides into right and left bundle branches which ramify into a subendocardial network of Purkinje fibres that transmit the activation wavefront rapidly across the ventricles. Activation of the ventricles proceeds from endocardium to epicardium.
Fig. 22.3 The normal electrocardiogram (ECG). The P wave results from activation (depolarisation of the atria). The PR interval is isoelectric as the activation wavefront proceeds slowly through the atrioventricular node. The QRS complex reflects activation of the ventricles and is large compared to the P wave because of the much greater mass of the ventricular myocardium, and brief, reflecting extremely rapid conduction in the His–Purkinje system. The T wave represents ventricular repolarisation.

and represented by the PR interval on the ECG. Conduction velocity in the AV node is increased by sympathetic nerve stimulation, circulating catecholamines or sympathomimetic drugs, mediated by β_1-adrenoreceptors while parasympathetic (vagus) nerve stimulation exerts the opposite effect via muscarinic cholinergic receptors.

The atria and ventricles are electrically isolated from each other by the annulus fibrosus, the electrically non-conductive fibrous tissue forming the valve rings. In the normal heart, there is just one electrical connection between the atria and ventricles, the bundle of His, which conveys the activation wavefront from the AV node and penetrates the annulus fibrosus before dividing into the right and left bundle branches. The bundle branches ramify into a sub-endocardial network of Purkinje fibres, which convey the activation wavefront rapidly across the ventricles ensuring near-simultaneous contraction of the ventricular myocardium, and are represented by the narrow QRS complex of the ECG. Finally, the activation wavefront spreads from endocardium to epicardium. A wave of repolarisation then spreads across the ventricles resulting in the T wave. The QT interval on the ECG, therefore, represents the duration of ventricular depolarisation and repolarisation. There is an inverse relationship between the time to activation of different areas of the ventricular myocardium and APD such that the latest areas to be activated have the shortest APD. The purpose of this relationship is that repolarisation is rapid and uniform throughout the ventricular myocardium, which serves to maintain electrical stability.

Arrhythmia mechanisms

Cardiac arrhythmias occur because of abnormalities of impulse formation or propagation.

Abnormal impulse formation

Abnormal automaticity

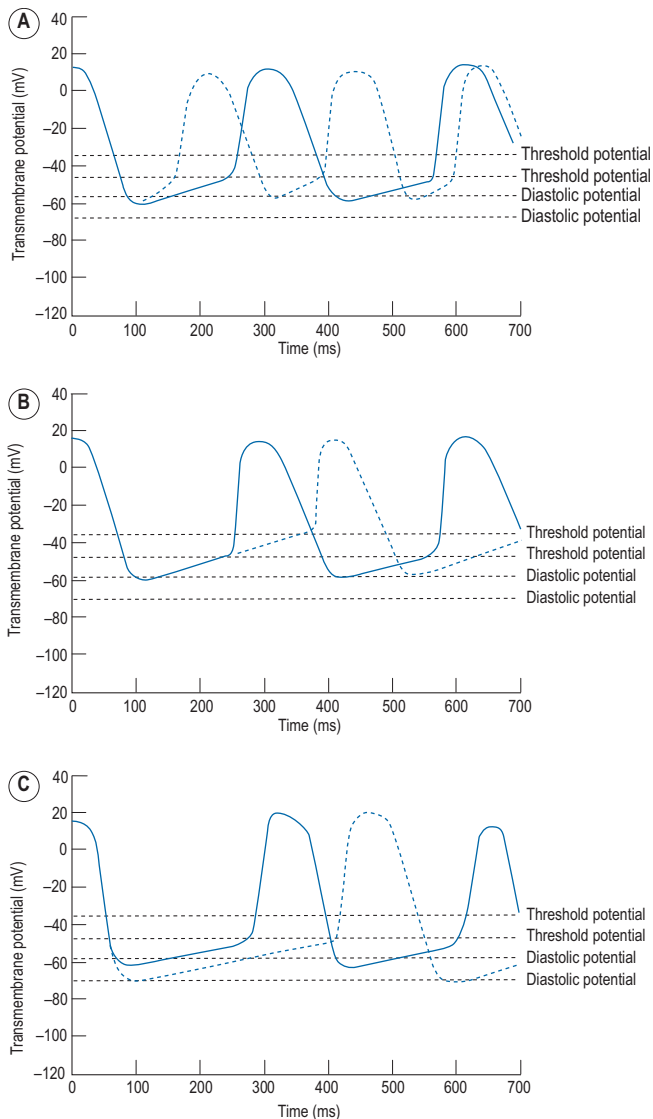
Automaticity is another term for pacemaker activity, a characteristic possessed by all cells of the specialised cardiac conduction system during health and, potentially, by other cardiac myocytes during certain disease states. The rate of firing of a pacemaker cell is largely determined by the duration of the phase 4 diastolic interval (Fig. 22.4). This in turn is determined by (i) the maximum diastolic potential following repolarisation of the preceding action potential, (ii) the slope of diastolic depolarisation due to pacemaker currents and (iii) the threshold potential for generation of a new action potential. In the healthy state, there is a hierarchy of firing rates within the specialised conduction system with the highest rate in the sinus node followed by the AV node and then the His–Purkinje system. The sinus node is, therefore, the dominant pacemaker and determines the heart rate, while the pacemaker activity in the distal conduction system is 'overdriven' by the sinus node. Abnormal automaticity describes either accelerated pacemaker activity in cells of the distal cardiac conduction system such that they escape from overdrive


Fig. 22.4 Abnormal automaticity. A sinus node action potential is shown (in bold) with a characteristic slow upstroke. Following repolarisation, gradual diastolic depolarisation occurs as a result of pacemaker currents. When the threshold potential is reached a further action potential is generated. The rate of firing of the pacemaker cell is governed largely by the duration of the diastolic interval which is in turn determined by (A) the slope of diastolic depolarisation, (B) the threshold potential and (C) the maximum diastolic potential. Each of these (shown by dotted lines) may be altered by disease states leading to abnormal automaticity.

suppression by the sinus node, or the development of pacemaker activity in cells that do not form part of the cardiac conduction system.

Triggered activity

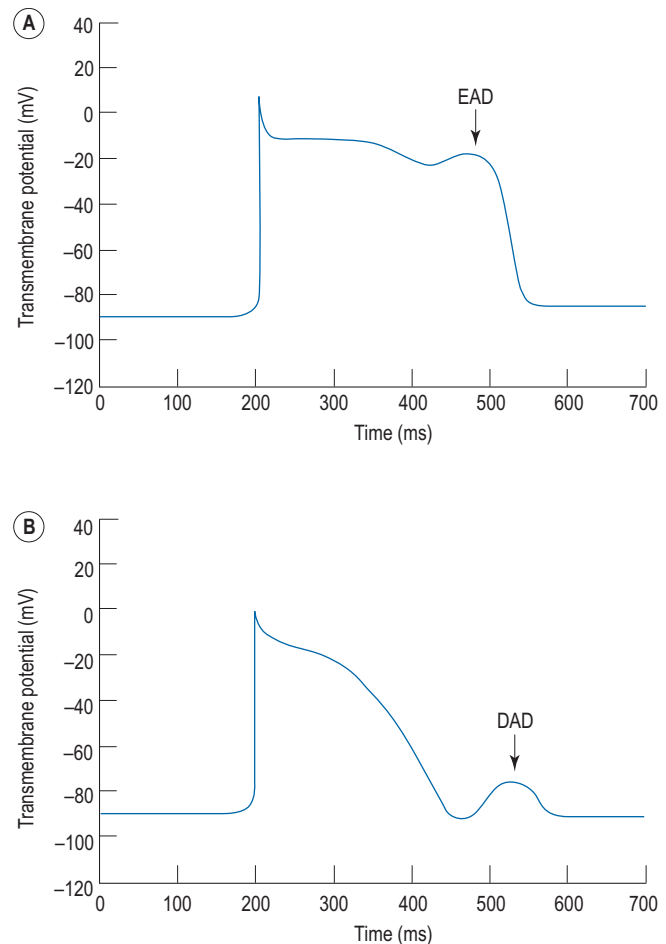
Triggered activity describes impulse formation dependent upon afterdepolarisations. Early afterdepolarisations (EADs) occur during phase 2 or 3 of the cardiac action potential whereas delayed afterdepolarisations (DADs) occur during phase 4 (Fig. 22.5). In both cases, afterdepolarisation may


Fig. 22.5 Triggered activity. (A) An early afterdepolarisation (EAD) occurring at the start of phase 3 of the cardiac action potential. (B) A delayed afterdepolarisation (DAD) occurring after repolarisation, during phase 4. Either EADs or DADs may reach the threshold potential for generation of a further action potential.

reach the threshold potential required for generation of a new action potential.

EADs are characteristic of the congenital and acquired long QT syndromes. The prolonged APD promotes reactivation of the inward calcium current I_{Ca} which may directly cause EADs during phase 2. Furthermore, action potential prolongation and ß-adrenoreceptor stimulation promote calcium overload in the sarcoplasmic reticulum. This in turn leads to the spontaneous release of calcium in bursts by the sarcoplasmic reticulum. The resultant increase in intracellular calcium concentration activates the transmembrane Na^+/Ca^{2+} exchanger which moves one calcium ion out of the myocyte in exchange for three sodium ions and, therefore, results in an EAD during phase 3. In the long QT syndromes, an EAD may initiate a form of polymorphic ventricular tachycardia (VT) known as Torsade de Pointes. EADs are more prominent at slow heart rates.

DADs are seen during reperfusion following ischaemia, heart failure, digitalis toxicity and in catecholaminergic polymorphic VT. They occur because of spontaneous release of calcium in bursts by the sarcoplasmic reticulum, activating the

Na$^+$/Ca^{2+} exchanger as described for EADs and resulting in a DAD during phase 4. A DAD may result in a single extrastimulus ('ectopic beat') or in repetitive firing, that is, tachycardia. DADs are more prominent at rapid heart rates and during sympathetic nervous stimulation of ß-adrenoreceptors.

Abnormal impulse propagation

Re-entry

Many clinically important arrhythmias are due to re-entry, in which an activation wavefront rotates continuously around a circuit. Re-entry depends upon a trigger in the form of a premature beat, and a substrate, that is, the re-entry circuit itself. A precise set of electrophysiological conditions must be met in order for re-entry to occur (Fig. 22.6): (i) there must be a central non-conducting obstacle around which the re-entry circuit develops, (ii) a premature beat must encounter unidirectional conduction block in one limb (a) of the re-entry circuit, (iii) conduction must proceed slowly enough down the other limb (b) of the re-entry circuit that electrical excitability has returned in the original limb (a), allowing the activation wavefront to propagate in a retrograde direction along that limb, and (iv) the circulating activation wavefront must continue to encounter electrically excitable tissue. This is a function of the length of the re-entry circuit, the conduction velocity of the activation wavefront and the effective refractory period of the myocardium throughout the circuit. Class I antiarrhythmic drugs block sodium channels and, therefore, reduce the amplitude and rate of rise of the cardiac action potential and in so doing, reduce the conduction velocity of an activation wavefront. Class I antiarrhythmic drugs may exert their major antiarrhythmic effect by abolishing conduction altogether in areas of diseased myocardium forming part of a re-entry circuit in which conduction is already critically depressed. Class III antiarrhythmic drugs prolong cardiac APD and hence the refractory period. If previously activated cells in a re-entry circuit (the 'tail') remain refractory when the re-entrant wavefront (the 'head') returns to that area, conduction will fail and

re-entry will be abolished. Drug-induced prolongation of the refractory period may, therefore, terminate and/or prevent re-entrant arrhythmias.

Clinical problems

Patients with a cardiac arrhythmia may present with a number of symptoms:

- The most common symptom is palpitation, an awareness of an abnormal heartbeat, although some patients with clearly documented arrhythmia have no palpitation. Arrhythmias start suddenly and, therefore, if the patient clearly describes palpitation of sudden onset ('like flicking a switch'), this is a useful pointer to an arrhythmia rather than heightened awareness of sinus tachycardia, which has a less sudden onset.
- The heart is designed to work most efficiently in sinus rhythm. Any arrhythmia compromises cardiac function. Classical symptoms that arise due to reduced cardiac output include reduced exercise capacity, breathlessness and fatigue.
- Angina may accompany tachycardia, even in the absence of coronary artery disease. Tachycardia increases the metabolic rate of cardiac muscle and hence its demand for blood flow. Myocardial perfusion occurs predominantly during diastole and during tachycardia proportionately less time is spent in diastole and so myocardial demand for blood can exceed supply, resulting in angina.
- A sudden drop in cardiac output may accompany either bradycardia or tachycardia, causing episodes of dizziness (presyncope), loss of consciousness (syncope) or, in extreme cases, sudden death from cardiac arrest.
- Atrial tachyarrhythmias such as atrial flutter and atrial fibrillation may be complicated by the development of intracardiac thrombus, usually within the left atrial appendage. This thrombus may embolise to any part of the body but the most common clinical presentation is with a transient ischaemic attack or stroke.

Arrhythmias may aggravate heart failure in two ways: (i) the haemodynamic effect of the arrhythmia may precipitate heart failure or aggravate existing heart failure and (ii) prolonged tachycardia of any type may lead to tachycardia-induced cardiomyopathy.
Fig. 22.6 Re-entry. During sinus rhythm, (A) an activation wavefront encounters a zone of fixed conduction block but can propagate anterogradely on either side of this zone, down limbs a and b of a potential re-entry circuit. A premature beat (B) encounters unidirectional conduction block in limb a but propagates anterogradely down limb b and re-enters limb a retrogradely. If limb a is now capable of retrograde conduction, the re-entry circuit is completed and re-entry continues (C) as long as the activation wavefront continually meets electrically excitable tissue.

Diagnosis

A detailed history should be obtained, covering all of the symptoms listed above. A characteristic of cardiac arrhythmias is their random onset. Symptoms occurring under specific circumstances are less likely to be due to arrhythmia, but there are exceptions including certain uncommon types of VT, some cases of supraventricular tachycardia (SVT) due to an accessory pathway and vasovagal syncope (faints). Other key features of the history include:

- A history of cardiac disease
- Other diagnosed medical conditions

- A full drug history, including over-the-counter medicines and recreational drugs including alcohol
- A family history of heart disease and of sudden unexpected death.

Physical examination is essential but often normal between episodes of arrhythmia. Mandatory investigation includes a 12-lead ECG and an echocardiogram to detect structural heart disease. Other investigations for structural and ischaemic heart disease may be indicated at this stage with the aim of detecting any underlying structural heart disease. If the history does not include sinister features such as syncope or a family history of sudden unexpected death at a young age, and the resting 12-lead ECG and echocardiogram are normal, then the patient can be reassured that they are extremely unlikely to have a serious heart rhythm disturbance. The extent of further investigation will be dictated by how troublesome the symptoms are.

The most certain way of reaching a firm diagnosis is a 12-lead ECG recorded during the patient's symptoms demonstrating arrhythmia. As many arrhythmias occur intermittently, some form of ECG monitoring is often necessary. This may include a continuous ambulatory ECG (Holter) recording for up to 7 days at a time if the symptoms occur frequently or, for less frequent symptoms an event recorder, which may store ECG strips automatically if it detects an arrhythmia or if activated by the patient during their symptoms. An insertable loop recorder may be implanted subcutaneously and is an ECG event recorder with a battery life of about 3 years, making it a useful tool for the diagnosis of infrequent arrhythmias.

Management

Pathological tachycardia is conventionally defined as a resting heart rate over 100 beats/min and can be classified according to whether it arises in or involves the atria (supraventricular tachycardias) or the ventricle (ventricular tachyarrhythmias).

Supraventricular tachycardias

These are tachycardias arising from or involving the atria.

Inappropriate sinus tachycardia

Although uncommon, inappropriate sinus tachycardia, that is, sinus tachycardia with no identifiable underlying cause, is one of the more difficult arrhythmias to treat. The presenting symptom is usually palpitation and the typical patient is a young, predominantly female, adult with no history of heart disease or other physical illness. The 12-lead ECG shows sinus tachycardia and ambulatory ECG monitoring demonstrates sinus tachycardia but with diurnal variation in heart rate. Echocardiography is required to exclude structural heart disease, and thyroid function and urinary catecholamine excretion should be measured to detect thyrotoxicosis and phaechromocytoma, respectively, as rare underlying causes

of sinus tachycardia. If treatment is required on symptomatic grounds, ß-blockers or verapamil are first line therapy. Ivabradine, a selective 'funny channel' blocker, has been used in resistant cases but is not currently licensed for this indication. Catheter ablation of the sinus node has been performed in highly symptomatic drug-resistant inappropriate sinus tachycardia but with limited success and risks including symptomatic sinus bradycardia and phrenic nerve palsy.

Atrial flutter

Atrial flutter is a right atrial tachycardia with a re-entry circuit around the tricuspid valve annulus. The atrial rate is typically 300 min^{-1}. The long refractory period of the AV node protects the ventricles from 1:1 conduction: In the presence of a healthy AV node and the absence of AV node-modifying drugs, there is usually 2:1 AV conduction resulting in a regular narrow-complex tachycardia with a ventricular rate of 150 min^{-1}.

Atrial flutter confers a risk of thromboembolism similar to that of AF and this risk should be managed in the same way. Emergency management of atrial flutter is dictated by the clinical presentation but may include d.c. cardioversion or ventricular rate control with drugs which increase the refractory period of the AV node such as ß-blockers, verapamil, diltiazem or digoxin. ß-Blockers, verapamil and digoxin may be given intravenously. As the re-entry circuit is confined to the right atrium and does not involve the AV node, adenosine will not terminate atrial flutter but will produce transient AV block, allowing the characteristic flutter waves to be seen on the ECG (Fig. 22.7).

There is a limited role for antiarrhythmic drugs, whether used acutely to achieve chemical cardioversion or in the longer term to maintain sinus rhythm. Class Ic antiarrhythmic drugs such as flecainide should be used only in conjunction with AV node-modifying drugs such as ß-blockers, verapamil, diltiazem or digoxin because they may otherwise cause slowing of the atrial flutter circuit and 1:1 conduction though the AV node which may be life-threatening. Sotalol and amiodarone have been used to restore and maintain sinus rhythm and have the advantage of controlling the ventricular rate where rhythm control is incomplete. Catheter ablation of atrial flutter is highly effective and safe and is increasingly used in preference to long-term drug treatment.

Focal atrial tachycardia

As its name implies, this relatively uncommon arrhythmia results from the repetitive discharge of a focal source within the atria or surrounding venous structures. The tachycardia mechanism may be caused by abnormal automaticity, triggered activity or microreentry. Management is as described for atrial flutter with three exceptions: (i) some focal atrial tachycardias terminate with adenosine, (ii) the potential for class Ic antiarrhythmic drugs to slow tachycardia and result in 1:1 AV conduction is lower than for atrial flutter, and (iii) catheter ablation of focal atrial tachycardia may be more challenging than that of atrial flutter, but is curative in a majority of cases.
Fig. 22.7 A 12-lead electrocardiogram (ECG) recorded during the administration of intravenous adenosine. The initial rhythm is atrial flutter with 2:1 conduction from atria to ventricles. The QRS complexes obscure the atrial activity on the ECG. Adenosine does not terminate the atrial flutter but causes temporary atrioventricular block revealing the characteristic 'sawtooth' ECG morphology of typical atrial flutter.

Junctional re-entry tachycardia

The term 'supraventricular tachycardia' (SVT) is widely used to describe junctional re-entry tachycardias but is a misnomer because it implies any tachycardia arising from the atria. Junctional re-entry tachycardia is a more specific term and may be preferable.

Two mechanisms account for most junctional re-entry tachycardias: both involve a macroreentry circuit (Fig. 22.8). AV nodal re-entry tachycardia (AVNRT) rotates around a circuit including the AV node itself and the so-called AV nodal fast and slow pathways, which feed into the AV node. Atrioventricular re-entry tachycardia (AVRT) comprises a re-entry circuit involving the atrial myocardium, the AV node, the ventricular myocardium and an accessory pathway, a congenital abnormality providing a second electrical connection between the atria and ventricles in addition to the His bundle, thus forming a potential re-entry circuit.

Many accessory pathways conduct only retrogradely from the ventricles to the atrium. In these cases, the ECG during sinus rhythm appears normal and the accessory pathway is described as 'concealed'. Other accessory pathways conduct anterogradely and retrogradely. In these cases, the ECG during sinus rhythm is abnormal and is described as having a Wolff–Parkinson–White pattern (Fig. 22.9). This abnormality is characterised by a short PR interval as the conduction velocity of an accessory pathway is usually faster than that of the AV node, and a delta wave, a slurred onset to the QRS complex which occurs because an accessory pathway inserts into ventricular myocardium which conducts more slowly than the His–Purkinje system.

Junctional re-entry tachycardias are characterised by a history of discrete episodes of rapid regular palpitation that start and stop suddenly and occur without warning and apparently at random. The peak age range at which symptoms begin is from the mid-teens to the mid-thirties and the condition is more common in women. There are no symptoms between episodes, and cardiac examination and investigation at these times are usually normal. The diagnosis is usually made on the basis of the history, ideally confirmed by an ECG recorded during an episode showing a regular narrow-complex tachycardia with no discernible P waves or P waves occurring in a 1:1 relationship with the QRS complexes.

Acute treatment of junctional re-entry tachycardia aims to terminate the tachycardia by causing transient conduction block in the AV node, an obligatory part of the re-entry circuit. Vagotonic manoeuvres such as carotid sinus massage, a Valsalva manoeuvre or eliciting the diving reflex by immersion of the face in ice-cold water may all result in a brief vagal discharge sufficient to block conduction in the AV node, terminating tachycardia. The same effect may be achieved with intravenous adenosine given as a rapid bolus injection in doses up to 12 mg. Intravenous verapamil 5 mg also as a rapid bolus injection is a good alternative where adenosine is contraindicated.

SA – sinoatrial   AV – atrioventricular
Fig. 22.8   The re-entry circuits of (A) AV nodal re-entry tachycardia (AVNRT) and (B) atrioventricular re-entry tachycardia (AVRT). (A) The AVNRT circuit comprises 'fast' and 'slow' pathways feeding into the AV node itself. The slow pathway is the target of catheter ablation. The AVRT circuit comprises atrial myocardium, the AV node and His bundle, ventricular myocardium and an accessory pathway, a small strand of muscle providing a second abnormal connection between atrium and ventricle, thus forming a potential re-entry circuit. The accessory pathway itself is the target of catheter ablation. SA, sinoatrial; AV, atrioventricular.
Fig. 22.9   An electrocardiogram showing a Wolff–Parkinson–White pattern. The PR interval is short and the QRS complex is abnormally broad, with a slurred upstroke or delta wave.

Junctional re-entry tachycardia is often recurrent. There is a limited role for prophylactic drug treatment as this is generally not a dangerous condition affecting young and otherwise healthy people. Among other factors, the efficacy, toxicity and acceptability of what may be long-term drug treatment require careful consideration. Options for prophylactic drug treatment include ß-blockers, verapamil, flecainide and sotalol. Particular importance should be given to discussion about the management of junctional re-entry tachycardia during pregnancy. Catheter ablation is curative in one sitting in a majority of cases.

Atrial fibrillation

AF is the most common sustained arrhythmia, affecting about 1% of the population. AF is rare before the age of 50 but its prevalence approximately doubles with each decade thereafter such that about 10% of those over 80 are affected. AF is characterised by extremely rapid and uncoordinated electrical activity in the atria and variable conduction through the AV node, resulting in irregular and usually rapid ventricular contraction.

The clinical importance of AF results from:

(i)   Symptoms including palpitation, reduced exercise capacity, breathlessness and fatigue
(ii) Increased risk of thomboembolic stroke
(iii) Exacerbation of heart failure through its direct haemodynamic effect and by causing tachycardia-induced cardiomyopathy
(iv) Increased all-cause mortality (odds ratio 1.5 for men and 1.9 for women)

AF may be classified as:

Paroxysmal: self-limiting episodes of AF lasting no more than 7 days

Persistent: AF lasting more than 7 days or requiring cardioversion

Longstanding persistent: continuous AF for more than 1 year

Permanent: where a decision has been made not to attempt cure of persistent AF.

Stroke risk. All patients presenting with AF (or atrial flutter) should undergo assessment of their risk of stroke. Although various risk stratification schemes exist, they are exemplified by the $CHADS_2$ score, which assigns one point each for Congestive cardiac failure, Hypertension, Age >75 years, and Diabetes mellitus and two points for if there is a history of previous Stroke. Surprisingly, the frequency of AF episodes does not seem to influence stroke risk. The risk of stroke is directly proportional to the $CHADS_2$ score. Meta-analysis of numerous trials of stroke prevention in AF has suggested a relative risk reduction for stroke of 64% with warfarin and 22% with aspirin (Fig. 22.10).

Warfarin is more difficult to take than aspirin because of the need for monitoring of the international normalised ratio (INR) and because of the potential for dietary and drug interactions with warfarin. Warfarin also increases the risk of serious bleeding. The absolute benefit of warfarin over aspirin for the prevention of stroke in AF is proportional to the $CHADS_2$ score and the point at which the benefit of warfarin is considered to outweigh the risk is an annual untreated stroke risk of 4%. For this reason, current guidelines recommend stroke prophylaxis with warfarin for those with a $CHADS_2$ score of ≥2, warfarin or aspirin for a $CHADS_2$ score of 1 and aspirin for those with a $CHADS_2$ score of 0.

While $CHADS_2$ is the most common guideline, in patients with AF and a $CHADS_2$ score of 1, a lower incidence of stroke and/or death from all causes has been found among patients treated with vitamin K antagonists (VKAs) when compared with no antithrombotic therapy. In contrast, prescription of an antiplatelet agent was not associated with a lower risk of events compared with no antithrombotic therapy.

Identification of the 'low risk' category clearly needed to be improved, so patients can be truly identified as low risk.
Fig. 22.10   Annual stroke risk is directly related to the $CHADS_2$ score (black bars). Aspirin reduces stroke risk by approximately 22% (dark blue bars) and warfarin by approximately 64% (light blue bars). This figure shows that, although the *relative* stroke risk reduction is higher with warfarin than with aspirin whatever the $CHADS_2$ score, the *absolute* difference is directly related to the $CHADS_2$ score. Warfarin is inconvenient to take and increases the risk of serious bleeding and, therefore, a clear benefit from taking warfarin rather than aspirin is apparent only for those with $CHADS_2$ scores of ≥2.

This can be achieved by using CHA2DS2–VASc [Cardiac failure, Hypertension, Age ≥75 (doubled), Diabetes, Stroke (doubled)–Vascular disease (prior myocardial infarction, peripheral artery disease, complex aortic plaque), Age 65–74 and Sex category (female =1, male = 0)]. This schema improves on $CHADS_2$ as it classifies a low proportion of subjects into the 'moderate risk' category, and helps better determine the truly 'low risk' patients who have very low event rates and no need for anticoagulation.

There is no evidence that any form of treatment for AF, other than warfarin or aspirin, reduces the risk of stroke regardless of how apparently successful it is in maintaining sinus rhythm. Current guidelines, therefore, recommend indefinite stroke prophylaxis with warfarin or aspirin on the basis of the risk stratification.

It is often difficult to maintain INR levels within the therapeutic range of 2.0–3.0. There is evidence that the INR may be outside of this range up to half of the time. A subtherapeutic INR substantially increases risk of stroke or arterial thromboembolism. Conversely, a high INR increases the risk of bleeding. The approximate annual frequency of major and minor bleeding with warfarin is 3% and 10%, respectively. Patients' and physicians' concern about the use of warfarin has resulted in its under-utilisation, particularly among elderly people, who are at the greatest risk of stroke. These difficulties have led to a search for alternative agents. The most advanced of these achieve their anticoagulant effect by inhibiting a single activated clotting factor, either thrombin (factor IIA) or factor XA. These drugs have a more predictable pharmacological profile that negates the need for frequent monitoring and may represent a step forward in the care of patients with AF. These agents are expected to offer advantages of enhanced or similar efficacy compared with warfarin without an increased risk of major bleeding.

Emergency management. AF associated with unstable angina, heart failure or hypotension requires emergency treatment. In most cases, the treatment of choice is d.c. cardioversion. Concerns about thromboembolism as the heart returns to sinus rhythm are valid but should not delay emergency treatment. Immediate d.c. cardioversion is appropriate when the onset of AF is clearly identified as within 48 h of presentation or when the patient is already taking warfarin and has had a therapeutic INR for at least 4 weeks. If facilities permit, a trans-oesophageal echocardiogram may be performed in patients not already on warfarin in order to exclude intracardiac thrombus. Heparin should then be given immediately and continued until the INR is within the therapeutic range. Anticoagulant therapy should be continued for at least 3 months following cardioversion. Long-term stroke prophylaxis is guided thereafter by the $CHADS_2$ score. If d.c. cardioversion is deemed inappropriate, rapid ventricular rate control may be achieved with intravenous ß-blockers, verapamil or digoxin.

Long-term management. There has been considerable debate about the pros and cons of a rate-control strategy, focusing on achieving adequate control of the ventricular rate with drugs modifying the AV node versus a rhythm-control strategy, in which an attempt is made to restore and maintain sinus rhythm

with antiarrhythmic drugs ± d.c. cardioversion. These strategies have been compared in several large-scale prospective randomised trials, which have failed to demonstrate an advantage to a rhythm-control strategy. Sinus rhythm has been associated with a 47% reduction in all-cause mortality, although this benefit was offset by a 49% increase in mortality associated with antiarrhythmic drugs (AFFIRM investigators, 2004). In that study, a wide variety of antiarrhythmic drugs were used at the discretion of the investigator. These included several class I antiarrhythmic drugs, sotalol and amiodarone. A rhythm-control strategy may be more appropriate in (i) younger patients, (ii) those with paroxysmal AF, (iii) AF associated with heart failure and (iv) patients who remain symptomatic despite adequate ventricular rate control.

Ventricular rate control. The mainstay of a ventricular rate-control strategy is the use of drugs which prolong the AV nodal refractory period, thus reducing the ventricular rate. Digoxin may control the ventricular rate at rest but is less successful at controlling the rate during exertion. ß-Blockers or calcium channel blockers (verapamil or diltiazem) are generally effective both at rest and on exertion, although a combination of these drugs is occasionally necessary. Where ventricular rate control cannot be achieved with drugs, catheter ablation of the AV node in combination with permanent pacemaker implantation can provide excellent symptom relief. The adverse effects of right ventricular apical pacing may offset some of the benefit of a slower ventricular rate and regular rhythm and, therefore, biventricular pacing may be more appropriate in this situation.

Rhythm control. Rhythm control can be considered in terms of either restoration or maintenance of sinus rhythm. The most rapid and effective means of restoring sinus rhythm is d.c. cardioversion. Where AF is of short duration, well tolerated and not associated with structural heart disease, class IC antiarrhythmic drugs such as flecainide and class III drugs such as amiodarone may be used intravenously in order to achieve chemical cardioversion. Stroke risk should be managed in the same way as described for the emergency management of AF.

Although sinus rhythm can be restored in most patients through d.c. cardioversion or antiarrhythmic drugs, alone or in combination, most patients will revert to AF without further treatment. The SAFE-T trial examined 665 patients with AF of at least 72 h duration. Sinus rhythm was restored with antiarrhythmic drugs (sotalol or amiodarone) or placebo, supplemented where necessary by d.c. cardioversion (Singh et al., 2005). Patients were then maintained on placebo, sotalol or amiodarone. By 2 years, that probability of remaining in sinus rhythm was 10% (placebo), 30% (sotalol) and 50% (amiodarone). Another similar study (Roy et al., 2000) demonstrated equivalent efficacy of sotalol and the class Ic antiarrhythmic propafenone in the maintenance of sinus rhythm (40% at 2 years) and confirmed the superiority of amiodarone (60%). Most heart rhythm specialists consider that the toxicity of amiodarone precludes its long-term use for the management of AF. Dronedarone, it was hoped, would provide efficacy similar to amiodarone but it has been shown to be less effective, although it has far fewer side effects.

Modern strategies for curative catheter ablation of AF followed the discovery in 1998 that paroxysmal AF is due, in most cases, to rapid firing by the musculature surrounding the pulmonary veins close to their junctions with the left atrium. The cornerstone of most current ablation strategies for paroxysmal AF is complete electrical isolation of all four pulmonary veins from the left atrium, using either radiofrequency ablation (cautery) or cryoablation to ablate in rings around the pairs of ipsilateral veins. Catheter ablation can cure a majority of paroxysmal AF but needs to be repeated in 30–40% of patients and carries risk including stroke (3/1000) and pericardial effusion (1–2/100). Catheter ablation has been shown in small randomised studies to be superior to antiarrhythmic drug therapy in maintaining sinus rhythm and improving symptoms and quality of life. Catheter ablation has also been shown in non-randomised studies to improve left ventricular ejection fraction and heart failure symptoms. No benefit has been demonstrated in terms of reduced stroke risk or mortality. The natural history of AF is for episodes of AF to increase in frequency and duration until persistent AF supervenes. This progression appears to occur as a result of atrial remodelling, a complex and incompletely understood process involving electrical and structural changes in the whole atrial myocardium predisposing to the development of AF independent of the pulmonary veins. Catheter ablation strategies for persistent AF are more complex than those for paroxysmal AF with a correspondingly higher rate of repeat procedures and a lower overall success rate. For all of these reasons, drug therapy remains the first line treatment of AF with catheter ablation reserved for patients with symptomatic AF that cannot be managed satisfactorily with drugs and whose symptoms trouble them enough to wish to undergo ablation.

Ventricular tachyarrhythmias

Ventricular tachycardia

VT is a rapid heart rhythm originating in the ventricles. VT may present with palpitation, chest pain, breathlessness, presyncope, syncope or sudden cardiac death (death occurring suddenly and unexpectedly within 1 h of the onset of symptoms from a presumed cardiac cause). It is clinically useful to subdivide VT in the following ways:

VT complicating structural heart disease. Most VT occurs in patients with significant structural heart disease. Most of these are associated with a healed myocardial infarction but other important causes include hypertensive and valvular heart disease and a variety of cardiomyopathies including dilated, hypertrophic or arrhythmogenic right ventricular cardiomyopathy. VT of this type is usually due to re-entry. Scarring of ventricular myocardium creates the central obstacle around which potential re-entry circuits develop forming the VT 'substrate'. In this setting, a single ventricular premature beat, the VT 'trigger', may induce VT. The importance of VT complicating structural heart disease is that there is a high chance of the VT recurring and patients are at substantially increased risk of sudden cardiac death.

'Normal heart' VT. These uncommon VTs occur in the context of a structurally normal heart and a normal ECG in sinus rhythm and are exemplified by right ventricular outflow tract (RVOT) tachycardia and fascicular tachycardia. The importance of recognising these VTs is that unlike VT associated with structural heart disease, they are associated with a normal prognosis, may be managed successfully with drugs (ß-blockers, verapamil or flecainide for RVOT tachycardia, verapamil for fascicular tachycardia) and are curable by catheter ablation.

Ventricular fibrillation

Ventricular fibrillation (VF) comprises rapid and totally disorganised electrical activity in the ventricles such that effective contraction ceases and results in sudden death unless sinus rhythm is restored either spontaneously or by defibrillation. Acute myocardial ischaemia and infarction are probably responsible for most VF, although virtually any structural heart disease may also be complicated by VF. Other cases occur in the context of a group of conditions known as channelopathies:

Channelopathies. This is a group of inherited conditions characterised by abnormal function of the protein channels present in the cardiac myocyte cell membrane that regulate the flow of ions responsible for generating the resting transmembrane potential and the action potential. These include the long QT syndromes, short QT syndrome, early repolarisation syndrome, Brugada syndrome and catecholaminergic polymorphic VT. A detailed description of these conditions is beyond the scope of this chapter but there are certain key points:

- With the exception of catecholaminergic polymorphic VT, each is associated with characteristic abnormalities of the resting ECG in sinus rhythm.
- Each may be complicated by ventricular tachyarrhythmias and sudden cardiac death.
- ß-Blockers reduce the likelihood of arrhythmia in long QT syndromes and catecholaminergic polymorphic VT.
- Many drugs lengthen the QT interval (Box 22.1) and are contraindicated in patients with long QT syndromes.

Box 22.1 Drugs associated with prolonged QT intervals (adapted from Crouch et al., 2003)

Inhalational agents: halothane, isoflurane
Macrolide antibiotics: erythromycin, clarithromycin
Halofantrine
Lithium
Fosphenytoin
Mizolastine
Phenothiazines
Pentamidine
Sertindole
Antihistamines: terfenadine, astemizole, mizolastine
Antipsychotics: haloperidol, droperidol, pimozole
Tricyclic antidepressants: amitriptyline, imipramine
Class IA or III antiarrhythmics

A list of drugs known to prolong the QT interval can be found at http://www.azcert.org.

- Class I antiarrhythmic drugs and a variety of other drugs are contraindicated in Brugada syndrome. A list of drugs to avoid in the Brugada syndrome can be found at http://www.azcert.org.
- Most patients with these conditions who experience syncope, cardiac arrest or who develop spontaneous ventricular arrhythmias will be considered for an implantable cardioverter-defibrillator (ICD).

Emergency management of ventricular arrhythmias. VF and pulseless VT should be managed according to Resuscitation Council (UK) guidelines for advanced life support, which are updated periodically and can be found at http://www.resus.org.uk.

VT associated with a pulse is also the subject of guidelines by the Resuscitation Council (UK). If the patient is hypotensive in a low cardiac output state or has heart failure, the correct treatment is prompt d.c. cardioversion. If none of these features is present, chemical cardioversion may be attempted with intravenous amiodarone 300 mg over 20–60 min followed by 900 mg over the next 24 h. Amiodarone must be given via a central vein because it can cause thrombophlebitis when given peripherally and limb threatening soft tissue damage if extravasation occurs.

Ongoing management of ventricular arrhythmias. Once stabilised, patients presenting with VT or VF should remain in hospital and their management should be discussed at an early stage with a specialist cardiac electrophysiology service. Investigations should be performed to establish the nature and extent of underlying heart disease, with emphasis on detecting structural heart disease, coronary artery disease, inducible myocardial ischaemia and consideration of channelopathies in those with structurally normal hearts.

Most patients with ischaemic heart disease should be treated with aspirin, statins, angiotensin converting enzyme (ACE) inhibitors or angiotensin II receptor antagonists and ß-blockers. ß-Blockers and ACE inhibitors reduce somewhat the risk of sudden cardiac death. Although these patients remain at high risk of sudden cardiac death due to recurrent ventricular tachyarrhythmias, there is no role for the routine use of anti-arrhythmic drugs. In patients with complex ventricular ectopy and impaired left ventricular systolic function following acute myocardial infarction, class IC antiarrhythmic drugs including flecainide were shown in the CAST study (Echt et al., 1991) to increase mortality while in other high-risk groups amiodarone has been shown to have no effect on all-cause mortality (Cairns et al., 1997; Julian et al., 1997). All patients should be considered for an ICD. These devices have been shown to improve prognosis following:

- Cardiac arrest due to VT or VF in the absence of a reversible underlying cause
- VT associated with syncope or significant haemodynamic compromise
- VT with a left ventricular ejection fraction of less than 35%.

Although ICDs treat further episodes of VT and VF, they do not prevent these arrhythmias from recurring and resulting in device therapies including shocks that are psychologically traumatic and lead to premature battery depletion. In the case of frequently recurring ventricular arrhythmias, patients should be on the maximum tolerated dose of a ß-blocker and there is a role for antiarrhythmic drugs including amiodarone and mexiletine. Catheter ablation of VT is an important adjunctive treatment in this situation.

Bradycardia

Bradycardia is conventionally defined as a resting heart rate below 60 min^{-1} when awake or 50 min^{-1} when asleep. Bradycardia can be classified as sinus bradycardia, where the sinus node discharges too slowly, or AV block ('heart block'), where conduction between the atria and ventricles is impaired. AV block may be subdivided into three classes:

First degree. Every P wave conducts to the ventricles but takes longer than normal to do so. The PR interval on the ECG is prolonged to greater than 200 ms (one large square on a standard ECG).

Second degree. Some but not all P waves conduct to the ventricles. Progressive PR interval prolongation followed by a non-conducted P wave is referred to as Mobitz type I or Wenckebach heart block and implies block occurring in the AV node. Mobitz type II heart block is the term used when a non-conducted P wave is not preceded by progressive PR interval prolongation and implies block occurring in the conducting system below the level of the AV node.

Third degree ('complete heart block'). No P waves conduct to the ventricles.

Bradycardia may be due to intrinsic cardiac disease or secondary to non-cardiac disease or drugs. In many cases, bradycardia due to intrinsic cardiac disease is idiopathic, that is, occurs without other identifiable heart disease. Bradycardia may also complicate acute myocardial infarction or virtually any form of structural heart disease and is also common following cardiac surgery. Non-cardiac causes of bradycardia include vasovagal syncope (faints), hypothyroidism, hyperkalaemia, hypothermia and raised intracranial pressure. Complete heart block may occur as a complication of Lyme disease (tick-borne borreliosis). Drugs commonly associated with bradycardia include ß-blockers, verapamil, diltiazem, digoxin and antiarrhythmic drugs of any class.

The management of bradycardia is as follows:

- Treat underlying medical conditions
- Consider stopping or reducing the dose of causative drugs
- Consider temporary or permanent pacemaker implantation. Permanent pacemaker implantation for sinus bradycardia is indicated for symptom relief whereas in the case of second and third degree AV block permanent pacemaker implantation is indicated on both symptomatic and prognostic grounds.

In an emergency situation, drugs may be used in an attempt to support the heart rate until trans-venous pacing can be established. The most useful drugs in this situation are atropine in 500 µcg boluses up to a total of 3 mg, adrenaline infused at a rate of 2–10 µcg/min or isoprenaline 1–10 µcg/min, titrated

against heart rate. External pacing is another useful measure until transvenous pacing can be established. More detailed guidance on the emergency management of bradycardia may be viewed at http://www.resus.org.uk.

Drug therapy

Antiarrhythmic drug therapy is used to control the frequency and severity of arrythmias, with the aim of maintaining sinus rhythm where possible. Although antiarrhythmic drug treatment has been the mainstay of arrhythmia treatment, many of these drugs have limited efficacy and important toxicity. Many arrhythmias are now curable by catheter ablation. Implantable devices such as permanent pacemakers and ICDs have assumed an increasingly important role in the treatment of arrhythmias and, in many cases, antiarrhythmic drugs have an adjunctive role. Antiarrhythmic drugs can be grouped according to their electrophysiological effects at a cellular level, using the Vaughan–Williams classification. Alternatively, antiarrhythmic drugs may be classified according to their main sites of action within the heart.

Vaughan–Williams Classification

All antiarrhythmic drugs act by altering the movement of electrolytes across the myocardial cell membrane. The Vaughan–Williams classification groups drugs according to their ability to block the movement of one or more of these ions across the myocardial cell membrane. Most drugs have several modes of action, and their effectiveness as antiarrhythmic agents depends upon the summation of these effects. The effect of the different drug classes on the various phases of the action potential in His–Purkinje fibres are shown in Table 22.1. The choice of which drug to use is based upon the origin of the arrhythmia, regardless of its pattern. However, the preference of one class over another may vary, depending on a clinician's experience with particular drugs, on the presentation of the arrhythmia and on patient characteristics. Such factors also govern the choice of drug within a class. The drug chosen should have the dosing schedule and adverse effect

profile that best suit the patient or inconvenience them least (see Tables 22.2–22.4). Thus, for example, a patient with glaucoma or prostatism should not be given disopyramide which possesses marked anticholinergic properties, and a patient with obstructive airways disease should preferably not be prescribed a ß-blocker (class II), though if considered essential they could have a cardioselective agent.

The pharmacokinetic profiles of selected antiarrhythmics are presented in Table 22.5.

Class I

Class I drugs act by blocking the fast sodium channels that are responsible for the rapid depolarisation phase of the cardiac action potential, thus reducing the rate of depolarisation (the slope of phase 0) and the amplitude of the action potential. The conduction velocity of an activation wavefront is determined partly by the slope and amplitude of the cardiac action potential and partly by the resistance to current flow through the myocardium. The effect of sodium channel blockade is a decrease in conduction velocity. Certain re-entrant arrhythmias such as VT complicating previous myocardial infarction depend upon slow conduction in part of the re-entrant circuit. Class I antiarrhythmic drugs may critically slow or even abolish conduction in these areas, thus terminating and/or preventing re-entry.

The action potential in the sinoatrial and AV nodes does not depend on fast sodium channels for depolarisation; instead, phase 0 depolarisation is carried by calcium channels. Class I antiarrhythmic drugs, therefore, have no direct effect on nodal tissue.

In addition to their effect on depolarisation, class I antiarrhythmic drugs may also alter the APD and hence the

Table 22.1 Effect of different drug classes on phases of action potential in His–Purkinje fibres

Phase	Dominant ion movement	Drug class	Effect
0	Sodium inward	IA IB IC	Block ++ Block + Block +++
2	Calcium inward	IV	Block
3	Potassium outward	III	Marked slowing
4	Sodium inward, potassium outward	I, II, IV	Slows

Table 22.2 Electrophysiological effects of some antiarrhythmics

Class	Antiarrhythmic agents	Effects on duration of		Sinus rate
		QRS	QT	
IA	Quinidine, procainamide, disopyramide	+	+	+
IB	Lidocaine (lignocaine), mexiletine, phenytoin	0/−	−	0
IC	Flecainide, propafenone	++	0	−−
II	Atenolol, metoprolol, sotalol, esmolol	0	++	−−
III	Amiodarone, bretylium, sotalol	0	+++	−
IV	Verapamil, diltiazem, adenosine	0	0	−−

+, increased; −, decreased; 0, no change.

Table 22.3 Adverse effects of antiarrhythmic drugs (class I)

Drug	Cardiac	Non-cardiac	Caution or avoid in
Disopyramide	Torsade de Pointes Myodepressant	Anticholinergic (urinary retention, constipation, dry mouth, blurred vision)	Glaucoma, prostatism, hypotension
Procainamide		Lupus, nausea, diarrhoea	Myasthenia gravis, slow acetylators (increased risk of lupus)
Quinidine	Torsade de Pointes Vasodilation (i.v.)	Diarrhoea, nausea, tinnitus, headache, deafness, confusion, visual disturbances, blood dyscrasias	Myasthenia gravis
Lidocaine (lignocaine)		Convulsions in overdose, paraesthesiae	Liver failure (reduce dose)
Mexiletine		Nausea, paraesthesiae	Second or third degree heart block
Flecainide	Proarrhythmic Myodepressant	Paraesthesiae, tremor	Not recommended if any cardiac dysfunction
Propafenone	Proarrhythmic Myodepressant	Gastro-intestinal disturbances	Not recommended if any cardiac dysfunction

Table 22.4 Adverse effects of antiarrhythmic drugs (classes II–IV)

Drug	Cardiac	Non-cardiac	Caution or avoid in
ß-blockers (general)	Myodepressant Heart block	Bronchoconstriction (β_2) Vasoconstriction Hallucinations/vivid dreams (greater with more lipophilic agents) Decreased renal blood flow Changes in serum lipid profile Drowsiness, fatigue	Asthma, COPD, Raynaud's disease, diabetes mellitus, depression
Dofetilide	Torsade de Pointes		Combination with disopyramide or amiodarone or drugs in Table 22.1
Amiodarone	Torsade de Pointes	Hyper-/hypothyroidism, pneumonitis, myopathy, neuropathy, hepatitis, corneal deposits, photosensitivity	Thyroid disease, liver dysfunction, lung disease (e.g. pneumonectomy)
Bretylium	Hypotension	Initial sympathomimetic response, nausea	
Verapamil	Heart block	Constipation, headaches, flushing, ankle oedema, light-headedness	Myasthenia gravis
Adenosine	Heart block	Bronchoconstriction, flushing, chest pain	Asthma, COPD, combination with dipyridamole Decompensated heart failure, patients with a history of convulsions/seizures or recent heart transplant (<1 year)

effective refractory period (ERP) via an effect on potassium channels responsible for action potential repolarisation. Class I antiarrhyhmic drugs are subdivided into three groups according to their effect on APD: class IA drugs increase the APD, class IB drugs shorten the APD, and class IC drugs have no effect on APD. These effects may be assessed by measurement of the QT interval on the ECG, which reflects average ventricular APD.

The properties of class I antiarrhythmic drugs may be summarised as follows:

Table 22.5 Pharmacokinetics of selected antiarrhythmics

	Oral absorption	% protein binding	Elimination, metabolism, half-life (therapeutic range if recommended to be measured)
Amiodarone	Slow, variable	>95	Extensive metabolism, very variable rate, $t_{1/2}$ 2 days initially increasing to 40–60 days
Bretylium	Intravenous/intramuscular only	Unbound	Renal, $t_{1/2}$ 5–10 h
Digoxin	Variable, 70%	25	70% renal, variable, $t_{1/2}$ 36 h (0.8–2 ng/mL)
Diltiazem	40% absorbed	80	Hepatic, $t_{1/2}$ 3 h
Disopyramide	Rapid, >80%	30–90	50% renal, 15% bile, active metabolite, $t_{1/2}$ 4–10 h
Flecainide	Complete, slow	40	30% renal, $t_{1/2}$ 20 h
Lidocaine	Intravenous/intramuscular only	60–80	10% renal, rapid hepatic metabolism to CNS-toxic products, $t_{1/2}$ 8–100 min increases with duration of dosing
Mexiletine	>90%	60–70	10% renal, $t_{1/2}$ 10–12 h, hepatic metabolites mostly inactive
Procainamide	Rapid, >75%	15–20	50% renal, 25–40% converted to *N*-acetylprocainamide (active, $t_{1/2}$ 6 h), procainamide $t_{1/2}$ 2.5–4.5 h
Propafenone	Complete, rapid	>95	Extensive first-pass metabolism, capacity-limited, $t_{1/2}$ 2–12 h
Quinidine	Rapid, >80%	80–90	Mixed renal and hepatic, $t_{1/2}$ 6 h
Verapamil	Rapid, >90%	90	Hepatic, $t_{1/2}$ 4–12 h, marked first-pass effect

All values quoted are subject to marked interindividual variability. Most therapeutic ranges are poorly defined. Oral absorption does not account for drug lost by first-pass hepatic metabolism. Rapid absorption indicates a peak plasma concentration in less than 2 h.
$t_{1/2}$ elimination half-life at normal renal function.

Sodium channel blockade
IC > IA > IB
Effect on APD and ERP
IA prolong
IB shorten
IC no effect

Increasing the APD, and hence the effective refractory period, may terminate and prevent re-entry tachycardias by prolonging the duration that tissue is refractory and prevent re-entrant wavefronts from re-exciting the tissue. Although contributing to the antiarrhythmic effects of these drugs, APD prolongation is also responsible for one of their important adverse effects, Torsade de Pointes.

Class IA antiarrhythmic drugs have additional anticholinergic actions and oppose vagal activity. This can lead to both sinus tachycardia and a shortened refractory period of the AV node, as both the sinus and AV nodes are densely innervated and tonically inhibited by the vagus nerve. One conseqence of this effect on the AV node is a more rapid ventricular rate during AF, necessitating co-treatment with drugs such as digoxin, ß-blockers or calcium channel blockers.

Class IA agents

Class IA antiarrhythmic drugs have been used for the treatment of a variety of atrial and ventricular arrhythmias but are now rarely used because of their proarrhythmic (Torsade de Pointes) and non-cardiac side effects and potential for drug interactions.

Quinidine was one of the earliest antiarrhythmic drugs developed. Quinidine, an alkaloid derived from the cinchona tree bark, had a significant role in the treatment of many arrhythmias. After concerns about increased risk of ventricular arrhythmia and death with quinidine emerged, the use of quinidine fell dramatically in favour of newer antiarrhythmic medications.

Disopyramide has been used to treat a wide variety of supraventricular and ventricular arrhythmias. The drug is given orally and excreted by the kidneys, with a half-life of 6–8 h, necessitating frequent dosing. Disopyramide has strong affinity for muscarinic cholinergic receptors (40 times that of quinidine) and commonly causes anticholinergic side effects such as blurred vision, dry mouth, constipation and urinary retention. Disopyramide may precipitate acute glaucoma in predisposed individuals. Disopyramide also causes sympathetic inhibition

resulting in vasodilation. Other adverse effects occur less frequently than with quinidine (e.g. gastro-intestinal, QRS prolongation, Torsade de Pointes and hypotension) and there is no interaction with digoxin.

Procainamide has been used in an initial attempt at the pharmacologic cardioversion of AF of recent onset. Procainamide may be given orally or intravenously. Procainamide is metabolised to *n*-acetyl procainamide. Both have antiarrhythmic activity and are excreted mainly by the kidneys. The half-life of procainamide is short (3–4 h), necessitating frequent dosing. The half-life of *n*-acetyl procainamide is considerably longer than that of procainamide. The risk of a lupus-like syndrome comprising a rash, fever and arthralgia (likeliest in slow acetylators) is about one in three of those patients treated for longer than 6 months. Hypotension due to an inhibitory effect on sympathetic ganglia, QRS and QT interval prolongation are common adverse effects with intravenous administration.

Class IB agents

As a group, class IB agents inhibit the fast sodium current (typical class I effect) while shortening the APD in non-diseased tissue. The former has the more powerful effect, while the latter might actually predispose to re-entrant arrhythmias, but ensures that QT prolongation does not occur. Class IB agents act selectively on diseased or ischaemic tissue, where they are thought to promote conduction block in slowly conducting tissue critical to the maintenance of re-entry, thereby interrupting re-entry circuits.

Lidocaine was previously the standard intravenous agent for the suppression of serious ventricular arrhythmias associated with acute myocardial infarction and following cardiac surgery but has now been almost completely superseded by ß-blockers. Lidocaine acts preferentially on ischaemic myocardium and is more effective in the presence of a high external potassium concentration. Therefore, hypokalaemia must be corrected for maximum efficacy. The kinetics of lidocaine is such that it is rapidly de-ethylated by the liver precluding oral administration. The two critical factors governing lidocaine metabolism, and hence its efficacy, are liver blood flow (decreased in old age and by heart failure and ß-blockade) and drugs that induce or inhibit the enzyme of the cytochrome P450 system. Lidocaine is rapidly distributed within minutes after an initial intravenous loading dose, requiring the need for a continuous infusion or repetitive dosing to maintain therapeutic blood levels. Lidocaine has no value in treating supraventricular tachyarrhythmias.

Mexiletine may be administered intravenously or orally to control VT. Frequent gastro-intestinal and central nervous system (CNS) side effects (dizziness, light-headedness, tremor, nervousness, difficulty with coordination) limit the dose and possible therapeutic benefit.

Class IC agents

The major electrophysioloical effects of these agents are that they are powerful inhibitors of the fast sodium channel causing a marked depression of the upstroke of the cardiac action potential. In addition, they may variably prolong the APD by delaying inactivation of the slow sodium channel and inhibition of the rapid component of the repolarising delayed rectifier current (I_{kr}) which may explain the prolongation of the QRS complex and QT interval. Class IC agents are potent antiarrhythmics used largely in the control of paroxysmal supraventricular and ventricular tachyarrhythmias resistant to other drugs, although they have acquired a particularly bad reputation as a result of the proarrhythmic effects seen in CAST (Cardiac Arrhythmia Supression Trial) and the CASH (Cardiac Arrest Study Hamburg) studies. Faster heart rates, increased sympathetic activity, and diseased or ischaemic myocardium all contribute to the proarrhythmic effects of these drugs. This has led to these drugs being contraindicated in patients with structural heart disease as poor systolic function exaggerates the proarrhythmic effects. However, flecainide is effective for the treatment of both supraventricular and ventricular arrhythmias in patients without structural heart disease and is moderately successful for maintenance of sinus rhythm after cardioversion of AF. Propafenone has mild ß-blocking properties, especially in higher doses so should be avoided in patients with reversible obstructive airways disease.

Class II agents: ß-Adrenoreceptor antagonists (ß-blockers)

$ß_1$- and $ß_2$-adrenoreceptors are present in the cell membranes of myocytes throughout the heart. Activation of ß-adrenoreceptors by norepinephrine released from postganglionic sympathetic neurones and circulating norepinephrine and epinephrine increases the rate of discharge of the sinus node (positive chronotropy), increases the conduction velocity and shortens the refractory period of the AV node (positive dromotropy) and increases the force of contraction (contractility) of myocytes (positive inotropy).

ß-Adrenoreceptors are coupled to G proteins, which activate adenylyl cyclase to form cAMP from ATP. Increased cAMP directly activates the pacemaker current I_f to increase the rate of diastolic depolarisation and hence to increase the sinus rate. cAMP also activates a cAMP-dependent protein kinase (PK-A) that phosphorylates L-type calcium channels, which causes increased calcium entry into the cell. Increased calcium entry during the plateau phase of the action potential leads to enhanced release of calcium by the sarcoplasmic reticulum and hence an increase in contractility. Intracellular calcium overload predisposes to the development of early or late afterdepolarisations which may result in arrhythmias due to triggered activity.

ß-Blockers prevent the normal ligand (norepinephrine or epinephrine) from binding to the ß-adrenoreceptor by competing for the binding site. The antiarrhythmic properties of ß-blockers are probably the result of several mechanisms: (i) reducing the likelihood of arrhythmias due to triggered activity, (ii) opposing the increased sympathetic activity in patients with sustained VT and in patients with acute myocardial infarction and (iii) indirectly preventing arrhythmia via their antihypertensive and anti-ischaemic effect.

ß-Blockers licensed for the treatment of arrhythmias include propranolol, acebutol, atenolol, esmolol, metoprolol and sotalol. The antiarrhythmic activity of the various ß-blockers is reasonably uniform, the critical property being $ß_1$-adrenoreceptor blockade. Atenolol, metoprolol propranolol and esmolol are available for intravenous use. Esmolol, a selective $ß_1$-adrenoreceptor antagonist, has a half-life of 9 min with full recovery from its ß-blockade properties within 30 min. Esmolol is quickly metabolised in red blood cells, independent of renal and hepatic function, and due to its short half-life, can be useful in situations where there are relative contraindications or concerns about the use of a ß-blocker. Sotalol has some class III activity as well as class II effects and bretylium is considered to have class II activity in addition to class III.

The use of ß-blockers is somewhat constrained by their adverse effects. $ß_2$-Adrenoreceptors on bronchial smooth muscle are tonically activated by circulating catecholamines to cause bronchodilation. ß-Blockers can, therefore, cause bronchoconstriction and are contraindicated in patients with asthma and should be used with caution in chronic obstructive pulmonary disease. $ß_2$-Adrenoreceptors are also found on vascular smooth muscle and are tonically activated by circulating catecholamines to cause vasodilatation. ß-Blockers may, therefore, cause vasoconstriction and exacerbate the symptoms of peripheral vascular disease.

Cardiac adverse effects of ß-blockers include sinus bradycardia, exacerbation of AV conduction block, reduced exercise capacity and exacerbation of acute heart failure. In patients with chronic, stable heart failure, however, due to mild to moderate LV systolic dysfunction and already treated by ACE inhibitors and diuretics, ß-blockers improve both symptoms and prognosis. Other adverse effects of ß-blockers include nightmares and impotence.

ß-Blockers vary in their lipid solubility. Agents such as propranolol and carvedilol are highly lipid-soluble whilst others such as atenolol and nadolol are more hydrophilic. Lipid solubility determines the degree of drug penetration into the CNS and the utility of haemodialysis or haemofiltration. High lipid solubility is associated with a larger volume of distribution and better CNS penetration. Lipophilic ß-blockers are primarily metabolised by the liver. Conversely, hydrophilic ß-blockers have a small volume of distribution and are eliminated essentially unchanged by the kidneys; this property allows hydrophilic ß-blockers to be removed by haemodialysis.

Class III agents

Class III antiarrhythmic drugs prolong cardiac APD by inhibiting repolarising outward potassium currents I_{Kr} and/or I_{Ks}. This action prolongs the effective refractory period, reducing the likelihood of arrhythmias due to re-entry. Prolongation of cardiac APD is reflected by QT interval prolongation on the ECG. Primary indications for class III agents are AF, atrial flutter and ventricular tachyarrhythmias.

Class III drugs include amiodarone, sotalol and bretylium. Amiodarone has additional class I, II and IV activity while sotalol has marked class II activity. An important limitation of class III agents is that action potential prolongation may be complicated by Torsade de Pointes. The development of Torsade de Pointes is attributed to a combination of triggered activity as a result of EADs and increased transmural dispersion of repolarisation within the ventricles as action potential prolongation is not uniform across the ventricular wall. Hypokalaemia, hypomagnesaemia or bradycardia increase the likelihood of Torsade de Pointes and, therefore, sotalol, with marked class II activity, may be uniquely arrhythmogenic.

Amiodarone. Amiodarone is a potent antiarrhythmic drug that is effective in treating a wide variety of atrial and ventricular arrhythmias but its use is constrained by complex pharmacokinetics and concern about toxicity. Many heart rhythm specialists would consider that the side effect profile of amiodarone precludes its use for the long-term treatment of atrial arrhythmias. Amiodarone may be extremely effective in the emergency treatment of VT and ventricular fibrillation, especially where recurrent. Amiodarone may also reduce the likelihood of recurrent ventricular arrhythmias when taken on a long-term basis but confers no prognostic benefit and should be considered as an adjunct to treatment with an ICD.

When rapid control of an arrhythmia is needed, the intravenous route is preferred, with 300 mg given over 30 min to an hour followed by 900 mg over 23–24 h, administered through a central vein. Higher loading doses may cause hypotension. A concurrent oral loading regimen of up to 2400 mg daily in two to four divided doses is usually given for 7–14 days and then reduced to a maintenance dose of 200 mg daily or less.

During the early stages of therapy with amiodarone (whether intravenous or oral), the kinetics of the drug are different from those after chronic administration. Amiodarone is highly lipid soluble and so has a very large volume of distribution. As the slowly equilibrating tissue stores are penetrated to a minimal extent during the early days of therapy, the effective elimination half-life ($t_{1/2}$) is initially dependent upon a more rapidly exchanging compartment, with a $t_{1/2}$ of 10–17 h, substantially shorter than the $t_{1/2}$ seen during chronic administration. The short $t_{1/2}$ becomes important during the acute phase and any intravenous to oral changeover period because the absorption of oral amiodarone is very slow, taking up to 15 h. The combination of a relatively fast elimination and a poor rate of absorption could lead to a significant fall in serum amiodarone levels if intravenous therapy is stopped abruptly when oral therapy is initiated, with the period of maximum risk being the first 24 h of oral therapy. It is, therefore, advisable to phase out intravenous therapy gradually and allow an intravenous/oral overlap period of at least 24 h. Once amiodarone has reached saturation, amiodarone is eliminated very slowly, with a half-life of about 25–110 days. Due to amiodarone's long terminal half-life, there is a potential for drug interactions to occur several weeks (or even months) after treatment with it has been stopped. Common interactions include antibacterials, other antiarrhythmics, lipid-regulating drugs and digoxin.

Amiodarone has been associated with toxicity involving the lungs, thyroid gland, liver, eyes, skin, and peripheral nerves. The incidence of most adverse effects is related to total

amiodarone exposure (i.e. dosage and duration of treatment). Therefore, practitioners must consider carefully the risk–benefit ratio of the use of amiodarone in each patient, use the lowest possible dose of amiodarone, monitor for adverse effects and, if possible, discontinue treatment if adverse effects occur.

Corneal microdeposits (reversible on withdrawal of treatment) develop in nearly all adult patients given prolonged amiodarone; these rarely interfere with vision, but drivers may be dazzled by headlights at night. However, if vision is impaired or if optic neuritis or optic neuropathy occur, amiodarone must be stopped to prevent blindness. Long-term administration of amiodarone is associated with a blue-grey discoloration of the skin. This is more commonly seen in individuals with lighter skin tones. The discoloration may revert upon cessation of the drug. However, the skin color may not return completely to normal.

Individuals taking amiodarone may become more sensitive to the harmful effects of UV-A light. Using sunblock that also blocks UV-A rays appears to prevent this side effect. Amiodarone contains iodine and can cause disorders of thyroid function. Both hypothyroidism and hyperthyroidism may occur. Clinical assessment alone is unreliable and laboratory tests should be performed before treatment and every 6 months including tri-iodothyronine (T3), T4 and thyroid stimulating hormone (TSH). A raised T3 and T4 with a very low or undetectable TSH concentration suggests the development of thyrotoxicosis. Amiodarone-associated thyrotoxicosis may be refractory to treatment and amiodarone should usually be withdrawn, at least temporarily, to help achieve control, although treatment with carbimazole is often required. Hypothyroidism can be treated safely with replacement therapy without the need to withdraw amiodarone if amiodarone is considered essential. Amiodarone is also associated with hepatotoxicity and treatment should be discontinued if severe liver function abnormalities or clinical signs of liver disease develop.

The most serious adverse effect of amiodarone therapy is pulmonary toxicity, typically acute pneumonitis or more insidious pulmonary fibrosis. In early studies, the frequency of pulmonary toxicity during amiodarone therapy was 2–17%. More recent studies have shown a lower incidence in patients receiving dosages of 300 mg/day or less. Although acute pneumonitis may respond to corticosteroids, pulmonary fibrosis is largely irreversible.

Class IV agents

The plateau phase of the cardiac action potential results from the inward movement of Ca^{2+} ions balanced by the outward movement of K^+ ions. Class IV agents (calcium channel blockers) block the inward movement of calcium ions during phase 2 by binding to L-type calcium channels on cardiac myocytes. The effect of class IV antiarrhythmic drugs is most marked in the sinoatrial and AV nodes, in which depolarisation is dependent upon calcium channels. Class IV antiarrhythmic drugs, therefore, cause sinus bradycardia (negative chronotropic effect), and, by reducing the conduction velocity and prolonging the AV nodal effective refractory period, reduce the ventricular rate during atrial tachyarrhythmias such as AF and flutter (negative dromotropic effect). By reducing intracellular calcium concentration class IV antiarrhythmic drugs also exert a negative inotropic effect. Only the non-dihydropyridine calcium channel blockers (verapamil and diltiazem) have direct cardiac effects.

Verapamil possesses a chiral carbon and is marketed as a racemic mixture of R- and S-stereoisomers. In humans, both isomers share qualitatively similar negative chronotropic and dromotropic effects on the sinoatrial and AV nodes, respectively, but the S-stereoisomer is 10–20 times more potent than the R with respect to these effects. Hence, the S-stereoisomer determines the negative chronotropic and dromotropic effects of verapamil, while the R-stereoisomer is of minor importance.

Verapamil also undergoes extensive stereoselective first-pass hepatic metabolism. S-verapamil is more rapidly metabolised than R-verapamil after oral administration, resulting in a lower bioavailability of the S-stereoisomer and a proportionally higher concentration of the R-stereoisomer in the systemic circulation (20% and 50%, respectively). However, because C_{max} is higher with the immediate-release formulation and S-verapamil is 10–20 times more potent than R-verapamil, it is unsurprising that this difference is also clinically significant. With the immediate-release formulation, a plot of PR-interval change versus time has the same shape as the concentration–time curve. The extended-release formulation does not have the same concentration–time effect relationship. This has been attributed to the difference in oral input rates, to the concentration-related saturable first-pass hepatic metabolism, or both.

Since the formulation of verapamil may play a role in the drug's complex pharmacokinetics and efficacy, one formulation of verapamil cannot be safely substituted for another. Immediate release preparations are preferred to maximise bioavailability of the S-stereoisomer.

Class IV antiarrhythmic drugs should be avoided in sick sinus syndrome or second- or third-degree heart block unless the patient has a permanent pacemaker. Combined therapy with a calcium channel blocker and ß-blocker should be instituted with caution because of the risk of excessive AV block, and should be used where only where monotherapy is insufficient to control ventricular rate during atrial flutter or fibrillation. Verapamil causes greater arterial vasoodilation than diltiazem and may be especially useful in patients with hypertension or angina. Both agents have a negative inotropic effect and are thus contraindicated in heart failure. Adverse effects are mostly predictable and include ankle oedema, flushing, dizziness, light-headedness and headache. Constipation is common in patients receiving verapamil whilst a rash is common with diltiazem.

Adenosine

The potassium channel opener adenosine and its pro-drug adenosine triphosphate (ATP) act as indirect calcium antagonists and resemble verapamil in their antiarrhythmic activity.

In cardiac tissue, adenosine binds to adenosine type 1 (A_1) receptors, which are coupled to Gi proteins. Activation of this pathway opens transmembrane potassium channels, which hyperpolarises the cell. Activation of the Gi protein also decreases cAMP, which inhibits L-type calcium channels and, therefore, calcium entry into the cell. In cardiac pacemaker cells located in the sinoatrial node, adenosine acting through A_1 receptors inhibits the pacemaker current (I_f), which decreases the slope of phase 4 of the pacemaker action potential thereby decreasing its spontaneous firing rate (negative chronotropy). Inhibition of L-type calcium channels also decreases conduction velocity of the AV node (negative dromotropy). Finally, adenosine, by acting on presynaptic purinergic receptors located on sympathetic nerve terminals, inhibits the release of norepinephrine.

The ultra-short duration of action (<10 s) of intravenous adenosine makes it very suitable as a diagnostic aid and for interrupting supraventricular arrhythmias in which the AV node is part of the re-entry pathway. Adenosine is, however, a bronchoconstrictor and causes dyspnoea, flushing, chest pain and further transient arrhythmias in a high proportion of patients, and its metabolism is inhibited by dipyridamole, a vasodilator drug that blocks adenosine uptake by cells, thereby reducing the metabolism of adenosine.

Digoxin

Digitalis compounds are potent inhibitors of transmembrane Na^+/K^+-ATPase. This ion transport system moves sodium ions out of the cell in exchange for potassium ions. The consequent rise in the intracellular sodium concentration increases the activity of a transmembrane Na^+/Ca^+ exchanger in cardiac myocytes as well as many other cells, which moves sodium out of the cell in exchange for calcium. The resulting increased intracellular calcium concentration stimulates calcium release from the sarcoplasmic reticulum which increases contractility (positive inotropic effect).

Digoxin also acts on the autonomic nervous system to increase vagal tone and reduce sympathetic nervous activity, reducing conduction velocity and increasing the effective refractory period of the AV node. Digoxin, therefore, reduces the ventricular rate during persistent atrial flutter and AF and may be particularly useful in patients with these arrhythmias in the context of congestive cardiac failure. Digoxin has limited efficacy in controlling the ventricular rate in situations where the sympathetic nervous system predominates such as during exercise. It is, therefore, only useful as monotherapy in sedentary patients. ß-Blockers and calcium channel blockers are more useful for controlling the ventricular rate on exertion as well as at rest.

Digoxin is no longer indicated for the treatment of paroxysmal AF as it has no direct antiarrhythmic effect and neither terminates an episode of AF nor reduces the likelihood of further episodes of AF occurring. Furthermore, digoxin has limited efficacy for ventricular rate control at the start of an episode of AF where sympathetic nervous system activity is often high.

The positive inotropic effect of digoxin has long been used in the treatment of patients with systolic heart failure and sinus rhythm. As evidence emerged that other positive inotropic agents such as milrinone increase mortality in heart failure the role of digoxin was reexamined. Perhaps the largest and best designed of these trials, the Digitalis Investigation Group (1997) trial, established that digoxin had no effect on all-cause mortality in patients with stable congestive cardiac failure, a left ventricular ejection fraction of under 45% and sinus rhythm but significantly reduced a combined endpoint of CHF mortality and hospitalisation due to heart failure. With a large body of evidence attesting to the morbidity and mortality benefits of ACE inhibitors, ß-blockers and spironolactone the role of digoxin has diminished. Digoxin may still be useful in patients who remain symptomatic despite comprehensive therapy with these drugs.

The long half-life of digoxin (about 36 h) warrants special consideration when treating arrhythmias as several days of constant dosing would be required to reach steady-state. Therefore, loading doses of up to 1.5 mg may be used rapidly to increase digoxin serum levels. Digoxin is given once daily thereafter, usually in 125 or 250 µcg doses and has a narrow therapeutic window with the ideal blood concentration regarded as 1–2 µcg/L. Since digoxin is excreted predominantly by the kidney (70% renal elimination in normal renal function), renal function is the most important determinant of the daily digoxin dosage. Importantly, in severe renal insufficiency, there is also a decrease in the volume of distribution of digoxin and, therefore, lower loading doses should be used.

Both the therapeutic and toxic effects of digoxin are potentiated by hypokalaemia and hypercalcaemia. There are also numerous drug interactions (Table 22.6), some of which are pharmacokinetic and some of which are pharmacological.

The occurrence of adverse drug reactions is common, owing to the narrow therapeutic index of digoxin. Adverse effects are concentration-dependent, and are rare when serum digoxin concentration is less than 0.8 µcg/L. Common adverse effects

Table 22.6 Interactions involving digoxin

Effect	Offending agent or condition
Serum level increased by	Amiodarone, verapamil, diltiazem, quinidine, propafenone, clarithromycin, broad-spectrum antibiotics (erythromycin, tetracyclines), decreased renal blood flow (ß-blockers, NSAIDs), renal failure, heart failure
Serum level decreased by	Colestyramine, sulfasalazine, neomycin, rifampicin, antacids, improved renal blood flow (vasodilators), levothyroxine (thyroxine)
Therapeutic effect increased by	Hypokalaemia, hypercalcaemia, hypomagnesaemia, antiarrhythmic classes IA, II, IV, diuretics that cause hypokalaemia, corticosteroids, myxoedema, hypoxia (acute or chronic), acute myocardial ischaemia or myocarditis
Therapeutic effect decreased by	Hyperkalaemia, hypocalcaemia, thyrotoxicosis

include loss of appetite, nausea, vomiting and diarrhoea as gastro-intestinal motility increases. Other common effects are blurred vision, visual disturbances (yellow-green halos and problems with colour perception), confusion and drowsiness. The often described adverse effect of digoxin, xanthopsia, the disturbance of colour vision (mostly yellow and green colour) is rarely seen.

Patient care

Patients with arrhythmias may experience considerable anxiety about the possibility that they will have a serious arrhythmia at any moment and may, therefore, require considerable reassurance with regular follow-up. The patient's family and friends may need to be advised on what to do in the event of an acute arrhythmia. An individual's anxiety may not be helped by the fact that most antiarrhythmic drugs work in only a proportion of patients and several treatment options may be tried before the most appropriate one is identified.

Patients should give informed consent for all interventions, and prescribers must be prepared for a patient to have a different view on the use of a medicine compared to their own. This was illustrated in a study of patients' and prescribers' attitudes to the use of aspirin and warfarin for stroke prevention in AF. Not only did prescribers differ markedly on the balance of risks between stroke prevention and bleeding caused by treatment but patients feared a stroke more than doctors. Prescribers should seek and respect patients' views on such treatment choices, rather than assume all patients are the same or that they will always agree with their own views.

Examples of some common therapeutic problems that may occur during the management of arrhythmias are set out in Table 22.7.

Table 22.7 Common therapeutic problems in the management of arrhythmias

Problem	Comment
All antiarrhythmics are proarrhythmic	Prevention is better than cure. Minimise the requirement for drugs by careful attention to precipitating factors. Consider use of pacemakers or non-pharmacological therapies if appropriate
Nausea and vomiting with blurred vision and visual discolouration on digoxin	Symptoms and signs of digoxin toxicity noting digoxin has a narrow therapeutic range. Poor renal function may have also contributed
ß-Blockers are generally contraindicated in bronchial and peripheral vascular disease	Consider verapamil or diltiazem
Calcium channel blockers-induced constipation	If it occurs, give regular osmotic laxatives
Torsade de Pointes may be precipitated by taking other medication with amiodarone or disopyramide	Patients should remind members of health care team that they are taking antiarrhythmic drugs, as well as consider electrolyte disturbance such as hypokalaemia
Patients experiencing myopathy	Healthcare professionals involved in screening prescriptions for antiarrhythmics should be aware of the clinically relevant interactions and how to manage these. Patients who are taking statins will need regular monitoring for signs of myopathy, particularly those on high-intensity statin therapy
Severe asthmatic patient admitted with SVT	Adenosine is contraindicated due to the risk of bronchospasm. Verapamil is a suitable alternative
Amiodarone is commonly associated with an increased tendency to sunburn	Warn all patients to stay covered up when outdoors, use sun block or stay indoors
Acutely treated patient with AF cardioverted initially with i.v. amiodarone, but on converting to oral therapy, converted back to AF	While amiodarone has a long terminal half-life once saturated, amiodarone has a very large volume of distribution and since tissue stores are penetrated to a minimal extent during the early days of therapy, the effective elimination half-life ($t_{1/2}$) is initially dependent upon a more rapidly exchanging compartment, with a $t_{1/2}$ of 10–17 h, substantially shorter than the $t_{1/2}$ seen during chronic administration. The shorter $t_{1/2}$ becomes important during the acute phase and any intravenous to oral changeover period because the absorption of oral amiodarone is very slow, taking up to 15 h. The combination of a relatively fast elimination and a poor rate of absorption could lead to a significant fall in serum amiodarone levels if intravenous therapy is stopped abruptly when oral therapy is initiated, with the period of maximum risk being the first 24 h of oral therapy. It is, therefore, advisable to phase out intravenous therapy gradually and allow an intravenous/oral overlap period of at least 24 h

SVT, supraventricular tachycardia; AF, atrial fibrillation.

Case studies

Case 22.1

A 25-year-old female presents to the hospital emergency department with a 2-h history of palpitation and chest tightness. She has experienced several similar episodes in the past, all of which have started abruptly at rest, and consisted of rapid, regular palpitations. Previous episodes have all stopped after a few minutes and between events she has been entirely well. She has no history of heart disease or other ongoing medical problems and is on no regular drug treatment. She drinks alcohol within recommended weekly limits and takes no other recreational drugs. On examination she is anxious, has a slightly cool periphery, her pulse is 190 bpm and regular and blood pressure is 130/90 mmHg. The remainder of the examination is unremarkable. A 12-lead ECG demonstrates a regular narrow-complex tachycardia with no discernible P waves.

Question

What is the most likely diagnosis and how should she be managed?

Answer

The patient has the signs and symptoms of SVT. Non-pharmacological means of restoring sinus rhythm include carotid sinus massage, subjecting the patient to the Valsalva manoeuvre or eliciting the diving reflex by immersion of the face in ice-cold water. Either approach should result in a brief vagal discharge sufficient to block conduction in the AV node and terminate the tachycardia. If these manoeuvres are unsuccessful, intravenous adenosine can be given in doses of up to 12 mg as a rapid bolus injection followed quickly by a saline flush. Intravenous verapamil 5 mg may also be administered as a rapid bolus injection and is a good alternative where adenosine is contraindicated.

Case 22.2

Mr DS was admitted to hospital for an emergency laparotomy for a perforated gut. He has a history of paroxysmal atrial fibrillation (AF) for which he is on long-term amiodarone 200 mg once daily.

Following the laparotomy he has new onset AF which the medical team would like to treat pharmacologically. His only other current medication is thromboprophylaxis with enoxaparin 20 mg once daily.

Questions

1. What treatment plan would you initially suggest?
2. What long-term monitoring would be appropriate for Mr DS?

Answers

1. If Mr DS has any electrolyte abnormalities these should be corrected. If he remains in AF he should be prescribed amiodarone by IV infusion, as the long-term maintenance dose is clearly no longer adequate following the laparotomy.

   The reduced dose of enoxaparin should be noted. This is because Mr DS is a post surgical patient and at high risk of bleeding.

   Mr DS cardioverts back to sinus rhythm following a bolus dose of 300 mg amiodarone. The plan is to maintain him on amiodarone long term.

2. Given that Mr DS is to continue amiodarone long term the following monitoring would be appropriate:

Chest X-ray: pulmonary	Baseline and if symptoms present
Thyroid panel	Baseline and every 3–6 months
Liver panel	Baseline and every 3–6 months
Eye examination	Baseline and every 12 months
ECG	Baseline and as required
Clinical evaluation	Baseline and every 3 months

Case 22.3

Mr SB is 77 years of age who attends the hospital emergency department with worsening shortness of breath. His previous medical history includes a myocardial infarction 10 years ago which left him with left ventricular dysfunction (ejection fraction < 40%). He also has hypertension. His current medication includes:

   Bisoprolol 5 mg daily
   Ramipril 5 mg daily
   Aspirin 75 mg daily
   Furosemide 80 mg each morning.

   His heart rate is 65 bpm and irregular, and he has a blood pressure of 160/85 mmHg. Mr SB's ECG shows atrial fibrillation (AF). It was decided to control his AF with bisoprolol with no alteration of dose.

Questions

1. What drug is most appropriate for stroke prevention in Mr SB?
2. The junior doctor asks you whether warfarin should be initiated along with aspirin or in place of it.

Answers

1. All patients presenting with AF (or atrial flutter) should undergo assessment of their risk of stroke. Although various risk stratification schemes exist, the CHADS$_2$ score is widely used. For Mr SB the following is determined:

   Congestive cardiac failure 1
   Hypertension 1
   Age >75 years 1
   Diabetes mellitus 0
   Stroke 0
   Given Mr SB has a CHADS$_2$ score of 3 this suggests an annual stroke risk of 5.9% if no therapy is prescribed. This risk will reduce to 4.7% if he is prescribed aspirin, or 2.1% if he is prescribed warfarin. Assuming no contraindications or concerns, warfarin should be prescribed.

2. In patients with stable vascular disease, such as those with no acute ischaemic events or PCI/stent procedure in the preceding year, warfarin monotherapy should be used. Concomitant antiplatelet therapy should not be prescribed. Published data support the use of warfarin for secondary prevention in patients with coronary artery disease. Warfarin is at least as effective as aspirin. It should be noted that any combination of an antiplatelet agent with a vitamin K antagonist such as warfarin will significantly increase the risk of a major bleed.

23 Thrombosis

P. A. Routledge and H. G. M. Shetty

Key points

Venous thromboembolism (VTE)

- VTE has an incidence of 2–5%.
- Combinations of sluggish blood flow and hypercoagulability are the commonest causes of VTE. Vascular injury is also a recognised causative factor.
- Treatment of VTE involves the use of anticoagulants and, in severe cases, thrombolytic drugs.
- Anticoagulant therapy usually involves an immediate-acting agent such as heparin followed by maintenance treatment with warfarin.
- Unfractionated heparins increase the rate of interaction of thrombin with antithrombin III 1000-fold and prevent the production of fibrin from fibrinogen.
- Low molecular weight heparins inactivate factor Xa, have a longer half-life and produce a more predictable response than unfractionated heparins.
- Warfarin is the most widely used coumarin because of potency, reliable bioavailability and an intermediate half-life of elimination (36 h).
- Warfarin consists of an equal mixture of two enantiomers, (R)- and (S)-warfarins, that have different anticoagulant potencies and routes of metabolism.

Arterial thromboembolism

- Arterial thromboembolism is normally associated with vascular injury and hypercoagulability.
- Acute myocardial infarction is the commonest form of arterial thrombosis.
- Arterial thromboembolism affecting the cerebral circulation results in either transient ischaemic attacks (TIAs) or, in severe cases, cerebral infarction (stroke).

Thrombosis is the development of a 'thrombus' consisting of platelets, fibrin, red cells and white cells in the arterial or venous circulation. If part of this thrombus in the venous circulation breaks off and enters the right heart, it may be lodged in the pulmonary arterial circulation, causing pulmonary embolism (PE). In the left-sided circulation, an embolus may result in peripheral arterial occlusion, either in the lower limbs or in the cerebral circulation (where it may cause thromboembolic stroke). Since the pathophysiology of each of these conditions differs, they will be discussed separately under the headings 'Venous thromboembolism' (VTE) and 'Arterial thromboembolism'.

Venous thromboembolism

Epidemiology

VTE is common, with an incidence of 2–5%. PE is now the commonest cause of maternal death, and deep vein thrombosis may result in not only PE but also subsequent morbidity as a result of the post-phlebitic limb. Thromboembolism appears to increase in prevalence over the age of 50 years, and the diagnosis is more often missed in this age group.

Aetiology

VTE occurs primarily due to a combination of stagnation of blood flow and hypercoagulability. Vascular injury is also a recognised causative factor but is not necessary for the development of venous thrombosis. In VTE, the structure of the thrombus is different from that in arterial thromboembolism. In the former, platelets seem to be uniformly distributed through a mesh of fibrin and other blood cell components, whereas in arterial thromboembolism the white platelet 'head' is more prominent and it appears to play a much more important initiatory role in thrombus.

Sluggishness of blood flow may be related to bed rest, surgery or reduced cardiac output, for example in heart failure. Factors increasing the risk of hypercoagulability include surgery, pregnancy, oestrogen administration, malignancy, myocardial infarction and several acquired or inherited disorders of coagulation (for further detail of genetic factors, see Rosendaal and Reitsma, 2009).

Protein C deficiency

Protein C deficiency is inherited by an autosomal dominant transmission. Such patients are at increased risk not only of VTE but also of warfarin skin necrosis. This occurs because protein C (and its closely related co-factor, protein S) is a vitamin K-dependent antithrombotic factor that can be further suppressed by the administration of warfarin. Thrombosis in the small vessels of the skin may occur if large loading (induction) doses of warfarin are given to such patients when the suppression of the antithrombotic effects of these factors occurs before the antithrombotic effects of blockade of vitamin K-dependent clotting factor (II, VII, IX and X) production has occurred. Although the prevalence of protein C deficiency is 0.2%, only one subject in 70 (i.e. 0.0003%) will be

symptomatic, and the condition accounts for around 4% of patients presenting with thromboembolic disease before the age of 45 years.

Protein S deficiency

Protein S deficiency is probably even rarer than protein C deficiency, but the familial form, inherited in an autosomal dominant fashion, is a high-risk state, accounting for possibly 5–8% of cases of thromboembolism in patients less than 45 years old.

Factor V Leiden

The presence of factor V Leiden, a point mutation in the factor V gene, causes the activated factor V molecule to be resistant to deactivation by activated protein C (APC). This defect may have a prevalence of 5% in Caucasian populations, and higher in patients with thromboembolic disease, and may in itself be of little consequence until there is another risk factor, such as immobility and use of the contraceptive pill. In these circumstances, the combination of risks may be responsible for the increased predisposition to thromboembolism in a high proportion of affected individuals.

Antithrombin III deficiency

Antithrombin III deficiency is a rare autosomal dominantly inherited abnormality associated with a reduced plasma concentration of this protein. The defect may not result in clinical problems until pregnancy or until patients enter their fourth decade, when venous and (to a lesser extent) arterial thrombosis becomes more common. Nevertheless, it has been estimated to be responsible for between 2% and 5% of thromboembolism occurring before age 45.

Lupus anticoagulant

Lupus anticoagulant, an antibody against phospholipid, is so named because it increases the clotting time in blood when measured by some standard coagulation tests. Patients affected are more prone to thromboembolism. This factor is found in 10% of patients with systemic lupus erythematosus (SLE) where it is associated with a threefold increase in thromboembolic risk; it is also found in the primary antiphospholipid syndrome (PAPS), where it may signify an increased risk of venous and arterial thrombosis and of recurrent miscarriage.

Prothrombin 20210 mutation

A mutation in part of the prothrombin gene (prothrombin 20210A) results in increased prothrombin concentrations and an increased risk of venous thrombosis. Carriers have a two- to threefold increased risk of venous thrombosis, and the variant is found with similar frequency as factor V Leiden in Caucasian populations.

Fibrinogen gamma 10034T

Approximately 6% of individuals carry this variant gene, which increases thrombotic risk approximately twofold.

Oestrogens

Oestrogens increase the circulating concentrations of clotting factors I, II, VII, VIII, IX and X and reduce fibrinolytic activity. They also depress the concentrations of antithrombin III, which is protective against thrombosis. This effect is dose-related, and venous thrombosis was more often seen with the high (50 μcg) oestrogen-containing contraceptive pill than with the present lower dose preparations. Hormonal replacement therapy, pregnancy and the puerperium (up to 6 weeks after delivery) are also recognised risk factors for VTE.

Malignancy

VTE is also commoner in malignancy (the risk may be up to fivefold greater). Although first described in association with carcinoma of the pancreas, all solid tumours seem to be associated with this problem. This may be related to the expression of tissue factor or factor X activators, but several other mechanisms may also be responsible. Cancer treatment also appears to be a risk factor.

Surgery

The increased risk of VTE in surgery is related in part to stagnation of venous blood in the calves during the operation and also to tissue trauma, since it appears to be more common in operations that involve marked tissue damage, such as orthopaedic surgery. This may in turn be related to release of tissue thromboplastin and to reduced fibrinolytic activity. The most important risk factors associated with clinical thromboembolism after surgery are age, varicose veins with associated phlebitis and obesity (body mass index > 30 kg/m^2), prolonged immobility or continuous travel of greater than 3 h approximately 4 weeks before or after surgery.

Other risk factors

There are several other patient-related risk factors for VTE. Age over 60 years is an important factor. Critical care admission, dehydration, and one or more significant medical comorbidities such as heart disease, metabolic, endocrine or respiratory pathologies, acute infectious diseases and inflammatory conditions are all important risk factors for VTE. A full list can be found in the relevant National Institute for Health and Clinical Excellence (2010) guideline.

Clinical manifestations

In 90% of patients, deep vein thrombosis occurs in the veins of the lower limbs and pelvis. In up to half of cases, this may not result in local symptoms or signs, and the onset of PE may be the first evidence of the presence of VTE. In other cases, patients classically present with pain involving the calf

or thigh associated with swelling, redness of the overlying skin and increased warmth. In a large deep venous thrombosis that prevents venous return, the leg may become discolored and oedematous. Massive venous thrombus can occasionally result in gangrene, although this occurs very rarely now that effective drug therapies are available.

PE may occur in the absence of clinical signs of venous thrombosis. It may be very difficult to diagnose because of the non-specificity of symptoms and signs. Clinical diagnosis is often made because of the presence of associated risk factors. Obstruction with a large embolus of a major pulmonary artery may result in acute massive PE, presenting with sudden shortness of breath and dull central chest pain, together with marked haemodynamic disturbance, for example severe hypotension and right ventricular failure, sometimes resulting in death due to acute circulatory failure unless rapidly treated.

Acute submassive pulmonary embolus occurs when less than 50% of the pulmonary circulation is occluded by embolus, and the embolus normally lodges in a more distal branch of the pulmonary artery. It may result in some shortness of breath but if the lung normally supplied by that branch of the pulmonary artery becomes necrotic, pulmonary infarction results with pleuritic pain and haemoptysis (coughing up blood), and there may be a pleural 'rub' (a sound like Velcro® being torn apart when the patient breathes in) as a result of inflammation of the lung. Patients may, rarely, develop recurrent thromboembolism. This may not result in immediate symptoms or signs but the patient may present with increasing breathlessness and signs of pulmonary hypertension (right ventricular hypertrophy) and, if untreated, progressive respiratory failure.

Investigations

Deep vein thrombosis

Although several conditions may mimic deep vein thrombus, such as a Baker's cyst, which involves rupture of the posterior aspect of the synovial capsule of the knee, deep vein thrombosis is the commonest cause of pain, swelling and tenderness of the leg. The clinical diagnosis of venous thrombosis is relatively unreliable, and venography is the most specific diagnostic test.

Venography. Venography involves injection of radio-opaque contrast medium, normally into a vein on the top of the foot, and subsequent radiography of the venous system.

Ultrasound. Ultrasound is a non-invasive alternative to venography that does not involve exposure to ionizing radiation or potentially allergenic contrast media. It is now the initial investigation of choice in clinically suspected deep vein thrombosis, although it is less sensitive for below-knee and isolated pelvic deep vein thrombosis.

Magnetic resonance imaging (MRI). MRI is also non-invasive and avoids radiation exposure. When used with direct thrombus imaging (DTI), which detects methaemoglobin in the clot, MRI DTI is sensitive and specific, even with below-knee and isolated pelvic deep vein thrombosis. However, it is not widely clinically available and ultrasound remains the primary initial investigation.

Pulmonary embolism

Pulmonary arteriography. The diagnosis of PE is most often made using one of two techniques: pulmonary arteriography or ventilation–perfusion scanning. Pulmonary arteriography is the most specific test. This requires catheterisation of the right side of the heart and an injection of contrast medium into the pulmonary artery. Adequate facilities and experienced personnel are, therefore, required and it is now generally reserved for those situations where massive or submassive PE is suspected but non-invasive tests have given indeterminate results.

Ventilation–perfusion scanning. Ventilation–perfusion scanning involves the injection of a radiolabelled substance into the vein and measurement of perfusion via the pulmonary circulation, using a scintillation counter. This is often combined with a ventilation scan in which radiolabelled gas, normally xenon, is inhaled by the patient. PE classically results in an area of under- or non-perfusion of a part of the lung that, nevertheless, because the airways are patent, ventilates normally. This pattern is called ventilation–perfusion mismatch and is a specific sign of PE.

Spiral computed tomography. Computed tomography angiography (CT angiography) using helical or spiral CT (sCT) is now being increasingly used in some centres and has a high accuracy rate. Although subsegmental emboli can be missed, visualisation of smaller arterial branches, and therefore detection of small emboli, may improve with the availability of multidetector scanners. Not only does sCT enable direct visualisation of emboli, but also visualisation of the lung parenchyma and mediastinum may help in the differential diagnosis in non-embolic cases. MRI is also being developed for the diagnosis of PE and early results are promising.

Other findings. Other findings occur in PE, such as changes in the chest radiograph, for example a raised right hemidiaphragm as a result of loss of lung volume (PE more commonly affects the right than the left lung). Hypoxia is also seen, and the larger the pulmonary embolus the worse this is. The electrocardiogram may show signs of right ventricular strain. The echocardiogram may show right ventricular overload and dysfunction in massive PE. However, all these changes are relatively non-specific and do not obviate the need for the specific tests mentioned above.

Treatment

The aim of treatment of venous thrombosis is to allow normal circulation in the limbs and, wherever possible, to prevent damage to the valves of the veins, thus reducing the risk of the swollen post-phlebitic limb. Second, it is important to try to prevent associated PE and also recurrence of either venous thrombosis or PE in the risk period after the initial episode.

In acute massive PE, the initial priority is to correct the circulatory defect that has caused the haemodynamic upset, and in these circumstances, rapid removal of the obstruction using thrombolytic drugs or surgical removal of the embolus may be necessary. In acute submassive PE, the goal of treatment is to prevent further episodes, particularly of the more serious acute massive PE. In both deep vein thrombosis and PE,

a search must be made for underlying risk factors, such as carcinoma, which may occur in up to 10% of patients, and particularly in those with repeated episodes of VTE.

The treatment of VTE consists of the use of anticoagulants and, in severe cases, thrombolytic drugs. Anticoagulant therapy involves the use of immediate-acting agents (particularly heparin) and oral anticoagulants, the commonest of which is warfarin. Not only do these treat the acute event, but they also prevent recurrence and may be necessary for some time after the initial event, depending on the persistence of risk factors for recurrent thromboembolism.

Prophylaxis

Prevention of initial episodes of VTE in those at risk is clearly of great importance. It was estimated that around 25,000 people in the UK die from preventable hospital-acquired VTE annually, including patients admitted to hospital for medical care as well as surgery. There is also widespread evidence of inconsistent use of prophylactic measures for VTE in hospital patients, including mechanical as well as pharmacological means of VTE prophylaxis. Some of the medicines described below contribute to those pharmacological measures. Guidelines on this are available (National Institute for Health and Clinical Excellence, 2010).

Heparins

Conventional or unfractionated heparin (UFH) is a heterogeneous mixture of large mucopolysaccharide molecules ranging widely in molecular weight between 3000 and 30,000, with immediate anticoagulant properties. It acts by increasing the rate of the interaction of thrombin with antithrombin III by a factor of 1000. It, thus, prevents the production of fibrin (factor I) from fibrinogen. Heparin also has effects on the inhibition of production of activated clotting factors IX, X, XI and XII, and these effects occur at concentrations lower than its effects on thrombin.

Unlike UFH, low molecular weight heparins (LMWHs) contain polysaccharide chains ranging in molecular weight between 4000 and 6000. Whereas UFH produces its anticoagulant effect by inhibiting both thrombin and factor Xa, LMWHs predominantly inactivate only factor Xa. In addition, unlike UFH, they inactivate platelet-bound factor Xa and resist inhibition by platelet factor 4 (PF4), which is released during coagulation. Bemiparin, dalteparin, enoxaparin, reviparin and tinzaparin are LMWHs with similar efficacy and adverse effects.

Because UFH and LMWHs all consist of high molecular weight molecules that are highly ionised (heparin is the strongest organic acid found naturally in the body), they are not absorbed via the gastro-intestinal tract and must be given by intravenous infusion or deep subcutaneous (never intramuscular) injection. UFH is highly protein-bound and it appears to be restricted to the intravascular space, with a consequently low volume of distribution. It does not cross the placenta and does not appear in breast milk. Its pharmacokinetics are complex, but it appears to have a dose-dependent increase in

half-life. The half-life is normally about 60 min, but is shorter in patients with PE. It is removed from the body by metabolism, possibly in the reticuloendothelial cells of the liver, and by renal excretion. The latter seems to be more important after high doses of the compound.

LMWHs have a number of potentially desirable pharmacokinetic features compared with UFH. They are predominantly excreted renally and have longer and more predictable half-lives than UFH and so have a more predictable dose response than UFH. They can, therefore, be given once or, at the most, twice daily in a fixed dose, sometimes based on the patient's body weight, without the need for laboratory monitoring, except for patients given treatment doses and at high risk of bleeding.

The major adverse effect of all heparins is haemorrhage, which is commoner in patients with severe heart or liver disease, renal disease, general debility and in women aged over 60 years. The risk of haemorrhage is increased in those with prolonged clotting times and in those given heparin by intermittent intravenous bolus rather than by continuous intravenous administration. UFH is monitored by derivatives of the activated partial thromboplastin time (APTT), for example the kaolin–cephalin clotting time (KCCT); in those patients with a KCCT three times greater than control, there is an eightfold increase in the risk of haemorrhage. The therapeutic range for the KCCT during UFH therapy, therefore, appears to be between 1.5 and 2.5 times the control values. Rapid reversal of the effect of heparin can be achieved using protamine sulphate, but this is rarely necessary because of the short duration of action of heparin. LMWHs may produce fewer haemorrhagic complications, and monitoring of effect is not routinely required. At doses normally used for treatment, they do not significantly affect coagulation tests and routine monitoring is not necessary (British Committee for Standards in Haematology, 2006a).

Heparins, particularly UFH, may also cause thrombocytopenia (low platelet count). This may occur in two forms. The first occurs 3–5 days after treatment and does not normally result in complications. The second type of thrombocytopenia occurs after about 6 days of treatment and often results in much more profound decreases in platelet count and an increased risk of thromboembolism. LMWHs are thought to be less likely to cause thrombocytopenia but this complication has been reported, including in individuals who had previously developed thrombocytopenia after UFH. For these reasons, patients should have a platelet count on the day of starting UFH and the alternate-day platelet counts should be performed from days 4 to 14 thereafter. For patients on LMWH, the platelet counts should be performed at 2–4 day intervals from day 4 to 14 (British Committee for Standards in Haematology, 2006b). If the platelet count falls by 50% and/or the patient develops new thrombosis or skin allergy during this period, heparin-induced thrombocytopenia (HIT) should be considered, and if strongly suspected or confirmed, heparin should be stopped and an alternative agent such as a heparinoid or hirudin commenced.

Heparin-induced osteoporosis is rare but may occur when the drug is used during pregnancy, and may be dose-related.

The exact mechanism is unknown. Other adverse effects of heparin are alopecia, urticaria and anaphylaxis, but these are also rare.

It has been shown that there is a non-linear relationship between the dose of UFH infused and the KCCT. This means that disproportionate adjustments in dose are required depending on the KCCT if under- or over-dosing is to be avoided (Box 23.1). Since the half-life of UFH is 1 h, it would take 5 h (five half-lives of the drug) to reach a steady state. A loading dose is, therefore, administered to reduce the time to achieve adequate anticoagulation. UFH in full dose can also be given by repeated subcutaneous injection, and in these circumstances the calcium salt appears to be less painful than the sodium salt. Opinions differ as to whether the subcutaneous or intravenous route is preferable. The subcutaneous route may take longer to reach effective plasma heparin concentrations but avoids the need for infusion devices.

Heparin is normally used in the immediate stages of venous thrombosis and PE until the effects of warfarin become apparent. In the past, it has been continued for 7–10 days, but recent evidence indicates that around 5 days of therapy may be sufficient in many instances. This shorter treatment may also reduce the risk of the rare but potentially very serious complications of severe HIT, which normally occurs after the sixth day. LMWH should be administered for at least 5 days or until the INR has been in the therapeutic range for two successive days, whichever is the longer. They have largely replaced UFH, since they can be given subcutaneously (without a loading dose), and without routine monitoring. A full blood count should be ordered after 5 days on LMWH and throughout the duration of LMWH treatment to monitor for heparin-related thrombocytopenia. Patients with previous exposure to heparin within the past 100 days should also have a platelet count performed before the second dose of heparin is administered (Winter et al., 2005).

Heparinoids

Danaparoid is a heparinoid that is licensed for prophylaxis of deep vein thrombosis in patients undergoing general or orthopaedic surgery. It is a mixture of the low molecular weight sulphated glycosaminoglycuronans: heparin sulphate, dermatan sulphate and a small amount of chondroitin sulphate. It acts by inhibiting factor Xa and, like LMWHs, is given by subcutaneous injection. It normally has a low cross-reactivity rate with heparin-associated antiplatelet antibodies and if this is not present can be used in the treatment of individuals who develop HIT but still need ongoing anticoagulation. It is administered intravenously, with monitoring of anti-Xa activity only required in those at high risk of bleeding, for example renal insufficiency. It should be avoided in severe renal insufficiency and severe hepatic insufficiency.

Hirudins

Lepirudin, a recombinant hirudin, is licensed for anticoagulation in patients with type II (immune) HIT who require parenteral antithrombotic treatment. The dose of lepirudin is adjusted according to the APTT, and it is given intravenously by infusion. Haemorrhage is greater in those with poor renal function. Severe anaphylaxis occurs rarely in association with lepirudin treatment and is more common in previously exposed patients (British Committee for Standards in Haematology, 2006b). Bivaluridin is an analogue of hirudin, but acts as a direct thrombin inhibitor. It is licensed for anticoagulation in patients undergoing percutaneous coronary intervention (PCI). It has to be administered parenterally and the activated clotting time (ACT) is used to assess its activity. Haemorrhage is also an important adverse effect of this agent.

Fondaparinux

Fondiparinux sodium is a synthetic pentasaccharide that binds to antithrombin III, thus inhibiting factor Xa but without effect on factor IIa. Therefore, at doses normally used for treatment, it does not significantly affect coagulation tests and routine monitoring of these is not necessary. It has to be given parenterally. It is used for prophylaxis of VTE in high-risk situations and for treatment of acute deep vein thrombosis and treatment of acute PE, except in haemodynamically unstable patients or patients who require thrombolysis or pulmonary embolectomy. It also has an indication for the treatment of unstable angina or non-ST-segment elevation myocardial infarction (NSTEMI) and for treatment of ST-segment elevation myocardial infarction (STEMI). Haemorrhage is the most important adverse effect.

Box 23.1 Guidelines to control unfractionated heparin (UFH) treatment

Loading dose
5000 iu over 5 min

Infusion
Start at 1400 iu/h (e.g. 8400 iu in 100 mL of normal saline over 6 h). Check after 6 h. Adjust dose according to ratio of the KCCT to the control value using the values below

KCCT ratio Infusion rate change

>7.0	Discontinue for 30 min to 1 h and reduce by >500 iu/h
>5.0	Reduce by 500 iu/h
4.1–5.0	Reduce by 300 iu/h
3.1–4.0	Reduce by 100 iu/h
2.6–3.0	Reduce by 50 iu/h
1.5–2.5	No change
1.2–1.4	Increase by 200 iu/h
<1.2	Increase by 400 iu/h

After each dose change, wait 10 h before next KCCT estimation unless KCCT >5, when more frequent (e.g. 4-hourly) estimation is advisable. Developed using Diogen (Bell and Alton); local validation may be necessary.

KCCT, Kaolin–cephalin clotting time.

Oral anticoagulants

Warfarin. Although not the only coumarin anticoagulant available, warfarin is by far the most widely used drug in this group because of its potency, duration of action and more reliable bioavailability. Acenocoumarol (nicoumalone) has a much shorter duration of action and phenindione may be associated with a higher incidence of non-haemorrhagic adverse effects. When given by mouth, warfarin is completely and rapidly absorbed, although food decreases the rate (but not the extent) of absorption. It is extremely highly plasma protein-bound (99%) and, therefore, has a small volume of distribution (7–14 L). It consists of an equal mixture of two enantiomers, (R)- and (S)-warfarins. They have different anticoagulant potencies and routes of metabolism.

Both enantiomers of warfarin act by inducing a functional deficiency of vitamin K and thereby prevent the normal carboxylation of the glutamic acid residues of the amino-terminal ends of clotting factors II, VII, IX and X. This renders the clotting factors unable to cross-link with calcium and thereby bind to phospholipid-containing membranes. Warfarin prevents the reduction of vitamin K epoxide to vitamin K by epoxide reductase. (S)-warfarin appears to be at least five times more potent in this regard than (R)-warfarin. Since warfarin does not have any effect on already carboxylated clotting factors, the delay in onset of the anticoagulant effect of warfarin is dependent on the rate of clearance of the fully carboxylated factors already synthesised. In this regard, the half-life of removal of factor VII is approximately 6 h, that of factor IX 24 h, factor X 36 h and factor II 50 h. Some of the variability in response to warfarin may be related to genetic variations in the gene encoding the vitamin K epoxide reductase multiprotein complex (*VKORC1* gene).

The effect of warfarin is monitored using the one-stage prothrombin time, for example the international normalised ratio (INR). This test is sensitive chiefly to factors VII, II and X (and to a lesser extent factor V, which is not a vitamin K-dependent clotting factor). However, factor VII, to which the INR is sensitive, is the most important factor in the extrinsic pathway of clotting. The optimum therapeutic range for the INR differs for different clinical indications since the lowest INR consistent with therapeutic efficacy is the best in reducing the risk of haemorrhage. Examples of therapeutic ranges recommended for certain indications are given in Table 23.1 (British Committee for Standards in Haematology, 1998, 2006c).

Warfarin is metabolised by the liver via the cytochrome P450 system. Only very small amounts of the drug appear unchanged in the urine. The average clearance is 4.5 L/day and the half-life ranges from 20 to 60 h (mean 40 h). It, thus, takes approximately 1 week (around five half-lives) for the steady state to be reached after warfarin has been administered. The enantiomers of warfarin are metabolised stereo-specifically, (R)-warfarin being mainly reduced at the acetyl side chain into secondary warfarin alcohols while (S)-warfarin is predominantly metabolised at the coumarin ring to hydroxywarfarin. The clearance of warfarin may be reduced in liver disease as well as during the administration of a variety of drugs known to inhibit either the (S) or (R), or both, enantiomers. These are shown in Table 23.2 which is not exhaustive. The number of possible interactions and the potential severity of their outcome mean that it is essential not to prescribe any medicine concomitantly with warfarin until a thorough check on all possible interactions has been undertaken. The British National Formulary contains comprehensive tables listing possible interactions between warfarin and other medicines.

Renal function is thought to have little effect on the pharmacokinetics of, or anticoagulant response to, warfarin. Some of the variability in warfarin dose requirement is related to genetic polymorphisms of the cytochrome (CYP2C9) mediating the rate of hepatic metabolism of (S)-warfarin. Individuals with the variant isoform (either heterozygotes or in particular homozygotes) metabolise this more active enantiomer more slowly and so require lower doses.

The major adverse effect of warfarin is haemorrhage, which often occurs at a predisposing abnormality such as an ulcer and a tumour. The risk of bleeding is increased by excessive anticoagulation, although this may not need to be present for severe haemorrhage to occur. Close monitoring of the degree of anticoagulation of warfarin is, therefore, important, and guidelines for reversal of excessive anticoagulation are shown in Table 23.3.

It is also important to reduce the duration of therapy of the drug to the minimum effective period to reduce the period of risk.

Skin reactions to warfarin may also occur but are rare. The most serious skin reaction is warfarin-induced skin necrosis, which may occur over areas of adipose tissue such as the breasts, buttocks or thighs, especially in women, and which is related to relative deficiency of protein C or S. This is important because these deficiencies result in an increased risk of thrombosis, and therefore warfarin may more often be used in such subjects. Preventing excessive anticoagulation in the initial stages of induction of therapy may reduce the severity of the reaction. A dosing schedule which helps to achieve this is shown in Table 23.4.

Warfarin may also be teratogenic, producing in some instances a condition called chondrodysplasia punctata. This is associated with 'punched-out' lesions at sites of ossification, particularly of the long bones but also of the facial bones, and may be associated with absence of the spleen. Although it has been associated predominantly with warfarin anticoagulation during the first trimester of pregnancy, other abnormalities, including cranial nerve palsies, hydrocephalus and microcephaly, have been reported at later stages of pregnancy if the child is exposed.

Although other coumarin anticoagulants are available, in the vast majority of cases these have not been shown to have any clear benefits over warfarin. They may be used occasionally where a patient does not tolerate warfarin. The necessary duration of anticoagulation in venous thrombosis and pulmonary embolus is still uncertain. On the basis of the available evidence, therapy may be required for approximately 6 months after the first deep vein thrombosis or pulmonary embolus. It may be possible to reduce the duration of therapy in patients who have

Table 23.1 Recommended target INRs for different conditions and grade of recommendation

Indication	Target INR	Grade of recommendation
Pulmonary embolus	2.5	A
Proximal deep vein thrombosis	2.5	A
Calf vein thrombus	2.5	A
Recurrence of venous thromboembolism when no longer on warfarin therapy	2.5	A
Recurrence of venous thromboembolism while on warfarin therapy	3.5	C
Symptomatic inherited thrombophilia	2.5	A
Antiphospholipid syndrome	3.5	A
Non-rheumatic atrial fibrillation	2.5	A
Atrial fibrillation due to rheumatic heart disease, congenital heart disease, thyrotoxicosis	2.5	C
Cardioversion	2.5	B
Mural thrombus	2.5	B
Cardiomyopathy	2.5	C
Mechanical prosthetic heart valve (caged ball or caged disk), aortic or mitral[a]	3.5	B
Mechanical prosthetic heart valve (tilting disc or bileaflet), mitral[a]	3.0	B
Mechanical prosthetic heart valve (tilting disc), aortic[a]	3.0	B
Mechanical prosthetic heart valve (bileaflet), aortic[a]	2.0	B
Bioprosthetic valve	2.0 (if anticoagulated)	A
Ischaemic stroke without atrial fibrillation	Not indicated	C
Retinal vessel occlusion	Not indicated	C
Peripheral arterial thrombosis and grafts	Not indicated	A
Arterial grafts	2.5 (if anticoagulated)	
Coronary artery thrombosis	2.5 (if anticoagulated)	
Coronary artery graft	Not indicated	A
Coronary angioplasty and stents	Not indicated	A

INR, international normalised ratio; A, at least one randomised controlled trial (RCT); B, well-conducted clinical trials but no RCT; C, expert opinion but no studies.
[a]If the valve type is not known, a target INR of 3.0 is recommended for valves in the aortic position and 3.5 in the mitral position.

had a postoperative episode since it is likely that the risk factor has been reversed (unless immobility continues). In patients with a second episode, therapy may be required for even longer and in patients with more than two episodes, life-long treatment may be necessary to reduce the risk of recurrence (British Committee for Standards in Haematology, 1998).

Dabigatran. Dabigatran is an orally active inhibitor of both free and clot-bound thrombin (Wittkowsky, 2010). It has a rapid onset of action and does not require laboratory monitoring. Dabigatran etexilate is a pro-drug which is hydrolysed to active dabigatran in the liver. Since 80% of activated dabigatran is excreted unchanged through the kidneys, it

Table 23.2 Some clinically important drug interactions with warfarin

Interacting drug	Effect of interaction on anticoagulant effect	Probable mechanism(s)
Colestyramine Colestipol	Reduced anticoagulant effect	Impaired absorption and increased elimination of warfarin. N.B. Long-term treatment may cause impaired vitamin K absorption and enhance anticoagulant effect
Barbiturates Carbamazepine Griseofulvin Phenytoin (see also below) Primidone Rifampicin Rifabutin St John's wort	Reduced anticoagulant effect	Induction of warfarin metabolism
Amiodarone Azapropazone Chloramphenicol Cimetidine Ciprofloxacin Clarithromycin Dextropopoxyphene Erythromycin Fluconazole Fluvastatin Itraconazole Ketoconazole Mefenamic acid Metronidazole Miconazole Nalidixic acid Norfloxacin Ofloxacin Phenylbutazone Sulfinpyrazone Sulphonamides (e.g. in co-trimoxazole) Voriconazole Zafirlukast	Increased anticoagulant effect	Inhibition of warfarin metabolism
Anabolic steroids Bezafibrate Danazol Gemfibrozil Levothyroxine Phenytoin (see also above) Salicylates/aspirin (high dose) Stanozolol Tamoxifen Testosterone	Increased anticoagulant effect	Pharmacodynamic potentiation of anticoagulant effect
Cranberry juice	Increased anticoagulant effect	Mechanism unknown
NSAIDs (including aspirin at all doses) Clopidogrel	Increased risk of bleeding	Additive effects on coagulation and haemostasis
Oral contraceptives, oestrogens and progestogens	Reduced anticoagulant effect	Pharmacodynamic antagonism of anticoagulant effect
Vitamin K (e.g. in some enteral feeds)		

Table 23.3 Recommendations for management of bleeding and excessive anticoagulation in patients receiving warfarin

Cause	Recommendation
3.0<INR<6.0 (target INR 2.5) 4.0<INR<6.0 (target INR 3.5)	1. Reduce warfarin dose or stop 2. Restart warfarin when INR <5.0
6.0<INR<8.0, no bleeding or minor bleeding	1. Stop warfarin 2. Restart when INR <5.0
INR>8.0, no bleeding or minor bleeding	1. Stop warfarin 2. Restart warfarin when INR <5.0 3. If other risk factors for bleeding give 0.5–2.5 mg of vitamin K (oral)
Major bleeding	1. Stop warfarin 2. Give prothrombin complex concentrate 50 units/kg or FFP 15 mL/kg 3. Give 5 mg of vitamin (oral or i.v.)

INR, international normalised ratio.

should be avoided in patients with severe renal impairment (creatinine clearance < 30 mL/min) and the dose should be reduced in moderate renal impairment (creatinine clearance 30–50 mL/min). Dabigatran is a substrate for the transport protein p-glycoprotein (p-GP), which facilitates renal elimination of certain drugs. Amiodarone, an inhibitor of p-GP, reduces the clearance of dabigatran and so doses should be reduced in patients who are on concurrent treatment with amiodarone. In patients who are on strong p-GP inhibitors such as verapamil and clarithomycin, dabigatran should be used with caution and it should not be used together with quinidine. Drugs such as rifampicin and St John's Wort, which are potent p-GP inducers, may potentially reduce its efficacy. Dabigatran can be used for prophylaxis of VTE in adults after total hip replacement or total knee replacement surgery (National Institute for Health and Clinical Excellence, 2008). Haemorrhage is the major adverse effect.

Rivaroxaban. Rivaroxaban is an orally active inhibitor of both the 'free' and prothombinase complex-bound forms of activated factor X (Xa) (Wittkowsky, 2010). Two thirds of the dose is metabolised, principally by CYP450 enzymes and the remaining third is excreted unchanged in the urine. Like dabigatran, rivaroxaban also appears to be a p-GP substrate and it should be used with caution when prescribed concomitantly with p-GP inhibitors and potent p-GP inducers. It should also be used with caution in patients with creatinine clearance less than 30 mL/min (severe renal impairment) and is contraindicated in those with creatinine clearance less than 15 mL/min. Several CYP3A4 inhibitors and inducers have been shown to affect its metabolism. Some CYP3A4 inhibitors significantly increase the AUC of rivaroxaban, particularly ketoconazole and other azole-antimycotics such as itraconazole, voriconazole and posaconazole and also HIV protease inhibitors such as ritonavir. Therefore, the use of rivaroxaban is not recommended in patients receiving concomitant systemic treatment with these agents. The CYP3A4 inducer rifampicin (and possibly other inducers of this cytochrome) reduces the AUC for rivaroxaban. It is recommended as an option for prophylaxis of VTE in adults after hip or knee replacement surgery (National Institute for Health and Clinical Excellence, 2009). It also does not require laboratory monitoring. Haemorrhage is the major adverse effect.

Fibrinolytic drugs

Thrombolytic therapy is used in life-threatening acute massive pulmonary embolus. It has been used in deep vein thrombosis, particularly in those patients where a large amount of clot exists and venous valvular damage is likely. However, fibrinolytic drugs are potentially more dangerous than anticoagulant drugs, and evidence is not available in situations other than acute massive embolism to show a sustained benefit from their use.

Streptokinase. Streptokinase was the first agent available in this class. It was produced from streptococci and is a large protein that binds to and activates plasminogen, thus encouraging the breakdown of formed fibrin to fibrinogen degradation products. It also acts on the circulating fibrinogen to produce

a degree of systemic anticoagulation. Since it is a large protein molecule, it cannot be administered orally and has to be given by intravenous infusion. The half-life of removal from the body is 30 min. It is cleared chiefly by the reticuloendothelial system in the liver.

Its major adverse effect is to increase the risk of haemorrhage but it may also be antigenic and produce an anaphylactic reaction. It may also cause hypotension during infusion and in some patients, particularly those who have been administered the drug within the previous 12 months, a relative resistance to the drug may occur. Thrombolytic therapy is contraindicated in patients who have had major surgery or with active bleeding sites in the gastro-intestinal or genitourinary tract, those who have a history of stroke, renal or liver disease, and those with hypertension. It should also be avoided during pregnancy and the postpartum period.

Alteplase. Tissue plasminogen activator (rt-PA) or alteplase was developed using recombinant DNA technology. Although this agent is much more expensive than streptokinase, it can be used in those situations where streptokinase may be less effective because of development of antibodies, for example within 1 year of previous streptokinase use or where allergy to streptokinase has previously occurred. Because it produces a lesser degree of systemic anticoagulation (it is more active against plasminogen associated with the clot), immediate use of heparin subsequently is necessary to prevent recurrence of thrombosis. Alteplase is also used for acute ischaemic stroke, where its prompt use may improve outcome in carefully selected individuals (National Institute for Health and Clinical Excellence, 2007). At the time of writing, it is the only thrombolytic licensed for this indication (see arterial thromboembolism).

Reteplase and tenectaplase. Reteplase, and more recently tenecteplase, are also fibrin-specific agents and so heparin is required to prevent rebound thrombosis. They are indicated for the treatment of acute myocardial infarction. In this clinical situation, reteplase is administered as an intravenous bolus, followed by a second bolus 30 min later (double bolus), and tenecteplase is given as a single intravenous bolus. They, therefore, have the advantage of convenience of administration compared with alteplase, and are the preferred option in pre-hospital settings, particularly when administered by paramedics (National Institute for Health and Clinical Excellence, 2002a).

Urokinase. Urokinase, like alteplase and streptokinase, can be used for the treatment of deep vein thrombosis and PE. It is also licensed to restore patency in intravenous catheters and cannulas blocked by fibrin thrombi.

Patient care

The patient on oral anticoagulants should be given full information on what to do in case of problems and what circumstances and drugs to avoid. An anticoagulant card with previous INR values and doses should also be provided. The patient should be told of the colour code for the different strengths of warfarin tablet and advised to carry their treatment card at all times. The likely duration of anticoagulant therapy should be made clear to the patient to avoid unnecessary and potentially dangerous prolongations of treatment. Patients who have received a fibrinolytic agent should also carry a card identifying the drug given and the date of administration.

Arterial thromboembolism

Acute myocardial infarction is the commonest clinical presentation of acute arterial thrombosis. Stroke is commonly caused by atherothromboembolism from the great vessels or embolism arising from the heart (approximately 80% of strokes). These two conditions are discussed elsewhere. Peripheral arterial thrombosis or thromboembolism may also occur, most often in the lower limb. Antiplatelet drugs are often used for prophylaxis, but surgical embolectomy and/or fibrinolytic therapy may be needed for treatment of acute thrombotic or thromboembolic events to avoid consequent ischaemic damage.

Aetiology

Arterial thromboembolism is normally associated with vascular injury and hypercoagulability. Vascular injury is most often due to atheroma, itself aggravated by smoking, hypertension, hyperlipidaemia or diabetes mellitus. Although the exact mechanism is not clear, it is thought that platelet aggregation may be induced by the sheer stresses caused by stenosis of an atherosclerotic vessel. This thrombotic material may embolise to cause occlusion further downstream. Hypercoagulability is also a risk factor. It may be associated with increased plasma fibrinogen levels and an increase in circulating cellular components, for example polycythaemia or thrombocythaemia. As mentioned earlier, the thrombus formed in the artery contains a much larger proportion of platelets, possibly reflecting the fact that other blood components that are not as readily adherent may be dissipated by the higher flow rates in the arterial circulation. Oestrogens, by the mechanisms described earlier, are likely to increase the risk of arterial as well as venous thrombosis. Hyperlipidaemia may also increase the risk of hypercoagulability as well as enhancing thrombotic risk through its role in the progression of atheroma and vascular injury.

Treatment and prevention

Aspirin

Aspirin (acetylsalicylic acid) is a potent inhibitor of the enzyme cyclo-oxygenase, which catalyses the production of prostaglandins. It reduces the production of pro-aggregatory prostaglandin, thromboxane A_2 in the platelet, an effect that lasts for the life of the platelet.

Aspirin is well absorbed after oral administration. It is rapidly metabolised by esterases in the blood and liver (so that its half-life is only 15–20 min) to salicylic acid and other metabolites that are excreted in the urine. In the doses used

in prophylaxis against thromboembolism, aspirin is largely metabolised by the liver but in overdose, urinary excretion of salicylate becomes a limiting factor in drug elimination.

The major adverse effect of aspirin is gastro-intestinal irritation and bleeding. This problem is much more common with higher doses of aspirin (300 mg or more) that were once used in the prevention of arterial thromboembolism but are less common with the doses (e.g. 75 mg) now recommended. There is evidence that concomitant use of ulcer-healing drugs, particularly proton pump inhibitors, can reduce the risk of non-steroidal anti-inflammatory drug (NSAID)-induced peptic ulceration in patients susceptible to the problem, but haemorrhagic risk may not be significantly reduced. There is also little evidence that buffered or enteric-coated preparations of aspirin are safer in this respect. However, the vast majority of patients tolerate low-dose aspirin well, and it is normally given as a single oral dose of soluble aspirin. Aspirin may also, rarely, induce asthma, particularly in patients with co-existing reversible airway obstruction. Other patients have a form of aspirin hypersensitivity that may result in urticaria and/or angioedema. In this situation, there may be cross-reactivity with other NSAIDs.

Haemorrhagic stroke is a rare but a very serious complication of therapy with aspirin (and with other antiplatelet agents). Recent evidence examining risks and benefits of aspirin has resulted in the recommendation that while long-term use of aspirin, in a dose of 75 mg daily, is of benefit for all patients with established cardiovascular disease, use of aspirin in primary prevention, in those with or without diabetes, is of unproven overall benefit. It must not be given to children or young people under 16 years of age because of the risk of the rare but life-threatening possibility of Reye's Syndrome (which may cause liver and renal failure).

Clopidogrel

Clopidogrel is a pro-drug that is metabolised in part to an active thiol derivative. The latter inhibits platelet aggregation by rapidly and irreversibly inhibiting the binding of adenosine diphosphate (ADP) to its platelet receptor, thus preventing the ADP-mediated activation of the glycoprotein IIb/IIIa receptor for the life of the platelet. It is an orally active pro-drug and is given once daily for the reduction of atherosclerotic events in those with pre-existing atherosclerotic disease. In this respect, it may be a useful alternative to aspirin in aspirin-allergic subjects but haemorrhage occurs with the same frequency as aspirin, and thrombocytopenia (sometimes severe) may be commoner than with aspirin therapy. Activation to its active metabolite may be subject to a genetic polymorphism of CYP450 2C19 and may also be reduced by the proton pump inhibitor, omeprazole or esomeprazole; so use of alternative gastroprotective agents may need to be considered if required.

Clopidogrel is also licensed for combination use with low-dose aspirin in the management of acute coronary syndrome without ST-segment elevation, when it is given for up to 12 months after the initial event (National Institute for Health and Clinical Excellence, 2004, 2005). Most benefit is obtained in the first 3 months and there is no evidence of benefit of clopidogrel after 12 months in this indication. In combination with low-dose aspirin, clopidogrel is also licensed for acute myocardial infarction with ST-segment elevation. It is recommended for at least 4 weeks in this indication, but the optimum treatment duration has not been established. Finally clopdogrel is sometimes used (with aspirin) in stenting procedures and this sometimes results in long-term use.

Prasugrel

Prasugrel inhibits platelet activation and aggregation. Its active metabolite binds to the $P2Y_{12}$ class of ADP receptors on platelets. It is recommended for use in combination with aspirin as an option for the prevention of atherothrombotic events in patients with acute coronary syndromes undergoing PCI, only when immediate primary PCI is necessary for STEMI, *or* stent thrombosis occurred during treatment with clopidogrel, or the patient has diabetes mellitus (National Institute for Health and Clinical Excellence, 2009).

Dipyridamole

Dipyridamole is used by mouth as an adjunct to oral anticoagulation for prophylaxis of thromboembolism associated with prosthetic heart valves. Modified-release preparations are licensed (alone or preferably in combination with low-dose aspirin) for secondary prevention of ischaemic stroke and TIAs (see treatment of stroke). There is evidence that the combination of modified-release dipyridamole and low-dose aspirin may reduce the risk of recurrent stroke and other cardiovascular events compared to aspirin alone. It is a phosphodiesterase inhibitor and, thus, elevates concentrations of cyclic AMP. It may also block the uptake of adenosine by erythrocytes and other cells. Adverse effects include headache (to which tolerance may gradually develop) gastro-intestinal problems, flushing and hypotension.

Glycoprotein IIb/IIIa inhibitors

Glycoprotein IIb/IIIa inhibitors prevent platelet aggregation by blocking the binding of fibrinogen to receptors on platelets.

Abciximab. Abciximab is a monoclonal antibody which binds to coronary glycoprotein IIb/IIIa receptors and to other related sites. It is licensed as an adjunct to heparin and aspirin for the prevention of ischaemic complications in high-risk patients undergoing percutaneous transluminal coronary intervention. Abciximab should be used once only to avoid further risk of thrombocytopenia.

Eptifibatide and tirofiban. Eptifibatide and tirofiban also inhibit glycoprotein IIb/IIIa receptors; they are licensed for use with heparin and aspirin to prevent early myocardial infarction in patients with unstable angina or non-ST-segment elevation myocardial infarction (NSTEMI).

Abciximab, eptifibatide and tirofiban all have to be administered parenterally and should be used by specialist clinicians only (National Institute for Health and Clinical Excellence, 2002b).

Patient care

Aspirin is normally well tolerated at the doses used for stroke prevention. However, it should not be given to patients with a history of gastro-intestinal ulceration. Since it may induce bronchospasm in susceptible individuals, it should be used cautiously in such circumstances. It is best tolerated if taken once daily as soluble aspirin after food.

Case studies

Case 23.1

A 75-year-old patient receiving warfarin to prevent deep vein thrombosis and previously well controlled comes to the clinic with an INR of 12, despite taking the same dose of drug. There is no evidence of bleeding.

Question

What should be done?

Answer

Since the patient's INR is >8 (even if there is no bleeding), the national guidelines recommend that warfarin be stopped. The patient should then be given phytomenadione (vitamin K₁) 2.5–5 mg by mouth using the intravenous preparation orally [unlicensed use], or 0.5–1 mg by slow intravenous injection (if complete reversal required 5–10 mg by slow intravenous injection). The dose of phytomenadione should be repeated if the INR is still too high after 24 h. The warfarin can be restarted when the INR is <5.0. However, a single dose often helps the INR to return to close to the target level at 24 h without causing warfarin resistance subsequently. A search for clinical conditions or drugs which might cause warfarin sensitivity should also be made. Measurement of plasma warfarin concentration may help in difficult cases.

Case 23.2

A patient receiving heparin for 7 days for extensive VTE develops arterial thrombosis.

Question

What would you suspect in this situation and what should be done?

Answer

The rare but serious HIT may be responsible. The platelet count should be measured immediately and if HIT is strongly suspected or confirmed, the heparin should be discontinued immediately. An alternative anticoagulant should be started in full dosage whilst specific confirmatory tests are being performed unless there are significant contraindications. Danaparoid and lepirudin may be considered as alternative anticoagulants in these circumstances.

Case 23.3

A patient admitted to an acute hospital with suspected myocardial infarction says that he had a myocardial infarction 4 years ago and was treated with a drug to 'dissolve the clot in the coronary artery'. The chest pain started 4 h earlier and his electrocardiogram shows ST-segment elevation in the anterior leads.

Question

What relevance may his previous treatment and present history and findings have to his management on this occasion?

Answer

Thrombolytic drugs are indicated for any patient with acute myocardial infarction, provided the likely benefits outweigh the possible risks. Trials have shown that the benefit is greatest in those with ECG changes that include ST-segment elevation, especially in those with anterior infarction, and in patients with bundle branch block. The patient has received a thrombolytic, possibly streptokinase, in the past. He should be asked if he was given a card with the identity of the therapy to carry with him. If the prior treatment was with streptokinase or anistreplase (no longer available), prolonged persistence of antibodies to streptokinase may reduce the effectiveness of subsequent treatment. Therefore, streptokinase should not be used again beyond 4 days of first administration of streptokinase (or anistreplase) and urgent consideration should be given to the use of an alternative thrombolytic agent such as alteplase, reteplase and tenecteplase.

Case 23.4

A 64-year-old male patient is to be prescribed aspirin therapy following an acute myocardial infarction.

Question

What questions should you ask the patient before starting treatment with aspirin?

Answer

The patient should be asked if he has had aspirin before and, if so, whether he tolerated it. Caution is necessary in patients with a previous history of gastro-intestinal ulceration, with uncontrolled hypertension; active peptic ulceration is also a contraindication. Other contraindications include severe hepatic impairment and severe renal failure. It may induce bronchospasm or angioedema in susceptible individuals, for example in asthmatics, and caution should be exercised in these circumstances.

Case 23.5

A 56-year-old woman on warfarin therapy for atrial fibrillation with mitral stenosis appears to become resistant to warfarin after previously good control on 5 mg daily. Her INR does not rise above 1.4 even when her warfarin dose is increased to 20 mg daily.

....

Question

What can be done to find the cause of the resistance?

....

Answer

The patient should be asked about any new medications which might have been introduced recently, including over-the-counter and herbal preparations. Some proprietary medicines may contain vitamin K which could cause resistance by pharmacodynamic mechanisms. Other medicines, including the herbal medicine St John's wort, might induce warfarin metabolism and result in resistance as a result of a pharmacokinetic interaction (see Table 23.2). One other cause of apparent resistance to warfarin is poor adherence and this should, therefore, be considered. Supervised administration of the dose and/or measurement of plasma warfarin concentrations may be of value if the latter is suspected.

Dyslipidaemia 24

R. Walker and H. Williams

Key points

- Elevated concentrations of total cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C) increase the risk of cardiovascular disease (CVD), while high-density lipoprotein cholesterol (HDL-C) confers protection.
- Two-thirds of the UK adult population have a serum TC above 5 mmol/L. The average TC concentration is 5.6 mmol/L.
- Dyslipidaemia may develop secondary to disorders such as diabetes mellitus, hypothyroidism, chronic renal failure, nephrotic syndrome, obesity, high alcohol intake and some drugs.
- Androgens, β-blockers, ciclosporin, oral contraceptives, diuretics, glucocorticoids and vitamin A derivatives are examples of drugs that can have an adverse effect on the lipid profile.
- There are five main classes of lipid-lowering agents: statins, fibrates, resins, nicotinic acid derivatives and absorption blockers.
- Statins are generally the drugs of choice in the treatment of primary prevention and secondary prevention of CVD.
- The aim of treatment in primary prevention (>20% risk of cardiovascular disease over 10 years) is to reduce overall cardiovascular risk by treatment with simvastatin 40 mg/day or a suitable alternate generic agent. No target treatment levels for TC or LDL cholesterol are recommended in primary prevention.
- In secondary prevention, treatment should be started with simvastatin 40 mg/day or a suitable alternate generic agent. If serum TC remains above 4 mmol/L or LDL-C remains above 2 mmol/L, the dose of statin can be increased, but this may increase the likelihood of side effects.

Disorders of lipoprotein metabolism together with high fat diets, obesity and physical inactivity have all contributed to the current epidemic of atherosclerotic disease seen in developed countries. Disorders of lipoprotein metabolism that result in elevated serum concentrations of total cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C) increase the risk of an individual developing cardiovascular disease (CVD). In contrast, high-density lipoprotein cholesterol (HDL-C) confers protection against CVD, with the risk reducing as HDL-C increases. It is, therefore, clear that the term hyper-lipidaemia, which was formerly used to describe disorders of lipoprotein metabolism, is inappropriate. It is more appropriate to use the term dyslipidaemia, which encompasses both abnormally high levels of specific lipoproteins, for example,

LDL-C, and abnormally low levels of other lipoproteins, for example, HDL-C, as well as disorders in the composition of the various lipoprotein particles. It is particularly appropriate when considering the individual at risk of CVD with a normal or high TC and low HDL-C (total cholesterol:HDL-C ratio).

Epidemiology

Lipid and lipoprotein concentrations vary among different populations, with countries consuming a Western type of diet generally having higher TC and LDL-C levels than those where regular consumption of saturated fat is low.

The ideal serum lipid profile is unknown and varies between different populations, even across Europe, and also within a given population. For practical purposes the values presented in Table 24.1 represent the target levels for TC and LDL-C in the UK for adults receiving treatment for secondary prevention of CVD. For completeness, the values for triglycerides and HDL-C are also presented, although the benefit of achieving the stated targets is less clear.

Despite a 50% reduction in the death rate from CVD over the past 25 years, it remains the leading cause of premature

Table 24.1 Optimal serum lipid profile	
Total cholesterol (TC)[a]	<4.0 mmol/L
LDL cholesterol (LDL-C)[a]	<2.0 mmol/L
Triglycerides[b]	<1.7 mmol/L
HDL cholesterol (HDL-C)	>1.0 mmol/L in men
	>1.2 mmol/L in women

[a]Target levels in individuals with established atherosclerotic disease, coronary heart disease, stroke, peripheral arterial disease, diabetes mellitus or where there is a cardiovascular disease risk >20% over 10 years. In these identified individuals, the aim is to achieve the value stated in the table or a 25% reduction in total cholesterol and a 30% reduction in LDL-C from their baseline levels should these set target levels lower than those stated in the table.
[b]Fasting levels.

death and morbidity in the UK (British Heart Foundation, 2008), and the higher the levels of TC in an individual the greater the chance of developing CVD. At the individual level there appears no level below which a further reduction of TC or LDL-C is not associated with a lower risk of CVD. The death rate from CVD is threefold higher in males than females, but because women live longer and are at increased risk of stroke after the age of 75 years their lifetime risk of disease is greater (National Institute of Health and Clinical Excellence, 2008a).

TC levels tend to increase with age such that 80% of British men aged 45–64 years have a level that exceeds 5 mmol/L and the population average is 5.6 mmol/L. In contrast, in rural China and Japan, the average is 4 mmol/L.

Population-based approaches to vascular screening have the potential to provide significant health gain for society as most deaths from CVD occur in individuals who are not yet identified as at increased risk. Moreover, a small reduction in average population levels of TC and LDL-C can potentially prevent many deaths. In England, a scheme was introduced in 2009 for everyone between 40 and 74 years of age to receive a free health check to include measurement of TC and the TC:HDL-C ratio. The intention was that individuals would be given the necessary information about their health to make changes to lifestyle and avoid preventable disease.

Lipid transport and lipoprotein metabolism

The clinically important lipids in the blood (unesterified and esterified cholesterol and triglycerides) are not readily soluble in serum and are rendered miscible by incorporation into lipoproteins. There are six main classes of lipoproteins: chylomicrons, chylomicron remnants, very low-density lipoproteins (VLDL-C), intermediate-density lipoproteins (IDL-C), low-density lipoproteins (LDL-C) and high-density lipoproteins (HDL-C).

The protein components of lipoproteins are known as apoproteins (apo), of which apoproteins A-I, E, C and B are perhaps the most important. Apoprotein B exists in two forms: B-48, which is present in chylomicrons and associated with the transport of ingested lipids, and B-100, which is found in endogenously secreted VLDL-C and associated with the transport of lipids from the liver (Fig. 24.1).

When dietary cholesterol and triglycerides are absorbed from the intestine they are transported in the intestinal lymphatics as chylomicrons. These are the largest of the lipoprotein particles of which triglycerides normally constitute approximately 80% of the lipid core. The chylomicrons pass through blood capillaries in adipose tissue and skeletal muscle where the enzyme lipoprotein lipase is located, bound to the endothelium. Lipoprotein lipase is activated by apoprotein C-II on the surface of the chylomicron. The lipase catalyses the breakdown of the triglyceride in the chylomicron to free fatty acid and glycerol, which then enter adipose tissue and muscle. The cholesterol-rich chylomicron remnant is taken up by receptors on hepatocyte membranes, and in this way dietary cholesterol is delivered to the liver and cleared from the circulation.

VLDL-C is formed in the liver and transports triglycerides, which again make up approximately 80% of its lipid core, to the periphery. The triglyceride content of VLDL-C is removed by lipoprotein lipase in a similar manner to that described for chylomicrons above, and forms IDL-C particles. The core of IDL-C particles is roughly 50% triglyceride and 50% cholesterol esters, acquired from HDL-C under the influence of the enzyme lecithin-cholesterol acyltransferase (LCAT). Approximately 50% of the body's IDL particles are cleared from serum by the liver. The other 50% of IDL-C are further hydrolysed and modified to lose triglyceride and apoprotein E1 and become LDL-C particles. LDL-C is the major cholesterol-carrying particle in serum.

LDL-C provides cholesterol, an essential component of cell membranes, bile acid and a precursor of steroid hormones to those cells that require it. LDL-C is also the main lipoprotein involved in atherogenesis, although it only appears to take on this role after it has been modified by oxidation. For reasons that are not totally clear, the arterial endothelium becomes permeable to the lipoprotein. Monocytes migrate through the permeable endothelium and engulf the lipoprotein, resulting in the formation of lipid-laden macrophages that have a key role in the subsequent development of atherosclerosis. The aim of treatment in dyslipidaemia is normally to reduce concentrations of LDL-C (and consequently atherogenesis) and thus reduce TC at the same time.

While VLDL-C and LDL-C are considered the 'bad' lipoproteins, HDL-C is often considered to be the 'good' anti-atherogenic lipoprotein. In general, about 65% of TC is carried in LDL-C and about 25% in HDL.

High-density lipoprotein

HDL-C is formed from the unesterified cholesterol and phospholipid removed from peripheral tissues and the surface of triglyceride-rich proteins. The major structural protein is apoA-I. HDL-C mediates the return of lipoprotein and cholesterol from peripheral tissues to the liver for excretion in a process known as reverse cholesterol transport.

Reverse cholesterol transport pathway

The reverse cholesterol transport pathway (Fig. 24.2) controls the formation, conversion, transformation and degradation of HDL-C and is the target site for a number of new, novel drugs and has recently been described (Chapman et al., 2010).

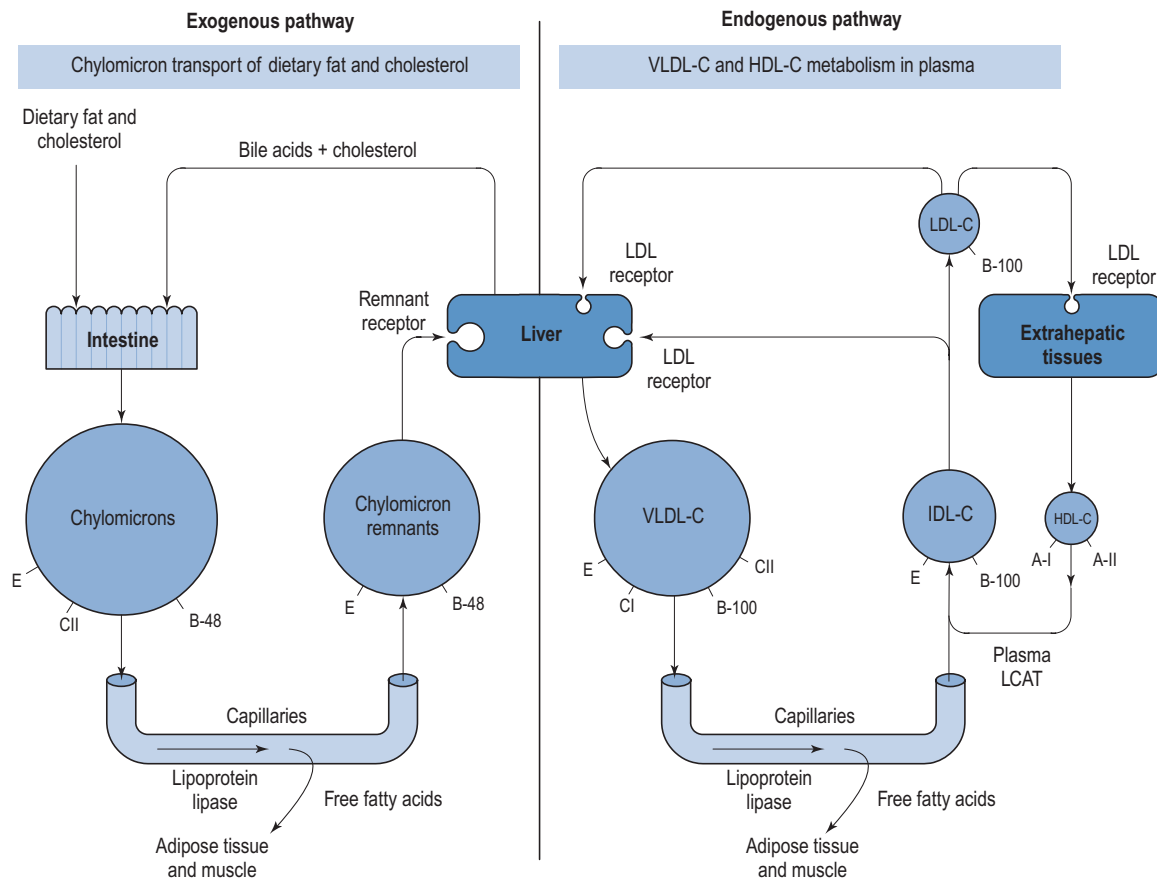
The reverse cholesterol transport system involves lipoprotein-mediated transport of cholesterol from peripheral, extra-hepatic tissues and arterial tissue (potentially including cholesterol-loaded foam cell macrophages of the atherosclerotic plaque) to the liver for excretion, either in the form of biliary cholesterol or bile acids. The ATP-binding cassette transporters, ABCA1 and ABCG1, and the scavenger receptor B1, are all implicated in cellular cholesterol efflux mechanisms to specific apoA-1/HDL acceptors. The progressive action of lecithin:cholesterol


Fig. 24.1 Schematic representation of lipoprotein metabolism in plasma. Dietary cholesterol and fat are transported in the exogenous pathway. Cholesterol produced in the liver is transported in the endogenous pathway.

acyl transferase on free cholesterol in lipid-poor, apolipoprotein A-I-containing nascent high-density lipoproteins, including pre-β-HDL, gives rise to the formation of a spectrum of mature, spherical high-density lipoproteins with a neutral lipid core of cholesteryl ester and triglyceride. Mature high-density lipoproteins consist of two major subclasses, large cholesteryl ester-rich HDL_2 and small cholesteryl ester-poor, protein-rich HDL_3 particles; the latter represent the intravascular precursors of HDL_2. The reverse cholesterol transport system involves two key pathways: (a) the direct pathway (blue lines), in which the cholesteryl ester content (and potentially some free cholesterol) of mature high-density lipoprotein particles is taken up primarily by a selective uptake process involving the hepatic scavenger receptor B1 and (b) an indirect pathway (dotted blue lines) in which cholesteryl ester originating in HDL is deviated to potentially atherogenic VLDL, IDL and LDL particles by cholesteryl ester transfer protein. Both the cholesteryl ester and free cholesterol content of these particles are taken up by the liver, predominantly via the LDL receptor which binds their apoB100 component. This latter pathway may represent up to 70% of cholesteryl ester delivered to the liver per day. The hepatic LDL receptor is also responsible for the direct uptake of high-density lipoprotein particles containing apoE; apoE may be present as a component of both HDL_2 and HDL_3 particles, and may be derived either by transfer from triglyceride-rich lipoproteins, or from tissue sources (principally liver and monocyte-mac-

rophages). Whereas HDL uptake by the LDL receptor results primarily in lysosomal-mediated degradation of both lipids and apolipoproteins, interaction of HDL with scavenger receptor B1 regenerates lipid-poor apoA-I and cholesterol-depleted HDL, both of which may re-enter the HDL/apoA-I cycle.

From the above it is evident that HDL-C plays a major role in maintaining cholesterol homeostasis in the body. As a consequence it is considered desirable to maintain both levels of the protective HDL-C and the integrity of the reverse cholesterol transport pathway. Low levels of HDL-C are found in 17% of men and 5% of women and may be a risk factor for atherogenesis that is comparable in importance to elevated levels of LDL-C. Drugs that reduce HDL-C levels are considered to have an undesirable effect on lipid metabolism and increase the risk of developing CVD.

Triglycerides

The role of hypertriglyceridaemia as an independent risk factor for coronary heart disease (CHD) is unclear because triglyceride levels are confounded by an association with low HDL-C, hypertension, diabetes and obesity, and a synergistic effect with LDL-C and/or low HDL-C. An isolated elevation of triglyceride may be the consequence of a primary disorder of lipid metabolism, it may be secondary to the use of medicines or it may be a component of the metabolic syndrome or type 2

diabetes mellitus. Many individuals have a mixed dyslipidaemia that includes elevated levels of triglycerides and LDL-C, but reduction of LDL-C normally remains the primary focus of treatment. A recent analysis, in over 73,000 individuals, of a genetic variant which regulates triglyceride concentrations has demonstrated a causal association between triglycerides and CHD (Triglyceride Coronary Disease Genetics Consortium and Emerging Risk Factors Collaboration, 2010).

Aetiology

Primary dyslipidaemia

Up to 60% of the variability in cholesterol fasting lipids may be genetically determined, although expression is often influenced by interaction with environmental factors. The common familial (genetic) disorders can be classified as:

- the primary hypercholesterolaemias such as familial hypercholesterolaemias in which LDL-C is raised
- the primary mixed (combined) hyperlipidaemias in which both LDL-C and triglycerides are raised

- the primary hypertriglyceridaemias such as type III hyperlipoproteinaemia, familial lipoprotein lipase deficiency and familial apoC-II deficiency.

Familial hypercholesterolaemia

Heterozygous familial hypercholesterolaemia (often referred to as FH) is an inherited metabolic disease that affects approximately 1 in 500 of the population. In the UK, this represents about 110,000 individuals. Familial hypercholesterolaemia is caused by a range of mutations, which vary from family to family, in genes for the pathway that clear LDL-C from the blood. The most common mutation affects the LDL receptor gene. Given the key role of LDL receptors in the catabolism of LDL-C, patients with FH may have serum levels of LDL-C two to three times higher than the general population. It is important to identify and treat these individuals from birth, otherwise they will be exposed to high concentrations of LDL-C and will suffer the consequences. Familial hypercholesterolaemia is transmitted as a dominant gene, with siblings and children of a parent with FH having a 50% risk of inheriting it. It is important to suspect FH in people that present with TC >7.5 mmol/L, particularly where there is

evidence of premature CV disease within the family. Guidance on diagnosis, identifying affected relatives and management are available but it is important to seek specialist advice for this group of high-risk patients (National Institute of Health and Clinical Excellence, 2008b).

In patients with heterozygous FH, CVD presents about 20 years earlier than in the general population, with some individuals, particularly men, dying from atherosclerotic heart disease often before the age of 40 years. The adult heterozygote typically exhibits the signs of cholesterol deposition such as corneal arcus (crescentic deposition of lipids in the cornea), tendon xanthoma (yellow papules or nodules of lipids deposited in tendons) and xanthelasma (yellow plaques or nodules of lipids deposited on eyelids) in their third decade.

In contrast to the heterozygous form, homozygous FH is extremely rare (1 per million) and associated with an absence of LDL receptors and almost absolute inability to clear LDL-C. In these individuals, involvement of the aorta is evident by puberty and usually accompanied by cutaneous and tendon xanthomas. Myocardial infarction has been reported in homozygous children as early as 1.5–3 years of age. Up to the 1980s, sudden death from acute coronary insufficiency before the age of 20 years was normal.

Familial combined hyperlipidaemia

Familial combined hyperlipidaemia has an incidence of 1 in 200 and is associated with excessive synthesis of VLDL-C. In addition to increases in triglyceride and LDL-C levels, patients also typically have raised levels of apoB and elevated levels of small, dense LDL particles. It is associated with an increased risk of atherosclerosis and occurs in approximately 15% of patients who present with CHD before the age of 60 years.

Familial type III hyperlipoproteinaemia

Familial type III hyperlipoproteinaemia has an incidence of 1 in 5000. It is characterised by the accumulation of chylomicron and VLDL remnants that fail to get cleared at a normal rate by hepatic receptors due to the presence of less active polymorphic forms of apoE. Triglycerides and TC are both elevated and accompanied by corneal arcus, xanthelasma, tuberoeruptive xanthomas (groups of flat or yellowish raised nodules on the skin over joints, especially the elbows and knees) and palmar striae (yellow raised streaks across the palms of the hand). The disorder predisposes to premature atherosclerosis.

Familial lipoprotein lipase deficiency

Familial lipoprotein lipase deficiency is characterised by marked hypertriglyceridaemia and chylomicronaemia, and usually presents in childhood. It has an incidence of 1 per million and is due to a deficiency of the extrahepatic enzyme lipoprotein lipase, which results in a failure of lipolysis and the accumulation of chylomicrons in plasma. The affected patient presents with recurrent episodes of abdominal pain, eruptive xanthomas, lipaemia retinalis (retinal deposition of lipid) and enlarged spleen. This disorder is not associated with an increased susceptibility to atherosclerosis; the major complication is acute pancreatitis.

Familial apolipoprotein C-II deficiency

In the heterozygous state, familial apoC-II deficiency is associated with reduced levels of apoC-II, the activator of lipoprotein lipase. Typically, levels of apoC-II are 50–80% of normal. This level of activity can maintain normal lipid levels. In the rare homozygous state, there is an absence of apolipoprotein C-II and despite normal levels of lipoprotein lipase, it cannot be activated. Consequently, homozygotes have triglyceride levels from 15 to above 100 mmol/L (normal range <1.7 mmol/L) and may develop acute pancreatitis. Premature atherosclerosis is unusual but has been described.

Lipoprotein(a)

There are many other familial disorders of lipid metabolism in addition to those mentioned above but most are very rare. However, a raised level of lipoprotein(a), otherwise known as Lp(a), appears to be a genetically inherited determinant of CVD. Lp(a) is a low-density lipoprotein-like particle synthesised by the liver and first described more than 40 years ago. It is found in the serum of virtually everyone in a wide concentration range (0.01–2 g/L) with up to 70% of the variation in concentration being genetically determined. The concentration of Lp(a) is not normally distributed and the contribution of inheritance to circulating Lp(a) levels is more pronounced than for any other lipoprotein or apoprotein. A parental history of early-onset CVD is associated with raised concentrations of Lp(a), and these appear to play a role in both atherogenesis and thrombosis. An important component of Lp(a) is apo(a), which is structurally and functionally similar to plasminogen and may competitively bind to fibrin and impair fibrinolysis.

Concentrations of Lp(a) above 0.3 g/L occur in about 20% of caucasians and increase the risk of coronary atherosclerosis and stroke. Under a wide range of circumstances, there are continuous, independent, and modest associations of Lp(a) concentration with the risk of CHD and stroke (Emerging Risk Factors Collaboration, 2009).

Secondary dyslipidaemia

Dyslipidaemias that occur secondary to a number of disorders (Box 24.1), dietary indiscretion or as a side effect of drug therapy (Table 24.2) account for up to 40% of all dyslipidaemias. Fortunately, the lipid abnormalities in secondary dyslipidaemia can often be corrected if the underlying disorder is treated, effective dietary advice implemented or the offending drug withdrawn.

On occasion, a disorder may be associated with dyslipidaemia but not the cause of it. For example, hyperuricaemia (gout) and hypertriglyceridaemia co-exist in approximately 50% of men. In this particular example, neither is the cause

Box 24.1 Examples of disorders known to adversely affect the lipid profile

Anorexia nervosa
Bulimia
Type 1 diabetes
Type 2 diabetes
Hypothyroidism
Pregnancy
Inappropriate diet
Alcohol abuse
Chronic renal failure
Nephrotic syndrome
Renal transplantation
Cardiac transplantation
Hepatocellular disease
Cholestasis
Myeloma

Table 24.2 Typical effects of selected drugs on lipoprotein levels

Drug	VLDL-C	LDL-C	HDL-C
Alcohol	↑	0	↑
Androgens, testosterone	↑	↑	↓
ACE-inhibitors	0	0	0
β-Blockers	↑	0	↓
Calcium channel blockers	0	0	0
Ciclosporin	↑	↑	↑
Oestrogens, oestradiol	↑	↓	↓
Glucocorticoids	↑	0	↑
Isotretinoin	↑	0	↓
Progestins	↓	↑	↓
Protease inhibitors	↑	0	0
Sertraline	↑	↑	0
Tacrolimus	↑	↑	↑
Thiazide diuretics	↑	↑	↓
Valproate	↑	0	↓

Effect seen may vary depending on dose, duration of exposure and drugs within same class.
↓, reduction; ↑, increase; 0, no change.

of the other and treatment of one does not resolve the other. There are, however, two notable exceptions to the rule with this example: nicotinic acid and fenofibrate. Both drugs reduce triglyceride levels but nicotinic acid increases urate levels while fenofibrate reduces them by an independent uricosuric effect.

Some of the more common disorders that cause secondary dyslipidaemias include the following.

Diabetes mellitus

Premature atherosclerotic disease is the main cause of reduced life expectancy in patients with diabetes. The atherosclerotic disease is often widespread and complications such as plaque rupture and thrombotic occlusion occur more often and at a younger age. The prevalence of CHD is up to four times higher among diabetic patients with more than 80% likely to die from a cardiovascular event. LDL levels are a stronger predictor of CV risk in diabetic patients than blood glucose control or blood pressure.

Type 1 diabetes. In patients with type 1 diabetes, HDL-C may appear high but for reasons which are unclear, it does not impart the same degree of protection against CVD as in those without diabetes. It is, therefore, not appropriate to use cardio-vascular risk prediction charts that utilise the TC:HDL-C ratio in patients with type 1 diabetes. Patients with type 1 diabetes have a two- to three-fold increased risk of developing CVD.

Type 2 diabetes. Patients with type 2 diabetes typically have increased triglycerides and decreased HDL-C. Levels of TC may be similar to those found in non-diabetic individuals but the patient with type 2 diabetes often has increased levels of highly atherogenic small dense LDL particles.

Individuals with type 2 diabetes and aged over 40 years, but without CVD, are often considered to have the same cardio-vascular risk as patients without diabetes who have survived a myocardial infarction. This assumption is generally appro-priate but influenced by patient age, duration of diabetes and gender and holds better for women than men. This probably occurs because the impact of type 2 diabetes is more marked in women than men. In some guidelines, the criteria for at risk is age above 40 years but with one other risk factor pres-ent, for example, hypertension, obesity, smoker, etc.

National Institute of Health and Clinical Excellence (2008a) consider an individual with type 2 diabetes to be at high premature cardiovascular risk for their age unless he or she:

- is not overweight
- is normotensive (<140/80 mmHg in the absence of antihypertensive therapy)
- does not have microalbuminuria
- does not smoke
- does not have a high-risk lipid profile
- has no history of CVD and
- has no family history of CVD.

Where the individual is found to be at risk the patient is typ-ically started on 40 mg simvastatin (or equivalent generic statin). Current guidance indicates the dose can be titrated up to simvastatin 80 mg a day if lipid levels are not reduced to less than 4 mmol/L for TC and less than 2 mmol/L for LDL-C on 40 mg simvastatin. In those who do not reach target with 80 mg simvastatin, 80 mg atorvastatin may be tried. However, with both drugs at the higher dose there is increasing concern about their side effect profile and consequently use is limited at these doses.

Individuals aged 18–39 with type 2 diabetes may also be at high risk and in need of treatment with a statin. Again at-risk individuals typically receive 40 mg simvastatin, or equivalent alternate statin, a day titrated up to 80 mg a day if levels for TC of less than 4 mmol/L and less than 2 mmol/L for LDL-C are not achieved. Again there are emerging concerns about use of these higher doses.

Hypothyroidism

Abnormalities of serum lipid and lipoprotein levels are common in patients with untreated hypothyroidism. Hypothyroidism may elevate LDL-C because of reduced LDL receptor activity and it frequently causes hypertriglyceridaemia and an associated reduction in HDL-C as a result of reduced lipoprotein lipase activity. Remnants of chylomicrons and VLDL-C may also accumulate. However, once adequate thyroid replacement has been instituted the dyslipidaemia should resolve.

Chronic renal failure

Dyslipidaemia is frequently seen in patients with renal failure in the predialysis phase, during haemodialysis or when undergoing chronic ambulatory peritoneal dialysis. The hypertriglyceridaemia that most commonly occurs is associated with reduced lipoprotein lipase activity and often persists despite starting chronic maintenance renal dialysis.

Nephrotic syndrome

In patients with the nephrotic syndrome, dyslipidaemia appears to be caused by an increased production of apoB-100 and associated VLDL-C along with increased hepatic synthesis of LDL-C and a reduction in HDL-C. The necessary use of glucocorticoids in patients with the nephrotic syndrome may exacerbate underlying lipoprotein abnormality.

Obesity

Chronic, excessive intake of calories leads to increased concentrations of triglycerides and reduced HDL-C. Obesity *per se* can exacerbate any underlying primary dyslipidaemia. Individuals with central obesity appear to be at particular risk of what has become known as the metabolic or DROP (*d*yslipidaemia, insulin *r*esistance, *o*besity and high blood *p*ressure) syndrome which represents a cluster of risk factors. Obesity and sedentary lifestyle coupled with inappropriate diet and genetic factors interact to produce the syndrome (Kolovou et al., 2005).

Alcohol

In the heavy drinker, the high calorie content of beer and wine may be a cause of obesity with its associated adverse effect on the lipid profile. In addition, alcohol increases hepatic triglyceride synthesis, which in turn produces hypertriglyceridaemia.

Light to moderate drinkers (1–3 units/day) have a lower incidence of CVD and associated mortality than those who do not drink. This protective effect is probably due to an increase in HDL-C, and appears independent of the type of alcohol. Men should be advised to limit their alcohol intake to 3–4 units a day, and not exceed 21 units a week. For women, the equivalent recommendation is 2–3 units a day with a maximum intake of 14 units a week. Everyone should be advised not to binge drink and have one or two alcohol free days a week.

Drugs

A number of drugs can adversely affect serum lipid and lipoprotein concentrations (see Table 24.2).

Antihypertensive agents. Hypertension is a major risk factor for atherosclerosis, and the beneficial effects of lowering blood pressure are well recognised. It is, however, a concern that, although treatment of patients with some antihypertensives has reduced the incidence of cerebrovascular accidents and renal failure, there has been no major impact in reducing the incidence of CHD. It has been suggested that some of these antihypertensive agents have an adverse effect on lipids and lipoproteins that override any beneficial reduction of blood pressure.

Diuretics. Thiazide and loop diuretics increase VLDL-C and LDL-C by mechanisms that are not completely understood. Whether these adverse effects are dose dependent is also unclear. Use of a thiazide for less than 1 year has been reported to increase TC by up to 7% with no change in HDL-C. However, there is evidence that the short-term changes in lipids do not occur with the low doses in current use. Studies of 3–5 years' duration have found no effect on TC.

ß-Blockers. The effects of β-blockers on lipoprotein metabolism are reflected in an increase in serum triglyceride concentrations, a decrease in HDL-C, but with no discernible effect on LDL-C. β-Blockers with intrinsic sympathomimetic activity appear to have little or no effect on VLDL-C or HDL-C. Pindolol has intrinsic sympathomimetic activity but is rarely used as an antihypertensive agent since it may exacerbate angina. Alternatively, the combined α- and β-blocking effect of labetalol may be of use since it would appear to have a negligible effect on the lipid profile.

Overall, the need to use a diuretic or a β-blocker must be balanced against patient considerations. A patient in heart failure should receive a diuretic if indicated regardless of the lipid profile. Likewise, the patient with heart failure may also benefit from a β-blocker such as bisoprolol or carvedilol. Patients who have had a myocardial infarction should be considered for the protective effect of a β-blocker and again the benefits of use will normally override any adverse effects on the lipid profile.

If an antihypertensive agent is required, that is, without adverse effects on lipoproteins, many studies would suggest that angiotensin converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, calcium channel blockers or α-adrenoceptor blockers could be used.

Oral contraceptives. Oral contraceptives containing an oestrogen and a progestogen provide the most effective contraceptive preparations for general use and have been well studied with respect to their harmful effects.

Oestrogens and progestogens both possess mineralocorticoid and glucocorticoid properties that predispose to hypertension and diabetes mellitus, respectively. However, the effects of the two hormones on lipoproteins are different. Oestrogens cause a slight increase in hepatic production of VLDL-C and HDL-C, and reduce serum LDL-C levels. In contrast, progestogens increase LDL-C and reduce serum HDL-C and VLDL-C.

The specific effect of the oestrogen or progestogen varies with the actual dose and chemical entity used. Ethinyloestradiol at a dose of 30–35 μcg or less would appear to create few problems with lipid metabolism, while norethisterone is one of the more favourable progestogens even though it may cause a pronounced decrease in HDL-C.

Corticosteroids. The effect of glucocorticoid administration on lipid levels has been studied in patients treated with steroids for asthma, rheumatoid arthritis and connective tissue disorders. Administration of a glucocorticoid such as prednisolone has been shown to increase TC and triglycerides by elevating LDL-C and, less consistently, VLDL-C. The changes are generally more pronounced in women. Alternate-day therapy with glucocorticoids has been suggested to reduce the adverse effect on lipoprotein levels in some patients.

Ciclosporin. Ciclosporin is primarily used to prevent tissue rejection in recipients of renal, hepatic and cardiac transplants. Its use has been associated with increased LDL-C levels, hypertension and glucose intolerance. These adverse effects are often exacerbated by the concurrent administration of glucocorticoids. The combined use of ciclosporin and glucocorticoid contributes to the adverse lipid profile seen in transplant patients. Unfortunately, the administration of a statin to patients treated with ciclosporin increases the incidence of myositis, rhabdomyolysis (dissolution of muscle associated with excretion of myoglobin in the urine) and renal failure. Use of a statin is, therefore, contraindicated in patients receiving ciclosporin.

Case reports of similar interactions between statins and other drugs used to prevent tissue rejection, including tacrolimus and sirolimus, have also been reported.

Hepatic microsomal enzyme inducers. Drugs such as carbamazepine, phenytoin, phenobarbital, rifampicin and griseofulvin increase hepatic microsomal enzyme activity and can also increase serum HDL-C. The administration of these drugs may also give rise to a slight increase in LDL-C and VLDL-C. The overall effect is one of a favourable increase in the TC:HDL-C ratio. It is interesting to note that patients treated for epilepsy have been reported to have a decreased incidence of CVD.

Risk Assessment

Primary prevention

In patients with no evidence of CHD or other major atherosclerotic disease, there are a number of CVD risk prediction charts, including those produced by the Joint British Societies

(JBS2) (British Hypertension Society, 2009) for males (Fig. 24.3) and females (Fig. 24.4). JBS2 recommends that all adults from the age of 40 years, with no history of CVD or diabetes, and not receiving treatment for raised blood pressure or dyslipidaemia, should receive opportunistic screening every 5 years in primary care. The cardiovascular risk calculated using the JBS2 charts is based on the number of cardiovascular events expected over the next 10 years in 100 women or men with the same risk factors as the individual being assessed. Those with a cardiovascular risk >20% over 10 years are deemed to require treatment according to current national and international guidelines, although individuals with a risk as low as 8% over 10 years will gain some benefit, this will be small.

Risk assessment is not required when the individual is 75 years of age or older, or they have pre-existing CVD. These individuals are already assumed to have a 10-year risk of at least 20%.

When using the JBS2 risk prediction charts a number of factors need to be taken into account at screening and include:

- *Age:* in individuals under 40 years of age the charts overestimate risk; over the age of 70 years risk is underestimated by the charts and most have a 10-year risk >20%.
- *Gender:* there are separate charts for men and women.
- *Ethnicity:* the risk prediction charts have only been validated in white caucasians and underestimate risk in individuals from the Indian subcontinent (India, Pakistan, Bangladesh and Sri Lanka) by a factor of 1.5.
- *Smoking history:* individuals who have stopped smoking within 5 years of assessment should be considered as current smokers.
- *Family history:* risk increases by a factor of 1.5 when CHD has occurred in a first-degree relative (parent, offspring, sibling) male <55 years or female <65 years, when a number of family members have developed CHD risk increases by a factor of 2 (Box 24.2).
- *Body mass index* (*BMI*) *and waist circumference:* the charts do not adjust for either BMI or waist circumference; these factors need to be taken into account in the clinical decision-making process.
- *Non-fasting blood glucose:* if non-fasting glucose >6.1 mmol/L, the individual should be assessed for impaired glucose regulation or diabetes.

Individuals with type 2 diabetes aged over 40 years and with an additional cardiovascular risk factor are considered to be at greater than 20% risk over 10 years and eligible for treatment. In those who are 40 years of age or older but without any additional risk factor, a specific risk engine is available (http://www.dtu.ox.ac.uk/riskengine/) based on data from the United Kingdom Prospective Diabetes Study.

Framingham

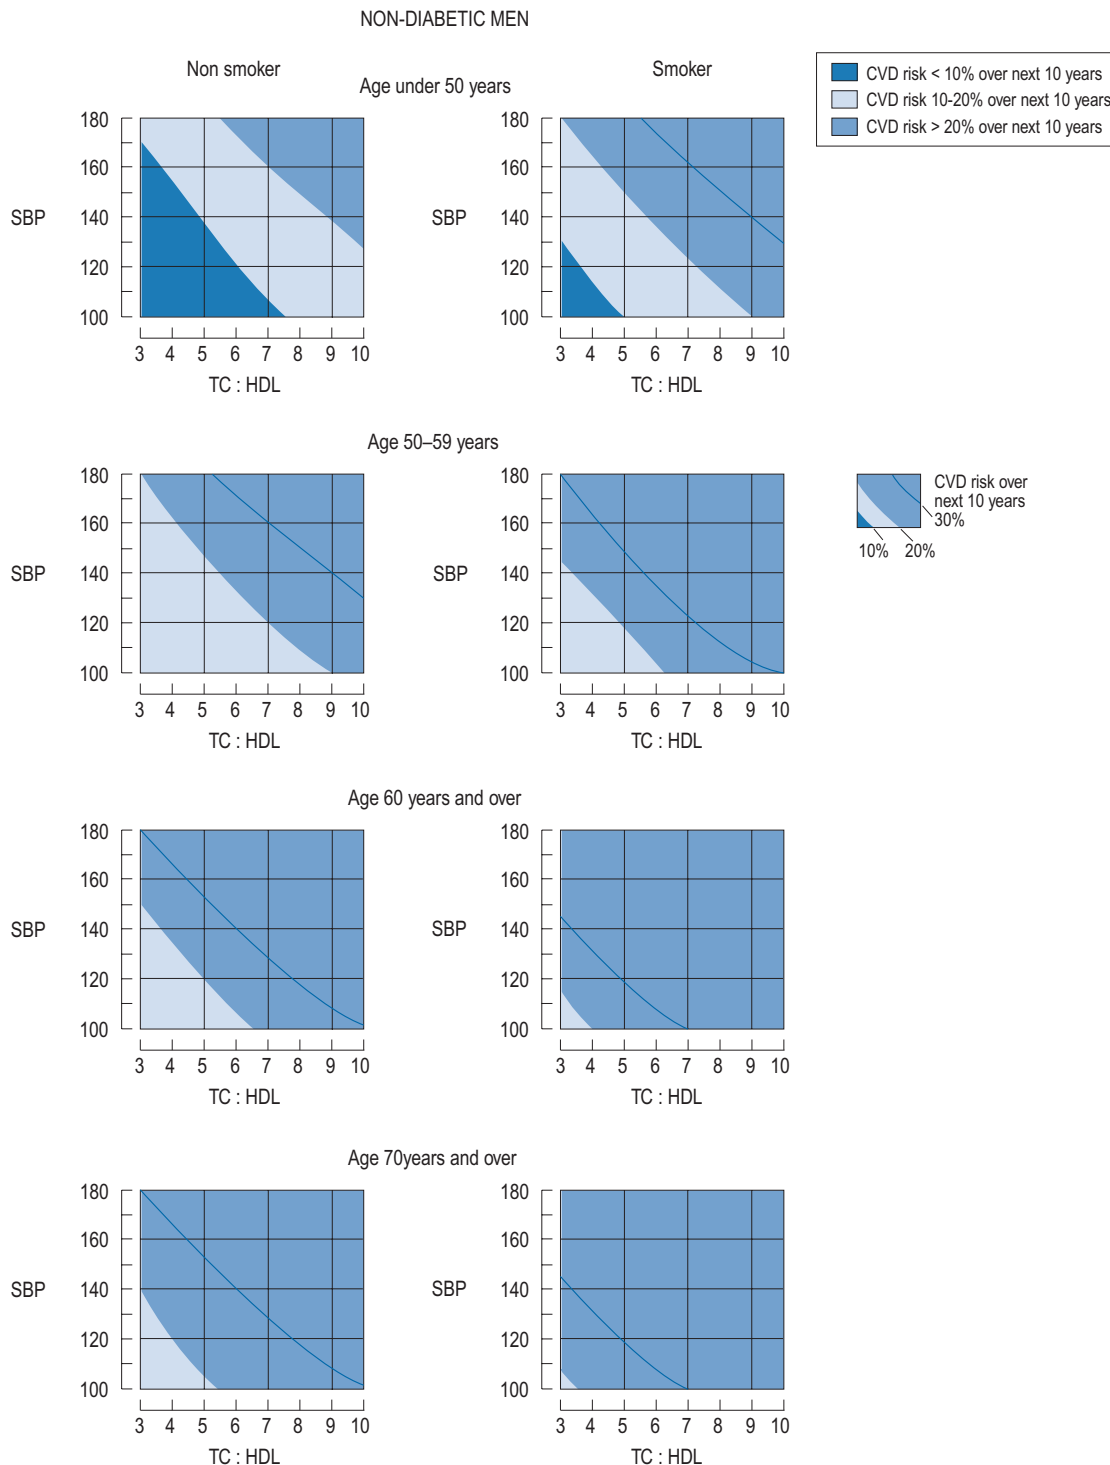
Up to 2008, risk charts and calculators based on Framingham data were the most widely used and researched approach for calculating cardiovascular risk, and are the data on which the risk


Fig. 24.3 Joint British Societies' cardiovascular disease risk prediction chart for non-diabetic men 2009 (reproduced with kind permission of University of Manchester). SBP, systolic blood pressure mmHg; TC:HDL, serum total cholesterol to HDL cholesterol ratio.

charts discussed above are based. The Framingham data derive from a North American population studied in the 1960s to 1980s. The data generally overestimate risk in the UK population but underestimate risk, as discussed, in those with a family history of premature CVD, South Asian men, people with diabetes and those from a deprived socioeconomic background.

Assign

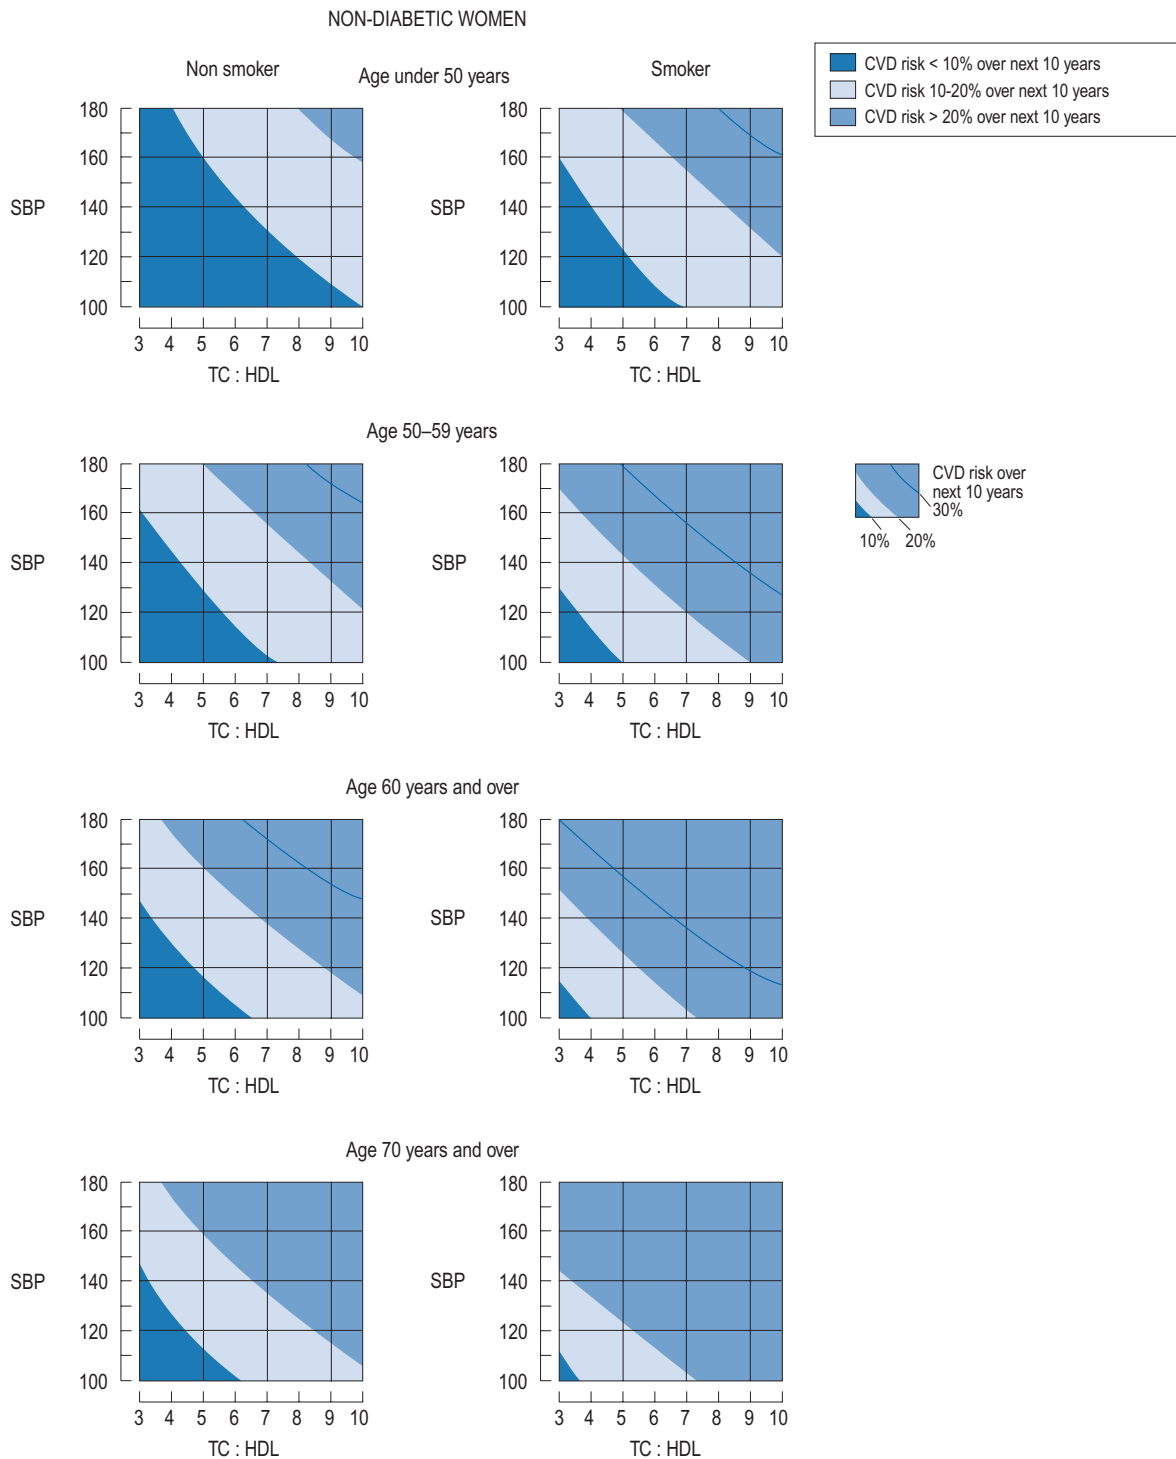
This is a risk calculator based on data from a Scottish population and includes many of the variables utilised in the Framingham-based model. It also takes into account social status, determined by postcode of residence in Scotland, and


Fig. 24.4 Joint British Societies' cardiovascular disease risk prediction chart for non-diabetic women 2009 (reproduced with kind permission of University of Manchester). SBP, systolic blood pressure mmHg; TC:HDL, serum total cholesterol to HDL cholesterol ratio.

family history of CVD (Woodward et al., 2007). The calculator can be found at: http://www.assign-score.com.

QRISK2

This is a relatively new CVD risk calculator, based on a database of anonymised UK primary care patients established in 2003. It contains over 10 million sets of encrypted patient records. A cohort of 1.28 million patients without evidence of diabetes mellitus or CVD was identified, and followed up for more than 5 years looking for the first development of CVD as an endpoint.

The current version of the calculator (QRISK2) uses the following parameters with any missing values calculated by a complex averaging procedure:

| **Box 24.2** | Criteria that indicate familial hypercholesterolaemia |

Family history of dyslipidaemia or cardiovascular disease:
- in first-degree female relative less than 65 years old
- in first-degree male relative less than 55 years old

Xanthelasma or corneal arcus under the age of 45

[a]Tendon xanthomata + TC >7.5 mmol/L at any age
[a]Tendon xanthomata + LDL-C >4.9 mmol/L

[a]Tendon xanthomata may not be readily apparent in younger people

- Patient age (35–74)
- Patient gender
- Current smoker (yes/no)
- Family history of heart disease aged <60 (yes/no)
- Existing treatment with blood pressure agent (yes/no)
- Postcode (postcode is linked to Townsend score measure of deprivation)
- BMI (height and weight)
- Systolic blood pressure (use current not pre-treatment value)
- Total and HDL cholesterol
- Self-assigned ethnicity (not nationality)
- Rheumatoid arthritis
- Chronic kidney disease
- Atrial fibrillation.

The QRISK2 calculator is available at http://www.qrisk.org/

The Department of Health and NICE endorse the use of either Framingham-based risk prediction tools or QRISK2.

Secondary prevention

Patients with CVD and levels of TC >4 mmol/L and LDL-C >2 mmol/L are the ones most likely to benefit from treatment with lipid-lowering agents. Typical of individuals who fall into this category are patients with a history of angina, myocardial infarction, acute coronary syndrome, coronary artery bypass grafting, coronary angioplasty or cardiac transplantation as well as patients with evidence of atherosclerotic disease in other vascular beds such as patients post-stroke or TIA, and those with peripheral arterial disease.

As in the situation with primary prevention outlined above, if an individual is to receive a lipid-lowering agent as part of a secondary prevention strategy, the possibility of a familial dyslipidaemia and the need to assess other family members must not be overlooked (National Institute of Health and Clinical Excellence, 2008b).

Treatment

Lipid profile

When a decision has been made to determine an individual's lipid profile, a random serum TC and HDL-C will often suffice. If a subsequent decision is made to commence treatment and monitor outcome, a more detailed profile that includes triglycerides is required. Treatment should not be initiated on the basis of a single random sample.

Serum concentrations of triglycerides increase after the ingestion of a meal and, therefore, patients must fast for 12–15 h before they can be measured. Patients must also be seated for at least 5 min prior to drawing a blood sample. TC level and HDL are little affected by food intake, and this is, therefore, not a consideration if only these are to be measured. However, it is important that whatever is being measured reflects a steady-state value. For example, during periods of weight loss, lipid concentrations decline as they do following a myocardial infarction. In the case of the latter, samples drawn within 24 h of infarct onset will reflect the preinfarction state. In general, measurement should be deferred for 2 weeks after a minor illness and for 3 months after a myocardial infarction, serious illness or pregnancy.

Once the TC, HDL-C and triglyceride values are known it is usual to calculate the value for LDL-C using the Friedewald equation:

$$LDL\text{-}C = (Total\ cholesterol - HDL\text{-}C) - (0.45 \times triglyceride)\ mmol/L.$$

The Friedewald equation should not be used in non-fasting individuals, it is less reliable in individuals with diabetes and is not valid if the serum triglyceride concentration >4 mmol/L.

Although lipid target levels are normally only defined for TC and LDL-C, increasingly non-HDL-C is measured. The value for non-HDL-C is obtained by subtracting the value for HDL-C from TC. Non-HDL-C consequently represents the total of cholesterol circulating on apoprotein B particles, that is, both LDL and triglyceride-rich lipoproteins, and represents the main atherogenic particles. A desirable value is <3 mmol/L.

Lifestyle

When a decision is made to start treatment with a lipid-lowering agent, other risk factors must also be tackled as appropriate, such as smoking, obesity, high alcohol intake and lack of exercise (Box 24.3). Underlying disorders such as diabetes mellitus and hypertension should be treated as appropriate. Issues around body weight, diet and exercise will be briefly covered in the following sections.

Body weight and waist measurement

The overweight patient is at increased risk of atherosclerotic disease and typically has elevated levels of serum triglycerides, raised LDL-C and a low HDL-C. This adverse lipid profile is often compounded by the presence of hypertension and raised blood glucose, that is, the metabolic syndrome. A reduction in body weight will generally improve the lipid profile and reduce overall cardiovascular risk.

It is useful to classify the extent to which an individual is overweight by calculating their BMI. The BMI (kg/m^2) in all but the most muscular individual gives a clinical measure of adiposity.

- BMI 18.5: underweight
- BMI 18.6 to 24.9: ideal
- BMI 25 to 29.9: overweight (low health risk)

- BMI 30 to 40: obese (moderate health risk)
- BMI >40: morbidly obese (high health risk)

The distribution of body fat is also recognised as a factor that influences CVD risk. Measurement of waist circumference is perhaps the easiest and most practical indicator of central obesity and correlates well with CVD risk. Target waist circumference should be <102 cm in white caucasian men, <88 cm in white caucasian females and in Asians <90 cm in men and <80 cm in females.

Diet

Diet modification should always be encouraged in a patient with dyslipidaemia but is rarely successful alone in bringing about a significant improvement in the lipid profile. Randomised controlled trials of dietary fat reduction or modification have shown variable results on cardiovascular morbidity and mortality. In pragmatic, community-based studies, reductions in TC of only 3–6% have been achieved. The overall picture is that patients with dyslipidaemia should receive dietary advice and a small number of those who adhere to the advice will experience a fall in TC.

There is a common misconception that a healthy diet is one that is low in cholesterol. However, generally it is the saturated fat content that is important, although many components of a healthy diet are not related to fat content. For example, the low incidence of cardiovascular disease in those who consume a Mediterranean-type diet suggests an increased intake of fruit and vegetables is also important. The typical Mediterranean diet has an abundance of plant food (fruit, vegetables, breads, cereals, potatoes, beans, nuts and seeds) minimally processed, seasonally fresh, and locally grown; fresh fruit as the typical daily dessert, with sweets containing concentrated sugars or honey consumed a few times per week; olive oil as the principal source of fat; dairy products (principally cheese and yoghurt) consumed daily in low to moderate amounts; 0–4 eggs consumed weekly; and red meat consumed in low to moderate amounts. This diet is low in saturated fat (<8% of energy) and varies in total fat content from <25% to >35% of energy.

Fish. Regular consumption of the long chain omega-3 fatty acids, principally ecosapentaenoic acid and docosahexaenoic acid, typically found in fatty fish and fish oils, has been linked to the low levels of CHD seen in Inuits (Eskimos). The risk of fatal myocardial infarction in those with CVD has been shown to be reduced by consuming omega-3 fatty acids. Consumption of omega-3 fatty acids decrease triglyceride levels but have little effect on LDL-C or HDL-C. The proposed mechanisms is thought to involve the omega-3 fatty acids and their antiarrhythmic properties, ability to reduce blood pressure and heart rate, lower triglyceride levels, stimulate endothelial-derived nitric oxide, increase insulin sensitivity, decrease platelet aggregation and decrease proinflammatory eicosanoids. There would appear to be benefits in consuming at least two portions (portion = 140 g) of fish per week, including a portion of oily fish, particularly in those who have had a myocardial infarction. Pregnant women are advised to limit their intake of oily fish to two portions per week because of the potential accumulation of low level pollutants in the fish.

Trans fats. Trans fats are unsaturated fatty acids with at least one double bond in the trans configuration. They are formed when vegetable oils are hydrogenated to convert them into semisolid fats that can be incorporated into margarines or used in commercial manufacturing processes. Trans fats are typically found in deep fried fast foods, bakery products, packaged snack foods, margarines and crackers. When the calorific equivalent of saturated fats, cis unsaturated fats and trans fats are consumed, trans fats raise LDL-C, reduce HDL-C and increase the ratio of TC:HDL-C. In addition to these harmful effects, trans fats also increase the blood levels of triglycerides, increase levels of Lp(a) and reduce the particle size of LDL-C, all of which further increase the risk of CHD. It is, therefore, necessary to reduce the dietary intake of trans fatty acids to less than 0.5% of total energy intake and this has led to calls for a complete ban on trans fats in foods.

Stanol esters and plant sterols. The availability of margarines and other foods enriched with plant sterols or stanol esters appears to increase the likelihood that LDL-C can be reduced by dietary change. Both stanol esters and plant sterols at a maximum effective dose of 2 g/day inhibit cholesterol absorption from the gastro-intestinal tract and reduce LDL-C by an average of 10%. They compete with cholesterol for incorporation into mixed micelles, thereby impairing its absorption from the intestine. However, as with other dietary changes, the reduction seen varies between individuals and is probably dependent on the initial cholesterol level. There is currently no evidence that ingestion lowers the risk of cardiovascular events.

Antioxidants. Antioxidants occur naturally in fruit and vegetables and are important components of a healthy diet. Their consumption is thought to be beneficial in reducing the formation of atherogenic, oxidised LDL-C. Primary and secondary prevention trials with antioxidant vitamin supplements,

however, have not been encouraging. Neither vitamin E nor beta-carotene supplements would appear to reduce the risk of CHD but likewise have not been shown to be harmful.

Salt. Dietary salt (sodium) has an adverse effect on blood pressure and, therefore, a potential impact on CHD and stroke. As part of dietary advice the average adult intake of sodium should be reduced from approximately 150 mmol (9 g)–100 mmol (6 g) of salt or even lower. This intake can be reduced by consuming fewer processed foods, avoiding many ready meals and not adding salt to food at the table.

Exercise

Moderate amounts of aerobic exercise (brisk walking, jogging, swimming, cycling) on a regular basis have a desirable effect on the lipid profile of an individual. These beneficial effects have been demonstrated within 2 months in middle-aged men exercising for 30 min, three times a week. Current advice for adults who are not routinely active is to undertake 30 min of moderate-intensity activity on at least 5 days of the week. This can be undertaken in bouts of 10 min. For active individuals, additional aerobic exercise of vigorous intensity is recommended for 20–30 min three times a week. Exercise *per se* probably has little effect on TC levels in the absence of a reduction in body weight, body fat or dietary fat. Perhaps the most important effect of regular exercise is to raise levels of HDL-C in a dose-dependent manner according to energy expenditure.

Overall, comprehensive dietary and lifestyle changes (stopping smoking, stress management training and moderate exercise) can bring about regression of coronary atherosclerosis. Unfortunately, many find it difficult to attain or sustain the necessary changes. In others, dietary and lifestyle changes alone will never be adequate or will not bring about the necessary improvement in lipid profile quickly enough. As a consequence, the use of lipid-lowering drugs is widespread.

Drugs

If an individual is found to be at risk of CVD (primary prevention) it may be appropriate to give a trial of dietary and lifestyle changes for 3–6 months. This rarely achieves the required effect on the lipid profile and drug therapy is required. This must not, however, negate a sustained effort by the individual to make appropriate dietary and lifestyle adjustments. In an individual requiring treatment for secondary prevention, a delay of several months in starting treatment is not appropriate and treatment will normally be commenced immediately with a lipid-lowering agent.

Primary prevention

In primary prevention, dyslipidaemia should not be treated in isolation and management must be embarked upon with clear goals. In addition to lifestyle advice, this will not only address management of dyslipidaemia but will also seek to optimise use of antihypertensive agents, other cardiovascular

protective therapies and achieve tight blood glucose control as appropriate. In patients without evidence of arterial disease, treatment must be considered if the risk of CVD is >20% or more over 10 years. Although some dispute the benefit of statins in primary prevention (Kausik et al., 2010), treatment will normally include:

- a lipid-lowering agent such as simvastatin 40 mg/day (or alternative) but no treatment targets are set
- personalised information on modifiable risk factors including physical activity, diet, alcohol intake, weight and tight control of diabetes
- advice to stop smoking
- advice and treatment to achieve blood pressure below 140 mmHg systolic and 90 mmHg diastolic.

Some also consider an isolated raised TC:HDL ratio >6.5 warrants treatment regardless of the risk assessment outcome, but this approach has received little support in national treatment guidelines.

Secondary prevention

In individuals diagnosed with CVD or other occlusive arterial disease, treatment should include:

- a lipid-lowering agent to lower TC aiming towards a TC <4 mmol/L and LDL-C <2 mmol/L
- advice to stop smoking
- personalised information on modifiable risk factors including physical activity, diet, alcohol intake, weight and diabetes
- advice and treatment to achieve blood pressure at least below 140 mmHg systolic and 90 mmHg diastolic
- tight control of blood pressure and glucose in those with diabetes
- low-dose aspirin (75 mg daily)
- ACE inhibitors especially for those with left ventricular dysfunction, heart failure, diabetes, hypertension or nephropathy
- β-blocker for those who have had a myocardial infarction and in those with heart failure
- warfarin (or aspirin) for those with atrial fibrillation and additional stroke risk factors.

Lipid-lowering therapy

There are five main classes of lipid-lowering agents available:

- Statins
- Fibrates
- Bile acid binding agents
- Cholesterol absorption inhibitors
- Nicotinic acid and derivatives.

Agents such as soluble fibre and fish oils have also been used to reduce lipid levels. A number of new agents are also under investigation for their novel effect on different parts of the cholesterol biosynthesis pathway (Table 24.3).

Table 24.3 Mechanism of lipid-lowering agents under investigation

Drug group	Mechanism
Acyl-coenzyme A: cholesterol acyltransferase (ACAT) inhibitors	ACAT esterifies excess intracellular cholesterol. Inhibition of ACAT prevents transport of cholesterol into the arterial wall and thereby prevents atheroma developing. Lowers VLDL-C and triglycerides
Bile acid sequestrants	Related to first-generation resins but improved patient tolerance. Sequester bile acids and prevent re-absorption. Reduce LDL-C while HDL-C and triglycerides increase or remain unchanged
Cholesteryl ester transfer protein (CETP) inhibitors	CETP is responsible for the transfer of cholesteryl ester from HDL-C to the atherogenic LDL-C and VLDL-C
Lipoprotein lipase (LPL) activity enhancers	LPL is responsible for VLDL-C catabolism with subsequent loss of triglycerides and increase in HDL-C. Protects against atherosclerosis
Microsomal triglyceride transfer protein (MTP) inhibitors	Inhibit absorption of lipid and reduce hepatic secretion of lipoproteins, thereby reducing atherosclerotic plaque formation
Peroxisome proliferator-activated receptor (PPAR) activators	PPAR-α and -γ regulate the expression of genes involved in lipid metabolism and inhibit atherosclerotic plaque rupture. They reduce entry of cholesterol into cells, lower LDL-C and triglycerides, and increase HDL-C
Squalene synthase inhibitors	Inhibit squalene synthase, upregulate LDL receptor activity and enhance removal of LDL-C

The choice of lipid-lowering agent depends on the underlying dyslipidaemia, the response required and patient acceptability. The various groups of drugs available have different mechanisms of action and variable efficacy depending on the lipid profile of an individual. Statins are currently the drugs of choice in the majority of patients with dyslipidaemia due to the overwhelming evidence that treatment with these agents reduces cardiovascular events.

Statins

The discovery of a class of drugs, the statins, which selectively inhibit 3-hydroxy-3-methylglutaryl-CoA reductase (HMG-CoA reductase) was a significant advance in the treatment of dyslipidaemia. Their primary site of action is the inhibition of HMG-CoA reductase in the liver and the subsequent inhibition of the formation of mevalonic acid, the rate-limiting step in the biosynthesis of cholesterol. This results in a reduction in intracellular levels of cholesterol, an increase in expression of hepatic LDL receptor, and enhanced receptor-mediated catabolism and clearance of LDL-C from serum. Production of VLDL-C, the precursor of LDL-C, is also reduced. The overall effect is a reduction in TC, LDL-C, VLDL-C and triglycerides with an increase in HDL-C. The reduction in LDL-C occurs in a dose-dependent manner, with a lesser and dose-independent effect on VLDL-C and triglycerides.

Simvastatin was the first member of the group to be marketed in the UK and it was followed by pravastatin, fluvastatin, atorvastatin, cerivastatin and rosuvastatin. Cerivastatin was withdrawn from the market in 2001 due to an observed increased risk of fatal rhabdomyolysis whilst rosuvastatin, the newest member of the group, was launched in March 2003. Lovastatin has been available in the USA for many years whilst pitavastatin, likewise, has been available in Japan since 2003 with little attempt, until recently, to market in the UK.

The efficacy of statins has been demonstrated in a number of landmark, randomised placebo-controlled trials. A greater absolute benefit was seen in those trials that involved established CVD, that is, secondary prevention studies, compared to those that involved individuals without established CVD, that is, primary prevention studies. Statins are currently the lipid-lowering agents of choice in both primary and secondary prevention of CVD.

There is much debate around the statin of choice. Simvastatin is currently the preferred agent because of its relatively low cost, safety profile and evidence of efficacy (see Table 24.4). Perhaps more important is the need to identify patients who need treatment, ensure they receive an appropriate, effective dose of a statin and adhere to treatment. Despite overwhelming evidence of benefit, effectiveness is frequently compromised by poor adherence with up to 50% of patients discontinuing treatment within 12 months and 75% within 3 years. Patient factors that influence this include perception of risk, side effects of medication, expected treatment duration and socio-demographic factors.

Rosuvastatin is the most potent of the statins with evidence of impact on morbidity and mortality. It is normally reserved for those individuals that have had an inadequate response to their first-line statin. There remain concerns about its safety profile, and rhabdomyolysis in particular, when used at the higher dose of 40 mg/day. It is recommended that this dose should only be used in individuals with severe FH and at high cardiovascular risk under specialist supervision. In patients of Asian origin (Japanese, Chinese, Filipino, Vietnamese, Korean and Indian), the maximum dose should not exceed 20 mg/day because of their increased predisposition to myopathy and rhabdomyolysis.

Table 24.4 Typical recommendations for use of lipid-lowering agents (UKMI, 2009) (LDL-C, low-density lipoprotein cholesterol; TG, triglycerides; TC, total cholesterol)						
Drug therapy	Primary prevention (If >40 years and 10-year risk ≥ 20%)		Secondary prevention (All adults with CVD)		Acute coronary syndrome	Familial hypercholesterolaemia (adults)
	WITHOUT diabetes	WITH diabetes (any age)	WITHOUT diabetes	WITH diabetes		
FIRST LINE						
Simvastatin dose	40 mg	40 mg	40 mg	40 mg	High intensity statin*	40 mg
SECOND-LINE AFTER INITIAL TREATMENT WITH SIMVASTATIN 40 MG (OR EQUIVALENT)						
High-intensity statin (simvastatin 80 mg or equivalent alternative)	No recommendations	Consider if TC >4.0 mmol/L AND LDL-C >2 mmol/L	Consider if TC >4.0 mmol/L AND LDL-C >2 mmol/L	Consider if TC >4.0 mmol/L AND LDL-C >2 mmol/L	*Simvastatin 80 mg or atorvastatin 80 mg	Give if needed to achieve a reduction in LDL-C of >50% from baseline
OTHER TREATMENT OPTIONS						
Ezetimibe	Only if statin not tolerated	No recommendations	Only if statin not tolerated	Add to statin if there is existing or newly diagnosed CVD or increased albumin excretion rate	Only if statin not tolerated	Use as monotherapy if: statins contraindicated or not tolerated, OR combined with a statin if: TC or LDL-C not controlled
Fibrates	Only if statin not tolerated	Add to statin if: TG > 4.5 mmol/L despite optimised glycaemic control TG 2.3 – 4.5 mmol/L and high CVD risk	Only if statin not tolerated	Add to statin if TG remains >4.5 mmol/L despite optimised glycaemic control	Only if statin not tolerated	Use only on the advice of a specialist: if statins or ezetimibe are contraindicated or not tolerated, in combination with a statin on specialist advice
Bile acid sequestrants	Only if statin not tolerated	No recommendations	Only if statin not tolerated	No recommendations	Only if statin not tolerated	
Nicotinic acid	No recommendations	Do not use routinely	Only if statin not tolerated	Do not use routinely	Only if statin not tolerated	

All the statins require the presence of LDL receptors for their optimum clinical effect, and consequently they are less effective in patients with heterozygous FH because of the reduced number of LDL receptors. However, even in the homozygous patient where there are no LDL receptors they can bring about some reduction of serum cholesterol, although the mechanism is unclear.

Adverse effects

Many side effects appear mild and transient. The commonest include gastro-intestinal symptoms, altered liver function tests and muscle aches. Less common are elevation of liver transaminase levels in excess of three times the upper limit of normal, hepatitis, rash, headache, insomnia, nightmares, vivid dreams and difficulty concentrating.

Myopathy (unexplained muscle soreness or weakness) leading to myoglobulinuria secondary to rhabdomyolysis is also a rare but serious potential adverse effect of all the statins that can occur at any dose. The risk of myopathy is increased:

- when there are underlying muscle disorders, a family history of muscle disorders, renal impairment, untreated hypothyroidism, alcohol abuse, or the recipient is aged over 65 years or female
- where statins are co-prescribed with other lipid-lowering drugs, for example, fibrates, nicotinic acid
- when there is a past history of myopathy with another lipid-lowering drug or statin
- where there is co-prescription of simvastatin or atorvastatin with drugs that inhibit CYP3A4.

The statins are a heterogeneous group metabolised by different CYP450 isoenzymes. Simvastatin, atorvastatin and lovastatin are metabolised by CYP3A4, fluvastatin is metabolised by CYP 2C9, and pravastatin and rosuvastatin are eliminated by other metabolic routes and less subject to interactions with CYP450 isoenzymes than other members of the family. Nevertheless, caution is still required as a 5- to 23-fold increase in pravastatin bioavailability has been reported with ciclosporin. Simvastatin and atorvastatin do not alter the activity of CYP3A4 themselves, but their serum levels are increased by known inhibitors of CYP3A4 (Table 24.5). Advice has been published for the prescribing of simvastatin and atorvastatin with inhibitors of CYP3A4 (Table 24.6).

Pleiotropic properties

While the effect of statins on the lipid profile contributes to their beneficial outcome in reducing morbidity and mortality from CVD, other mechanisms, known as pleiotropic effects, may also play a part. These effects include plaque stabilisation, inhibition of thrombus formation, reduced serum viscosity and anti-inflammatory and antioxidant activity. These pleiotropic properties, that is, cholesterol-independent effects, are far reaching and reveal a clinical impact beyond a process of reducing TC. For example, lowering TC produces only modest reductions of a fixed, atherosclerotic, luminal stenosis but results in a qualitative change of the plaque and helps stabilise it. This protects the plaque from rupturing and triggering further coronary events.

Table 24.5 Examples of drug interactions involving statins and the cytochrome P450 enzyme pathway

CYP 450 isoenzyme	Inducers	Inhibitors
CYP3A4		
Atorvastin	Phenytoin	Ketoconazole
Lovastatin	Barbiturate	Itraconazole
Simvastatin	Rifampicin	Fluconazole
	Dexamethasone	Erythromycin
	Cyclophosphamide	Clarithromycin
	Carbamazepine	Tricyclic
	Omeprazole	antidepressants
		Nefazodone
		Venlafaxine
		Fluoxetine
		Sertraline
		Ciclosporin
		Tacrolimus
		Diltiazem
		Verapamil
		Protease inhibitors
		Midazolam
		Corticosteroids
		Grapefruit juice
		Tamoxifen
		Amiodarone
CYP2C9		
Fluvastatin	Rifampicin	Ketoconazole
	Phenobarbitone	Fluconazole
	Phenytoin	Sulfaphenazole

Table 24.6 Advice for prescribing simvastatin or atorvastatin with inhibitors of CYP3A4

Avoid simvastatin with potent inhibitors of CYP3A4:	HIV protease inhibitors, azole, antifungals, erythromycin, clarithromycin, telithromycin
Do not exceed the following doses:	Simvastatin 10 mg daily with ciclosporin, gemfibrozil or niacin (>1 g/day) Simvastatin 20 mg daily with verapamil or amiodarone Simvastatin 40 mg daily with diltiazem
Avoid grapefruit juice when taking simvastatin	
Atorvastatin to be used cautiously with CYP3A4 inhibitors:	Additional care required at high doses of atorvastatin; avoid drinking large quantities of grapefruit juice

Inflammation is thought to play a prominent part in the development of atherosclerosis and increased levels of C-reactive protein have been used to identify individuals at risk of plaque rupture and consequent myocardial infarction and stroke. Statins have been shown to reduce the levels of C-reactive protein in several trials.

An important aspect of vascular endothelium dysfunction is the impaired synthesis, release and activity of endothelial-derived nitric oxide, an important and early marker of atherosclerosis. After the administration of a statin, one of the earliest effects observed (within 3 days) is an increased endothelial nitric oxide release, thereby mediating an improvement in vasodilation of the endothelium.

For some while it has been thought that part of the beneficial effect of statins on CVD could be attributed to an effect on blood coagulation. It is now evident that statins, amongst their many actions, decrease platelet activation and activity, reduce prothrombin activation, factor Va generation, fibrinogen cleavage and factor XIII activation, and increase factor Va inactivation.

Over-the-counter sale

Low-dose (10 mg) simvastatin can be purchased from community pharmacies in the UK to treat individuals at moderate cardiovascular risk. Men aged 55–70 years with or without risk factors and men aged 45–54 years or women aged 55–70 years with at least one risk factor (smoker, obese, family history of premature CHD or of South Asian origin) are eligible for treatment. Simvastatin cannot be sold to individuals who have CVD, diabetes or familial dyslipidaemia or are taking lipid-lowering agents or medication that may interact with simvastatin. The rationale for over-the-counter sale is to reduce the risk of a first major coronary event in adults at moderate risk but sales have been low. Moreover, the evidence base to support the use of 10 mg simvastatin and achieve long-term cardiovascular benefit is limited.

Patient counselling

In patients receiving a statin, a once-daily regimen involving an evening dose is often preferred. Several of the statins (fluvastatin, pravastatin, simvastatin) are claimed to be more effective when given as a single dose in the evening compared to a similar dose administered in the morning. This has been attributed to the fact that cholesterol biosynthesis reaches peak activity at night. However, atorvastatin and rosuvastatin may be taken in the morning or evening with similar efficacy. A reduction in TC and LDL-C is usually seen with all statins within 2 weeks, with a maximum response occurring by week 4 and maintained thereafter during continued therapy.

Fibrates

Members of this group include bezafibrate, ciprofibrate, fenofibrate and gemfibrozil. They are thought to act by binding to peroxisome proliferator-activated receptor α (PPAR-α) on hepatocytes. This then leads to changes in the expression of genes involved in lipoprotein metabolism. Consequently, fibrates reduce triglyceride and, to a lesser extent, LDL-C levels while increasing HDL-C. Fibrates take 2–5 days to have a measurable effect on VLDL-C, with their optimum effect present after 4 weeks. In addition to their effects on serum lipids and lipoproteins, the fibrates may also have a beneficial effect on the fibrinolytic and clotting mechanisms. The fibrates also produce an improvement in glucose tolerance, although bezafibrate probably has the most marked effect.

In the patient with elevated triglycerides and gout, only fenofibrate has been reported to have a sustained uricosuric effect on chronic administration. Overall, there appears little to differentiate members of the group with regard to their effect on the lipid profile, with fenofibrate and ciprofibrate being the most potent members of the group.

In patients with diabetes, the typical picture of dyslipidaemia is one of raised triglycerides, reduced HDL-C and near normal LDL-C. Despite the effect of fibrates to reduce triglycerides and increase HDL-C, statins are first-line lipid-lowering agent in most guidelines because of a lack of clear evidence that fibrates prevent CVD in diabetes. It was hoped that a 5-year study of fenofibrate in individuals with type 2 diabetes (FIELD Investigators, 2005) would clarify the issue. However, in the final analysis the results provided little convincing evidence to change from recommending a statin, although they did confirm the safety of using a combination of a statin and fenofibrate. In contrast, gemfibrozil should not be used with a statin.

Overall, fibrates should not be used first line to reduce lipid levels in either primary or secondary prevention. Fibrates can be used first line in patients with isolated severe hypertriglyceridaemia. In individuals with mixed hyperlipidaemia, fibrates may be considered when a statin or other agent is contraindicated or not tolerated.

Adverse effects

Overall, the side effects of fibrates are mild and vary between members of the group. Their apparent propensity to increase the cholesterol saturation index of bile renders them unsuitable for patients with gallbladder disease. Gastro-intestinal symptoms such as nausea, diarrhoea and abdominal pain are common but transient, and often resolve after a few days of treatment. Myositis has been described, and is associated with muscle pain, unusual tiredness or weakness. The mechanism is unclear but it is thought fibrates may have a direct toxic action on muscle cells in susceptible individuals.

Fibrates have been implicated in a number of drug interactions (Table 24.7), of which two in particular are potentially serious. Fibrates are known to significantly increase the effect of anticoagulants, while concurrent use with a statin is associated with an increased risk of myositis and, rarely, rhabdomyolysis. Concurrent use of cerivastatin and gemfibrozil was noted to cause rhabdomyolysis and this contributed to the withdrawal of cerivastatin from clinical use in 2001.

Bile acid binding agents

The three members of this group in current use are colestyramine, colestipol and colesevelam. Both colestyramine and colestipol were formerly considered first-line agents in the management of patients with FH but now have limited use. Colesevelam is the most recent of the bile acid binding agents to receive marketing authorisation (in 2004) and consequently has never had a first-line indication. Each of the bile acid binding agents reduce TC and increase triglyceride levels.

Table 24.7 Typical drug interactions involving bile acid binding agents and fibrates[a]

Drug group	Interacting drug	Comment
Bile acid binding agents Colestyramine/colestipol		All medication should be taken 1 h before or at least 4 h after colestyramine/colestipol to reduce absorption caused by binding in the gut
	Acarbose	Hypoglycaemia enhanced by colestyramine
	Digoxin	Absorption reduced
	Diuretics	Absorption reduced
	Levothyroxine	Absorption reduced
	Mycophenolate mofetil	Absorption reduced
	Paracetamol	Absorption reduced
	Raloxifene	Absorption reduced
	Valproate	Absorption reduced
	Statins	Absorption reduced
	Vancomycin	Effect of oral vancomycin antagonised by colestyramine
	Warfarin	Increased anticoagulant effect due to depletion of vitamin K or reduced anticoagulant effect due to binding or warfarin in gut
Colesevelam		All medication should be taken at least 4 h before or 4 h after colesevelam to reduce absorption caused by binding in the gut
	Ciclosporin	Absorption reduced
	Digoxin	Absorption unchanged
	Glyburide	Absorption reduced
	Levothyroxine	Absorption reduced
	Oral contraceptive	Absorption reduced
	Statins	Absorption unchanged
	Valproate	Absorption unchanged
	Warfarin	Absorption unchanged. Increased anticoagulant possible due to depletion of vitamin K
Fibrates	Antidiabetic agents	Improvement in glucose tolerance
	Ciclosporin	Increased risk of renal impairment
	Colestyramine/colestipol	Reduced bioavailability of fibrate if taken concomitantly
	Statin	Increased risk of myopathy
	Warfarin	Increased anticoagulant effect

[a]Absorption studies involve concomitant administration.

Following oral administration, neither colestyramine, colestipol nor colesevelam are absorbed from the gut. They bind bile acids in the intestine, prevent re-absorption and produce an insoluble complex that is excreted in the faeces. The depletion of bile acids results in an increase in hepatic synthesis of bile acids from cholesterol. The depletion of hepatic cholesterol upregulates the hepatic enzyme 7-α-hydoxylase which increases the conversion of cholesterol to bile acids. This increases LDL receptor activity in the liver and removes LDL-C from the blood. Hepatic VLDL-C synthesis also increases and it is this which accounts for the raised serum triglycerides.

Colestyramine has a starting dose of one 4 g sachet twice a day. Over a 3- to 4-week period the dose should normally be built up to 12–24 g daily taken in water or a suitable liquid as a single dose, or up to four divided doses each day. Occasionally, 36 g a day may be required, although the benefits of increasing the dose above 16 g a day are offset by gastro-intestinal disturbances and poor patient adherence.

Colestipol is also available in a granular formulation and can be mixed with an appropriate liquid at a dose of 5 g once or twice daily. This dose can be increased every 1–2 months to a maximum of 30 g in a single- or twice-daily regimen.

Colesevalam is up to six times as potent as the other bile acid binding agents, probably because of a greater binding to glycocholic acid. Whether this translates into better clinical outcomes or more, or less, problems with drugs administered concurrently is unclear. Colesevalam is administered as a 625-mg tablet to a maximum dose of 4.375 g/day (7 tablets). There is limited evidence to suggest it may achieve a higher adherence than colestyramine or colestipol. It can be taken as a single- or twice-daily regimen.

Adverse effects

With all three agents, side effects are more likely to occur with high doses and in patients aged over 60 years. Bloating, flatulence, heartburn and constipation are common complaints. Constipation is the major subjective side effect, and although usually mild and transient, it may be severe.

Colestyramine, colestipol and colesevelam are known to interact with many drugs primarily by interfering with absorption (Table 24.7). Whether these absorption-type interactions are qualitatively and quantitatively similar between the different agents is unclear and the picture is confused when the

absorption of a given drug is known to interact with one bile acid binding agent but has not been tested with other members of the group.

Long-term use of bile acid binding agents may also interfere with the absorption of fat soluble vitamins and supplementation with vitamins A, D and K is recommended.

Patient counselling

Palatability is often a major problem with the bile acid binding agents and patients need to be well motivated and prepared for the problems they may encounter.

Both colestyramine and colestipol are available in an orange flavour and/or as a low sugar (aspartame-containing) powder. Colestipol is without taste and is odourless. Each sachet of colestyramine or colestipol should be added to at least 150 or 100 mL of liquid, respectively, and stirred vigorously to avoid the powder clumping. The powder does not dissolve but disperses in the chosen liquid, which may be water, fruit juice, skimmed milk or non-carbonated beverage. Both may also be taken in soups, with cereals, and with pulpy fruits with high moisture content, such as apple sauce.

All patients receiving a bile acid binding agent should be advised that reduced absorption with co-administered drugs should be anticipated. Medication that has to be taken should be administered 1 h before (at least 4 h for colesevelam) or at least 4 h after the bile acid binding agent. As a consequence, for individuals on multiple drug therapy, bile acid binding agents may not be appropriate for this reason alone.

Cholesterol absorption inhibitors

Ezetimibe is a 2-azetidinone derivative that interacts with a putative cholesterol transporter in the intestinal brush border membrane and thereby blocks cholesterol re-absorption from the gastro-intestinal tract. It can reduce LDL-C by 15–20% when added to diet. Ezetimibe also brings about a small increase in HDL-C and a reduction in triglycerides. When added to a statin, ezetimibe lowers LDL-C more than with a statin alone.

Ezetimibe should be prescribed either with a statin, a fibrate or a nicotinic acid derivative and rarely by itself, and then only in statin intolerant individuals. Although apparently well tolerated, no long-term trials (Kastelein et al., 2008; Rossebø et al., 2008) have demonstrated an additional reduction in cardiovascular morbidity or mortality that could be attributed to ezetimibe.

Nicotinic acid and derivatives

Nicotinic acid in pharmacological doses (1.5–6 g) lowers serum LDL-C, TC, VLDL-C, apolipoprotein B, triglycerides and Lp(a) and increases levels of HDL-C (particularly the beneficial HDL_3 subfraction). It clearly has a range of beneficial effects on the lipid profile and is licensed for use in combination with a statin, or by itself if the patient is statin-intolerant or a statin is inappropriate.

The commonest side effect of nicotinic acid is flushing which is most prominent in the head, neck and upper torso and occurs in over 90% of patients. It is cited as the major reason for discontinuation of treatment in 25–40% of patients. A number of strategies have been devised to overcome this, including co-administration of a cyclo-oxygenase inhibitor such as aspirin. Other strategies include regular consistent dosing, the use of extended-release formulations, patient education, dosing with meals or at bedtime, and the avoidance of alcohol, hot beverages, spicy foods, and hot baths or showers close to or after dosing. Less common side effects of nicotinic acid include postural hypotension, diarrhoea, exacerbation of peptic ulcers, hepatic dysfunction, gout and increased blood glucose levels.

Acipimox is structurally related to nicotinic acid, has similar beneficial effects on the lipid profile and a better side effect profile but appears to be less potent. An extended-release preparation of nicotinic acid has also been marketed to reduce the incidence of side effects, but up to 30% of users still report problems.

The most recent nicotinic acid-based product to be marketed is a fixed dose combination of nicotinic acid with laropriprant marketed as Tredaptive® in 2008. It is licensed for use in combination with a statin or as monotherapy when a statin is inappropriate or not tolerated. Tredaptive® possesses the general benefit of nicotinic acid whilst the laropriprant is a potent, selective antagonist of the prostaglandin D_2 receptor subtype 1 (DP_1). Given that prostaglandin D_2 mediates the flushing associated with nicotinic acid the rationale for the combination is sound, but there are currently no long-term trials of efficacy and tolerability.

Fish oils

Fish oil preparations rich in omega-3 fatty acids have been shown to markedly reduce serum triglyceride levels by decreasing VLDL-C synthesis, although little change has been observed in LDL-C or HDL-C levels. The effect is, however, inconsistent and significant increases in LDL-C have also been reported to accompany the use of fish oils. Data from several studies suggest that omega-3 fatty acids protect against CHD mortality, particularly sudden death, rather than non-fatal events, but this may not be due to the lipid-lowering efficacy. Commercial products available contain omega-3-acid ethyl esters (Omacor®) and omega-3-marine triglycerides (Maxepa®). Either can be used as an alternative to a fibrate or in combination with a statin.

Soluble fibre

Preparations containing soluble fibre, such as ispaghula husk, have been shown to reduce lipid levels. The fibre is thought to bind bile acids in the gut and increase the conversion of cholesterol to bile acids in the liver. However, their role in the management of dyslipidaemia is unclear and they are much less effective than statins in reducing TC and LDL-C.

Cholesterol ester transfer protein (CETP) inhibitors

Low levels of CETP are associated with increased levels of HDL-C and reduced cardiovascular risk. CETP transfers cholesterol from HDL-C to LDL-C and VLDL-C, thereby

altering the HDL-C:LDL-C ratio in a potentially unfavourable manner. As a consequence, inhibitors of CETP are expected to have a beneficial cardiovascular effect. Torcetrapib was a potent inhibitor of CETP and in trials demonstrated a dose-dependent ability to increase HDL-C, with little effect on LDL-C or triglycerides. Increases in serum HDL-C of more than 100% were reported. Unfortunately, the side effect profile of torcetrapib included an increase in cardiovascular events and all cause mortality thereby preventing it reaching the market. Newer inhibitors of CETP include dalcetrapib and anacetrapib and these look more promising.

Case studies

Case 24.1

Mr DF is a 43-year-old man who has been relatively fit and well for the past 20 years during which he has rarely visited his primary care doctor. Two weeks ago he was admitted to hospital having suffered a myocardial infarction. On questioning it was revealed that his brother had died in a road traffic accident at the age of 19 and his father had died from CHD aged 54 years.

Examination of Mr DF revealed a corneal arcus and tendon xanthomas. Blood drawn within 2 h of the onset of his myocardial infarction revealed TC 7.8 mmol/L, HDL-C 0.9 mmol/L and triglycerides 2.3 mmol/L.

Questions

1. What is the likely diagnosis of Mr DF?
2. What are the treatment options?
3. Mr DF wants to know why he was not identified as being at high risk of CHD before he suffered his myocardial infarction.

Answers

1. Mr DF has the signs and family history of classic heterozygous FH, most likely due to a genetic defect in the LDL receptor on hepatocytes. His presentation with an acute cardiac event at such an early age is indicative of the raised cardiovascular risk present for individuals with FH.
2. Mr DF has a high level of LDL-C and action is required to reduce it. Appropriate lifestyle advice is necessary but a statin will be required to achieve the desired outcome of at least a 50% reduction in LDL-C. In addition, this patient has recently suffered a myocardial infarction, which in itself is an indication for a high intensity statin first line, such as atorvastatin 80 mg daily. This patient should be managed by a specialist in the first instance and relatives, including any children, should be screened for the presence of FH to allow initiation of early lipid-lowering therapy.
3. Unfortunately, Mr DF's father probably died of heart disease at a time when the practice of detecting affected families and screening first-degree relatives was not widespread. The early, unrelated death of his brother and Mr DF's previous good health would not have given an opportunity to identify any underlying familial disorder.

    From population data it is known that the prevalence of heterozygous FH is about 1 in 500. Consequently, 120,000 cases would be expected in the UK. However, far fewer cases are known and screening programmes to track cases in affected families are now in place. A family history of elevated TC or death

from CHD before the age of 55 in a first-degree male relative, as in the case of Mr DF, is an important sign that should highlight the potential risk to other family members.

Case 24.2

Mr PT is a 52-year-old active school teacher. Four years ago he was found to have a raised TC and elevated blood pressure for which he was started on 10 mg simvastatin and 2.5 mg bendroflumethiazide. Over the years his dose of simvastatin has been gradually increased to 40 mg a day, but apart from this his medication has remained unchanged. He presents at the clinic complaining of aches and pains in his legs over the past 10 days. On questioning he reveals that over recent months he has been eating fresh grapefruit and consuming the occasional glass of grapefruit juice. A tentative diagnosis of myopathy is initially made.

Questions

1. What is the likelihood that grapefruit juice has contributed to Mr PT's problem?
2. Are any additional biochemical tests warranted?
3. Would atorvastatin, rosuvastatin or pravastatin be a more appropriate statin to prescribe if Mr PT wanted to continue with the occasional glass of grapefruit juice?

Answers

1. Grapefruit juice is known to interact with statins through its inhibition of the cytochrome P450 CYP3A4 enzyme. It has been suggested that it is the furanocoumarin in the grapefruit juice which binds to CYP3A4 and inactivates it in both the liver and the gastro-intestinal tract. As little as 200 mL of grapefruit juice may inhibit CYP3A4, thereby prolonging the half-life of the statin and increasing serum levels. When taken on a regular basis this can increase the risk of dose-related side effects such as rhabdomyolysis and increase the risk of myopathy. Current advice is that grapefruit juice should be avoided altogether when taking simvastatin, regardless of whether it is fresh grapefruit or grapefruit juice, grapefruit juice diluted from concentrate or frozen grapefruit juice.
2. A creatine kinase (CK) level should be checked in patients complaining of significant muscle pain to exclude overt myopathy.
   • If CK is raised significantly (>5 times upper normal level), temporary withdrawal of the statin is warranted. Once the CK falls to normal levels, and in view of the suspicion that grapefruit intake was a precipitating factor, the statin could be reinitiated and the patient warned to avoid grapefruit and seek advice promptly should the muscle aches recur.
   • If the CK is normal, then this is a simple myalgia. Grapefruit should be avoided and hopefully the symptoms resolve. If the pain does not resolve this may have an impact on adherence and an alternate statin should be considered. Of all the agents currently on the UK market, simvastatin is more likely to cause myalgia and myopathy.
3. Atorvastatin is also metabolised by CYP3A4. Although the effect is less dramatic than with simvastatin, the concurrent intake of large quantities of grapefruit juice with atorvastatin is not recommended. Neither pravastatin nor rosuvastatin is substantially metabolised by P450 and may be better alternatives. However, when there is a past history of myopathy the need for caution remains as the risk of recurrence is enhanced whatever lipid-lowering agent is prescribed. It should also be noted that rosuvastatin, unlike pravastatin, has no clinical outcome data and would not be appropriate for use in this

patient. There are also separate concerns regarding the muscle toxicity of rosuvastatin, especially when used at the higher dose of 40 mg. This again would indicate that rosuvastatin is not the best option for Mr PT.

As this patient is being treated with a statin for primary prevention, National Institute of Health and Clinical Excellence (2008a) guidelines suggest that only generic statin agents are cost-effective and, therefore, pravastatin should be considered as a first-line alternative for this patient.

Case 24.3

Mrs MC is a very active, 51-year-old caucasian lady who for the past 6 months has been suffering from the classic symptoms of the menopause. Six months ago on a routine visit to her doctor she had her lipid profile measured and this revealed an HDL-C of 0.8 mmol/L and TC of 5 mmol/L. Her blood pressure was 140/80 mmHg. She is currently prescribed no medication but is receiving intensive lifestyle support to lower her cholesterol. She has no other medical history of note other than a record that her mother died at the age of 66 years from a heart attack.

Mrs MC would like to be prescribed hormone replacement therapy to control her menopausal symptoms and reduce her risk of CVD.

Questions

1. Is it appropriate to prescribe hormone replacement therapy to reduce Mrs MC's cardiovascular risk?
2. What is the value of measuring HDL-C?
3. Does Mrs MC have a risk of CVD that requires treatment with a lipid-lowering agent?

Answers

1. Most epidemiological studies have demonstrated a beneficial effect of hormone replacement therapy on the development of CHD in postmenopausal women. However, randomised controlled trials with defined clinical endpoints have failed to support a reduction in cardiovascular events. Whether this has arisen because of how the body responds to hormone replacement therapy, the age of the women studied or the influence of the type of hormone replacement therapy, the dose, route of administration and duration of treatment is unclear. At present there are no compelling data to justify the use of hormone replacement therapy for the prevention or treatment of CVD in postmenopausal women. In fact, current evidence indicates that HRT may increase the risk of breast cancer, ovarian cancer, CVD and thromboembolic disease. If Mrs MC is to be prescribed HRT, then this should be based on the need to control her menopausal symptoms and improve her quality of life.
2. HDL-C is a major fraction of cholesterol in serum and an important determinant of cardiovascular risk in men and women, even when the level of TC appears to be within the normal range. The incidence of myocardial infarction is positively correlated with the cholesterol concentration and inversely related to the concentration of HDL-C. The TC:HDL-C ratio is another way to represent this risk and has been shown to have good predictive capabilities in women. Until the menopause, women generally have high levels of HDL-C as a result of the circulating oestrogen. However, following the menopause, HDL-C levels fall rapidly. Lifestyle advice may improve the TC/HDL ratio, especially via increased physical activity.

3. With reference to the Joint British Societies risk prediction charts, it can be determined that with a TC:HDL-C ratio of 6.25 (5/0.8) and a systolic blood pressure of 140 mmHg, Mrs MC has a 10–20% risk of developing CVD over the next 10 years. This would not automatically make her a candidate for treatment with a lipid-lowering agent as her 10-year cardiovascular risk is not >20%. Knowledge of Mrs MC's BMI and blood glucose level would be useful additional information, as would a more detailed insight into her family history of CVD. It is only when all the relevant information has been gathered that a final decision on the use of a lipid-lowering agent can be made. It would also be of interest to determine whether the lifestyle support has brought about any improvement in Mrs MC's lipid profile or blood pressure.

Case 24.4

Mr EC is a 48-year-old executive for a large multinational company who works long hours and frequently has to travel abroad. He has a family history of CHD and 9 months ago he attended a coronary screening clinic for a health check. At the clinic he was found to have a normal blood pressure but a blood screen revealed a TC of 5.7 mmol/L and triglycerides of 11.8 mmol/L. When he revisited the clinic 4 weeks later after trying to follow dietary advice, a fasting blood sample revealed a TC of 5 mmol/L and triglycerides of 2.7 mmol/L. Liver function tests were normal. He is a non-smoker and claims never to drink more than 10 units of alcohol per week.

After repeated requests to revisit the clinic he eventually turned up stating he had been away from home for 6 months on a series of business trips. He was trying to keep to a low-fat diet and his blood profile revealed TC 5.7 mmol/L, triglycerides 4.3 mmol/L, HDL-C 0.8 mmol/L and LDL-C 3 mmol/L.

Questions

1. Is Mr EC at high risk of CHD?
2. Is Mr EC a candidate for lipid-lowering therapy?
3. Should Mr EC's children be screened for dyslipidaemia?

Answers

1. Mr EC has a TC:HDL-C ratio of 7.1 (5.7/0.8). If the Joint British Societies risk charts were used they would indicate he has a 10-year risk of CHD of 10–20% and does not require lipid-lowering treatment. However, the tables underestimate the risk of CHD in those with familial hyperlipidaemia or a history of premature CHD.

   Mr EC would appear to have a mixed lipaemia, although it is difficult to interpret non-fasting triglycerides because of the influence of food intake. The low HDL-C suggests he is overweight and/or has a non-ideal lifestyle. Exclusion of diabetes, high alcohol intake, liver and renal impairment is necessary. The possibility of impaired glucose tolerance should not be overlooked and a glucose tolerance test should be performed.
2. Given the elevated triglycerides and TC, Mr EC is certainly a candidate for lifestyle advice. The use of a statin may be considered if the lifestyle changes do not bring about the necessary improvements in the lipid profile. However, the dyslipidaemia may be secondary to obesity, alcoholism, diabetes or hypothyroidism. If any of these disorders are present the appropriate treatment may correct the underlying dyslipidaemia.

3. The family history of CHD is important but is only significant if the age of onset in a parent or sibling was under 55 years of age for an affected male or under 65 years for an affected female. A rare familial disorder, for example, familial dysbetalipoproteinaemia, may be the causative factor. If this was confirmed his children should be screened after puberty as the offending gene may not express itself in the younger child.

Mr EC was subsequently found to have diabetes for which he initially received metformin together with a statin. In this scenario where a patient is diagnosed with type 2 diabetes, it is also important to consider advising children about lifestyle issues and the need to control weight throughout life.

Case 24.5

Mr JT is a 68-year-old man with stable angina. He is currently receiving simvastatin 40 mg daily with well controlled lipid levels (TC 3.8 mmol/L; LDL-C 1.8 mmol/L; HDL-C 0.9 mmol/L, triglycerides 1.3 mmol/L). He has been on simvastatin for the past 7 years, and has complained previously about muscle aches, but on this visit he states that his muscle pain has become more troublesome, to the extent that he wishes to come off the statin. He asks if there is nothing else he can take to control his cholesterol.

Questions

1. What action would you take immediately?
2. What options are available for Mr JT?
3. What would you recommend to Mr JT?

Answers

1. A CK level should be checked to exclude myopathy in this patient, as this can occur at any time during statin treatment. Assuming the CK is normal and this is myalgia, then it is still essential to address this patient's concerns, as this muscle pain is likely to impact on patient adherence over time.

An important issue is to ensure that the patient understands why they are taking a statin. The emphasis should be on the expected reduction in the risk of death, heart attack or stroke; rather than on simply achieving cholesterol treatment targets.

It may be worth temporarily stopping the statin to demonstrate the causal relationship. If the aches and pains remain despite cessation of simvastatin, then this is unlikely to be a statin-related

issue. Many people complain of aches and pains, particularly as they get older and it is easy to blame the statin for all these complaints.

2. Options for Mr JT include:
   a. Reducing the dose of simvastatin

   Mr JT has been on simvastatin for many years and a simple reduction in dose to 20 mg may improve tolerability without compromising the lipid control substantially. While an increase in TC and LDL-C is expected with dose reduction, this is usually small (in the order of 6%) and should have little overall impact on risk.
   b. Substituting an alternative statin

   Simvastatin causes more myalgia and myopathy than other statins; therefore, an alternative agent may be better-tolerated. Pravastatin is particularly well tolerated and may be a suitable alternative in this patient where potency is less of an issue. Where greater potency is required, atorvastatin (starting at a dose of 10–20 mg daily and increasing as required to control lipids) or rosuvastatin are a possibility.
   c. Switching to an alternative agent, such as ezetimibe

   Non-statin agents could be used to lower cholesterol but should be reserved for patients unable to tolerate statins. Ezetimibe monotherapy may be a suitable alternative, although use is not supported by cardiovascular outcome data.
   d. Using a low dose of statin plus an alternative agent, such as ezetimibe

   This may be a suitable option if this patient can only tolerate small doses of statins, and the ezetimibe is introduced to increase the degree of cholesterol lowering achieved. This is a useful combination in some patients, but every effort should be made to maximise the statin dose prior to adding ezetimibe to ensure maximal outcome benefits.
3. In this patient, a good starting point would be a reduction in the dose of simvastatin to 20 mg daily, providing the patient is willing to continue to take this drug. Myalgia appears to be dose related and the symptoms may resolve with the lower dose. An alternative is to try pravastatin, perhaps at a starting dose of 20 mg to see if this is better tolerated. The dose will probably need increasing to give adequate control of lipid levels. The use of ezetimibe should be reserved as an add-in if only low doses of statins can be tolerated or for monotherapy if that patient cannot be persuaded to take any statin at all. This patient should be reviewed regularly over the next few months until his concerns regarding his lipid-lowering therapy have been addressed, to encourage on-going adherence.

25 Asthma

K. P. Gibbs and D. Cripps

Key points

- Asthma is a common and chronic inflammatory condition of the airways whose cause is not completely understood.
- Common symptoms are caused by hyperresponsive airways and include coughing, wheezing, chest tightness and shortness of breath.
- The only reliable, simple and objective way to diagnose asthma is to demonstrate reversible airflow limitation.
- In the UK, there are approximately 1400 deaths from asthma each year.
- Asthma is still a poorly controlled disease despite effective treatments.
- Asthma triggers should be avoided or controlled.
- Pharmacological therapy should involve early anti-inflammatory treatment in all but the mildest asthmatics and follow national, evidence-based guidance.
- Optimum treatment involves the lowest doses of therapy that provide good symptom control with minimal or no side effects, and the best drug delivery device is one that the patient can use correctly.
- Patients should be encouraged and educated to take an active role in their disease management, be given individualised self-management plans and be regularly supervised by the health care team.

Asthma means 'laboured breathing' in Greek and was first described 3000 years ago. It is a broad term used to refer to a disorder of the respiratory system that leads to episodic difficulty in breathing. The national UK guidelines (BTS/SIGN, 2009) define asthma as 'a chronic inflammatory disorder of the airways which occurs in susceptible individuals; inflammatory symptoms are usually associated with widespread but variable airflow obstruction and an increase in airway response to a variety of stimuli. Obstruction is often reversible either spontaneously or with treatment'.

Epidemiology

The exact prevalence of asthma remains uncertain because of the differing ways in which airway restriction is reported, diagnostic uncertainty (especially for children under 2 years) and the overlap with other conditions such as chronic obstructive pulmonary disease (COPD). Over 5 million people in the UK have asthma (Asthma UK, 2001) and around 300 million worldwide. Mortality from asthma is estimated at approximately 0.4 per 100,000 with around 1400 deaths per annum in the UK. Most deaths occur outside hospital; the most common reasons for death are thought to be inadequate assessment of the severity of airway obstruction by the patient and/or clinician and inadequate therapy with inhaled or oral steroids.

The probability of children having asthma-like symptoms is estimated to be between 5% and 12%, with a higher occurrence in boys than girls and in children whose parents have an allergic disorder. Between 30% and 70% of children will become symptom free by adulthood. Individuals who develop asthma at an early age, however, do have a poorer prognosis.

The prevalence of asthma actually appears to be rising despite advances in therapy. There is some doubt about this, however, due to the differing criteria for the diagnosis of asthma used in different studies. Asthma is considered to be one of the consequences of Western civilisation and appears to be related to a number of environmental factors. Air pollution resulting from industrial sources and transport may be interacting with smoking, dietary and other factors to increase the incidence of this debilitating problem.

Aetiology

The two main causes of asthma symptoms are airway hyperresponsiveness and bronchoconstriction. Hyperresponsiveness is an increased tendency of the airway to react to stimuli or triggers to cause an asthma attack. Bronchoconstriction is a narrowing of the airways that causes airflow obstruction. Possible triggers are listed in Table 25.1. One of the most common trigger factors is the allergen found in the faeces of the house dust mite, which is almost universally present in bedding, carpets and soft furnishing. Pollen from grass (prevalent in June and July) can lead to seasonal asthma. The role of occupation in the development of asthma has become apparent with increased industrialisation. There are many causes of occupational asthma, and bronchial reactivity may persist for years after exposure to the trigger factor. Drug-induced asthma can be severe and the most common causes are β-blocker drugs and prostaglandin synthetase inhibitors. The administration of β-adrenoceptor blockers to a patient, even in the form of eye drops, can cause β_2-receptor

Table 25.1 Examples of asthma triggers

Trigger	Examples
Allergens	Pollens, moulds, house dust mite, animals (dander, saliva and urine)
Industrial chemicals	Manufacture of, for example, isocyanate-containing paints, epoxy resins, aluminium, hair sprays, penicillins and cimetidine
Drugs	Aspirin, ibuprofen and other prostaglandin synthetase inhibitors, β-adrenoceptor blockers
Foods	A rare cause but examples include nuts, fish, seafood, dairy products, food colouring, especially tartrazine, benzoic acid and sodium metabisulfite
Environmental pollutants	Traffic fumes. cigarette smoke, sulphur dioxide
Other industrial triggers	Wood or grain dust, colophony in solder, cotton, dust, grain weevils and mites
Miscellaneous	Cold air, exercise, hyperventilation, viral respiratory tract infections, emotion or stress, swimming pool chlorine

blockade and consequent bronchoconstriction. Selective β-adrenoceptor blockers are thought to pose slightly less risk, but as these lose their selectivity at higher doses, it is generally recommended that this group of drugs is avoided altogether in asthma patients. Aspirin and related non-steroidal anti-inflammatory drugs can cause severe bronchoconstriction in susceptible individuals. Aspirin inhibits the enzyme cyclo-oxygenase, which normally converts arachidonic acid to (bronchodilatory) prostaglandins. When this pathway is blocked, an alternative reaction predominates, leading to an increase in production of bronchoconstrictor (cys-) leukotrienes. Figures from differing studies vary, but between 2% and 20% of the adult asthma population are thought to be sensitive to aspirin.

Pathophysiology

Asthma can be classified according to the underlying pattern of airway inflammation with the presence or absence of eosinophils in the airways (eosinophilic vs. non-eosinophilic). Traditionally patients are described as having 'extrinsic asthma' when an allergen is thought to be the cause of their asthma. This is more common in children with a history of atopy, where triggers, such as dust mite, cause IgE production. Other environmental factors are also important, such as exposure to rhinovirus during the first 3 years of life (Holgate et al., 2010). 'Intrinsic asthma' develops in adulthood, with symptoms triggered by non-allergenic factors such as a viral

infection, irritants which cause epithelial damage and mucosal inflammation, emotional upset which mediates excess parasympathetic input or exercise which causes water and heat loss from the airways, triggering mediator release from mast cells. In practice, patients often have features of both types of asthma and the classification is unhelpful and oversimplifies the pathogenesis of asthma.

Mast cell components are released as a result of an IgE antibody-mediated reaction on the surface of the cell. Histamine and other mediators of inflammation are released from mast cells, for example, leukotrienes, prostaglandins, bradykinin, adenosine and prostaglandin-generating factor of anaphylaxis, as well as various chemotactic agents that attract eosinophils and neutrophils. Macrophages release prostaglandins, thromboxane and platelet-activating factor (PAF). PAF appears to sustain bronchial hyperreactivity and cause respiratory capillaries to leak plasma, which increases mucosal oedema. PAF also facilitates the accumulation of eosinophils within the airways, a characteristic pathological feature of asthma. Eosinophils release various inflammatory mediators such as leukotriene C_4 (LTC_4) and PAF. Epithelial damage results and thick viscous mucus is produced that causes further deterioration in lung function. These cell-derived mediators also play a role in causing marked hypertrophy and hyperplasia of bronchial smooth muscle (these structural changes are described as 'airway remodelling'), mucus gland hypertrophy leading to excessive mucus production and airway plugging, airway oedema, acute bronchoconstriction and impaired mucociliary clearance.

Mucus production is normally a defence mechanism, but in asthma patients, there is an increase in the size of bronchial glands and goblet cells that produce mucus. Mucus transport is dependent on its viscosity. If it is very thick, it plugs the airways, which also become blocked with epithelial and inflammatory cell debris. Mucociliary clearance is also decreased due to inflammation of epithelial cells. The environmental insults causing asthma are also thought to affect the structure and function of the airway epithelium. The exact role of these cytokines, cellular mediators and the interrelationships with each other and with the causative allergenic or non-allergenic mechanisms has, however, yet to be fully determined and may vary over time (Douwes et al., 2002; Holgate et al., 2010). Fig. 25.1 outlines the main cellular mechanisms involved.

Clinical manifestations

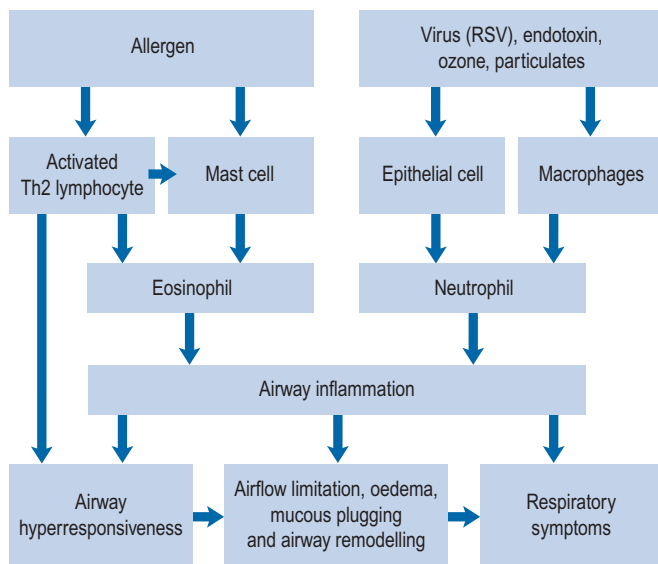
Asthma can present in a number of ways. It may manifest as a persistent cough, but most commonly, it is described as recurrent episodes of difficulty in breathing (dyspnoea) associated with wheezing (a high-pitched noise due to turbulent airflow through a narrowed airway). Diagnosis is usually made from the clinical history confirmed by demonstration of reversible airflow obstruction and measures of lung function. The history of an asthma patient often includes the presence of atopy and allergic rhinitis in the close family. Symptoms of asthma are often intermittent, and the frequency and severity of an episode can vary from individual to individual. Between periods


Fig. 25.1 Postulated cellular mechanisms involved in airway inflammation (adapted from Douwes et al., 2002).

of wheezing and breathlessness, patients may feel quite well. The absence of an improvement in ventilation, however, cannot rule out asthma, and in younger children, it is sometimes very difficult to perform lung function tests; in this case, diagnosis relies on subjective symptomatic improvement in response to bronchodilator therapy.

Acute severe asthma is a dangerous condition that requires hospitalisation and immediate emergency treatment. It occurs when bronchospasm has progressed to a state where the patient is breathless at rest and has a degree of cardiac stress. This is usually progressive and can build up over a number of hours or even days. The breathlessness, with a peak flow rate <100 L/min, is so severe that the patient often cannot talk or lie down. Expiration is particularly difficult and prolonged as air is trapped beneath mucosal inflammation. The pulse rate can give an indication of severity; severe acute asthma can increase the pulse rate to more than 110 beats/min in adults. It is common to see hyperexpansion of the thoracic cavity and lowering of the diaphragm, which means that accessory respiratory muscles are required to try to inflate the chest. Breathing can become rapid (>30 breaths/min) and shallow, leading to low oxygen saturation (SpO_2 < 92%) with the patient becoming fatigued, cyanosed, confused and lethargic. The arterial carbon dioxide tension ($PaCO_2$) is usually low in acute asthma. If it is high, it should respond quickly to emergency therapy. Hypercapnia (high $PaCO_2$ level) that does not diminish is a more severe problem and indicates progression towards respiratory failure.

Some patients remain difficult to control with persistent symptoms and/or despite treatment at BTS/SIGN step 4 or 5. This is known as 'refractory' or 'difficult to treat' asthma. These patients must be carefully evaluated by a respiratory specialist; this will include confirming an accurate diagnosis of asthma, adherence to therapy and individual psychological factors.

Investigations

The function of the lungs can be measured to help diagnose and monitor various respiratory diseases. A series of routine tests has been developed to assess asthma as well as other respiratory diseases such as COPD.

The most useful test for abnormalities in airway function is the forced expiratory volume (FEV). This is measured by means of lung function assessment apparatus such as a spirometer. The patient inhales as deeply as possible and then exhales forcefully and completely into a mouthpiece connected to a spirometer. The FEV_1 is a measure of the FEV in the first second of exhalation. The forced vital capacity (FVC) can also be measured, which is an assessment of the maximum volume of air exhaled with maximum effort after maximum inspiration. The FEV_1 is usually expressed as a percentage of the total volume of air exhaled, reported as the FEV_1/FVC ratio. This ratio is a useful and highly reproducible measure of the capabilities of the lungs. Normal individuals can exhale at least 70% of their total capacity in 1 s. In obstructive lung disorders, such as asthma, the FEV_1 is usually decreased, the FVC normal or slightly reduced and the FEV_1/FVC ratio decreased, usually <0.7 (Fig. 25.2).

A peak flow meter is a useful means of self-assessment for the patient. It gives slightly less reproducible results than the spirometer but has the advantage that the patient can do regular tests at home with a hand-held meter. The peak flow meter measures peak expiratory flow (PEF) rate, the maximum flow rate that can be forced during expiration. The PEF can be used to assess the improvement or deterioration in the disease as well as the effectiveness of treatment. For all three measurements (FEV_1, FVC and PEF), there are normal values with which the patient's results can be compared. However, these normal values vary with age, race, gender, height and weight. The measurement of FEV_1, FVC or PEF does not detect early deterioration of lung function such as bronchospasm and mucus plugging in the smaller airways.

The diagnosis of asthma can be confirmed by measuring the response to a bronchodilator or by examining a patient's day-to-day variation in PEF readings. A diurnal variability of 60 L/min (or more than 20%) is highly suggestive of asthma
Fig. 25.2 Typical lung spirometry in normal subjects and asthma patients.

(GINA, 2009). However, individuals may not have airflow obstruction at the time of the test, so the absence of an improvement does not rule out asthma. In this situation, peak flow readings can be done at home with repeated pre- and post-bronchodilator readings taken at various times of the day.

Treatment
